- Hierarchical design. Hierarchy facilitates the reuse, debugging, and readability of the design, but certain guidelines should still be followed. To facilitate reusability, blocks should be built as standardized as possible (registers, FIFO's, etc.). To facilitate readability, the interblock data flow must be appropriate, with minimal routing between blocks. To facilitate documentation, both the different components used and the different elements inside preferably should be tagged and comments should be added.

- Use of parametrizable blocks. The main synthesis tools support construction of a generic unit that can be assigned the values of certain parameters at the moment of instantiation. The value assignment is done by including "generic" sentences in the entity, which makes it possible to have a library of intellectual property (IP) components that can be used and adapted for different designs.
- Avoid embedded IF instructions. Usually, tools do not synthesize efficiently several embedded conditions. It is advisable to use more ELSIF clauses or to separate the IF-THEN sentences. In some cases, it may be better to use CASE sentences because synthesis tools have a model based on multiplexers that is generally better than the description of the same using IFs.
- Use the style most appropriate for the state machines. Many digital problems can be solved simply by means of a state machine. VHDL has many different styles to describe state machines, but the synthesis tool may not identify them and may not produce the optimum end circuit. Usually, synthesis tool manuals contain examples of how to produce such descriptions in such a manner that they will be understood as state machines.
- Types of binary data. For binary signals, it is advisable to use "std_logic" types for 1-bit signals and "std_logic_vector" for buses. These types contain not only the '0' and '1' values but also contain additional values such as 'X', and 'Z', which allow the functional simulation to imitate reality more effectively by incorporating unknown values into the data.
- Buses with binary numbers. For those buses that contain binary data to be used for synthesizable arithmetical operations (add, subtract, and product), it is advisable to use the "signed" and "unsigned" types for signed and unsigned numbers, respectively. The latest versions of functions packages do not have definitions of arithmetical operators for the "std_logic_vector" type.
- Use of integers. Integers may be used in synthesis, but should be limited in range to ensure the minimum number of bits is employed when implemented by the synthesis tool. Integer values are capped at the moment of declaration:

```
signal number1: integer range 0 to 15;
```

Inference of Combinational Circuits

Synthesis tools do not involve elements of memory unless the elements are necessary. In VHDL, combinational logic can be described via concurrent signal assignation or via processes. A set of concurrent signal assignations describes combinational logic whenever the assigned signal does not form part of the assignation and the set of concurrent assignations has no combinational links that loop assignations.

Combinational logic can also be described through processes. A process describes combinational logic whenever its sensitivity list includes all of the signals involved in the assignations and all of the output signals are specified completely, which usually applies to conditional instructions. The presence of a condition for which the signal is not assigned—that is, it remains unchanged—implies a latch.

Inference of Sequential Circuits

The synthesis of sequential circuits via VHDL descriptions is more effective for synchronous processes than for asynchronous implementations. Synchronous circuits work better because events are propagated on the clock edges, that is, at well-defined intervals. Logic stage outputs also have the whole clock cycle to pass on to the next stage, and skew between data arrival times is tolerated within the same clock period. The description of asynchronous circuits in VHDL employed for synthesis is more difficult.

A clock signal exists in synchronous circuits, for which both event and clock edge must be identified. In VHDL, the most usual form of specification is:

```
clk'event and clk = '1'
```

In this case, a rising edge has been specified. Clock signals should be used in accordance with a series of basic principles:

- Only one edge detection should be allowed per process: That is, processes may only have one clock signal.
- When a clock edge is identified in an IF, it should not be followed by an ELSE.
- The clock, when specified with an edge, should not be used as an operand. The instruction

```
IF NOT (clk'event and clk = '1')
THEN ... is incorrect.
```

These language restrictions are imposed with hardware implementation results in mind. Other alternatives either do not make sense or are not synthesizable. One consequence of these restrictions is that signals can only change with one single edge of one single clock.

In accordance with these restrictions, two basic structures exist to describe synchronous circuits, one with asynchronous reset and the other without asynchronous reset. These two structures are shown in Fig. 2. For processes with asynchronous reset, the process sensitivity list should include only the clock signal and the asynchronous reset.

FSM Descriptions

Generally an FSM is used to describe a system's control unit. In this case such a machine generates the values of the control signals that act on the data path or that act as

```
process
begin
  wait on clk'event until clk = '1';
  Q <= Din;
end process;
```

a)

```
process(clk, reset)
begin
 if (reset = `1') then
      Q <= '0';
 elsif (clk'event and clk = `1') then
      Q <= Din;
 end if;
end process;
```

b)

Figure 2. Synchronous processes, (a) edge triggered flip-flop, (b) edge triggered flip-flop with asynchronous reset.

system output control signals. State machines can be defined in VHDL using different description styles, but the results obtained may vary with the style used. Some are recognized directly by the synthesis tools and can therefore take full advantage of the optimizations offered by such tools. Although a distinction generally is drawn between descriptions for Moore machines and descriptions for Mealy machines, the codes are very similar; the only difference is that the codes for Mealy machine outputs are dependent on both the current state and the input taking place at that moment.

A typical style describes a state machine using two processes. One of them is totally combinational and describes the next state function and the output assignations. The second is sequential, triggered by a clock signal, and controls assignations on the state register. The corresponding code scheme is as follows:

```
entity FSM is
port (clock, reset: in std_logic; -- clock and
  reset signals
      x1, ..., xn: in std_logic; -- input signals
      z1, ..., zm: out std_logic); -- output
        signals
end FSM;
architecture BEHAVIOR1 of FSM is
 type STATE_TYPE is (S0, S1, ..., Sp);
 signal CURRENT_STATE, NEXT_STATE: STATE_TYPE;
begin
-- Process to hold combinational logic
COMBIN: process(CURRENT_STATE, x1, ..., xn)
begin
 NEXT_STATE <= CURRENT_STATE;
 case CURRENT_STATE is
      when S0 => -- state s0 assignations
                 -- next state assignation
                 -- output assignations
      when S1 =>
                 -- state s1 assignations
                 -- next state assignation
                 -- output assignations
      ...
      when Sp => -- state Sp assignations
                 -- next state assignation
                 -- output assignations
 end case;
end process;
-- Process to hold synchronous elements (flip-flops)
SYNCH: process
begin
 wait until CLOCK event and CLOCK = 1;
 CURRENT_STATE <= NEXT_STATE;
end process;
end BEHAVIOR;
```

The sequential process may also include a synchronous reset signal:

```
SYNCH: process
begin
 wait until CLOCK event and CLOCK = 1;
 if (reset = '1') then
       CURRENT_STATE <= S_reset;
 else
       CURRENT_STATE <= NEXT_STATE;
 end if;
end process;
```

This form of description is the one recommended, for example, for the commercial synthesis tool Design Compiler by Synopsys, Inc. (13).

Application Example

In the state machine example below, the control unit (see Fig. 3) for the sequential adder described in Fig. 1 is implemented. The corresponding VHDL code architecture is:

```
architecture fsm of control_unit is
       type STATE_TYPE is (S0, S1, S2, S3, S4);
       signal CURRENT_STATE, NEXT_STATE:
         STATE_TYPE;
begin

COMBIN: process(CURRENT_STATE)
begin
-- NEXT_STATE <= CURRENT_STATE;
case CURRENT_STATE is
     when S0 =>
           wa <= '0'; wb <= '0'; cl <= '0';
             sr_a <= '0'; srb <= '0';
           up <= '0'; cd <= '0'; w <= '0';
             srs <= '0'; s_end <= '0';
           if start = '0' then
                 NEXT_STATE <= S0;
           else
```

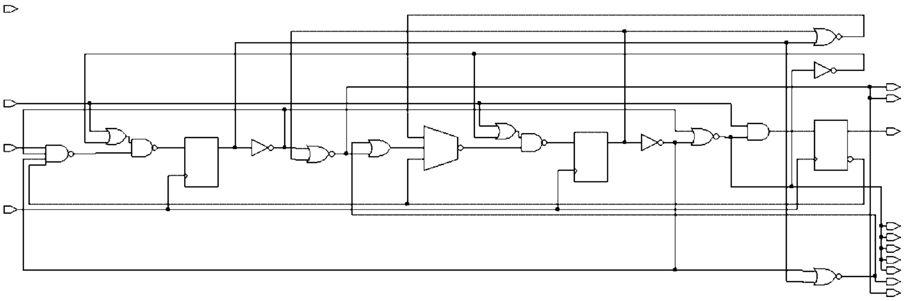

Figure 3. Control unit schematic.

```
                NEXT_STATE <= S1;
           end if;
     when S1 =>
           wa <= '1'; wb <= '0'; cl <= '1';
             sr_a <= '0'; srb <= '0';
           up <= '0'; cd <= '1'; w <= '0';
             srs <= '0'; s_end <= '0';
           NEXT_STATE <= S2;
     when S2 =>
           wa <= '0'; wb <= '1'; cl <= '0';
             sr_a <= '0'; srb <= '0';
           up <= '0'; cd <= '0'; w <= '0';
             srs <= '0'; s_end <= '0';
           NEXT_STATE <= S2;
     when S3 =>
           wa <= '0'; wb <= '0'; cl <= '0';
             sr_a <= '1'; srb <= '1';
           up <= '1'; cd <= '0'; w <= '1';
             srs <= '1'; s_end <= '0';
           if cy = '0' then
                NEXT_STATE <= S3;
           else
                NEXT_STATE <= S4;
           end if;
     when S4 =>
           wa <= '0'; wb <= '0'; cl <= '0';
             sr_a <= '0'; srb <= '0';
           up <= '0'; cd <= '0'; w <= '0';
             srs <= '0'; s_end <= '1';
           NEXT_STATE <= S2;
  end case;
end process;

-- Process to hold synchronous elements (ip-ops)
SYNCH: process
begin
     wait on clk until clk = '1';
     CURRENT_STATE <= NEXT_STATE;
end process;
end fsm;
```

The corresponding FSMD includes the operation of the datapath instead of the control signals assignations (14). Each state defines the operations that execute the processing unit in a single clock cycle. The code of the above example is shown as follows:

```
architecture fsmd of example is
       type STATE_TYPE is (S0, S1, S2, S3, S4);
       signal CURRENT_STATE, NEXT_STATE:
         STATE_TYPE;
begin

SUM(N-1) <= DA(0) + DB(0);

COMBIN: process(CURRENT_STATE)
begin
-- NEXT_STATE <= CURRENT_STATE;
case CURRENT_STATE is
       when S0 =>
            if start = '0' then
                   NEXT_STATE <= S0;
            else
                   NEXT_STATE <= S1;
            end if;
       when S1 =>
            DA <= Din; CNT <= (others=>'0');
              D <= (others=>'0');
            NEXT_STATE <= S2;
       when S2 =>
            DB <= Din;
            NEXT_STATE <= S2;
       when S3 =>
            CNT <= CNT+1; D <= C;
            DA <= shr(DA); DB <= shr(DB);
              SUM <= shr(DB);
            if cy = '0' then
                  NEXT_STATE <= S3;
            else
                  NEXT_STATE <= S4;
            end if;
       when S4 =>
       s_end <= '1';
       NEXT_STATE <= S2;
  end case;
end process;

-- Process to hold synchronous elements (ip-ops)
SYNCH: process
begin
     wait on clk until clk = '1';
     CURRENT_STATE <= NEXT_STATE;
end process;
end fsmd;
```

MICROPROGRAMMING

INTRODUCTION

At the heart of any synchronous digital system is one or more state machines that, on each clock edge, examines inputs received from the system and generates control outputs. The traditional method of implementing such state machines has been combinational logic followed by flip-flops that hold the machine state. Design of the combinational logic for such state machines now can be automated by describing the state transitions in a hardware descrip tion language like VHDL or Verilog.

Microprogramming was introduced by Wilkes (1) in the early 1950s as an alternative to the traditional approach for implementing complex state machines like those found in computer control units (2–5) In this application, many inputs need to be examined, such as status register bits (carry, overflow, sign, etc.), and bus data ready. Many outputs also are needed, such as arithmetic-logic-unit function select, register load enables, memory access control bits, and so on. In the 1980s, standalone microsequencers became popular for other complex state machine tasks like network and direct memory access controllers (6,7). One reason for the early popularity of microprogramming was that, before the advent of hardware description languages, it translated the hardware design problem into a programming problem, which made it tractable to a wider range of designers. Control information is stored in the microprogram memory, and a new microinstruction is fetched from memory every clock cycle. In this way, microprogramming is similar to assembly language programming and typically supports subroutines, loops, and other structured programming concepts. Because program changes only require a change in memory contents, the rate at which the controller can be clocked does not change, no matter how significant the program change. This approach is in contrast to the traditional approach where design changes dramatically can impact the logic equations, amount of combinational logic, and clock frequency. This impact is true even if a hardware description language is used to automate the traditional design process. Complex state machines that fit and meet timing requirements before a design change may either not fit, not meet timing constraints, or both, following even simple modifications. On the other hand, once a microprogrammed design meets clock rate and logic resource requirements, state machines of any size within the microprogram memory capacity can be implemented and modified without changing this maximum clock frequency or the logic resources required.

A BASIC MICROPROGRAM SEQUENCER

The block diagram of a typical microprogram control unit is shown in Fig. 1(5). To simplify labeling the diagram, it is assumed that the microprogram memory has N address lines (2^N microinstruction locations) and that each location is $N + \mathrm{L} + 4$ bits wide, where L is the number of control output lines. In this example it also is assumed that seven (or fewer) condition inputs are to be examined. The two registers are standard clocked D registers, and the incrementer outputs a value equal to the input plus one. Multiplexer MUX1 is eight-input multiplexer used to select either logic 0 or one of the seven condition inputs, and multiplexer MUX2 represents N two-input multiplexers used to select the source of the microprogram memory address.

The microprogram memory address can be forced to location zero to fetch the first microinstruction by taking the $\overline{\text{Reset}}$ line low to force the MUX2 outputs to zero. In its simplest form, all that is required of the sequencer is to fetch and output the contents of successive microprogram memory locations. Such instructions are referred to as continue instructions and are implemented by setting the polarity bit to logic 0 with the select bits picking the Logic-0 input of MUXl. In this way, the MUX2 select input is always 0 and the incrementer and microprogram counter register form a counter. For the microprogram control unit to be able to select other than the next sequential address, it is necessary that it be able to load a branch address. Such unconditional branch instructions are implemented by setting the polarity bit to 1 with the select bits picking the logic-0 input of MUXl, which forces the next address to come from the branch address lines. Notice that in this case, the incrementer output becomes the branch address plus one so that the microprogram counter register is loaded with the correct value following the branch. The controller gains decision-making capability whenever the select inputs choose one of the condition inputs. In this case, assuming the polarity input is 0, the next sequential address is taken if the condition is 0 and the branch address is taken if the condition is 1. Such an instruction is referred to as a conditional branch if 1. Polarity of the branch can be reversed by setting the polarity bit that inverts the exclusive–or gate output.

Example 1 shows the state diagram of a very simple sequence detector, along with an equivalent microprogram for the control unit of Fig. 1 The detector input is shown on the transition arrows, and the detector output in a given state is shown within the state circle. In the state diagram and in the microprogram, X represents a "don't care." It is assumed that the sequence detector input is applied to MUX1 input 1 so that it is selected by condition select 001. Unconditional continue and branch are obtained by selecting MUX1 input 0, which is always 0.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

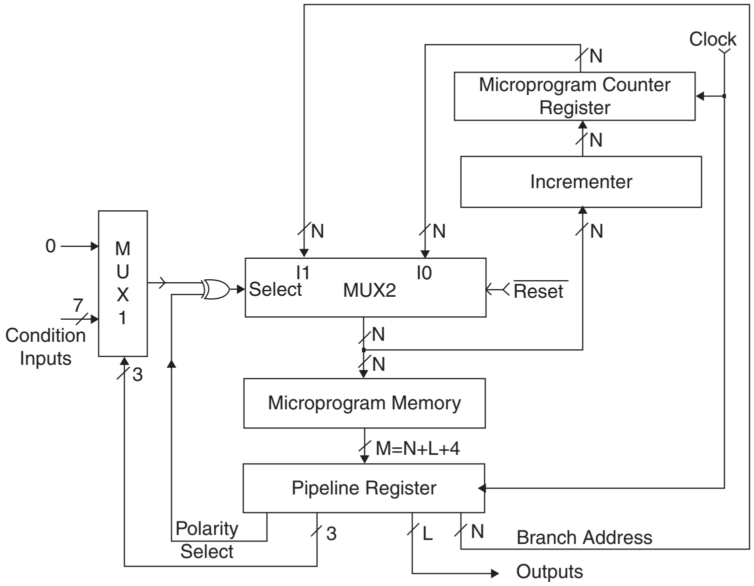

Figure 1. Basic microprogram control unit.

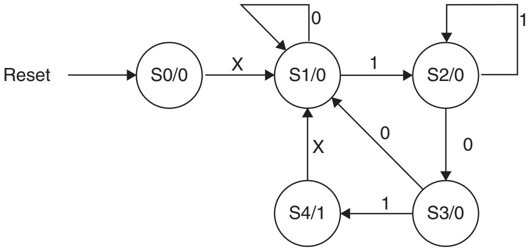
SUBROUTINES AND LOOPS

Figure 2 is a block diagram of an enhanced microprogram control unit that permits microprogram subroutines and microprogram loops. This microsequencer has a novel architecture that takes advantage of the enhancements that exist in coarse-grained FPGAs to implement efficiently four basic functions: registers, multiplexers, adders, and counters. Subroutine capability has been added to the basic design of Fig. 1 by including a subroutine last-in first-out (LIFO) stack for storing return addresses. Subroutine calls simply are branches for which what would have been the next sequential address is stored into the stack from the microprogram counter register. Microcode subroutines return to the calling program by selecting input C on the next address select logic and popping the stack.

Looping capability has been included with an *N*-bit down counter that can be loaded, via MUX2, either from another LIFO stack or from the branch address field. Counter load instructions are special continue instructions for which the branch address bit field is selected in MUX2 and loaded into the counter. Then it is possible to define a loop instruction that decrements the counter and selects either the branch address (top of loop) or, the next sequential address, based on the value of the counter. When the counter is zero at the time of the decrement, the counter holds at zero and the loop



Memory Location	State	Instruction	Branch Address	Condition Select	Polarity	Output
0	S0	Continue	X	0 0 0	0	0
1	S1	Branch if 0	1	0 0 1	1	0
2	S2	Branch if 1	2	0 0 1	0	0
3	S3	Branch if 0	1	0 0 1	1	0
4	S4	Branch	1	0 0 0	1	1

Example 1. Example Microprogram.

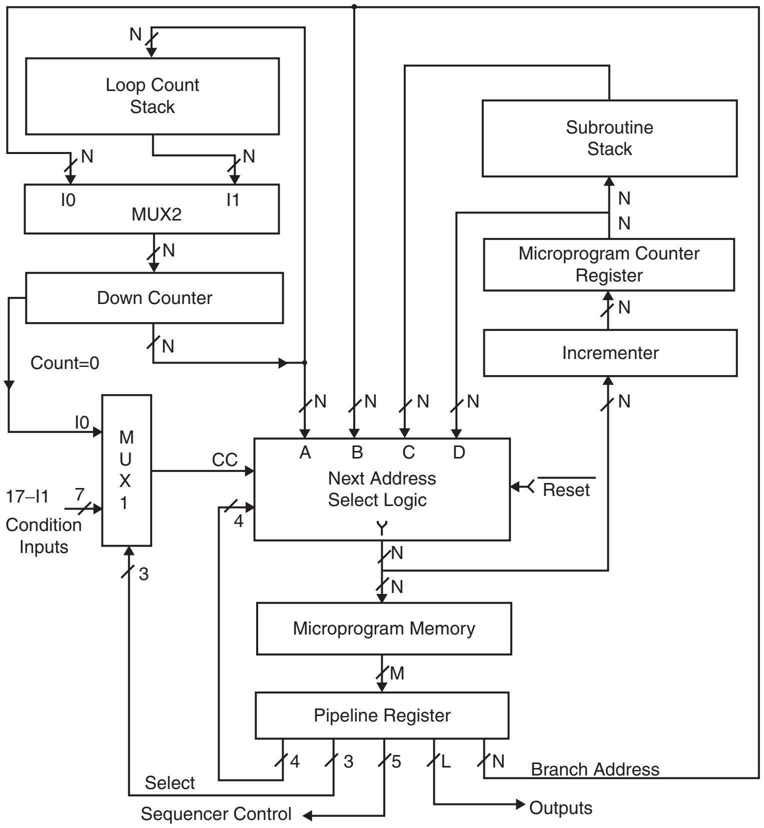


Figure 2. Enhanced microprogram control unit.

is exited. Thus, loading the counter with zero causes a loop to execute once, and loading it with K causes the loop to execute K + 1 times. The LIFO stack is used to store the counter value, if desired, whenever a new counter value is loaded, so loops can be nested. A load counter and pop counter stack instruction would be used to load the counter from the stack and pop the stack.

An alternate use of the down counter is in two-way branching. By loading the counter with an instruction address rather than a count, it is possible to use a condition input to select either the counter address (next address select logic input A) or the branch address (input B). In this way, one of two non sequential addresses can be selected.

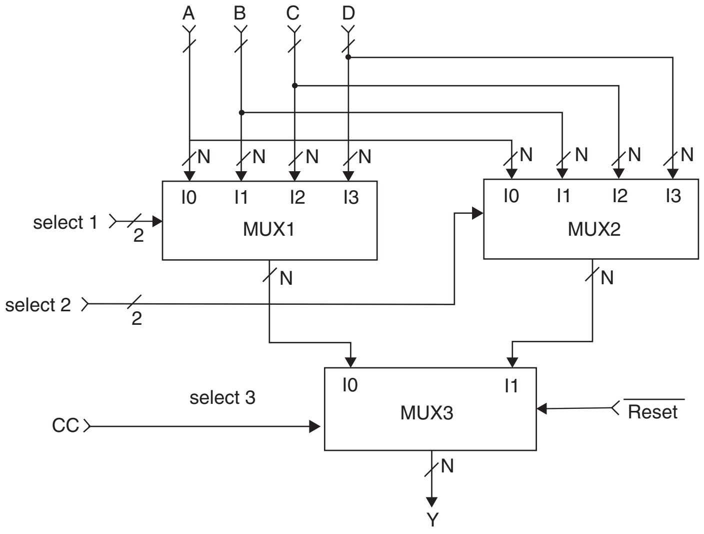

Figure 3. Multiplexer-based next address select logic.

Table 1. Instruction set

Instruction Mnemonic	Function
CONT	Continue to the next sequential instruction.
LDCT	Load counter and continue.
PSHLDCT	Push counter value onto the stack; load counter and continue.
POPCT	Load counter from the stack and pop the stack;
LOOP	Decrement the counter. If the counter was not zero prior to the decrement, take the branch address. Otherwise, take the next sequential address.
BR	Unconditional branch.
CBF(C)	Conditional branch if condition input C is false (next sequential address if C is true).
CBT(C)	Conditional branch if C is true.
TWB(C)	Two-way branch. Take the counter value if C is false and the branch address if C is true.
CALL	Unconditional subroutine call.
RET	Unconditional return from subroutine.

Figure 3 shows an implementation of the next address select logic based on multiplexers. This approach has an advantage in field programmable gate array (FPGA) implementations because FPGAs are designed to be capable of efficiently implementing multiplexers (8). Notice that the four bits from the pipeline register form two separate multiplexer-select fields, selectl and select2, for multiplexers MUX1 and MUX2. The condition input, CC, serves as the select for MUX3. If both selectl and select2 are set to the same input, then that becomes the output regardless of the condition input. However, different values for selectl and select2 allow conditional selection of one of two inputs. Reversing selectl and select2 swaps the polarity of this conditional selection. Because MUX3 is composed of simple 2-input multiplexers, the $\overline{\text{Reset}}$ input is brought into this multiplexer. In this way, each bit of each multiplexer can be implemented in a single look-up table block on most FPGAs. Something to observe about this implementation is that the delay through MUX1 and MUX2 in Fig. 3 occurs in parallel with the delay through the condition code selection multiplexer (MUX1 of Fig. 2). This balancing of delays is important for achieving high-speed operation because the maximum clock rate of the sequencer usually is limited by the path from the pipeline register through the select inputs of MUX1 to the next address select logic.

MICROINSTRUCTION DEFINITION

The microsequencer of Fig. 2 and Fig. 3 can be used to define and implement many different microinstructions. Table 1 lists one possible set of instructions that would be sufficient for most applications, and Table 2 shows how they are encoded. Referring to Fig. 2, these instructions are defined by 12 bits from the pipeline register. Three of these bits select the condition input via MUX1 and will be referred to as the *CC select* bits. This field would increase if a larger MUX1 were used to look at more than seven condition inputs. Four more of the instruction bits are the four bits from the pipeline register to the next address select logic that form the select 1 and select2 fields on Fig. 3. These bits will be referred to as *multiplexer control* bits. Finally, the 5 bits are shown as *sequencer control* bits on Fig. 2. These consist of an enable line for each stack, a push/$\overline{\text{pop}}$ line common to both stacks, and an enable and count/ $\overline{\text{load}}$ lines for the down counter. Referring to Table 2, the Xs represent bits that are "don't cares." For example, push/$\overline{\text{pop}}$ is a "don't care" if neither stack is enabled. Because the instruction bits will be stored in the microprogram memory, no advantage exists to considering them as "don't cares" and they simply can be set to 0. The value of C ranges from 1 to 7 depending on the condition input selected, and its binary value appears as C C C in the table. The encoding of select2 and selectl reflects the binary value of the input number shown on Fig. 3.

Figure 4 demonstrates how the microcode can be represented in a microassembly language format. The first field contains address labels for reference when performing branches and subroutine calls. The values in square brackets in the second field are the desired control outputs. The third field contains the instruction mnemonic, and the last field contains branch and subroutine addresses and loop counts. This example shows how to set up a nested loop and perform a conditional branch, a two-way branch, and a subroutine call. The nested loop will cause the innermost statements to execute 2500 times. The reader familiar with representing state machines in VHDL or Verilog will note that this microassembly language representation is more compact. However, it does have the disadvantage of requiring familiarity with a custom language. Conversion of microassembly language to microprogram memory contents is a simple matter of converting the instruction mnemonic to a bit pattern using Table 2 and entering the proper value for the branch address lines. A standard meta assembler with proper definition files can be used to accomplish this conversion with automatic determination of the correct address information from the label field.

PIPELINING

The maximum clock frequency of a microprogrammed control unit usually can be improved by modifying the sequencer, as shown in Fig. 5 to pipeline the microprogram memory address (8). Observe that the microprogram counter register has been moved to the output of the next address generation logic. In this way, the delay through the memory takes place in parallel with the delay through the next address logic. However, now a one clock cycle delay exists between when an address is generated

Table 2. Instruction encoding

	CC Select			Sequencer Control Bits					Multiplexer Control Bits			
Instruction Mnemonic	Select-2	Select-1	Select-0	Counter Stack Enable	Subroutine Stack Enable	Push/$\overline{\text{Pop}}$	Counter Enable	Count/$\overline{\text{Load}}$	Select2-1	Select2-0	Select1-1	Select1-0
CONT	X	X	X	0	0	X	0	X	1	1	1	1
LDCT	X	X	X	0	0	X	1	0	1	1	1	1

RET	X	X	X	0	1	0	0	X	1	0	1	0

and when the corresponding microinstruction appears at the output of the pipeline register. Therefore, when a branch instruction of any type takes place, the change in program flow is delayed a clock cycle. This delay means that whenever a branch appears in microcode, one additional instruction will always exist following the branch that is executed before the branch actually takes place. This delay is true of both conditional and unconditional branches, as well as loop instructions, subroutine calls, and subroutine returns. Such delayed branching is common in pipelined digital signal processors like the Texas Instruments TMS320C3X family where as many as three instructions may follow a branch (9). The use of pipelining is very beneficial if high clock rates are needed and most instructions execute sequentially, or if a productive operation can be placed in many microinstruction locations that follow branches. However, if many branches exist and nothing productive can be done in the microinstruction that follows most of them, then pipelining may not be beneficial. It is worth noting that in some FPGA architectures, the address lines to embedded memory are registered within the embedded memory block. In such cases, pipelining must be used and it may be necessary to take the memory address directly from the next address select logic to the embedded memory, with duplicate microprogram counter registers in the sequencer logic and in the embedded memory block.

Figure 4. Microassembly code listing.

SUMMARY AND CONCLUSIONS

Microprogramming should be considered as a control technique for complex finite state machines where flexibility with fixed timing characteristics is important. Examples include computer control units, digital filters, hardware to compute fast Fourier transforms, disk controllers, and so forth. The key advantage to the microprogrammed

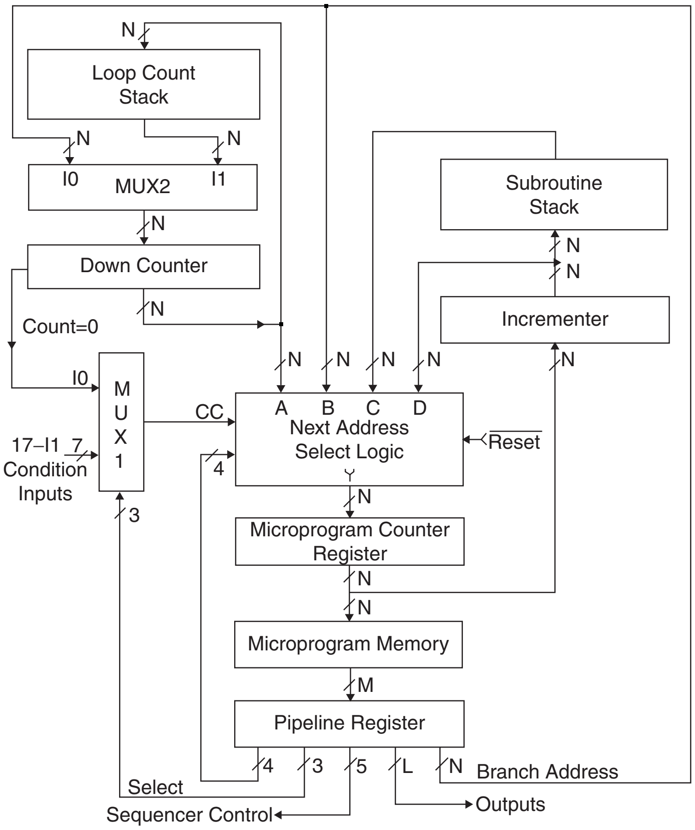

Figure 5. Pipelined microprogram control unit.

approach is that the state machine can adapt to changing algorithms by changing a bit pattern in memory that has no impact on logic resources or timing. An added benefit of the microprogrammed approach can be a more structured organization of the controller.

Although the microprogrammed approach has advantages over a traditional state machine described in a hardware description language, it has the disadvantage of requiring a custom microassembly language. However, this disadvantage may be offset for large state machines by the ability to do nested loops and subroutines, to take advantage of embedded memory blocks in FPGAs, and by the faster and more efficient design that can result. As FPGAs get larger and implement entire computing circuits for tasks like digital signal processing, the control requirement becomes correspondingly complex. In such applications, the microprogrammed approach provides an attractive solution.

PEN-BASED COMPUTING

INTRODUCTION

An Overview of Pen-Computing

Pen-based computing first came under the mainstream spotlight in the late 1980s when *GO Computers* developed the first computer operating system (OS) customized for pen/stylus input called *PenPoint,* which was used in the early tablet PCs by companies such as Apple Computer (cuperline CA) and IBM (Among NY). A pen-based computer replaces the keyboard and the mouse with a pen, with which the user writes, draws, and gestures on the screen that effectively becomes digital paper. The value proposition of pen-based computing is that it allows a user to leverage familiarity and skills already developed for using the pen and paper metaphor. Thus, pen-based computing is open to a wider range of people (essentially everybody that can read and write) than conventional keyboard and mouse-based systems, and is inline with the theme of Ubiquitous Computing, as such a computer is perceived as an electronic workbook, and thus provides a work environment resembling that which exists without computers. pen-based computers exist primarily in two forms, as mentioned above; tablet PCs, which often have a clip board-like profile and personal digital assistants (PDAs) that have a portable/handheld profile. Both forms (particularly the PDA) lend themselves very well to applications such as on site data entry/manipulation where the conventional approach is pen and paper-form based (1).

The Digitizing Tablet

The function of the digitizing tablet within a pen-based computer is to detect and to measure the position of the pen on the writing surface at its nominal sampling rate. Typically, this sampling rate varies between 50–200 Hz depending on the application, in which a higher sampling rate causes a finer resolution of cursor movement, and the computer can measure fast strokes accurately. The digitizing tablet is combined with the display to give the user the same high level of interactivity and short cognitive feedback time between their pen stroke/gesture and the corresponding digital ink mark. The user perceives the digitizing tablet and screen as one, which makes it a direct-manipulation input device and gives the user a similar experience to that of writing/drawing using the conventional pen and paper method. To enable this high level of interactivity, the digitizer must also operate with speed and precision. The display must be a flat panel display for the integrated unit to provide the user with the optimum writing surface. The display and digitizer can be combined in two ways. If the digitizer is mounted on top of the display (as illustrated below in Fig.1), the digitizing tablet must be transparent, although it can never be so infinitely, and thus the display's contrast is reduced and the user sees a blurred image.

The other way to combine the two is to mount the display on top of the digitizer; although it does not have to be transparent, the accuracy of the digitizer is reduced because of the greater distance between its surface and the tip of the pen when it is in contact with the writing surface.

The two types of digitizers are active and passive. Active digitizers are the most common type used in pen-based computers. These digitizers measure the position of the pen using an electromagnetic/RF signal. This signal is either transmitted by a two-dimensional grid of conducting wires or coils within the digitizer or transmitted by the pen.

The digitizer transmits the signal in two ways: it is either induced through a coil in the pen and conducted through a tether to the computer, or as is more commonly seen the pen, it reflects the signal back to the digitizer or disturbs the magnetic-field generated by the set of coils in the exact location of the pen tip. This reflection or disturbance is detected subsequently by the digitizer. Figure 2 depicts the latter configuration where a magnetic-field is transmitted and received by a set of coils, and this is disturbed by the inductance in the tip of a pen/stylus.

In this type of configuration, the horizontal and vertical position is represented in the original signal/magnetic-field transmitted by either signal strength, frequency, or timing, where each wire or coil in the grid carries a higher value than its neighboring counterpart. The position of the pen is evaluated using the values reflected back or disturbed.

The configuration where the pen reflects or disturbs the signal is found more commonly in modern day pen-based computers, as it allows for a lighter pen that is not attached to the computer, which provides the user with an experience closer to that of using conventional pen and paper. This method also allows more advanced information about the user's pen strokes to be measured, which can be used to provide more sophisticated and accurate handwriting recognition. The pressure being exerted on the screen/tablet can be measured using a capacitative probe within the tip of the pen, where its capacitance changes as it closes (as a result of being pressed against the screen/tablet), which changes the strength of the signal being reflected back. The angle of the pen can be measured using electronic switches that change the frequency of the signal reflected back, and these switches operate in a similar manner to tilt-switches. However, these advanced features require the pen to be powered by a battery or by the computer via a cord.

Typically, passive digitizers consist of two resistive sheets separated by a grid of dielectric spacers, with a voltage applied across one of the sheets in both the horizontal and vertical directions. When the pen makes contact with the screen/tablet, it connects the two sheets together at the point of impact, which acts to change the resistance (which is proportional to length of the resistive material) across the sheet in the two directions. In turn, it changes the two voltages across the sheet. essentially, these voltages represent a coordinate-pair of the pen's position.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

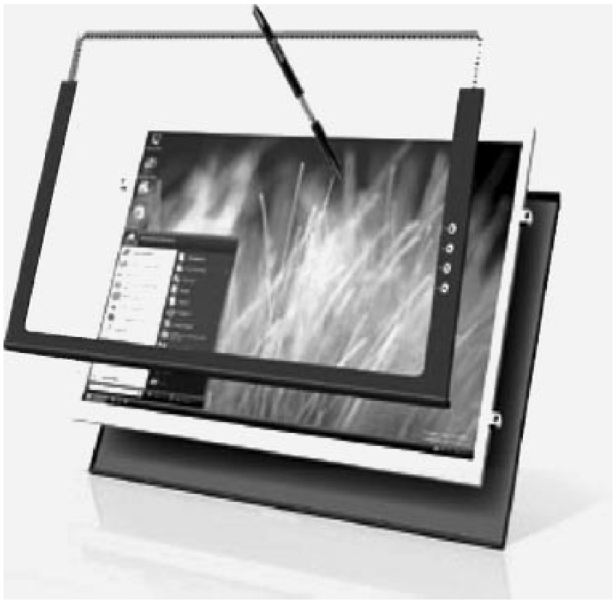

Figure 1. A digitizing tablet shown in the configuration where the digitizer is mounted on top of the screen (2) .

Being sensitive to pressure, passive digitizers also can receive input from the users fingers, and thus the computer can provide the user with a more natural/familiar mechanism for pressing on-screen (*virtual*) buttons. A disadvantage of this pressure-based operation is an increase in errors when using the pen, which are caused by the user resting against or holding the screen/tablet. However, passive digitizers can also be configured to be sensitive only to pen input by placing the dielectric spacers between the two resistive sheets closer together, where the higher amount of pressure needed to force the two sheets together can only be exerted through the small area of the pen tip.

Handwriting Recognition

Handwriting recognition (HWX) gives the user the ability to interface to a computer through the already familiar activity of handwriting, where the user writes on a digitizing tablet and the computer then converts this to text. Most users, especially those without prior knowledge of computing and the mainstream/conventional interface that is the keyboard and mouse, initially see this as a very intuitive and attractive human-computer interface as it allows them to leverage a skill that has already been acquired and developed. Although a major disadvantage of pen-based computers is that current HWX methods are not completely accurate. Characters can be recognized incorrectly and these recognition errors must be corrected subsequently by the user. Another aspect of current HWX technology that impacts the user's productivity and experience in a negative way is the fact that characters have to be entered one at a time, as the technology required to support the recognition of cursive handwriting is still a long way off and possibly requires a new programming paradigm (4). Handwriting of individuals varies immensely, and an individual's handwriting tends to change over time in both the short-term and the long-term. This change is apparent in how people tend to shape and draw the same letter differently depending on where it is written within a word what the preceding and subsequent letters are, all of which complicates the HWX process.

The two types of handwriting recognition are *on line* (real-time) and *Off line* (performed on stored handwritten data). When using conventional pen and paper, the user sees the ink appear on the paper instantaneously; thus, on line recognition is employed in pen-based computers for the user to be presented with the text form of their handwriting immediately. The most common method for implementing a HWX engine (and recognition engines in general) is a neural network, which excel in classifying input data into one of saveral categories. Neural networks are also ideal for HWX as they cope very well with noisy input data. This quality is required as each user writes each letter slightly different each time, and of course altogether differently from other users as explained previously. Another asset of neural networks useful in the HWX setting is their ability to learn over time through back-propagation, where each time the user rejects a result (letter) by correcting it,

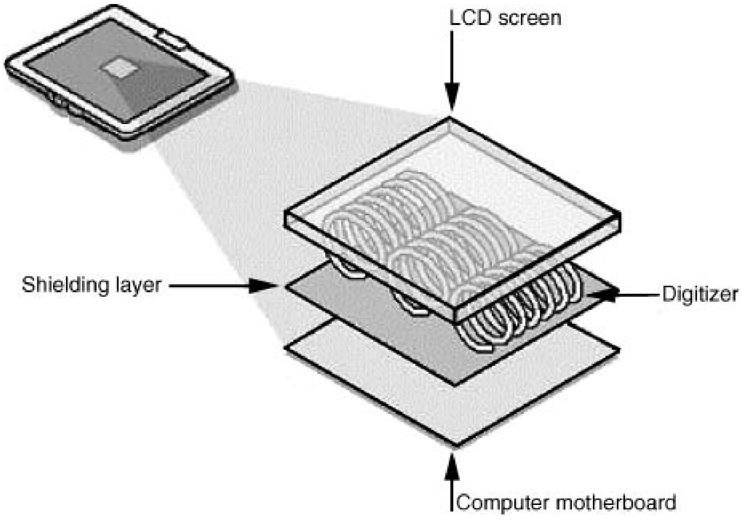

Figure 2. A digitizing tablet shown in the configuration where a set of colls generated a magenetic-field which is disturbed by the presence of the pen tip in that exact location (3).

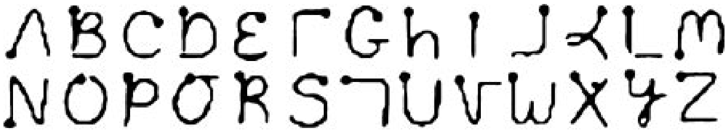

Figure 3. The Graffiti character set developed by palm computing. The dot on each character shows its starting point.

the neural network adjusts its weights such that the probability of the HWX engine making the same error again is reduced. Although this methodology can be used to reduce the probability of recognition errors for a particular use. When met with another user, the probability of a recognition error for each letter may have increased compared to what it would have been before the HWX engine was trained for recognizing the handwriting of a specific user. These problems are overcome to a good extent by using a character set where all the letters consist of a single stroke and their form is designed for ease of recognition (i.e., a specific HWX engine has been pre trained for use with that particular character set). One such character set is shown in Fig 3.

As can be seen in Fig. 3, the characters are chosen to resemble their alphabetic equivalents as much as possible. The use of such a character set forces different users to write largely the same way and to not form their own writing style, which is the tendency when using more than one stroke per letter.

The User Interface

The overall objective of a user interface that supports handwriting recognition is to provide the user with virtually the same experience as using conventional pen as paper. Thus, most of its requirements can be derived from the pen and paper interface. This means that ideally, no constraints should as to where on the digitizing tablet/screen (paper) the user writes, the size of their writing, or even when they write and when online recognition can take place. Obviously, conventional pen and paper does not impose any restrictions on special characters with accents, so ideally the user could write such characters and they should be recognized and converted to text form. Although even in pen-based computing, the standard character set used is ASCII as opposed to Unicode, which is the standardized character set that contains all characters of every language throughout the world.

As the pen is the sole input device, it is used for all the user's interfacing action. As well as text entry, it is also used for operations that a conventional mouse would be used for, such as selecting menu options, clicking on icons, and so. The action of moving the mouse cursor over a specific icon/menu-option and clicking on it is replaced entirely with simply tapping the pen on the item you would have clicked on. A dragging operation is performed by tapping the pen on the item to be dragged twice in quick succession (corresponding to the double clicking associated with the mouse), keeping the pen in contact with the tablet after the second tap and then dragging the selected item, and finally lifting the pen off the tablet to drop the item. A pen-based computer has no function keys or control keys (such as return, space-bar, etc.) like a keyboard does, and as such a pen-based computer's user interface must support something called *gesture recognition*, where the functions and the operations associated with these keyboard keys are activated by the user drawing a gesture corresponding to that function/operation. Typical examples common among most pen-based computing user interfaces are crossing a word out to delete it, circling a word to select it for editing, and drawing a horizontal line to insert a space within text.

The user will enter textual, as well as gesture and graphic (drawing/sketching) input, and thus the user interface is required to distinguish between these forms of input. The user interface of some pen-based computing OS, especially those that are extensions of conventional OS, separate the different types of input by forcing the user to set the appropriate mode, for example pressing an on-screen button to enter the drawing/sketching mode. This technique is uncomfortable for the user as it detracts from the conventional pen and paper experience, and so the preferred method is for the OS to use semantic context information to separate the input. For example, if the user is in the middle of writing a word and they write the character ‘O’, the OS would consider the fact that they were writing a word and so would not confuse the character ‘O’ with a circle or the number zero. This latter method is typical of OS written specifically for pen-based computing (Pen-centric OS).

The causes of recognition errors fall into two main categories. One is where the errors are caused by indistinguishable pairs of characters, (for example the inability of the recognizer to distinguish between ‘2’ and ‘Z’). The best solution in this case is for the OS to make use of semantic context information. The other main source of errors is when some of the user's character forms are unrecognizable. As explained previously, this situation can be improved in two ways. One is for the user to adapt their handwriting style, so that their characters are a closer match to the recognizer's pre-stored models; the other way is to adapt the recognizer's pre-stored models; to be a closer match with the user's character forms (trained recognition) (5).

An Experiment Investigating the Dependencies of User Satisfaction with HWX Performance

A joint experiment carried out by Hewlett Packard (palo Alto, CA) and The University of Bristol Research. Laboratories (Bnstd, UK) in 1995 investigated the influence of HWX performance on user satisfaction (5). Twenty-four subjects with no prior knowledge of pen-based computing carried out predetermined tasks using three test applications as well as text copying tasks, after being given a brief tutorial on pen-based computing. The applications were run on an IBM-compatible PC with Microsoft Windows for Pen Software and using a Wacom digitizing tablet (which

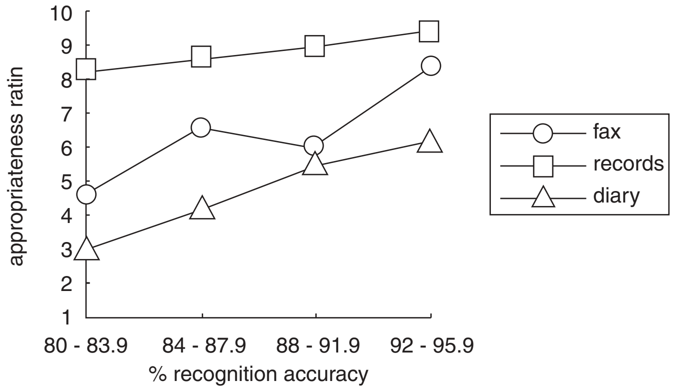

Figure 4. Plots of appropriateness rating against recognition accuracy .

did not present a direct-manipulation input device as it was not integrated with the screen). The three applications were Fax/Memo, Records, and Diary, and they were devised to contrast with each other in the amount of HWX required for task completion, tolerance to erroneous HWX text, and the balance between use of the pen for text entry and other functions performed normally using a mouse. The mean recognition rate for lowercase letters was found to be 90.9%, and 76.1% for upper case letters, with the lower recognition rate for uppercase letters caused mainly by identical upper and lower case forms with letters such as 'C', 'O', 'S', 'V'. Pen-based computing OS' attempt to deal with this problem by comparing the size of drawn letters relative to each other or relative to comb-guides when the user input is confined to certain fields/boxes.

As can be observed Fig. 4, the application that required the least amount of text recognition (Records) was rated as most appropriate for use with pen input, and the application with the most amount of text recognition (Diary) was rated as the least appropriate in this respect. Figure 4 also shows that higher recognition accuracy is met with a higher appropriateness rating by the user, and the more dependent an application is on text recognition the stronger this relationship is.

An indication of this last point can be observed from the plots shown in Fig. 4, as the average gradient of an application's plot increases as it becomes more dependent on text recognition. The results shown in fig. 4 also suggest that the pen interface is most effective in performing the non textual functions associated normally with the mouse. Thus, improving recognition accuracy would increase the diversity of applications in pen-based computing, as those more dependent on text entry would be made more effective and viable.

COGNITIVE MODELLING

Introduction to Cognitive Models

Cognitive models as applied to human–computer interaction represent the mental processes that occur in the mind of the user as they perform tasks by way of interacting with a user interface. A range of cognitive models exits, and each models a specific level within the user's goal-hierarchy from high-level goal and task analysis to low-level analysis of motor-level (physical) activity. cognitive models fall into two broad categories: those that address how a user acquires or formulates a plan of activity and those that address how a user executes that plan. Considering applications that support pen input, whether they are extensions of conventional applications that support only keyboard and mouse input or special pen-centric applications, the actual tasks and associated subtasks that need to be performed are often the same as those in conventional applications. Only the task execution differs because of the different user interface. Thus, only cognitive models that address the user's execution of a plan once they have acquired/formulated it shall be considered, as a means of evaluating the pen interface.

Adaptation of the Keystroke-Level Model for Pen-based Computers

The keystroke-level model (KLM) (6) is detailed in Table 1. This model was developed and validated by Card, Newell, and Moran, and is used to make detailed predictions about user performance with a keyboard and mouse interface in terms of execution times. It is aimed at simple command sequences and low-level unit tasks within the interaction hierarchy and is regarded widely as a standard in the field of human-computer interaction.

KLM assumes a user first builds up a mental representation of a task in working out deciding exactly how they will accomplish the task using the facilities and functionality offered by the system. This assumption means that no high-level mental activity is considered during the second phase of completing a task, which is the actual execution of the plan acquired and is this execution phase that KLM focuses on. KLM consists of seven operators, five *physical motor* operators, a *mental* operator, and a system response operator. The KLM model of the task execution by a user consists of interleaved instances of the operators. Table 2 details the penstroke-level model (PLM), which represents a corresponding set of operators for pen-based systems.

As stated previously, the actual tasks that need to be performed to achieve specific goals are largely the same with pen-based and keyboard and mouse-based systems,

Table 1. A description of the KLM model's seven operators

Operator	Description
K	Key stroking, actually striking keys, including shifts and other modifier keys
B	Pressing a mouse button
P	Pointing, moving the mouse (or similar device) as a target
H	Homing, switching the hand between mouse and keyboard
D	Drawing lines using the mouse
M	Mentally preparing for physical action
R	System response which may be ignored if the user does not have to wait for it, as in copy typing

Table 2. The PLM model, a set of operators for a pen-based user interface corresponding to those of the KLM model

Operator	Description
K'	Striking a key or any combination of keys is replaced in pen-based systems with writing a single character or drawing a single gesture. It is widely accepted in the field of HCI that a reasonably good typist can type faster than they can write. Although holding down a combination of keys is effectively one individual key press for each key, as the position of each key is stored as a one *chunk* in human memory. Some keys are not as familiar to a user as the character keys, as they are used less frequently. Thus if the user has to look for a key (e.g. the shift key) then it is reasonable to assume that the action of drawing a single gesture would be of a comparable speed.
B'	This operation is replaced in pen-based systems with tapping the pen once on the screen, which is essentially the same action as marking a full-stop/period or doting an 'i' or 'j', and it is a better developed motor skill. No reason exists to believe or evidence either way to suggest that B or B' is faster than the other for a specific user.
P'	This operation is replaced in pen-based systems with the action of moving the pen over the screen, but the pen does not have to be in continuous contact with the digitizing tablet. Thus, the cursor can be moved from one side of the screen to the other simply by lifting it from one side and placing it on the other side. This action makes the pen interface more ergonomic than the mouse in this type of situation as the user's hand need no longer be in a state of tension while performing this action. This action is a prime example of the benefits of a direct-manipulation interface.
H'	The homing operator is one for which no corresponding operator exists for pen-based systems, as the pen is the sole input device. This decreases the overall execution time when using a pen interface compared with a keyboard and mouse.
D'	This operation is replaced in pen-based systems with the action of drawing with the pen, where again the benefits of direct manipulation are observed, as it is just like drawing using pen and paper, which is a much better developed set of motor-skills, especially when drawing curved lines/strokes that compose a sketch/drawing.
M'	Because the KLM model assumes the user has formulated a plan and worked out how to execute it, the mental preparation modelled by the M and M'-operator is simply the time taken by the user to recall what to do next. Thus it is reasonable to assume that the time taken up by an occurrence of an M or M'-operator is the same for pen-based systems as it is for keyboard and mouse-based systems for each user. Although it is reasonable to assume that if one was the slower of the two it would be M, because with keyboard and mouse-based systems, the user has to recall which input device (keyboard or mouse) they need to use.
R'	Assuming the two systems were of a similar overall capability, it is reasonable to assume that the system response time for a pen-based system and a keyboard and mouse-based system would be the same. However, the process of HWX is more intensive computationally than reading keyboard input, so a pen-based system's processor would need to be faster than that of a keyboard and mouse-based system to be perceived by the user as being of comparable speed.

and I have thus adapted the KLM model into the PLM model for application to pen-based systems.

From Table 2, it can be reserved that at worst, pen-based systems have one less physical motor operator than keyboard and mouse-based systems, and at best two of its four physical motor operators have quicker execution times compared with the corresponding operators of keyboard and mouse-based systems for each user. This abservation suggests that pen-based systems are faster to use than keyboard and mouse-based systems, and the previous discussion would suggest that this is especially true for applications that contain many pointing and dragging tasks.

Experiment to Compare the Performance of the Mouse, Stylus and Tablet and Trackball in Pointing and Dragging Tasks

An experiment by Buxton, et al. in 1991 (7) compared the performance of the mouse, stylus (and digitizing tablet), and the trackball (which is essentially an upside-down mouse, with a button by the ball) in elemental pointing and dragging tasks. Performance was measured in terms of mean execution times of identical elemental tasks. However, the digitizing tablet was used in a form where it was not integrated with the display and sat on the users desktop, and thus it could not be considered a direct-manipulation interface as is the case when it is integrated with the screen. The participants of the experiment were 12 paid volunteers who were computer-literate college students. During both the pointing and the dragging task, two targets were on either side of the screen as shown in Fig. 5.

In the experiment, an elemental pointing action was considered to be moving the cursor over a target and then clicking the mouse/trackball button or pressing the pen down onto the tablet to close its tip-switch, (as opposed to the tapping action with the modern stylus and digitizer combinations which terminated an action and initiated the next action. An elemental dragging action was considered to be selecting an object within one target and holding down the mouse/trackball button or maintaining the pressure of the stylus on the tablet, dragging it to within the other target and then releasing the mouse/trackball button or pressure on the tablet to drop the object in that target, which terminated an action and initiated the next action where each time the new object would appear halfway between the two targets. Fitts' law provides a formula [shown below in its most common form in Equation (1) to

Figure 5. The on-screen user-interface used for dragging tasks.

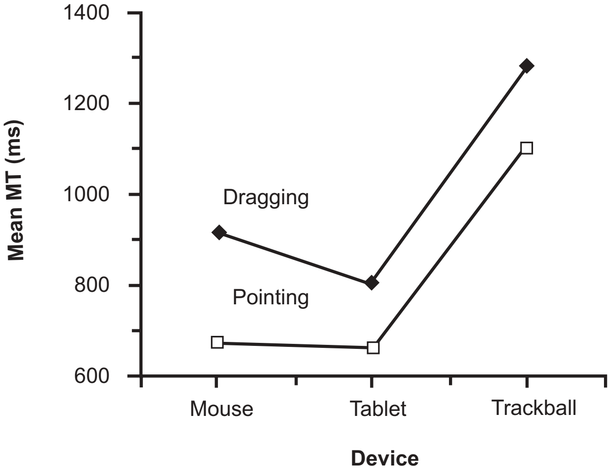

Figure 6. Graph showing execution times of three devices for elemental pointing and dragging tasks.

calculate the time taken for a specific user to move the cursor to an on-screen target.

$$\text{Movement\_Time} = a + b\log2(\text{Distance}/(\text{Size} + 1)) \tag{1}$$

As can be observed from Equation (1), according to Fitts' law the time taken to move to the target depends on the distance the cursor needs to be moved and the size of the target. Constants a and b are determinable empirically for each user. As Equation (1) shows, a greater distance is moved in a greater time, and a smaller target is more difficult to acquire and thus also increases movement time. The distance between the targets shown in Fig. 5 was varied over the range of discrete values (A = 8, 16, 32, 64 units) where a unit refers to eight pixels. The size parameter of Equation (1) was represented by the width of the targets, as the movement of the cursor would largely be side-to-side, and this too was varied over the discrete range (W = 1, 2, 4, 8 units). All values of the distance between targets A were fully crossed with all values of the width of the targets W for both the pointing and the dragging tasks, and each A-W combination was used for a block of 10 elemental tasks (pointing or dragging), where the user's objective was to carry out the ten tasks in succession as quickly and a accurately as possible. Sixteen blocks were ordered randomly into a session, and five sessions were completed for each device for each of the two types of tasks. The results showed that subjects occasionally would drop the object a long way from the target. This was not because of normal motor variability but occurred because of the difficulty in sustaining the tension in the hand required to perform dragging. It was particularly evident with the trackball, where the ball has to be rolled with the fingers while holding the button down with the thumb. The results were adjusted to remove these errors by eliminating elemental task executions within each block that were terminated (by a click or release) a horizontal distance from the mean termination distance greater than three standard deviations. This adjustment was made separately for each subject, A-W combination, device, and task type. Elemental task executions immediately after those that were terminated erroneously (which the user was notified of via a beep) were also eliminated, as many people who had investigated repetitive, self paced, and serial tasks concluded that erroneous executions were disruptive to the user and could cause an abnormally long response time for the following trial, which would have skewed the average execution time. Analysis also showed a significant reduction in execution times after the first session, and thus the entire first session for each subject, for each device task type combination was also eliminated. Figure 6 and Table 3 show the mean movement times (execution times) over all blocks for each device and for the two task types, after the adjustments mentioned above were made.

Table 3. Tabulated form of the plots shown in Figure 6

Input device	Average MT: elemental pointing	Average MT: elemental dragging
Stylus & Tablet	665 ms	802 ms
Mouse	674 ms	916 ms
Trackball	1101 ms	1284 ms

As can be seen in Fig. 6 and in Table 3, the pen and digitizing tablet was fastest in both task types, although the performance of the mouse was comparable in the pointing task. The results show that the performance of each device was better in the pointing task than in the dragging task. This seems reasonable as when dragging the hand (and the forearm in the case of the pen and digitizing tablet) is in a state of greater tension compared with when pointing. The big difference in performance between the mouse and the pen and digitizing tablet was in the dragging task, where the performance gap for the pointing task was the greatest with the mouse. Error rates for each device-task type were also evaluated and are shown in Fig. 7.

As with mean movement time, error rates were worse for the dragging task than they were for pointing. The unadjusted results were evaluated before making the modifications described above. The adjustment of eliminating errors greater than three standard deviations from the mean

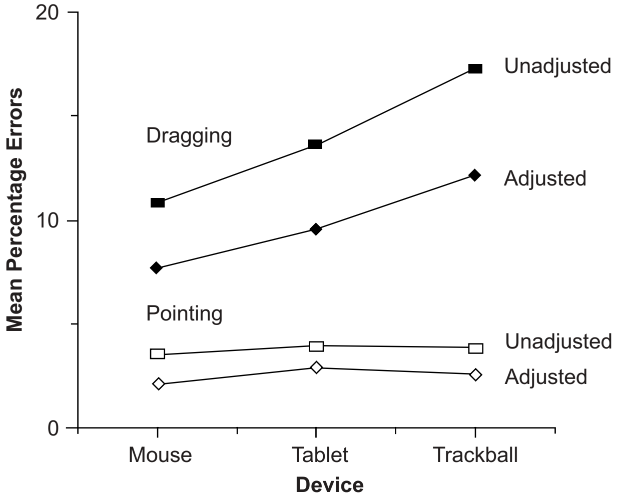

Figure 7. Graphs to show the mean error rates for three devices during pointing and dragging tasks.

termination distance from the target (as described above) was also applied to the pointing task, although dropping errors could not have occurred during the pointing task. The results shown in Fig. 7 show that the mouse had a lower (but comparable) error rate compared with the pen and digitizing tablet in the pointing task, and had a much lower error rate than in the dragging task. The 12 participants were computer literate, and because the mouse is the standard interface device for pointing and dragging, this finding suggests that on average they would have been more familiar with the mouse than they were with the pen and digitizing tablet (in the non–direct-manipulation form that was employed in this experiment). Thus, they would have had better developed motor skills for pointing and dragging using a mouse. It is reasonable to assume that the pen and digitizing tablet interface in its direct-manipulation form would have yielded fewer errors all round, but almost certainly in pointing as the user would no longer have to track the position of the cursor between the targets. The user could simply perform a dotting action on the targets in an alternate fashion, which as well as eliminating errors would have boosted the speed of elemental pointing tasks.

CONCLUSIONS

The results of the experiment conducted by Hewlett Packard and The University of Bristol research labs (5) discussed previously suggest that the pen interface is very effective for pointing and dragging tasks. Although subject feedback gave applications a lower appropriateness rating (for use with pen input), its handwriting recognition functionality was more significant and vital in task execution. Overall, the results of the experiment conveyed the impression that the pen was comparable with the mouse for pointing and dragging tasks, but not as good as the keyboard for text entry because of relatively high recognition error rates.

In my attempt at a direct comparison of pen-based and keyboard and mouse-based systems it was shown that pen-based systems are the simpler of the two in a cognitive sense, because the overhead associated with switching the hand between the mouse and the keyboard is removed with pen-based systems as the pen is the sole input device. The other operators in the model most likely have quicker execution times than their KLM equivalents for a specific user as a result of the direct-manipulation input device that is the integrated digitizer and screen and because of the more advanced motor skills that most users will have for using a pen than for using a mouse. The only exception to this is the B or B'-operator (pressing a mouse button/ tapping the pen on the digitizing tablet), with which no evidence suggests which is faster than the other, but usually this operator is combined with the P or P'-operator (pointing), and reasons exist to believe this method is faster using pen-based systems than keyboard and mouse-based systems.

The results of the experiment conducted by Buxton et al. (7) discussed previously support these facts by showing the pen to be faster than the mouse (and the trackball) for both pointing and dragging tasks. Although the results showed higher error rates during both pointing and dragging for the pen than for the mouse. It is reasonable to assume that this was because the experiment used the indirect-manipulation form of the digitizing tablet (where it is not integrated with the screen). With this configuration of the digitizing tablet the user is confined to using a low interactivity-level input mechanism just as they are when using a mouse, but with a less familiar input device as this configuration of the digitizing tablet does not resemble the conventional pen and paper metaphor like the direct-manipulation configuration does.

PROGRAMMABLE LOGIC ARRAYS

INTRODUCTION

Programmable logic arrays (PLAs) are widely used traditional digital electronic devices. The term "digital" is derived from the way digital systems process information; that is by representing information in digits and operating on them. Over the years, digital electronic systems have progressed from vacuum-tube circuits to complex integrated circuits, some of which contain millions of transistors. Currently, digital systems are included in a wide range of areas, such as communication systems, military systems, medical systems, industrial control systems, and consumer electronics.

Electronic circuits can be separated into two groups, digital and analog. Analog circuits operate on analog quantities that are continuous in value, where as digital circuits operate on digital quantities that are discrete in value and are limited in precision. Analog signals are continuous in time and are continuous in value. Most measurable quantities in nature are in analog form, for example, temperature. The measurements of temperature changes are continuous in value and in time; the temperature can take any value at any instance of time without a limit on precision but with the capability of the measurement tool. Fixing the measurement of temperature to one reading per an interval of time and rounding the value recorded to the nearest integer will graph discrete values at discrete intervals of time that could be coded into digital quantities easily. From the given example, it is clear that an analog-by-nature quantity could be converted to digital by taking discrete-valued samples at discrete intervals of time and then coding each sample. The process of conversion usually is known as analog-to-digital conversion (A/D). The opposite scenario of conversion is also valid and known as digital-to-analog conversion (D/A). The representation of information in a digital form has many advantages over analog representation in electronic systems. Digital data that is discrete in value, discrete in time, and limited in precision could be efficiently stored, processed, and transmitted. Digital systems are more noise-immune than analog electronic systems because of the physical nature of analog signals. Accordingly, digital systems are more reliable than their analog counterpart. Examples of analog and digital systems are shown in Fig. 1.

A BRIDGE BETWEEN LOGIC AND CIRCUITS

Digital electronic systems represent information in digits. The digits used in digital systems are the *0* and *1* that belong to the *binary* mathematical number system. In logic, the *0* and *1* values correspond to *true* and *false*. In circuits, the *true* and *false* correspond with *high* voltage and *low* voltage. These correspondences set the relations among logic (*true* and *false*), *binary* mathematics (*0* and *1*), and circuits (*high* and *low*).

Logic, in its basic shape, checks the validity of a certain proposition — a proposition could be either *true* or *false*. The relation among logic, *binary* mathematics, and circuits enables a smooth transition of processes expressed in propositional logic to *binary* mathematical functions and equations (*Boolean* algebra) and to digital circuits. A great scientific wealth exists to support strongly the relations among the three different branches of science that led to the foundation of modern digital hardware and logic design.

Boolean algebra uses three basic logic operations *AND*, *OR*, and *NOT*. If joined with a proposition *P*, the *NOT* operation works by negating it; for instance, if *P* is *True* then *NOT P* is *False* and vice versa. The operations *AND* and *OR* should be used with two propositions, for example, *P* and *Q*. The logic operation *AND*, if applied on *P* and *Q* would mean that *P AND Q* is *True* only when both *P* and *Q* are *True*. Similarly, the logic operation *OR*, if applied on *P* and *Q* would mean that *P OR Q* is *True* when either *P* or *Q* is *True*. Truth tables of the logic operators *AND*, *OR*, and *NOT* are shown in Fig. 2a. Figure 2b shows an alternative representation of the truth tables of *AND*, *OR*, and *NOT* in terms of *0s* and *1s*.

Digital circuits implement the logic operations *AND*, *OR*, and *NOT* as hardware elements called "gates" that perform logic operations on binary inputs. The *AND*-gate performs an *AND* operation, an *OR*-gate performs an *OR* operation, and an *Inverter* performs the negation operation *NOT*. Figure 2c shows the standard logic symbols for the three basic operations. With analogy from electric circuits, the functionality of the *AND* and *OR* gates are captured as shown in Fig. 3. The actual internal circuitry of gates is built using transistors; two different circuit implementations of inverters are shown in Fig. 4. Examples of *AND*, *OR*, *NOT* gates integrated circuits (ICs) are shown in Fig. 5. Besides the three essential logic operations, four other important operations exist—the *NOR*, *NAND*, exclusive-*OR* (*XOR*), and Exclusive-*NOR*.

A logic circuit usually is created by combining gates together to implement a certain logic function. A logic function could be a combination of logic variables (such as A, B, C, etc.) with logic operations; logic variables can take only the values *0* or *1*. The created circuit could be implemented using *AND-OR-Inverter* gate-structure or using other types of gates. Figure 6 shows an example combinational implementation of the following logic function *F(A, B, C)*:

$$F(A,B,C) = ABC + A'BC + AB'C'$$

In this case, *F(A, B, C)* could be described as a sum-of-products (SOP) function according to the analogy that exists between *OR* and addition (+), and between *AND*

PROGRAMMABLE LOGIC

Basically, three types of IC technologies exist that can be used to implement logic functions on which Ref. 1, include, full-custom, semi-custom, and programmable logic devices (PLDs). In full-custom implementations, the designer is concerned about the realization of the desired logic function to the deepest details, which include the transistor-level optimizations, to produce a high-performance implementation. In semi-custom implementations, the designer uses ready logic-circuit blocks and completes the wiring to achieve an acceptable performance implementation in a shorter time than full-custom procedures. In PLDs, the logic blocks and the wiring are ready. To implement a function on a PLD, the designer will decide which wires and blocks to use; this step usually is referred to as programming the device.

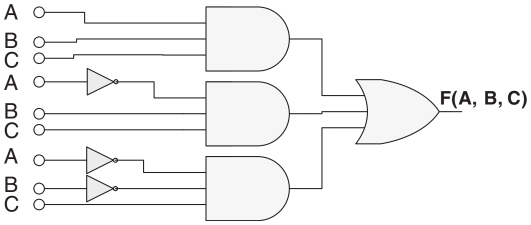

Figure 6. AND-OR-Inverter implementation of the function $F(A, B, C) = ABC + A'BC + AB'C'$.

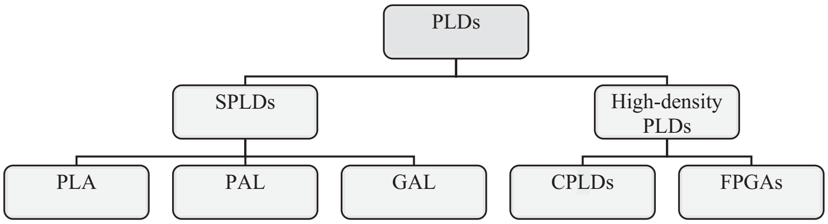

Figure 7. Typical PLD device classification.

Obviously, the development time using a PLD is shorter than the other full-custom and semi-custom implementation options. The performance of a PLD varies according to its type and complexity; however a full-custom circuit is optimized to achieve higher performance. The key advantage of modern programmable devices is their reconfiguration without rewiring or replacing components (reprogrammability). Programming a modern PLD is as easy as writing a software program in a high-level programming language.

The first programmable device that achieved a widespread use was the programmable read-only memory (PROM) and its derivatives Mask-PROM, and Field-PROM (the erasable or electrically erasable versions). Another step forward led to the development of PLDs. Programmable array logic, programmable logic array (PLA), and generic array logic are commonly used *PLDs* designed for small logic circuits and are referred to as simple-PLDs (SPLDs). Other types, Such as the mask-programmable gate arrays, were developed to handle larger logic circuits. Complex-PLDs (CPLDs) and field programmable gate arrays (FPGAs) are more complicated devices that are fully programmable and instantaneously customizable. Moreover, FPGAs and CPLDs have the ability to implement very complex computations with millions of gates devices currently in production. A classification of PLDs is shown in Fig. 7.

PLAs

A (PLA) is an (SPLD) that is used to implement combinational logic circuits. A PLA has a set of programmable *AND* gates, which link to a set of programmable *OR* gates to produce an output (see Fig. 8). Implementing a certain function using a PLA requires the determination of which connections among wires to keep. The unwanted routes could be eliminated by burning the switching device (possibly a fuse or an antifuse) that connects different routs. The *AND-OR* layout of a *PLA* allows logic functions to be implemented that are in an SOP form.

Technologies used to implement programmability in PLAs include fuses or antifuses. A fuse is a low resistive element that could be blown (programmed) to result in an open circuit or high impedance. An antifuse is a high

resistive element (initially high impedance) and is programmed to be low impedance.

Boolean expressions can be represented in either of two standard forms, *SOPs* and the product-of-sums (POSs). For example, the equations for *F* (an SOP) and *G* (a POS) are as follows:

$$F(A,B,C) = ABC + A'BC + AB'C'$$
$$G(A,B,C) = (A+B+C).(A'+B+C).(A+B'+C')$$

A product term consists of the *AND* (Boolean multiplication) of literals (*A*, *B*, *C*, etc.). When two or more product terms are summed using an *OR* (*Boolean* addition), the resulting expression is an SOP. A standard SOP expression $F(A,B,C,\ldots)$ includes all variables in each product term. Standardizing expressions makes evaluation, simplification, and implementation much easier and systematic.

The implementation of any *SOP* expression using *AND*-gates, *OR*-gates, and inverters, could be replaced easily using the structure offered by a PLA. The algebraic rules of hardware development using standard SOP forms are the theoretical basis for designs targeting PLAs. The design procedure simply starts by writing the desired function in an SOP form, and then the implementation works by choosing which fuses to burn in a fused-PLA.

In the following two examples, we demonstrate the design and the implementation of logic functions using PLA structures. In the first example, we consider the design and the implementation of a three-variable majority function. The function *F(A, B, C)* will return a *1* (*high* or *true*) when the number of *1s* in the inputs is greater than or equal to the number of *0s*. The truth-table of *F* is shown in Fig. 9. The terms that make the function *F* return a *1* are the terms *F(0, 1, 1)*, *F(1, 0, 1)*, *F(1, 1, 0)*, or *F(1, 1, 1)*. which could be formulated alternatively as in the following equation:

$$F = A'BC + AB'C + ABC' + ABC$$

In Fig. 10, the implementations using a standard *AND-OR-Inverter* gate-structure and a PLA are shown.

Another function G(A, B, C, D) could have the following equation:

$$G = A'B + AB'CD + AB' + ABD + B'C'D'$$

Input A	*Input B*	*Input C*	*Output F*
0	0	0	0
0	0	1	0
0	1	0	0
0	1	1	1
1	0	0	0
1	0	1	1
1	1	0	1
1	1	1	1

Figure 9. Truthtable of the majority function.

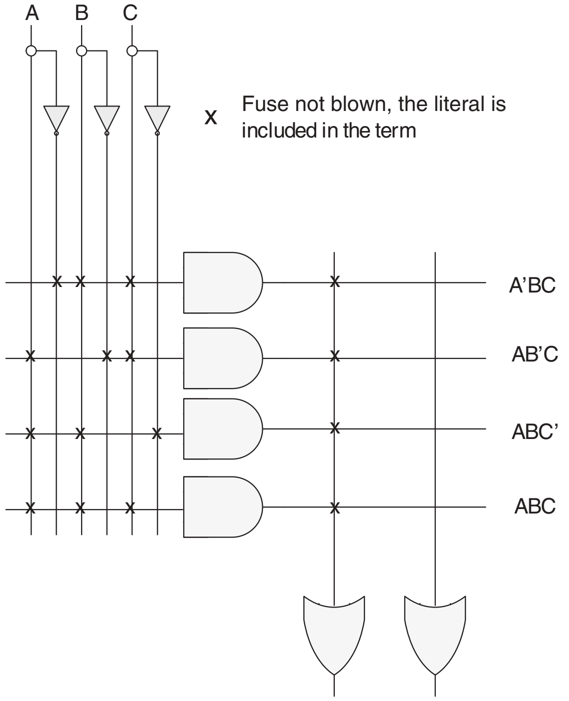

Figure 10. PLA implementation of F(A, B, C).

The implementation of *G* using a PLA is shown in Fig. 11.

EARLY PLAs

Near the beginning of 1970s, companies such as *Philips*, *Texas Instruments*, *National Semiconductor*,*Intersil*, *IBM*(2),and *Signetics* introduced early PLA and PLA-based devices. Early PLAs had limited numbers of input/output ports (around 20), array cells count (from hundreds to few thousands), and speeds (with around 1 to 35 nanoseconds delay). Later PLAs performed with greater speeds (with around 2 to 5 nanoseconds delay), with array sizes of thousands of cells, and input/output ports number of around 100 (3). Currently, some PLA-structures are parts of high-density, high-performance, and CPLDs.

Currently,*PLAs* are available in the market in different types. PLAs could be stand-alone chips, or parts of bigger processing systems. Stand-alone PLAs are available as mask programmable (MPLAs) and field programmable (FPLAs) devices. MPLAs are programmed at the time of manufacture, whereas FPLAs can be programmed by the user with a computer-aided design tool.

PLAs IN MODERN COMPLEX SYSTEMS AND AREAS OF APPLICATION

PLAs have largely motivated the development of many modern programmable systems. usually, PLAs are used as a part of a more complicated processing system. PLAs have also inspired the creation of complex PLA-based

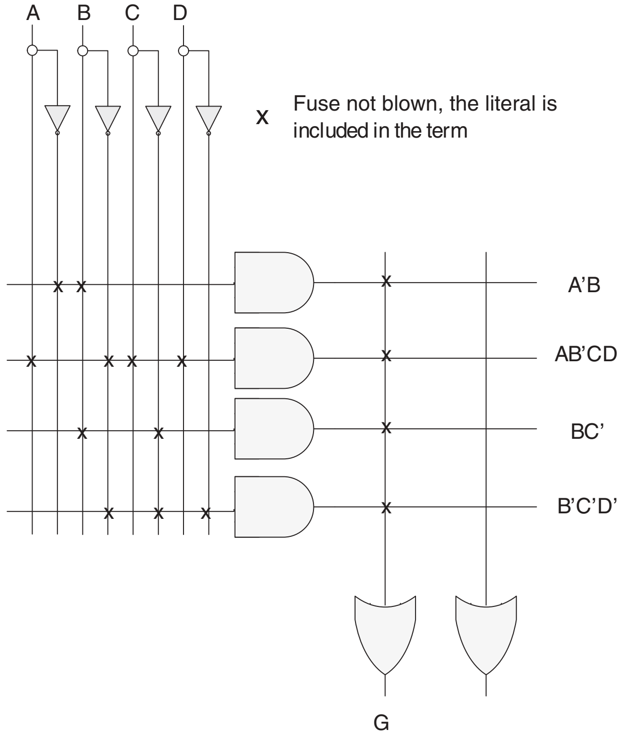

Figure 11. PLA implementation of G(A, B, C, D).

systems with PLA-like structure. The available variety of PLAs and PLA-based systems paved the way for their employment in many areas of application.

The *CoolRunner II* CPLD from *Xilinx* uses a PLA-type structure. This device has multiple function blocks (FBs). Each FB contains 16 macrocells and the FBs are interconnected by an advanced interconnect matrix. A basic architectural block diagram for the CoolRunner II with a greatly simplified diagram of an FB is shown in Fig. 12.

The CoolRunner II series of CPLDs contains from 32 macrocells to 512 macrocells. The number of FBs range from 2 to 32. The PLA structure contains a programmable *AND* array with *56 AND*-gates, and a programmable *OR* array with *16 OR*-gates. With the PLA structure, any product term can be connected to any *OR*-gate to create an SOP output. Each FB can produce up to *16* SOP outputs each with *56* product terms.

The main additions to the traditional PLA structure in a device such as *CoolRunner II* are the complex macrocells. A macrocell can be configured for combinational logic or sequential logic (with availability of flip-flops). The macrocell in a CoolRunner II also contains an XOR-gate to enable complementing the SOP output (coming from the PLA OR-gate) to produce a POS form. A *1* on the input of the XOR-gate complements the *OR* output (a POS form is produced) and a *0* keeps the output uncomplemented (in an SOP form). Choices between SOP forms and POS forms, various clock inputs, flip-flop include or bypass, are completed using different multiplexers.

Another famous device with a PLA-like structure is the ICT programmable electrically erasable logic (PEEL) array (4). PEEL arrays are large PLAs that include macrocells with flip-flops. The PEEL array structure is shown in Fig. 13 with its PLA-like planes; the outputs of the *OR*-plane are divided into groups of four, and each group can be input to any of the logic cells. The logic cells, depicted in Fig. 14, provide registers for the sum terms and can feed back the sum terms to the *AND*-plane. The logic cells can also connect the sum terms to the input–output pins. The multiplexers each produce an output of the logic cell and can provide either a registered or a combinational output. Because of their PLA-like planes, the PEEL arrays are well-suited to applications that require SOP terms.

The multiple *ALU* architecture with reconfigurable interconnect experiment system (MATRIX) is another modern architecture that benefits from the PLA architecture (5). The MATRIX architecture is unique because it aims to unify resources for instruction storage and computation. The basic unit (BFU) can serve either as a memory or a computation unit. The *8* BFUs are organized in an array, and each BFU has a *256*-word memory, an ALU-multiply unit, and a reduction control logic. The interconnection network has a hierarchy of three levels; it can deliver up

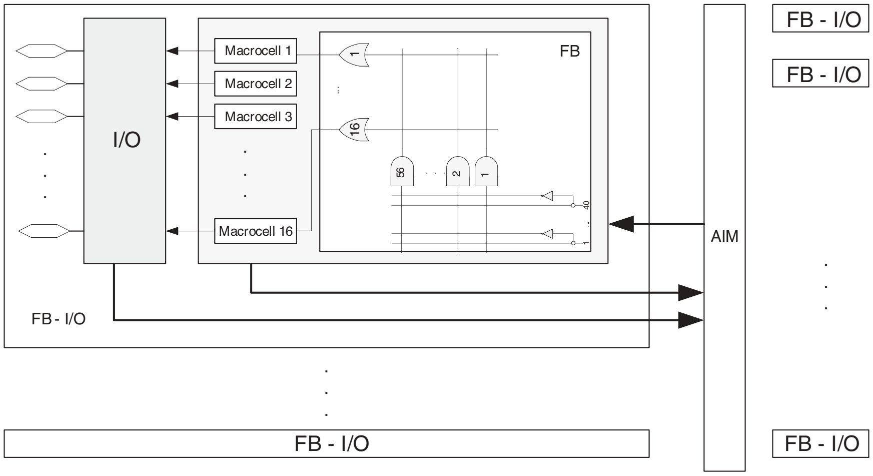

Figure 12. Architectural block diagram for the CoolRunner II.

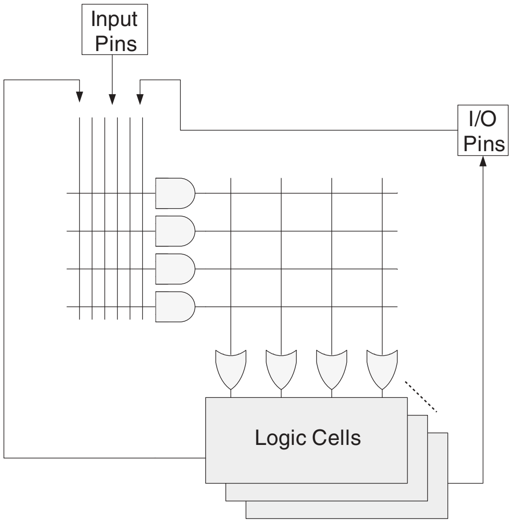

Figure 13. Main components in the architecture of ICT PEEL Arrays.

to 10 GOPS with 100 BFUs when operating at 100 MHz. The MATRIX controller is composed of a pattern matcher to generate local control from the ALU output, a reduction network to generate local control, and a 20-input, *8*-output NOR block that serves as half of a PLA.

One famous application of PLAs is to implement the control over a datapath in a processor. A datapath controller usually follows predefined sequences of states. In each control state, the PLA part of the controller will determine what datapath control signals to produce and the next state of the controller. The design of the controller usually starts by formulating different states and transitions using a state diagram. The state diagram is then formulated in a truth-table form (state transition table), where SOP equations could be produced. Then, the derived SOP equations are mapped onto the PLA. A design example of a datapath controller is shown in Figs. 16, 17, and 18. Figure 16 shows a typical controller state diagram. Figure 17 depicts the block diagram of the datapath controller. Figure 18 suggests a *PLA* implementation of the controller.

Many areas of application have benefited from PLAs and PLA-based devices, such as cryptography (6), signal processing (7), computer graphics (8), image processing (9), data mining (9), and networking (10).

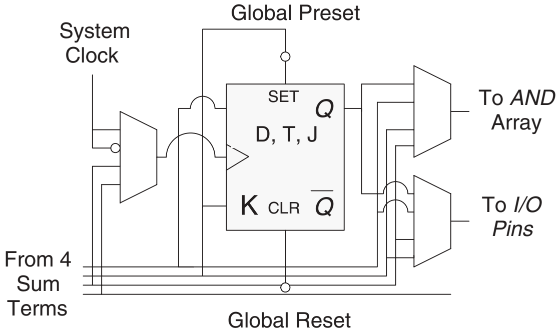

Figure 14. Structure of PEEL Array Logic Cell.

PROGRAMMING PLAs

Traditional PLAs usually are programmed using a PLA device programmer (such as traditional PROMs and EPROM-based logic devices). Some more complex PLA-based devices, such as CPLDs, can be programmed using device programmers; modern CPLDs are in-circuit programmable. In other words, the circuit required to perform device programming is provided within the CPLD chip. In-circuit programmability makes it possible to erase and reprogram the device without an external device programmer.

Modern CPLDs, which include the internal *PLA*-like structures, benefit from the latest advances in the area of hardware/software codesign. Descriptions of the desired hardware structure and behavior are written in a high-level context using hardware description languages such as Verilog. Then, the description code is compiled and downloaded in the programmable device before execution. Schematic captures are an option for design entry. Schematic captures have become less popular especially with complex designs. The process of hardware describe-and-synthesize development for programmable logic devices is shown in Fig. 15.

Hardware compilation consists of several steps. Hardware synthesis is the first major step of compilation, where an intermediate representation of the hardware design (called a netlist) is produced. A netlist usually is stored in a standard format called the electronic design interchange format and it is independent of the targeted device details. The second step of compilation is called place and route, where the logical structures described in the netlist are mapped onto the actual macrocells, interconnections, and input and output pins of the targeted device. The result of the place and route process is a called a bitstream. The bitstream is the binary data that must be loaded into the

PLD to program it to implement a particular hardware design.

THE RENEWABLE USEFULNESS OF PLAs

PLAs and their design basis have witnessed a renewable importance and have been the choice of designers for many systems as well as the target of different design methodologies. The renewable usefulness of PLAs is clear from the number of investigations carried out relying on the basis of PLAs.

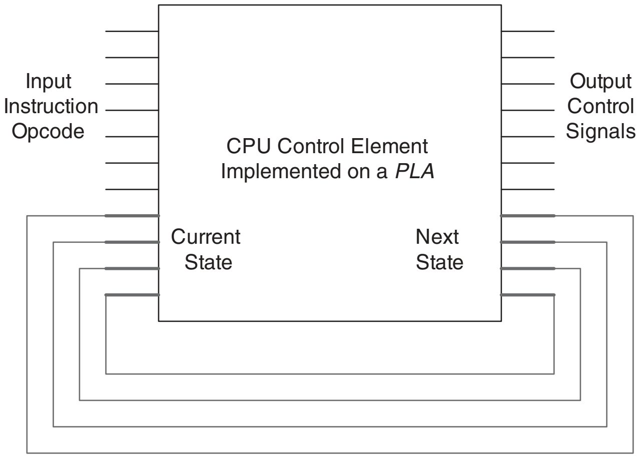

Figure 17. A design example of a datapath controller; Control Element block diagram,

A subthreshold circuit design approach based on asynchronous micropipelining of a levelized network of PLAs is investigated in Ref.11. The main purpose of the presented approach is to reduce the speed gap between subthreshold and traditional designs. Energy saving is noted when using the proposed approach in a factor of four as compared with a traditional designed networks of PLAs.

In Ref. 12, the authors propose a maximum crosstalk minimization algorithm that takes logic synthesis into consideration for PLA structures. To minimize the crosstalk, technique of permuting wires is used. The PLA product terms lines are partitioned into long set and short set, then product lines in the long set and the short set are

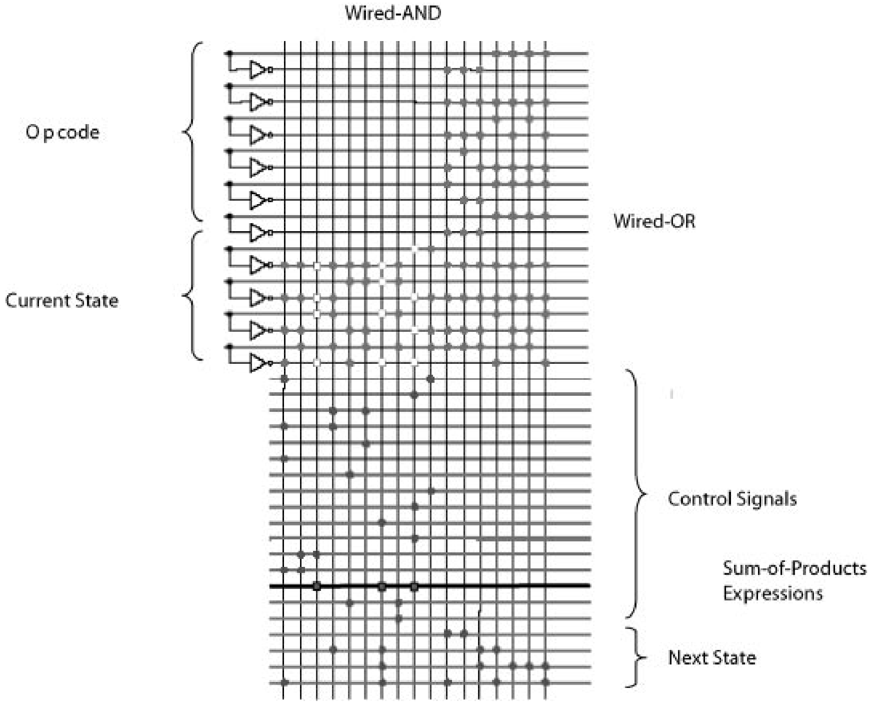

Figure 18. A design example of a datapath controller; PLA internal implementation.

interleaved. The interleaved wires are checked for the maximum coupling capacitance to reduce the maximum crosstalk effect of the PLA.

A logic synthesis method for an *AND-XOR-OR* type sense-amplifying PLA is proposed in Ref.13. Latch sense-amplifiers and a charge sharing scheme are used to achieve lowpower dissipation in the suggested PLA.

Testable design to detect stuck-at and bridging faults in *PLAs* is suggested in Ref. 14. The testable design is based on double fixed-polarity reed-muller expressions. An *XOR* part is proposed in the design implemented in a tree structure to reduce circuit delay.

A VLSI approach that addresses the cross-talk problem in deep sub-micron IC design is investigated in Ref.15. Logic netlists are implemented in the form of a network of medium-sized PLAs. Two regular layout "fabrics" are used in this methodology, one for areas where PLA logic is implemented, and another to route regions between logic blocks.

In Ref. 16, a PLA-based performance optimization design procedure for standardcells is proposed. The optimization is completed by implementing circuits' critical paths using PLAs. PLAs are proven to be good for such a replacement approach because they exhibit a gradual increase in delay as additional items are added. The final optimized hybrid design contains standard cells and a PLA.

A performance-driven mapping algorithm for CPLDs with a large number of PLA-style logic cells is proposed in Ref .17 .The primary goal of the mapping algorithm is to minimize the depth of the mapped circuit. The algorithm included applying several heuristic techniques for area reduction, threshold control of PLA fan-outs and product terms, slack-time relaxation, and PLA-packing.

The attractions of PLAs for mainstream engineers include their simplicity, relatively small circuit area, predictable propagation delay, and ease of development. The powerful but simple nature of PLAs brought them to rapid prototyping, synthesis, design optimization techniques, embedded systems, traditional computer systems, hybrid high-performance computing systems, and so on. Indeed, there has been renewable interests in working with the simple *AND*-to-*OR* PLAs.

REDUCED INSTRUCTION SET COMPUTING

ARCHITECTURE

The term *computer architecture* was first defined in the article by Amdahl, Blaauw, and Brooks of International Business Machines (IBM) Corporation announcing the IBM System/360 computer family on April 7, 1964 (1,2). On that day, IBM Corporation introduced, in the words of an IBM spokesperson, "the most important product announcement that this corporation has made in its history."

Computer architecture was defined as the attributes of a computer seen by the machine language programmer as described in the *Principles of Operation*. IBM referred to the Principles of Operation as a definition of the machine that enables the machine language programmer to write functionally correct, time-independent programs that would run across a number of implementations of that particular architecture.

The architecture specification covers all functions of the machine that are observable by the program (3). On the other hand, Principles of Operation are used to define the functions that the implementation should provide. In order to be functionally correct, it is necessary that the implementation conforms to the Principles of Operation.

The Principles of Operation document defines computer architecture, which includes:

- Instruction set
- Instruction format
- Operation codes
- Addressing modes
- All registers and memory locations that may be directly manipulated or tested by a machine language program
- Formats for data representation

Machine Implementation was defined as the actual system organization and hardware structure encompassing the major functional units, data paths, and control.

Machine Realization includes issues such as logic technology, packaging, and interconnections.

Separation of the machine architecture from implementation enabled several embodiments of the same architecture to be built. Operational evidence proved that architecture and implementation could be separated and that one need not imply the other. This separation made it possible to transfer programs routinely from one model to another and expect them to produce the same result which defined the notion of *architectural compatibility*. Implementation of the whole line of computers according to a common architecture requires unusual attention to details and some new procedures which are described in the Architecture Control Procedure. The design and control of system architecture is an ongoing process whose objective is to remove ambiguities in the definition of the architecture and, in some cases, adjust the functions provided (1,3,4).

RISC Architecture

A special place in computer architecture is given to RISC. RISC architecture has been developed as a result of the 801 project which started in 1975 at the IBM Thomas J. Watson Research Center and was completed by the early 1980s (5). This project was not widely known to the world outside of IBM, and two other projects with similar objectives started in the early 1980s at the University of California Berkeley and Stanford University (6,7). The term RISC (reduced instruction set computing), used for the Berkeley research project, is the term under which this architecture became widely known and recognized today.

Development of RISC architecture started as a rather "fresh look at existing ideas" (5,8,9) after revealing evidence that surfaced as a result of examination of how the instructions are actually used in the real programs. This evidence came from the analysis of the *trace tapes*, a collection of millions of the instructions that were executed in the machine running a collection of representative programs (10). It showed that for 90% of the time only about 10 instructions from the instruction repertoire were actually used. Then the obvious question was asked: "why not favor implementation of those selected instructions so that they execute in a short cycle and emulate the rest of the instructions?" The following reasoning was used: "If the presence of a more complex set adds just one logic level to a 10 level basic machine cycle, the CPU has been slowed down by 10%. The frequency and performance improvement of the complex functions must first overcome this 10% degradation and then justify the additional cost" (5). Therefore, RISC architecture starts with a small set of the most frequently used instructions which determines the pipeline structure of the machine enabling fast execution of those instructions in one cycle. If addition of a new complex instruction increases the "critical path" (typically 12 to 18 gate levels) for one gate level, then the new instruction should contribute at least 6% to 8% to the overall performance of the machine.

One cycle per instruction is achieved by exploitation of parallelism through the use of pipelining. It is *parallelism through pipelining* that is the single most important characteristic of RISC architecture from which all the remaining features of the RISC architecture are derived. Basically we can characterize RISC as a *performance-oriented architecture based on exploitation of parallelism through pipelining*.

RISC architecture has proven itself, and several mainstream architectures today are of the RISC type. Those include SPARC (used by Sun Microsystems workstations, an outgrowth of Berkeley RISC), MIPS (an outgrowth of

Stanford MIPS project, used by Silicon Graphics), and a superscalar implementation of RISC architecture, IBM RS/6000 (also known as PowerPC architecture).

RISC Performance

Since the beginning, the quest for higher performance has been present in the development of every computer model and architecture. This has been the driving force behind the introduction of every new architecture or system organization. There are several ways to achieve performance: technology advances, better machine organization, better architecture, and also the optimization and improvements in compiler technology. By technology, machine performance can be enhanced only in proportion to the amount of technology improvements; this is, more or less, available to everyone. It is in the machine organization and the machine architecture where the skills and experience of computer design are shown. RISC deals with these two levels—more precisely their interaction and trade-offs.

The work that each instruction of the RISC machine performs is simple and straightforward. Thus, the time required to execute each instruction can be shortened and the number of cycles reduced. Typically the instruction execution time is divided into five stages, namely, machine cycles; and as soon as processing of one stage is finished, the machine proceeds with executing the second stage. However, when the stage becomes free it is used to execute the same operation that belongs to the next instruction. The operation of the instructions is performed in a pipeline fashion, similar to the assembly line in the factory process. Typically, those five pipeline stages are as follows:

IF: Instruction Fetch

ID: Instruction Decode

EX: Execute

MA: Memory Access

WB: Write Back

By overlapping the execution of several instructions in a pipeline fashion (as shown in Fig. 1), RISC achieves its inherent execution parallelism which is responsible for the performance advantage over the complex instruction set architectures (CISC).

The goal of RISC is to achieve an execution rate of one cycle per instruction (CPI = 1.0), which would be the case when no interruptions in the pipeline occurs. However, this is not the case.

The instructions and the addressing modes in RISC architecture are carefully selected and tailored upon the most frequently used instructions, in a way that will result in a most efficient execution of the RISC pipeline.

The simplicity of the RISC instruction set is traded for more parallelism in execution. On average, a code written for RISC will consist of more instructions than the one written for CISC. The typical trade-off that exists between RISC and CISC can be expressed in the total time required to execute a certain task:

$$\text{Time (task)} = I \times C \times P \times T_0$$

where

$I =$ number of instructions/task

$C =$ number of cycles/instruction

$P =$ number of clock periods/cycle (usually $P=1$)

$T_0 =$ clock period (ns)

While CISC instruction will typically have less instructions for the same task, the execution of its complex operations will require more cycles and more clock ticks within the cycle as compared to RISC (11). On the other hand, RISC requires more instructions for the same task. However, RISC executes its instructions at the rate of one instruction per cycle, and its machine cycle requires only one clock tick (typically). In addition, given the simplicity of the instruction set, as reflected in simpler machine implementation, the clock period T_0 in RISC can be shorter, allowing the RISC machine to run at the higher speed as compared to CISC. Typically, as of today, RISC machines have been running at the frequency reaching 1 GHz, while CISC is hardly at the 500 MHz clock rate.

The trade-off between RISC and CISC can be summarized as follows:

1. CISC achieves its performance advantage by denser program consisting of a fewer number of powerful instructions.
2. RISC achieves its performance advantage by having simpler instructions resulting in simpler and therefore faster implementation allowing more parallelism and running at higher speed.

RISC MACHINE IMPLEMENTATION

The main feature of RISC is the architectural support for the exploitation of parallelism on the instruction level. Therefore all distinguished features of RISC architecture should be considered in light of their support for the RISC pipeline. In addition to that, RISC takes advantage of the principle of locality: *spatial* and *temporal*. What that means is that the data that was used recently is more likely to be used again. This justifies the implementation of a relatively large general-purpose register file found in RISC machines as opposed to CISC. Spatial locality means that the data most likely to be referenced is in the neighborhood of a location that has been referenced. It is not explicitly stated, but that implies the use of caches in RISC.

Load/Store Architecture

Often, RISC is referred to as Load/Store architecture. Alternatively the operations in its instruction set are defined as Register-to-Register operations. The reason is that all the RISC machine operations are between the operands that reside in the General Purpose Register File (GPR). The result of the operation is also written back to GPR. When restricting the locations of the operands to the GPR only, we allow for determinism in the RISC operation. In the other words, a potentially multicycle and unpredictable access to memory has been separated from the operation. Once the operands are available in the GPR, the operation can proceed in a deterministic fashion. It is almost certain that once commenced, the operation will be completed in the number of cycled determined by the pipeline depth and the result will be written back into the GPR. Of course, there are possible conflicts for the operands which can, nevertheless, be easily handled in hardware. The execution flow in the pipeline for a Register-to-Register operation is shown in Fig. 2.

Memory Access is accomplished through Load and Store instructions only; thus the term *Load / Store Architecture* is often used when referring to RISC. The RISC pipeline is specified in a way in which it must accommodate both operation and memory access with equal efficiency. The various pipeline stages of the Load and Store operations in RISC are shown in Fig. 3.

Carefully Selected Set of Instructions

The principle of locality is applied throughout RISC. The fact that only a small set of instructions is most frequently

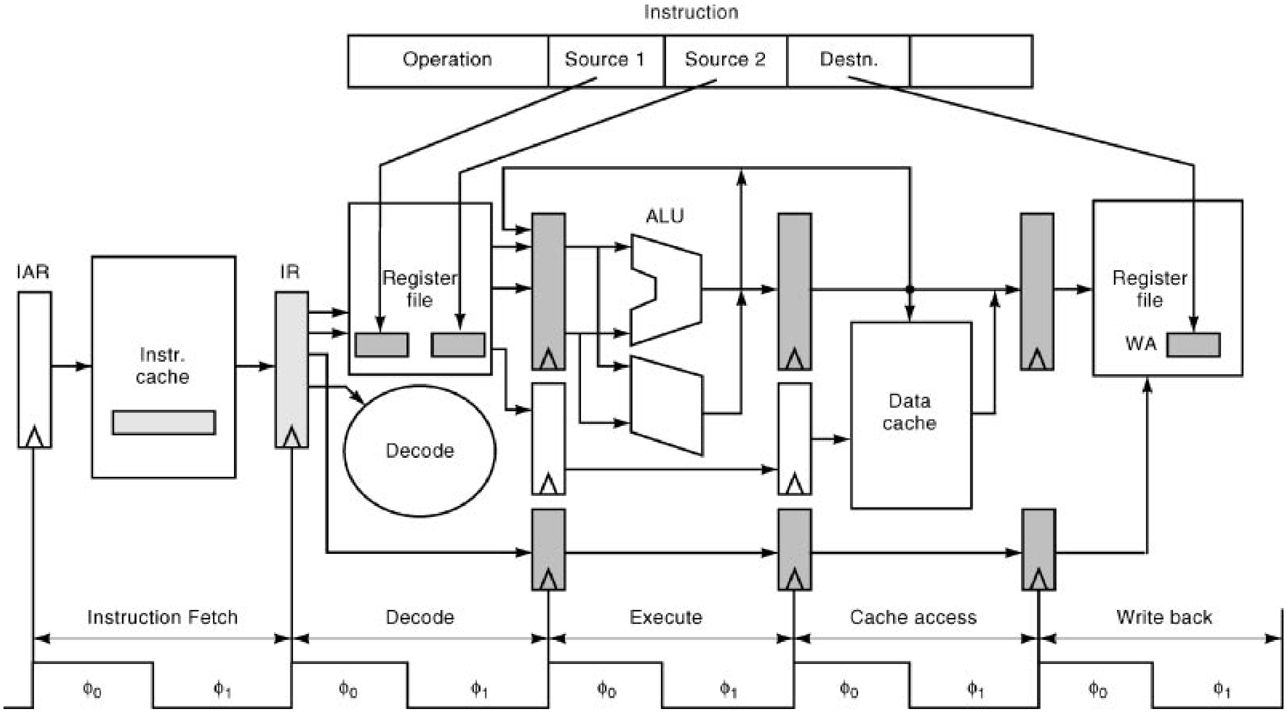

Figure 2. Pipeline flow of a Register-to-Register operation.

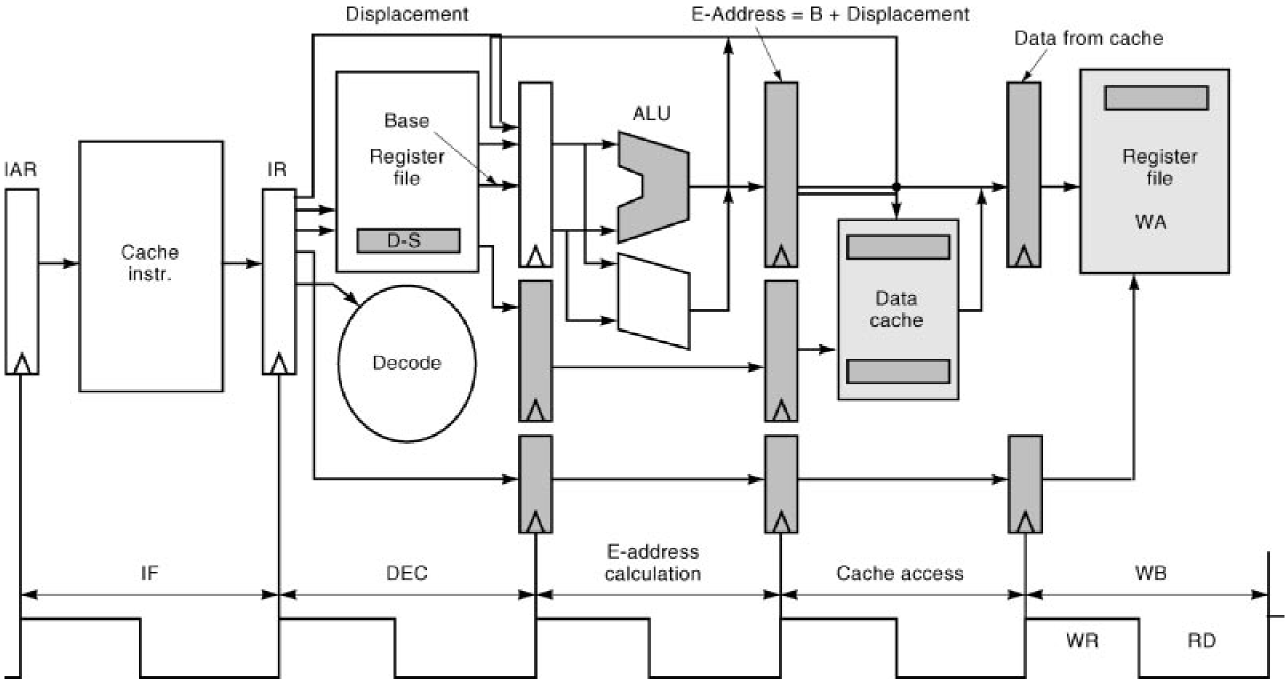

Figure 3. The operation of Load/Store pipeline.

used, was used in determining the most efficient pipeline organization with a goal of exploiting instruction level parallelism in the most efficient way. The pipeline is “tailored” for the most frequently used instructions. Such derived pipelines must serve efficiently the three main instruction classes:

- Access to Cache: Load/Store
- Operation: Arithmetic/Logical
- Branch

Given the simplicity of the pipeline, the control part of RISC is implemented in hardware—unlike its CISC counterpart, which relies heavily on the use of microcoding.

However, this is the most misunderstood part of RISC architecture which has even resulted in the inappropriate name: RISC. Reduced instruction set computing implies that the number of instructions in RISC is small. This has created a widespread misunderstanding that the main feature characterizing RISC is a small instruction set. This is not true. The number of instructions in the instruction set of RISC can be substantial. This number of RISC instructions can grow until the complexity of the control logic begins to impose an increase in the clock period. In practice, this point is far beyond the number of instructions commonly used. Therefore we have reached a possibly paradoxical situation, namely, that several of representative RISC machines known today have an instruction set larger than that of CISC.

For example: IBM PC-RT Instruction architecture contains 118 instructions, while IBM RS/6000 (PowerPC) contains 184 instructions. This should be contrasted to the IBM System/360 containing 143 instructions and to the IBM System/370 containing 208. The first two are representatives of RISC architecture, while the latter two are not.

Fixed Format Instructions

What really matters for RISC is that the instructions have a fixed and predetermined format which facilitates decoding in one cycle and simplifies the control hardware. Usually the size of RISC instructions is also fixed to the size of the word (32 bits); however, there are cases where RISC can contain two sizes of instructions, namely, 32 bits and 16 bits. Next is the case of the IBM ROMP processor used in the first commercial RISC IBM PC/RT. The fixed format feature is very important because RISC must decode its instruction in one cycle. It is also very valuable for superscalar implementations (12). Fixed size instructions allow the Instruction Fetch Unit to be efficiently pipelined (by being able to determine the next instruction address without decoding the current one). This guarantees only single I-TLB access per instruction.

One-cycle decode is especially important so that the outcome of the Branch instruction can be determined in one cycle in which the new target instruction address will be issued as well. The operation associated with detecting and processing a Branch instruction during the Decode cycle is illustrated in Fig. 4. In order to minimize the number of lost cycles, Branch instructions need to be resolved, as well, during the Decode stage. This requires a separate address adder as well as comparator, both of which are used in the Instruction Decode Unit. In the best case, one cycle must be lost when Branch instruction is encountered.

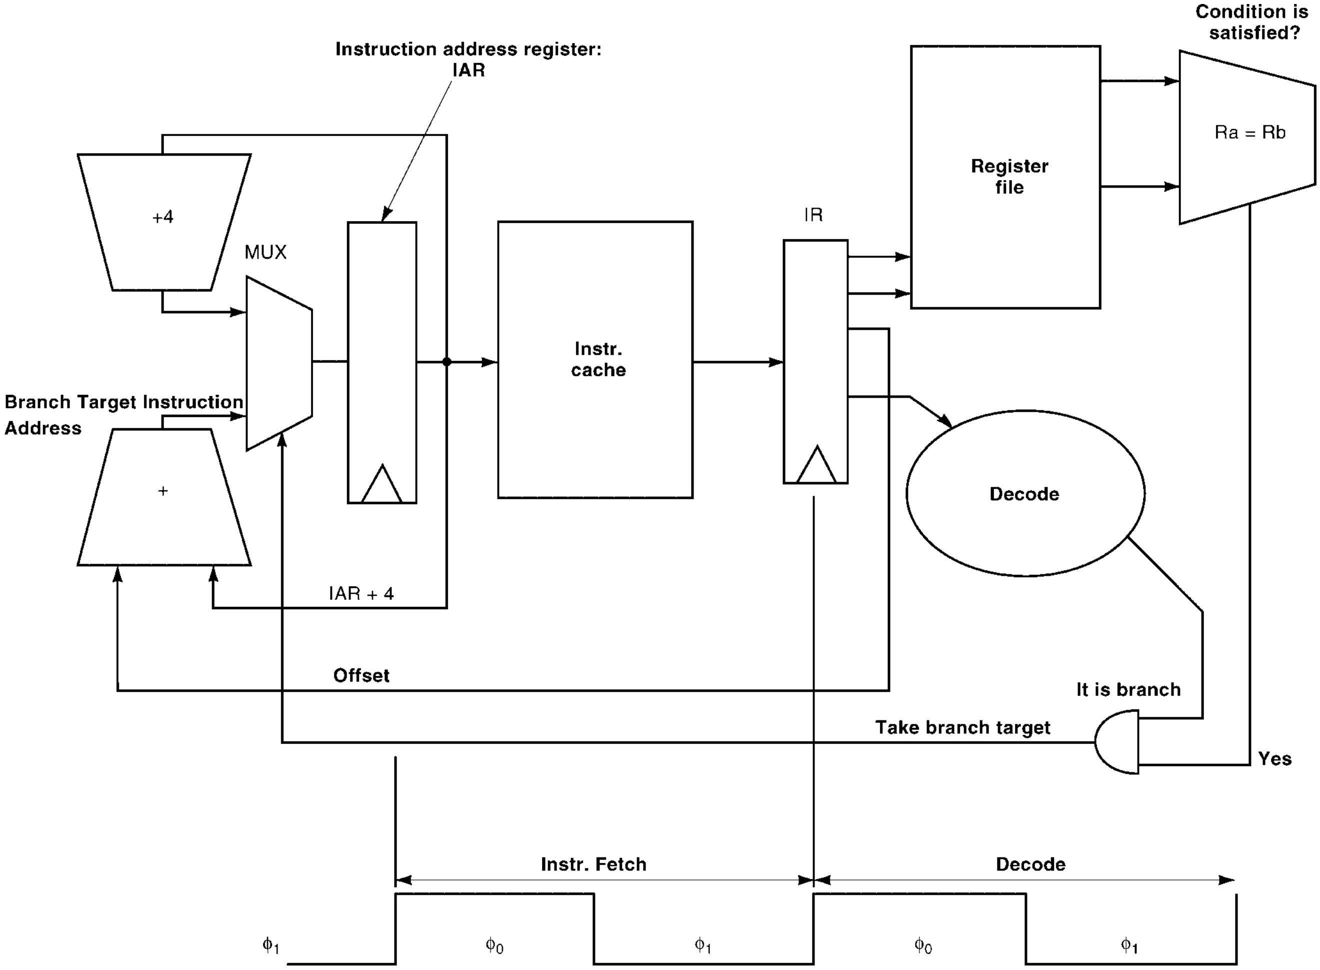

Figure 4. Branch instruction.

Simple Addressing Modes

Simple Addressing Modes are the requirements of the pipeline. That is, in order to be able to perform the address calculation in the same predetermined number of pipeline cycles in the pipeline, the address computation needs to conform to the other modes of computation. It is a fortunate fact that in real programs the requirements for the address computations favors three relatively simple addressing modes:

1. Immediate
2. Base+Displacement
3. Base+Index

Those three addressing modes take approximately over 80% of all the addressing modes according to Ref. (3): (1) 30% to 40%, (2) 40% to 50%, and (3) 10% to 20%. The process of calculating the operand address associated with Load and Store instructions is shown in Fig. 3.

Separate Instruction and Data Caches

One of the often overlooked but essential characteristics of RISC machines is the existence of cache memory. The second most important characteristic of RISC (after pipelining) is its use of the locality principle. The locality principle is established on the observation that, on average, the program spends 90% of the time in the 10% of the code. The instruction selection criteria in RISC is also based on that very same observation that 10% of the instructions are responsible for 90% of the code. Often the principle of the locality is referred to as a 90–10 rule (13).

In case of the cache, this locality can be spatial and temporal. *Spatial locality* means that the most likely location in the memory to be referenced next will be the location in the neighborhood of the location that was just referenced previously. On the other hand, *temporal locality* means that the most likely location to be referenced next will be from the set of memory locations that were referenced just recently. The cache operates on this principle.

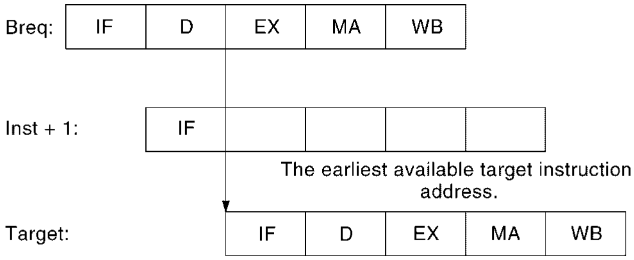

Figure 5. Pipeline flow of the Branch instruction.

The RISC machines are based on the exploitation of that principle as well. The first level in the memory hierarchy is the general-purpose register file GPR, where we expect to find the operands most of the time. Otherwise the Register-to-Register operation feature would not be very effective. However, if the operands are not to be found in the GPR, the time to fetch the operands should not be excessive. This requires the existence of a fast memory next to the CPU—the Cache. The cache access should also be fast so that the time allocated for Memory Access in the pipeline is not exceeded. One-cycle cache is a requirement for RISC machine, and the performance is seriously degraded if the cache access requires two or more CPU cycles. In order to maintain the required one-cycle cache bandwidth the data and instruction access should not collide. It is from there that the separation of instruction and data caches, the so-called Harvard architecture, is a must feature for RISC.

Branch and Execute Instruction

Branch and Execute or Delayed Branch instruction is a new feature of the instruction architecture that was introduced and fully exploited in RISC. When a Branch instruction is encountered in the pipeline, one cycle will be inevitably lost. This is illustrated in Fig. 5.

RISC architecture solves the lost cycle problem by introducing Branch and Execute instruction (5,9) (also known as Delayed Branch instruction), which consists of an instruction pair: *Branch* and the *Branch Subject* instruction which is always executed. It is the task of the compiler to find an instruction which can be placed in that otherwise wasted pipeline cycle.

The subject instruction can be found in the instruction stream preceding the Branch instruction, in the target instruction stream, or in the fall-through instruction stream. It is the task of the compiler to find such an instruction and to fill-in this execution cycle (14).

Given the frequency of the Branch instructions, which varies from 1 out of 5 to 1 out of 15 (depending on the nature of the code), the number of those otherwise lost cycles can be substantial. Fortunately a good compiler can fill-in 70% of those cycles which amounts to an up to 15% performance improvement (13). This is the single most performance contributing instruction from the RISC instruction architecture.

However, in the later generations of superscalar RISC machines (which execute more than one instruction in the pipeline cycle), the *Branch and Execute* instructions have been abandoned in favor of *Brand Prediction*(12,15).

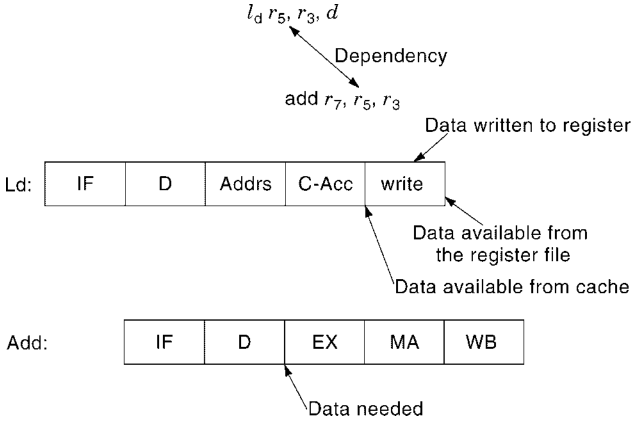

Figure 6. Lost cycle during the execution of the load instruction.

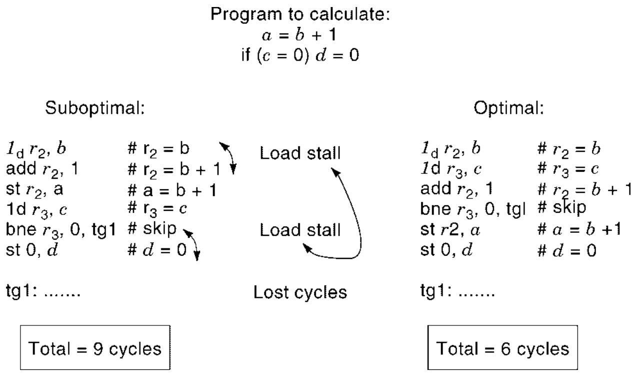
The Load instruction can also exhibit this lost pipeline cycle as shown in Fig. 6.

The same principle of scheduling an independent instruction in the otherwise lost cycle, which was applied for in Branch and Execute, can be applied to the Load instruction. This is also known as delayed load.

An example of what the compiler can do to schedule instructions and utilize those otherwise lost cycles is shown in Fig. 7 (13,14).

Optimizing Compiler

A close coupling of the compiler and the architecture is one of the key and essential features in RISC that was used in order to maximally exploit the parallelism introduced by pipelining. The original intent of the RISC architecture was to create a machine that is only *visible through the compiler*(5,9). All the programming was to be done in High-Level Language and only a minimal portion in Assembler. The notion of the "Optimizing Compiler" was introduced in RISC (5,9,14). This compiler was capable of producing a code that was as good as the code written in assembler (the hand-code). Though there was strict attention given to the architecture principle (1,3), adhering to the absence of the implementation details from the principle of the operation, this is perhaps the only place where this principle was violated. Namely, the optimizing compiler needs to "know"



```
1d r2, b            # r2 = b
add r2, 1           # r2 = b + 1
st r2, a            # a = b + 1
1d r3, c            # r3 = c
bne r3, 0, tg1      # skip
st 0, d             # d = 0

tg1: .......
```

```
1d r2, b            # r2 = b
1d r3, c            # r3 = c
add r2, 1           # r2 = b + 1
bne r3, 0, tgl      # skip
st r2, a            # a = b +1
st 0, d             # d = 0

tg1: .......
```

Figure 7. An example of instruction scheduling by compiler.

the details of the implementation, the pipeline in particular, in order to be able to efficiently schedule the instructions. The work of the optimizing compiler is illustrated in Fig. 7.

One Instruction per Cycle

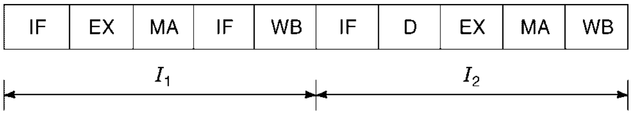
The objective of *one instruction per cycle* (CPI = 1) execution was the ultimate goal of RISC machines. This goal can be theoretically achieved in the presence of infinite size caches and thus no pipeline conflicts, which is not attainable in practice. Given the frequent branches in the program and their interruption to the pipeline, Loads and Stores that cannot be scheduled, and finally the effect of finite size caches, the number of "lost" cycles adds up, bringing the CPI further away from 1. In the real implementations the CPI varies and a CPI=1.3 is considered quite good, while CPI between 1.4 to 1.5 is more common in single-instruction issue implementations of the RISC architecture.

However, once the CPI was brought close to 1, the next goal in implementing RISC machines was to bring CPI below 1 in order for the architecture to deliver more performance. This goal requires an implementation that can execute more than one instruction in the pipeline cycle, a so called *superscalar* implementation (12,16). A substantial effort has been made on the part of the leading RISC machine designers to build such machines. However, machines that execute up to four instructions in one cycle are common today, and a machine that executes up to six instructions in one cycle was introduced in 1997.

Pipelining

Finally, the single most important feature of RISC is pipelining. The degree of parallelism in the RISC machine is determined by the depth of the pipeline. It could be stated that all the features of RISC (that were listed in this article) could easily be derived from the requirements for pipelining and maintaining an efficient execution model. The sole purpose of many of those features is to support an efficient execution of RISC pipeline. It is clear that without pipelining, the goal of CPI = 1 is not possible. An example of the instruction execution in the absence of pipelining is shown in Fig. 8.

We may be led to think that by increasing the number of pipeline stages (the pipeline depth), thus introducing more parallelism, we may increase the RISC machine performance further. However, this idea does not lead to a simple and straightforward realization. The increase in the number of pipeline stages introduces not only an overhead in hardware (needed to implement the additional pipeline registers), but also the overhead in time due to the delay of the latches used to implement the pipeline stages as well as the cycle time lost due to the clock skews and clock jitter. This could very soon bring us to the point of diminishing returns where further increase in the pipeline depth would result in less performance. An additional side effect of deeply pipelined systems is hardware complexity necessary to resolve all the possible conflicts that can occur between the increased number of instructions residing in the pipeline at one time. The number of the pipeline stages is mainly determined by the type of the *instruction core* (the most frequent instructions) and the operations required by those instructions. The pipeline depth depends, as well, on the technology used. If the machine is implemented in a very high speed technology characterized by the very small number of gate levels (such as GaAs or ECL), and a very good control of the clock skews, it makes sense to pipeline the machine deeper. The RISC machines that achieve performance through the use of many pipeline stages are known as *superpipelined* machines.



Total of cycles for two instructions

Figure 8. Instruction execution in the absence of pipelining.

Today the most common number of pipeline stages encountered is five (as in the examples given in this text). However, 12 or more pipeline stages are encountered in some machine implementations.

The features of RISC architecture that support pipelining are listed in Table 1.

Table 1. Features of RISC Architecture

Feature	Characteristic
Load/store architecture	All operations are Register to Register, so *Operation* is decoupled from *access to memory*
Carefully selected subset of instructions	Control implemented in hardware (no microcoding in RISC); set of instructions not necessarily small[a]
Simple addressing modes	Only most frequently used addressing modes used; important to fit into existing pipeline
Fixed size and fixed field instructions	Necessary to decode instruction and access operands in one cycle (there are, however, architectures using two sizes for instruction format (IBM PC-RT))
Delayed branch instruction (known also as *Branch* and *Execute*)	Most important performance improvement through instruction architecture (no longer true in new designs)
One instruction per cycle execution rate (CPI = 1.0)	Possible only through use of pipelining
Optimizing compiler	Close coupling between architecture and compiler (compiler *knows* about pipeline)
Harvard architecture	Separation of *Instruction* and *Data Cache* resulting in increased memory bandwidth

[a] IBM PC-RT Instruction architecture contains 118 instructions, while IBM RS/6000 (PowerPC) contains 184 instructions. This should be contrasted to the IBM System/360 containing 143 instructions and IBM System/370 containing 208. The first two are representatives of RISC architecture; the latter two are not.

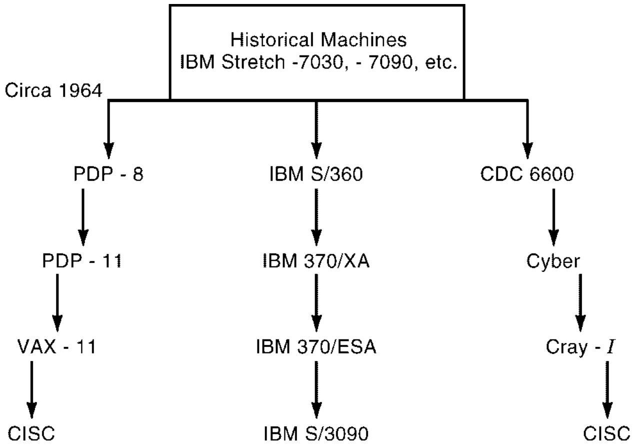


Figure 9. Main branches in development of computer architecture.

HISTORICAL PERSPECTIVE

The architecture of RISC did not come about as a planed or a sudden development. It was rather a long and evolutionary process in the history of computer development in which we learned how to build better and more efficient computer systems. From the first definition of the architecture in 1964 (1), there are the three main branches of the computer architecture that evolved during the years. They are shown in Fig. 9.

The CISC development was characterized by (1) the PDP-11 and VAX-11 machine architecture that was developed by Digital Equipment Corporation (DEC) and (2) all the other architectures that were derived from that development. The middle branch is the IBM 360/370 line of computers, which is characterized by a balanced mix of CISC and RISC features. The RISC line evolved from the development line characterized by Control Data Corporation CDC 6600, Cyber, and ultimately the CRAY-I supercomputer. All of the computers belonging to this branch were originally designated as *supercomputers* at the time of their introduction. The ultimate quest for performance and excellent engineering was a characteristic of that branch. Almost all of the computers in the line preceding RISC carry the signature of one man: Seymour Cray, who is by many given the credit for the invention of RISC.

History of RISC

The RISC project started in 1975 at the IBM Thomas J. Watson Research Center under the name of the 801. 801 is the number used to designate the building in which the project started (similar to the 360 building). The original intent of the 801 project was to develop an emulator for System/360 code (5). The IBM 801 was built in ECL technology and was completed by the early 1980s (5,8). This project was not known to the world outside of IBM until the early 1980s, and the results of that work are mainly unpublished. The idea of a simpler computer, especially the one that can be implemented on the single chip in the university environment, was appealing; two other projects with similar objectives started in the early 1980s at the University of California Berkeley and Stanford University (6,7). These two academic projects had much more influence on the industry than the IBM 801 project. Sun Microsystems developed its own architecture currently known as SPARC as a result of the University of California Berkeley work. Similarly, the Stanford University work was directly transferred to MIPS (17).

The chronology illustrating RISC development is illustrated in Fig. 10.

The features of some contemporary RISC processors are shown in Table 2.

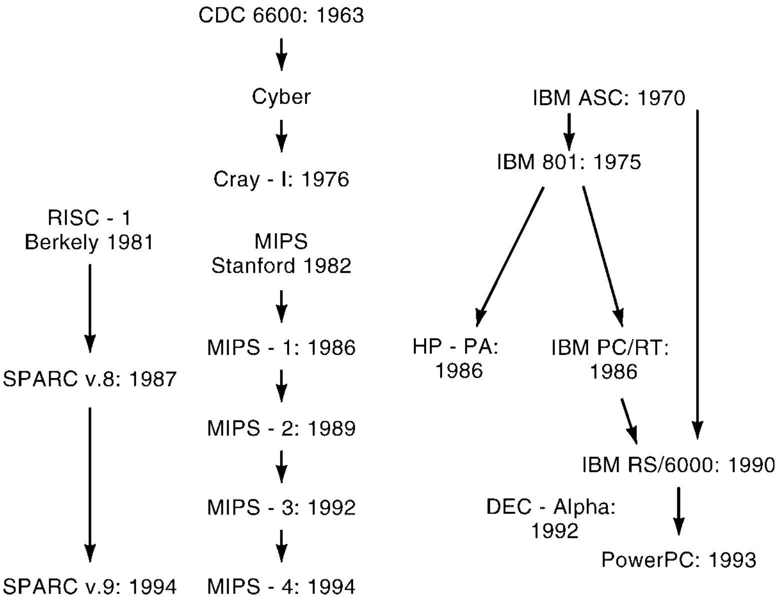

Figure 10. History of RISC development.

Table 2. Some features of RISC Processors

Feature	Digital 21164	MIPS 10000	PowerPC 620	HP 8000	Sun UltraSparc
Frequency (MHz)	500	200	200	180	250

SPECULATION

Modern compilers and processors employ many different kinds of speculation to improve parallel execution. Broadly speaking, the speculation can be categorized into three different groups.

1. Control speculation: Guess which instructions will be executed.
2. Value speculation: Guess the output value computed by an instruction.
3. Data access speculations: Guess what data will be accessed by a program.

Several things must be taken into consideration when deciding whether to speculate, such as the number of situations that may benefit from the speculation, the potential gain of the speculation, the accuracy of the speculation, and the penalty of misspeculation. If a particular form of speculation provides only modest performance improvement each time it is applied, it may be worthwhile if the speculation is applicable often, the speculation accuracy is sufficiently high, and the misspeculation penalty is small. On the other hand, speculation that offers huge performance gains may be inappropriate if the speculation accuracy is low or the misspeculation penalty is too high.

The remainder of this article will discuss various forms of speculation employed in modern processors and compilers. For each situation, the need for speculation will be described, the speculation and recovery mechanisms will be outlined, and the benefits of the speculation will be discussed.

CONTROL SPECULATION

In the von Neumann architecture, programs are expressed as a sequence of instructions executed by the processor. The processor retrieves each instruction from memory, performs the computation indicated by the instruction, and stores its result. The process then repeats for the instruction that lies in the adjacent memory location. Branch instructions interrupt this sequential processing and instruct the processor to begin executing from a new memory address (rather than the next sequential address). Most modern processors, however, do not implement the von Neumann architecture directly. Instead, several instructions execute in parallel (via pipelining, superscalar execution, very long instruction word execution). With multiple instructions in flight simultaneously, processors normally fetch later instructions from memory *before* prior instructions have completed. This action proceeds unhindered during sequential execution, but branch instructions create *control hazards*. To fetch from the correct location, a nonspeculative processor must wait for the result of a branch instruction to know from where to fetch subsequent instructions. Stalling for these control hazards reduces the processor's instruction throughput. These stalls lead to many unused cycles and resources because control instructions occur frequently (every 5 to 10 instructions) in program streams (1).

Branch Prediction

To alleviate the performance degradation imposed by branch instructions, processor microarchitectures employ *branch prediction*, which is a form of control speculation. When using branch prediction, rather than waiting for the result of a branch instruction, the processor predicts what the next instruction address will be and begins fetching and executing instructions from this location speculatively. When the branch instruction completes execution, the actual target address of the branch is compared with the predicted address. If the addresses match, then no recovery action is taken and the processor can continue executing normally. Otherwise, the processor must discard the results of the speculative instructions (because they should not have been executed) and begin executing instructions from target of the branch.

Although it may seem that predicting an arbitrary 64-bit (or even 32-bit) target address would be extremely difficult, several factors in instruction set architecture (ISA) design and programming paradigms make this task far less challenging (although the task is still nontrivial). Branch instructions in most modern ISAs can be classified along two orthogonal axes. First, branch instructions can be unconditional or conditional. Unconditional branches always transfer control to a new target. Conditional branches, as the name suggests, may redirect control to a new address or may allow execution to continue sequentially depending on a condition that guards branch. Second, branch instructions can be direct or indirect. Direct branches encode the target of the control transfer directly in the instruction. Indirect branches, on the other hand, refer to a register or memory location that contains the target of the branch. Consequently, the target for an indirect branch can be computed by other instructions whereas the target for a direct branch is known at program compile time.

The majority of branch instructions in a program are unconditional or conditional direct branches. Consequently, a branch predictor must only decide whether the branch will be taken. Predicting this binary value is more simple than speculating a target address. Many schemes for predicting branches have been presented in the literature and infact, this was a principle research focus in computer architecture in the past decade. The simplest scheme is to always predict a single direction for the branch (2). For example, a processor could predict statically that all branches will be taken. Such an approach works surprisingly well because loop back-edge branches are taken more often than not. More advanced techniques make predictions based on the history of past branches. Empirical observations show that if previous instances of a branch

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

in the program have gone in a particular direction, then future instances are likely to go the same way. Consequently, using branch history can improve prediction accuracy tremendously. Other techniques that leverage correlations between different branches or hints provided by compilers are also used frequently (3). Branch predictors implemented in commercial processors, using the techniques described here as well as more advanced techniques, have been able to predict in excess of 95% of conditional branches in many programs successfully.

Although the mechanisms just described allow predictions to be made for direct jumps, they are inadequate for indirect jumps. Many branch predictors include a structure called a *branch target buffer* (BTB) to help predict indirect jumps. The BTB stores the target for the last execution of a particular branch in the program (2).When the branch is encountered again, the target stored in the BTB is predicted. This target can be combined with traditional branch prediction for conditional indirect jumps.

In the event of a branch misprediction, it is necessary for the processor to discard the results of speculative instructions and restart execution at the correct point in the program. Depending on the microarchitecture, the hardware support necessary to roll back speculative instructions varies. In an in-order pipelined processor, the predicted branch instruction is guaranteed to execute *before* later instructions reach the pipeline stages where results are stored to the register files or memory. Consequently, when encountering a branch misprediction, the microprocessor need only throw out all instructions that were initiated after the branch and then begin re-executing at the correct target. On machines that execute instructions out of order, instructions that follow a speculated branch can execute before the branch. To ensure that the effects of these instructions can be undone, out-of-order processors allow instructions to complete in an arbitrary order but ensure that they *commit* in program order. Architectural state is only updated when an instruction commits, not when it completes. Consequently, if misspeculation occurs, all instructions after the branch can be discarded safely because none of them have yet committed. Various microarchitectural structures are used to guarantee in-order commit: a reorder buffer tracks instructions that have not yet committed, a store buffer manages values that need to be written to memory upon commit, physical register files and register rename tables store the results of uncommitted instructions. Despite the complexity of branch prediction and misspeculation recovery, branch prediction plays a vital role to provide performance on modern processors.

Compiler Control Speculation

In addition to branch prediction performed at runtime by the microprocessor, compilers also employ control speculation. During the scheduling phase of compilation, the compiler may choose to move an instruction after a branch to a position before the branch. The compiler must ensure that the hoisted instruction will not interfere with the program's execution if, in the original program, the instruction would not have executed. The code motion is speculative because it may not improve performance. If, in the original code, the instruction would not have been executed frequently, then this extra computation may hurt (or in the best case may not improve) performance. However, if the instruction has long latency, this code motion may separate a data definition and data use by many cycles to prevent or reduce stalls later in the program. Note however, that no recovery is needed here in the case of misspeculation; the transformation is always legal, it is just the performance benefit that is speculative.

Memory loads that miss in the processor's cache have particularly long latency. Unfortunately, hoisting a load above a branch is not always safe because the address used by the load may be invalid when the branch is not taken. In certain architectures (like Intel's Itanium architecture), the ISA has a speculative load instruction. Rather than throw an exception when given a bad address, the speculative load will fail by setting a bit on the destination register. Code is placed after the branch in the load's original location to verify that the load occurred successfully (4). Compiler control speculation can be important on architectures like Intel's Itanium that execute instructions in order. Because any stalled instruction prevents the machine from making forward progress, it is particularly important to prevent the stall conditions by hoisting long latency instructions (such as loads) as early as possible.

VALUE SPECULATION

Branch prediction involved predicting the outcome of branch instructions to prevent processor stalls while fetching instructions. The concept of predicting an instructions outcome can be extended beyond branch instructions and applied to other instructions. This type of speculation is classified broadly as value speculation. In value speculation, the goal is to break dependences between data producing instructions and definite or potential data consuming instructions. By breaking the dependence, the producing instruction (or chain of instructions) can be run in parallel with the consumer or potential consumers to enhance the amount of parallelism exploitable by the processor. Value speculation is often employed in aggressive out-of-order processors to allow load instructions to execute before prior store instructions. Other types of value speculation are less common but have been studied in the literature (5).

Data Dependence Speculation

Out-of-order processors attempt to execute instructions as soon as the instructions' operands have been computed. Unfortunately, it is difficult for the instruction dependence tracking hardware in out-of-order processors to know when memory operands (for load instructions) have been computed because any earlier (not-yet-executed) store instruction could potentially write to the location read by the load instruction.

Because the address written to by store instructions is computed dynamically by other instructions, the processor must wait until the store instruction executes to know what location in memory it will alter. Rather than wait for the store instructions to complete, many processors will speculate that no data dependence exists between the unexecuted stores and the pending load instruction. The load instruction then speculatively executes ahead of the store instruction (6). When the address for the store instruction is known, the speculation can be verified by comparing the address of the load with the address of the store. If the two addresses match, then the data dependence speculation has failed and appropriate recovery steps must be taken. Otherwise, the load instruction has received the correct value from the memory subsystem and the processor can continue executing instructions. More recently, the research community has investigated similar techniques to speculate data dependences across program threads. Transactional memories (7) and thread-level speculation (8,9) represent two significant thrusts in this effort. Much like control misspeculations, when the a data dependence misspeculation occurs, the processor needs to undo the effects of the misspeculated instructions. The mechanism used for branch mispredictions can be used for data dependence misspeculations as well. When misspeculation is detected, the processor discards all instructions after (and including) the misspeculated load instruction and restarts execution at the load instruction. By this time, some of the stores that precede the load have completed, so the load may reissue this time speculating fewer dependences. If all preceding stores have completed, then the load is nonspeculative and will not misspeculate again. To reduce the penalty associated with misspeculation, the processor may decide *not* to execute the load instruction speculatively a second time. That is to say, once a misspeculation has been detected, the processor will wait until all previous store instructions have completed before re-executing the load.

Various techniques have been proposed (10–13) to improve the accuracy of speculation. Rather than always assuming that a load does not alias with a not-yet-executed store, these techniques use a history of previous aliases to speculate more accurately. This improvement in accuracy retains the benefit of correct speculation while mitigating the penalty of misspeculation.

Compiler Data Speculation

The compiler can perform data dependence speculation instead of, or in addition to, the hardware. This technique was implemented in Intel's Itanium architecture. While performing scheduling, the compiler may not know whether it is legal to move a load instruction above an earlier store instruction. The compiler has two ways it can hoist the load while ensuring the resulting code behaves correctly. First, it can use static memory alias analysis techniques to determine whether the load and store could *possibly* access the same location, and if not hoist the load. The alternative is to move the load above the store speculatively and then insert code to check whether the load and store aliased. In the event that an alias *did* occur, the program would have to branch to fixup code where the load, and any already executed dependent instructions, are re-executed with the correct data values. The fixup code would then branch back to the normal code and resume normal execution.

To facilitate an efficient check and fixup mechanism, the Intel Itanium architecture provides two specialized instructions and a dedicated hardware structure for data speculation. The architecture provides an advanced load instruction and a load check instruction. The processor provides a table, known as the, advanced load address table (ALAT), which records the addresses accessed by all advanced loads. When the processor executes an advanced load, a bit is set in the ALAT. Any subsequent store to the same address clears the bit in the ALAT. The load check instruction inspects the bit in the ALAT, and if it is set, the instruction does nothing. On the other hand, if the bit is unset, the load check instruction branches to recovery code where any necessary fix up can occur. Note, that even in the absence of an ALAT, it is possible for the compiler to insert an instruction sequence to detect whether or not a store aliased with a given load. The problem, however, is that each store that is bypassed requires a small section of code to check for a potential aliasing. Consequently, the overhead of detecting misspeculation will probably outweigh the benefits of correct speculation.

DATA ACCESS SPECULATION

The growing speed differential between microprocessors and main memory has created a problem feeding data to a microprocessor. In an attempt to make memory access faster, most modern processors have several layers of cache memories. The goal of these small, fast memories is to store data that is likely to be accessed in the future, which reduces the latency of accesses. Unlike the previous two speculation techniques, cache memories do not try to predict information to run instructions earlier. Rather, the cache memories speculate on what *data* will be accessed soon, which allows fast memory accesses. Caches operate by storing data that has been accessed recently in the hope that it will be accessed again (a phenomenon known as *temporal locality*). Similarly, caches store data near recently accessed data in the hope that it will be accessed (a phenomenon known as *spatial locality*). A related speculation technique, prefetching, goes one step further by bringing values into cache memories by using the program's past memory access patterns to predict future accesses. This section will discuss both of these techniques and their relation to speculation.

Caches

Caches are small, fast memories that store a subset of the data that a program has stored into memory. Each time a processor performs a load or store instruction, the cache memory is consulted to see if the address being accessed is stored in the cache. If so, a *cache hit* has occurred, and the cache returns the data (or stores the new value in the case of stores). If the data is absent, a *cache miss* has occurred, and main memory (or a lower level of the cache hierarchy) is accessed.

Caches are considered speculative because of how data are added to the cache memory. Each time a cache miss occurs, the cache must choose whether or not to take the data returned by the remainder of the memory hierarchy and store it into the cache. Typically, all read misses will result in a cache block (the basic unit of storage in a cache) to be allocated to hold the resulting data. On cache writes, however, two different policies can be employed: allocate on write and no allocate on write. As the name implies, in one policy a write miss will cause a cache block to be allocated, whereas the other does not allocate a block. When an allocate on write policy is employed, the data to fill the cache block is fetched from the memory hierarchy, and then the piece that is being written is stored into the cache.

Unfortunately, when allocating a cache block, other data from the cache must be evicted. This eviction occurs because the cache memory is full (a capacity miss has occurred) or restrictions on where data can be placed forces another piece of data out of the cache (a conflict miss has occurred). Because it is possible that the data being evicted will be the next data accessed, the decision to store data in the cache may be detrimental. On the other hand, if the data just read is accessed again, storing the data in the cache will improve performance. Consequently, the decision is speculative. Because programs typically exhibit *temporal locality*, that is the same address is often accessed more than once in a local window of time, storing recently accessed data is typically a good guess when speculating.

Programs also exhibit *spatial locality*. That is to say, if a particular address is accessed, it is likely that adjacent locations will also be accessed. Spatial locality is a result of several programming paradigms. First, data structures are typically larger than a word and are often accessed together. Iteration across an array also creates significant amounts of spatial locality. Even local variables stored on a procedure's stack create spatial locality since variables within a single function are accessed together. Caches exploit spatial locality by operating at the cache block granularity rather than operating at the byte or word granularity. Block sizes vary from tens of bytes to hundreds of bytes. By placing an entire block into the cache memory, the processor is speculating that adjacent memory locations will be accessed.

Prefetching

Although most programs exhibit some amount spatial and temporal locality, not all accesses result in cache hits. However, patterns in the access streams often hint at which addresses will soon be accessed. For example, the addresses accessed by a processor pipeline's instruction fetch stage often form a linear sequence. Consequently, it is fairly simple to predict which memory locations will be accessed next. A technique known as *prefetching* attempts to exploit this regularity in accesses to pull data preemptively into caches. Once again, it is possible that prefetching will displace useful data from the caches and consequently is a speculative optimization.

The most basic prefetching algorithm is stride-based prefetching. If addresses that form an arithmetic sequence are observed, then the prefetch hardware predicts that the sequence will continue and accesses lower levels of memory to pull this data into the cache. The intent is that when the program accesses the data, it will already be present in the cache. Furthermore, prefetehers strive to avoid evicting other useful data. Instruction prefetchers often use stride prefetching because th access pattern forms a arithmetic sequence. Stride prefetchers are also used for data caches to improve the access speeds for array traversals. More complex prefetchers have been suggested in the literature for prefetching recursive data structures and other irregular access patterns (14,15).

In addition to hardware-based prefetching, certain architectures provide prefetch instructions. These instructions resemble load instructions in which the result of the instruction is never used. The compiler can insert these instructions if it has a prediction of what addresses will soon be accessed. The compiler may be able to prefetch more effectively than hardware because it is able to statically analyze an entire program region and can predict accesses that are not related directly to any previous accesses.

STORAGE AREA NETWORKS

With both the quantity and the quality of information growing at unprecedented rates in recent years, data has become an increasingly vital asset for organizations of all sizes. This fact has fostered efforts to ensure that a suitable infrastructure exists to support, manage, protect, and reconfigure this data. Many organizations also require nearly continuous availability of their mission-critical data, which requires planning for business continuity and disaster recovery, including data replication over extended distances. All of these requirements are different from the traditional mainframe or enterprise computing environment, in which processing and storage resources are centralized. Traditional computing models based on the mainframe approach featured storage devices that were connected directly to a host server, and managed by dedicated information technology (IT) staff. Historically, the earliest approaches to storage management included server-attached storage, which tightly coupled storage devices to a server to reduce overhead. With storage devices dedicated to a single server, it was not necessary for any intelligence to reside on the disk and tape storage devices. Later devices incorporated storage control units, or storage off-load servers, which can perform more advanced functions such as cacheing of input/output (I/O) requests or dual redundant data copying. The advent of client/server-based computing created a new set of issues, as data was distributed among many servers and storage devices. With the complexity that developed from multiple operating systems, access methods, load balancing requirements, and disseminated management, this environment required a different approach to manage stored information. The various efforts to improve connectivity between these isolated storage resources and to manage distributed storage resources has led to the concept of a storage area network (SAN).

The terminology for different types of networks can be somewhat ambiguous and may not be used consistently in the technical literature. The term SAN is usually identified with block I/O services, rather than file access services. It can also refer to a storage system that consists of storage elements and devices, computer systems, and/or appliances, plus all of the associated control software, communicating over a network. Today, most SANs are based on either Fibre Channel, FICON, SCSI, or Ethernet protocols, although some other protocols such as ESCON or InfiniBand can also be involved; the parallel SCSI interface can also be run over Fibre Channel, where it is known as the Fibre Channel Protocol (FCP). This definition is not standardized, however; for example, the Storage Network Industry Association definition does not identify specifically the term *SAN* with Fibre Channel technology; instead, this group encourages the use of a qualified phrase such as "Fibre Channel SAN." Furthermore, according to the broadest definition, an Ethernet-based network whose primary purpose is to provide access to storage elements would be considered a SAN, although the term *network attached storage* (*NAS*) can also be applied. SANs are sometimes also used for system interconnection in computing clusters. For our purposes, the SAN constitutes any type of high speed network that provides interconnections between storage devices and servers, usually employing a dedicated switch fabric, regardless of the underlying protocol. It is based on the classic three-tiered computing model, which distinguishes among the presentation layer (end users with desktop personal computers), the middle tier (application servers), and the bottom tier (storage devices that contain the actual data). A SAN can be shared between multiple serves and storage devices. Although the most common implementations reside in a single data center, the SAN may be extended over large geographic distances for disaster recovery applications using protocol-specific channel extenders or wavelength division multiplexing (WDM). Although a WDM network is protocol independent, care must be taken to accommodate the performance and topology requirements of a SAN environment. For example, WDM equipment can be used to construct a ring topology that is not compliant with the Fibre Channel Arbitrated Loop (FC-AL) specifications.

In other publications, Ethernet and other IP or file-based storage networks are also known as NAS, which basically refers to a LAN-attached file server that uses a network access protocol, such as network file system (NFS) or CIFS. Thus, NAS is a generic term to refer to storage elements that connect to a network and provide file access services to computer systems. A NAS storage element consists of a processing engine that implements the file services (using access protocols such as NFS or CIFS), and one or more devices on which data is stored. Although Ethernet is the most common approach, NAS elements may be attached to any type of network. NAS devices can also coexist in a SAN environment, and various gateways between NAS and SAN environments are available. From a SAN perspective, a SAN-attached NAS engine is treated just like any other server. NAS solutions have evolved over time. Early NAS implementations used a standard UNIX or NT server with NFS or CIFS software to operate as a remote file server. Clients and other application servers access the files stored on the remote file server as though the files are located on their local disks. The location of the file is transparent to the user. Several hundred users could work on information stored on the file server, each one unaware that the data is located on another system. The file server has to manage I/O requests accurately, queuing as necessary, fulfilling the request, and returning the information to the correct client. As in many SANs, the NAS server handles most aspects of security and lock management.

Many different types of devices exist in a SAN besides storage and switching equipment. Host bus adapters (HBAs) are devices that connect to a server or storage

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

device and control the protocol for communications. These adapter cards will contain optical transceivers that will interface to channel extension or WDM equipment when the SAN is extended over longer distances (native SAN links based on Ethernet or Fibre Channel can accommodate up to about 10 km without using repeaters or channel extenders). A gateway (also referred to as a bridge or a router) is a fabric device used to interconnect one or more storage devices with different protocol support, such as SCSI to FC or FC to SCSI devices. Typically, hubs are used in a SAN to attach devices or servers that do not support switched fabrics but only FC-AL. Switches are useful to interconnect large numbers of devices, increase bandwidth, reduce congestion, and provide high aggregate throughput. The Fibre Channel protocol was designed specifically by the computer industry to remove the barriers of performance with legacy channels and networks. When a Fibre Channel switch is implemented in a SAN, the network is referred to as a fabric or switched fabric. Each device connected to a port on the switch can access potentially any other device connected to any other port on the switch, which enables an on-demand connection to every connected device. Various FC switch offerings support both switched fabric and/or loop connections. As the number of devices increases, multiple switches can be cascaded for expanded access (known as fanout). Inter-switch links (ISLs) can also be used to cascade multiple switches together, which may be more cost effective than constructing a single large switch. No industry standards for ISL connections exist, however, and many will operate only with the same vendor's equipment attached to either end of the link. Some ISLs also support trunking (the concatenation of multiple data channels using time division multiplexing techniques), which reduces the number of links in the SAN. Trunking between remote locations for data backup and disaster recovery can be done over WDM to increase the supported distances; in this case, trunking also reduces the number of inter-site links required. Directors are SAN devices, similar in functionality to switches, but because of the redundancy of many hardware components, they can supply a higher level of reliability, availability, and serviceability with a smaller footprint. Today, many directors can be used to connect FICON or FC devices at the same time. In the SAN environment, an extended distance gateway component [for example, an optical extender or a dense wave length division multiplexing (DWDM) device can connect two different remote SANs with each other over a wide area network (WAN).

SAN topologies may include point-to-point, arbitrated loops, fabrics, and other configurations. In particular, one topology specific to the SAN is the FC-AL, which is designed such that for a node to transfer data, it must first arbitrate to win control of the loop. Once the node has control, it is now free to establish a point-to-point (virtual) connection with another node on the loop. After this connection is established, the two nodes consume all of the loop's bandwidth until the data transfer operation is complete. Once the transfer is complete, any node on the loop can now arbitrate to win control of the loop. Support of up to 126 devices is possible on a single loop, but the more devices that are on a single loop, the more competition to win arbitration. A loop is self-discovering, and logic in the port allows a failed node to be isolated from the loop without interfering with other data transfers. A loop can be interconnected to other loops essentially to form its own fabric. An arbitrated loop supports communication between devices that do not recognize fabrics (private devices), and the resulting arbitrated loops are sometimes called private loops. Some unique implementations exist; for example, a Fibre Channel topology known as QuickLoop that combines arbitrated loop and fabric topologies is implemented only on the IBM 2109 family of switches (except the IBM TotalStorage SAN Switch M12), which allows a device with a private-loop HBA to communicate with FC-AL storage devices through IBM TotalStorage SAN switches. It is also possible to mix a switched fabric with an arbitrated loop, provided that the switches can detect and act on the correct protocols.

A SAN can be used to bypass traditional network bottlenecks. It facilitates direct, high speed data transfers between servers and storage devices and allows the same storage device to be accessed serially or concurrently by multiple servers. SANs also enable new network architectures where multiple hosts access multiple storage devices connected to the same network. A SAN may be used for high speed, high volume communications between servers or between storage devices. This outboard data movement capability enables data to be moved with minimal or no server intervention, thereby freeing up server processor cycles for other activities like application processing. Examples include a disk device backing up its data to a tape device without server intervention, or remote device mirroring across the SAN. When implemented properly, the ability for storage to be accessible through multiple data paths offers better reliability, application availability, and serviceability. If storage processing is off-loaded from servers and moved onto a separate network, higher application performance can result. SANs can centralize and consolidate storage systems, which reduces management overhead and improves scalability and flexibility of the storage design. Finally, SANs extended over remote distances enable disaster recovery, business continuity, and data vaulting applications.

The term *data sharing* describes the access of common data for processing by multiple computer platforms or servers. Data sharing can be between platforms that are similar or different; this term is also referred to as homogeneous and heterogeneous data sharing. With storage sharing, two or more homogeneous or heterogeneous servers share a single storage subsystem whose capacity has been partitioned physically so that each attached server can access only the units allocated to it. Multiple servers can own the same partition but only with homogeneous servers. Data-copy sharing allows different platforms to access the same data by sending a copy of the data from one platform to the other. In the ideal case, only one copy of the data is accessed by multiple platforms, whether homogeneous or heterogeneous. Every platform attached has read and write access to the single copy of data. This approach, sometimes called "true" data sharing, exists in practice only on homogeneous platforms. SANs enable multiple copy, data vaulting, and data backup operations on servers to be faster and independent of the primary network (LAN), which has led to the delivery of data movement applications such as LAN-free backup and server-less backup (to be discussed in more detail later).

Much attention is also being given to storage virtualization or the pooling of physical storage from multiple network storage devices into what seems to be a single storage device that is managed from a central console. Storage virtualization forms one of several layers of virtualization in a storage network; generally, it refers to the abstraction from physical volumes of data storage to a logical view of data storage. Storage virtualization separates the representation of storage to the operating system (and its users) from the actual physical components. Storage virtualization has been represented and taken for granted in the mainframe environment for many years.

SAN MANAGEMENT

SAN fabric monitoring and management is an area where a great deal of standards work is being focused. Two management techniques are in use: in-band and out-of-band management.

Device communications to the network management facility are most commonly done directly across the Fibre Channel or other network transport. This process is known as in-band management. It is simple to implement, requires no LAN connections, and has inherent advantages, such as the ability for a switch to initiate a SAN topology map by means of queries to other fabric components. However, in the event of a failure of the network transport itself, the management information cannot be transmitted. Therefore, access to devices is lost, as is the ability to detect, isolate, and recover from network problems. This problem can be minimized by a provision of redundant paths between devices in the fabric. In-band management is evolving rapidly. Proposals exist for low level interfaces such as return node identification and return topology identification to gather individual device and connection information, and for a management server that derives topology information. In-band management also allows attribute inquiries on storage devices and configuration changes for all elements of the SAN. Because in-band management is performed over the SAN itself, administrators are not required to make additional TCP/IP connections.

Out-of-band management means that device management data are gathered over a TCP/IP connection such as Ethernet, separate from the paths for the data traffic. Commands and queries can be sent using Simple Network Management Protocol (SNMP), Telnet (a text-only command line interface), or a Web browser Hyper Text Transfer Protocol (HTTP). Telnet and HTTP implementations are more suited to small networks. Out-of-band management does not rely on the transport network. Its main advantage is that management commands and messages can be sent even if a loop or fabric link fails. Integrated SAN management facilities are implemented more easily, especially by using SNMP. However, unlike in-band management, it cannot automatically provide SAN topology mapping.

A management information base (MIB) organizes the statistics provided by the out-of-band management interface. The MIB runs on an SNMP device and on the managed device. The SNMP protocol is supported widely by LAN/WAN routers, gateways, hubs, and switches, and it is the predominant protocol used for multivendor networks. Device status information (vendor, machine serial number, port type and status, traffic, errors, and so on) can be provided to an enterprise SNMP manager. Usually this runs on a workstation attached to the network. A device can generate an alert by SNMP, in the event of an error condition. The device symbol, or icon, displayed on the SNMP manager console, can be made to turn red or yellow, and messages can be sent to the network operator. Element management is concerned with providing a framework to centralize and to automate the management of heterogeneous elements, and to align this management with application or business policy. Several industry standard MIBs have been defined for the LAN/WAN environment. Special MIBs for SANs are being built by SNIA, which will enable multivendor SANs to be managed by common commands and queries. Two primary SNMP MIBs are being implemented for SAN fabric elements that allow out-of-band monitoring. The ANSI Fibre Channel Fabric Element MIB provides significant operational and configuration information on individual devices. The emerging Fibre Channel Management MIB provides additional link table and switch zoning information that can be used to derive information about the physical and logical connections between individual devices. Even with these two MIBs, out-of-band monitoring is incomplete. Most storage devices and some fabric devices do not support out-of-band monitoring. In addition, many administrators simply do not attach their SAN elements to the TCP/IP network.

A key aspect of SAN management is the ability to virtualize storage resources, or to isolate selected resources for security or performance reasons. This task can be done through logical partitioning and zoning. Zoning allows for finer segmentation of the switched fabric. Zoning can be used to instigate a barrier between different environments. Only members of the same zone can communicate within that zone, and all other attempts from outside are rejected. Zoning could also be used for test and maintenance purposes. For example, not many enterprises will mix their test and maintenance environments with their production environment. Within a fabric, it is possible to separate the test environment from the production bandwidth allocation on the same fabric using zoning.

One approach to securing storage devices from hosts wishing to take over already assigned resources is logical unit number (LUN) masking. Every storage device offers its resources to the hosts by means of LUNs. For example, each partition in the storage server has its own LUN. If the host (server) needs to access the storage, it needs to request access to the LUN in the storage device. The purpose of LUN masking is to control access to the LUNs. The storage device itself accepts or rejects access requests from different hosts. The user defines which hosts can access the LUN by means of the storage device control program. Whenever the host accesses a particular LUN, the storage device will check its access list for that LUN, and it will allow or disallow access to the LUN.

MULTIPROTOCOL ROUTING

Multiprotocol routers provide the means to connect SAN islands over multiple networks and across longer distances, which includes a combination of services such as FCP channel-to-channel routing, FCIP tunneling, iSCSI gateways, or encapsulation of other data protocols in a digital wrapper. These services can be supported on a switch or a router with a centralized management function, and they can be deployed on a per port basis. The primary advantage of this approach is the ability to connect devices between two or more fabrics without merging those fabrics, which provides a more flexible storage networking environment. Potential applications of this approach include connecting SAN environments across multiple geographies, functions, or departments (with centralized security and control), enabling low-cost SCSI-based servers and IP networks to support fabric-based business continuity and disaster recovery solutions over longer distances, and improving asset use through more efficient resource sharing. This function makes it possible to interconnect devices without having to redesign and reconfigure their entire environment, thereby eliminating the potential risks and costs of downtime. Moreover, the need to ensure secure connectivity for selected resources—especially in heterogeneous environments—additionally compounds the troubleshooting, fault isolation, and management challenges posed by large SANs. FCP routing addresses these issues by enabling organizations to connect devices in different SANs without merging the fabrics. Using this capability, organizations can share resources across multiple SANs and scale beyond current SAN port count support constraints. The benefits of enhanced SAN connectivity must be weighted against the potential increase in administrative workload, risk, and expense.

When devices on different fabrics are allowed to communicate through a multiprotocol router, the resulting connectivity group may be known as a logical SAN (LSAN). LSANs enable selective and secure resource sharing across multiple SANs by leveraging current zoning tools and methodologies. In addition to optimizing resource use, this approach helps to improve scalability by minimizing the risk and the complexity of large fabrics, simplifying management and fault isolation, and future-proofing current technology investments (LSANs are a logical or virtual construct, so they do not require changes to the existing SAN switches or attached edge devices).

Tunneling FCP over an IP network, known as FCIP, enables organizations to extend their Fibre Channel SANs over longer distances that would be technically impractical or prohibitively expensive with native Fibre Channel links, or in situations where dark fiber links would be impractical but in which IP WAN connectivity already exists. Furthermore, FCP routing enables two fabrics connected to an FCIP link to remain separate rather than merging them into a single fabric, which would permit any-to-any connectivity between all devices. This level of SAN connectivity facilitates applications such as migration to new storage (multiprotocol routers can be used to migrate data from lower data rate to higher data rate storage systems), data center consolidation, or data migration between test/development SANs and production SANs (enabling data movement between physically or logically separated environments).

As another example, iSCSI-to-Fibre Channel protocol conversion provides a standards-based iSCSI integration solution. The primary benefit is that low-cost servers can access centrally managed Fibre Channel resources. This approach leverages existing Ethernet infrastructure with IT staff knowledge to simplify implementation and management. It also reduces costs by eliminating the need to purchase HBAs in order for servers to access SAN resources.

LONG-DISTANCE SAN EXTENSION

With the advent of industry compliance regulations that govern the retention and the privacy of data, requirements have emerged to store and recover data over longer distances as part of an overall business continuance solution. One approach is the use of optical WANs equipped with wavelength multiplexing technology; this technology is capable of consolidating multiple fiber-optic connections over a single network, while providing distance extension using optical amplifiers. If a Fibre Channel protocol is being used with guaranteed data packet delivery, then performance at extended distances will be limited by credit-based flow control at layer 2 and 4. This difficulty can be overcome by using special adapters that provide large amounts of buffer credits, or by pooling buffer credits from multiple switch ports to serve a single extended distance port. Some types of channel extension have implemented "spoofing," which defeats true credit flow control in order to achieve higher performance; however, recovery from lost packets or link failures is problematic in such cases.

Sharing SAN resources and moving data over geographical boundaries introduces the complexity of merging resources and overcoming the distance and performance limitations caused by credit-based flow control on native Fibre Channel networks. It is possible to use an FCIP tunneling service to enable remote devices to connect to SANs by leveraging the existing IP WAN infrastructure for longer distance connectivity. As a result, organizations can share SAN resources and can move data between geographies much more efficiently. Integrating an FCIP tunneling solution within the fabric simplifies overall manageability by minimizing protocol conversion events. This standards-based FCIP approach, in combination with FC-to-FC routing, does not require connected fabrics to merge or to reconfigure. As a result, organizations can extend remote replication and backup functions over longer distances through a single platform hosting fabric-based applications. This approach increases resource use as well as reduces management, training, and troubleshooting requirements.

The advent of SANs enables data to be transferred directly from disk storage to the backup server and then directly over the SAN to tape. This process is called LAN-free backup. This process not only reduces LAN traffic but also reduces traffic through the backup server. Generally, this traffic is processor-intensive because of TCP/IP translations. With LAN-free backup, the backup server orchestrates the data movement, manages the tape library and drives, and tells the clients what data to move. The client is connected to the SAN; its data can be on the SAN, or the data can be on storage attached directly to the server. The LAN still is used to pass metadata back and forth between the backup server and the client. However, the actual backup data is passed over the SAN. The metadata is the data needed by the backup server to manage the entire backup process and includes the file name, the file location, the date and time of the data movement, and where the new copy resides. The metadata is small compared with the actual client data being moved. Server-less backup refers to the ability to take a snapshot of the data to be backed up with minimal or no disruption to productive work, then move it intelligently between tape and disk without the data going through a server.

REMOTE COPY SOLUTIONS

To improve availability, avoid outages, and minimize the adverse effects on business critical applications when they do occur, many businesses are using some form of remote copy service to mirror their critical data to a backup location. This service can be done over a WDM network to reduce the required number of inter-site optical fibers and to extend the native attached distance of many protocols. It protects the data against both planned outages (for maintenance, application software updates, or other reasons) and unplanned outages of various types.

A good disaster recovery plan must establish a recovery point objective (how much data can afford to be lost), a recovery time objective (how long critical systems can be unavailable), and a network recovery objective (how much of the network must be restored for operations to continue). Some research in this field has proposed a seven-tier recoverability model, based on the recovery method and recovery time. The nature of these recovery objectives will determine whether the remote backup solution needs to be synchronous or asynchronous. Generally, synchronous replication (also called synchronous mirroring) ensures that an I/O write is committed at the remote site before committing it to the primary site, and maintains data integrity with the remote site. This approach is required if no data loss can be tolerated, and immediate data restoration is required (such as applications in stock trading or airline reservation systems). Note that when using a synchronous solution, the distance and latency can impact performance because the writing application has to incur a round-trip delay; as a rule of thumb, practical systems are limited to about 50–100 km distances. Beyond this, asynchronous data replication is used, in which the data is copied to a remote site as expediently as possible, but not in real time. This approach is suited for users who can absorb some minimal data loss and cannot afford to have application performance impacted by the network round-trip delays.

One example of a remote copy solution is peer to peer remote copying (PPRC), also known as Metro Mirror, developed by IBM. This solution is an example of hardware-based synchronous replication that has been used for many years in mainframe environments. Similar technologies are available for other types of storage devices. It is used primarily to protect an organization's data against disk subsystem loss or, in the worst case, complete site failure. Metro Mirror is a synchronous protocol that allows real-time mirroring of data from one LUN to another LUN. Because the copying function occurs at the disk subsystem level, Metro Mirror is application independent. The protocol guarantees that the secondary copy is up to date by ensuring that the primary copy will be written only if the primary receives acknowledgment that the secondary copy has been written.

A related data copy solution is PPRC extended distance (PPRC-XD), which is intended to replicate log copies or static point-in-time copies of data. This solution maintains a "fuzzy" copy of the data on a secondary, remote volume, which can be synchronized with the source on demand. Thus, it is not a disaster recovery solution on its own, because the remote data is not in a state of integrity with its local copy. Technically, it is not asynchronous remote copy either, because that requires time stamp consistency between multiple control units, which is not part of PPRC-XD. Instead, this approach requires that the user periodically quesces the application writes, builds consistency between the local and remote copies, and then establishes application consistency over multiple storage volumes. Although the remote data integrity cannot be guaranteed at all times, PPRC-XD allows much greater distances (theoretically unlimited) and has a much lower impact on application performance because it does not require processor resources.

Although PPRC/Metro Mirror was developed by IBM, this technology has been licensed to other companies and is also supported on their platforms. Other remote copy solutions are available, for example, EMC Corporation offers a hardware-based solution that runs on the firmware of their Symmetrix disk storage array, called the Symmetrix remote data facility (SRDF). It provides several modes of operation, including synchronous copy, semisynchronous (which eases the latency impact a bit by allowing for one write behind), multihop (which uses a daisy chain of multiple storage arrays to reduce latency), and adaptive copy (which asynchronously updates the remote volumes without regard for the local volume write sequence). SRDF typically requires ESCON connectivity over channel extenders or WDM, but it can also operate over IP or Fibre Channel connections. Concurrent SRDF allows for simultaneous mirroring of data from one location to two different target locations; however, having two synchronous mirrors active at the same time may cause sensitivity to response time. The multihop solution can also be used to generate three or more copies of the data. As another example of remote copy solutions, Hitachi Data Systems offers several features including Hitachi remote copy (which is similar to PPRC), Hitachi extended remote copy (similar to XRC), and

Hitachi asynchronous remote copy, which timestamps all data and offers host-independent XRC functions. There is also a semisynchronous option similar to the EMC product. Typically, all of these solutions reach extended distances using a DWDM infrastructure.

Although the above solutions protect against hardware failures or environmental disasters in a SAN, they do not necessarily protect against user or application logical errors. In such cases, a hot standby database would be in the same inconsistent state as the live database. Split mirror backup/recovery functions as a high availability backup/recovery scenario, where the backup is taken on a remote disk subsystem that is connected to an application disk subsystem. Normally, the connection is suspended (mirror split) and will only be resumed for the resynchronization of the primary and the secondary volumes. In the case of a user or application error, the primary database is available for analysis, while a secondary database is recovered to a consistent point in time.

FlashCopy, another mirroring technique originally developed by IBM, provides an instant or point-in-time copy of a logical volume. The point-in-time copy functions provides an instantaneous copy of the original data at a specific point-in-time, known as the T0 (time-zero) copy. When a FlashCopy is invoked, the command returns to the operating system as soon as the FlashCopy pair has been established and the necessary control bitmaps have been created. This process takes only a few seconds to complete. Thereafter, the systems have access to a copy of the source volume. As soon as the pair has been established, it is possible to read and write to both the source and the target volumes. The point-in-time copy created by FlashCopy typically is used where a copy of production data needs to be produced with minimal application downtime.

An alternative approach is extended distance remote copy (XRC) also known as Global Mirror. It is an asynchronous, software-centric remote copy implementation. A software component called system data mover (SDM) will copy writes issued to primary volumes by primary systems, to the secondary devices. XRC uses the concept of a consistency group that contains records that have their order of update preserved across multiple logical partitions within a storage control unit, across multiple control units, and across other storage subsystems that participate in the same XRC session. Maintaining the update sequence for applications whose data is being copied in real time is a critical requirement for applications that execute dependent write I/Os. If data is copied out of sequence, serious integrity exposures could render the recovery procedures useless. XRC uses special algorithms to provide update sequence consistency for all data. XRC connectivity is provided by FICON or Fibre Channel links, and it is also part of the FICON extended distance solution. Various hybrid solutions are available that use components of both synchronous and asynchronous technology, such as a three-site solution in which two sites are close together enough to enable synchronous copy, whereas the third is far enough away that asynchronous copy is preferred for performance reasons.

REMOTE TAPE VAULTING AND CONSOLIDATION

Many companies have deployed SANs for tape backup and archiving using applications such as LAN-free backup and server-less backup. These near-zero backup window environments have driven the need for backup and archiving at remote and/or off-site locations; this process is called remote tape vaulting. An extension of remote tape vaulting is remote tape disaster tolerance, which involves a tape library at each of the sites. Remote tape vaulting consists of transmitting electronically and creating backup tapes at a secure off-site facility, moving mission-critical data off-site faster and with greater frequency than traditional data backup processes. The traditional backup process involves creating a tape in a locally attached tape library, ejecting it from the library, and removing it to an off-site location.

Tape backup solutions can be done with a combination of ESCON, FICON, or Fibre Channel links; the number of links depends on the size of the database concerned (terabytes or petabytes) and may be large. Many variations and proprietary implementations are not discussed here, such as IBM's point-to-point virtual tape server. All of these devices are suported by optical networking solutions, which usually are qualified by the storage device provider; an example is IBM's Total Storage Proven program. The major performance consideration with a long-distance solution is calculating the correct number of links between sites. This number can only be determined by performing a detailed performance profile of the servers and storage that will be remote. Overestimating the number of links will increase costs dramatically, whereas under sizing the number of links will affect the performance of the SAN dramatically. It is vital that detailed performance data is available prior to sizing the number of links required. Typically, latency will increase over long distances; a good rule of thumb is 4.8 microseconds per kilometer. Performance is highly application-dependent and requires careful configuration planning; for example, a remote disk consolidation solution might work well with a server-to-storage ratio of 6:1, whereas a tape vaulting solution may be acceptable with half this value.

Related concepts (which have no industry standard definition) include tape library sharing and tape drive pooling. A tape library consists of the physical robotics that move cartridges, one or more tape drives, and slots for tape storage. It must also have a mechanism to control the robotics (a library controller), and may also have a library manager, which maintains inventory and mediates sharing. Tape library sharing has been practiced for some time by partitioning a physical library into multiple logical libraries. Alternatively, the library can seem to be shared by multiple hosts when, in reality, one of the hosts (the library manager) is issuing all the library commands both for itself and for the other hosts (clients), but all of them have direct access to the tape drives (tape pooling). Tape pooling is the ability to allow two or more servers to logically share tape drives within a tape library. In this case, the servers need to be attached to the same SAN as the tape drives. Partitioning is the ability to partition tape drives and slots to create logical libraries within the same physical library. The server attached to each logical library has no knowledge of any drives or slots outside the partition, and the partitions are fixed.

Organizations can also use FC-to-FC routing functions to consolidate their backup activities in a SAN environment, sometimes known as tape backup consolidation. By centralizing the backup of multiple SANs in a single location, it is possible to streamline the overall backup process and help to ensure that both data and networks remain highly available. Additional benefits include reduced tape drive requirements, fewer idle resources, better overall use of tape libraries, and the ability to leverage off-peak network connectivity. A centralized backup architecture also optimizes the value of backup devices and resources, reduces management overhead, and increases asset utilization. The ability to share a tape library fabric without merging disk fabrics improves the overall flexibility and quality of SAN management. In addition, this approach saves money by eliminating the need to deploy separate HBAs on every backup server on every SAN fabric.

An example of the highest level of availability in remote copy systems is the Geographically Dispersed Parallel Sysplex (GDPS) developed by IBM and recently licensed to other vendors. It provides a combination of software and hardware to switch all resources automatically from one location to another. In 1994, IBM developed the Parallel Sysplex architecture for the System/390 (S/390) mainframe computing platform. This proprietary architecture uses high speed, fiber optic data links to couple processors together in parallel, thereby increasing reliability, performance, server capacity, and scalability. Several possible configurations exist for a Parallel Sysplex. First, the entire sysplex may reside in a single physical location, within one data center. Second, the sysplex can be extended over multiple locations with remote fiber optic data links. Finally, a multisite sysplex in which all data is remote copied from one location to another is known as a GDPS. This architecture provides the ability to manage remote copy configurations, automates both planned and unplanned system reconfigurations, and provides rapid failure recovery from a single point of control. Different configuration options exist for a GDPS. The single site workload configuration is intended for those enterprises that have production workload in one location (site 1) and discretionary workload (system test platforms, application development, etc.) in another location (site 2). In the event of a system failure, unplanned site failure, or planned workload shift, the discretionary workload in site 2 will be terminated to provide processing resources for the production work from site 1 (the resources are acquired from site 2 to prepare this environment, and the critical workload is restarted). The multiple site workload configuration is intended for those enterprises that have production and discretionary workload in both site 1 and site 2. In this case, discretionary workload from either site may be terminated to provide processing resources for the production workload from the other site in the event of a planned or unplanned system disruption or site failure.

Four building blocks exist for a Parallel Sysplex, with optical fiber links between them; the host processor (or Parallel Enterprise Server), the coupling facility (CF), the Sysplex Timer or Server Time Protocol source, and a storage network based on ESCON, FICON, or Fibre Channel. Remote copy functions are implemented between the storage at each physical location. Many different processors may be interconnected through the CF, which allows them to communicate with each other and with data stored locally. The CF provides data caching, locking, and queuing (message passing) services. By adding more processors to the configuration, the overall processing capacity of the sysplex will increase. Software allows the sysplex to break down large database queries into smaller ones, which can then be passed to the separate processors; the results are combined to arrive at the final query response. The CF may be implemented either as a separate piece of hardware or as a logical partition of a larger system. Fiber optic coupling links (also known as InterSystem Channel (or HiPerLinks) are used to connect a processor with a CF. Because the operation of a Parallel Sysplex depends on these links, it is highly recommended that redundant links and CFs be used for continuous availability. Coupling links are based on (but not fully compliant with) the ANSI Fibre Channel Standard. In synchronous applications, all servers must be connected to a common time-of-day clock, provided by either a Sysplex Timer or Server Time Protocol (STP) connection. Connectivity between remote locations is provided by a protocol independent WDM solution.

Many other data replication solutions over WDM exist; these include the High Availability Geographic Clustering software (HAGEO) from IBM, which operates over IP networks at essentially unlimited distances. This software provides options for either manual or automatic failover between two locations. Data I/O rates can be a problem, and HAGEO does not work well on high latency or low bandwidth networks. A properly designed application can run over thousands of kilometers. Another offering similar to this that provides real-time data mirroring over IP networks of RS/6000 or pSeries class workstations is GeoRM. Because the network is IP based, distances once again are unlimited essentially and many-to-one mirroring of critical data at remote location is possible; both synchronous and asynchronous versions are available. Many other SAN solutions exist that will not be discussed in detail here; these include Tivoli Storage Manager, logical volume mirroring with either sequential or parallel copy ordering and optional mirror write consistency checks, Microsoft MSCS for Fibre Channel SANs, Sun StorEdge Network Data Replicator, DataCore SAN Symphony, Veritas Volume Manager, and many others.

FUTURE DEVELOPMENTS

Looking beyond today's SAN requirements, some researchers are working on a model for on-demand storage networks that will adjust rapidly to spikes in usage, natural disasters, electronic viruses, and other dynamic changes to provide continuous access to data; this has been called e-business on demand. This concept includes utility computing (or pay-as-you-go models), autonomic or self-healing networks, server and storage capacity on demand, pervasive computing (computing elements embedded in distributed devices from laptops to cell phones), and other technologies beyond the scope of the optical network. All of these factors will influence the type and amount of traffic placed on future SANs.

VIRTUAL MEMORY AND BUFFER STORAGE

CONCEPT

As applications become larger and more complex, and numerous applications are loaded onto computer systems, some processes may need memory larger than the physical main memory whereas a combined number of applications/processes may also overload the allowable physical main memory. Also, to make the operating system (OS) user-friendly, the OS has become complex using huge amounts of memory to maintain the OS. As it is not cost effective to have a huge physical memory, the *virtual memory* concept is used in almost all of the computer systems today to augment that lack of memory. The virtual memory is a technique that combines the main memory and the slower storage (usually hard disk) to provide the appearance of having a larger memory than actually installed to the computer system. This technique allows the execution of processes that are larger than the physical main memory and allows more processes to be in the physical memory simultaneously. Using the virtual memory concept, it can be assumed that the computer has near unlimited amount of memory at its disposal for use in loading various applications and processes. Here “unlimited” means that the programmer usually does not need to be concerned with the memory size requirements of his/her application that needs to be executed.

Consider the types of memory accesses that would be required to execute a single machine instruction: The instruction is fetched from memory, the data on which the instruction will operate is read from memory, and after the instruction completes, the results of the instruction are written back to memory. The actual number of bytes necessary for each memory access varies according to the CPU’s architecture, the actual instruction, and the data type. However, the memory requirement for several instructions will be still a lot less than the memory necessary to load the whole application. Using a method to keep track of an application’s memory requirements as it executes, it would be possible to keep that application running while using less than its total memory space. The virtual memory technique allows this, and only part of the application is in main memory at any given time, whereas the rest of the application remains on disks. This method might at first seem to have a very large performance problem as disk drives are so much slower than the main memory. Although the problem is there, it is possible to take advantage of the sequential and localized access behavior of applications and eliminate most of the performance implications of using disk space for virtual memory. This is done by structuring the virtual memory system so that it attempts to ensure that parts of the application that are currently needed, or likely to be needed in the near future (using locality among other information), are kept in the main memory only for as long as they are needed. In many aspects this is similar to the relationship between the cache and the main memory: making a little fast storage and a lot of slow storage look like a lot of fast storage. The main differences, in current computer systems, are that replacement on cache misses are primarily controlled by hardware, whereas virtual memory replacement is primarily controlled by the operating system and the size of the processor address determines the size of the virtual memory but not for caches.

For physical memory, there is *physical address space* where the address is used to access the physical memory (i.e., main memory). Whereas *virtual address space* is the program’s address space, that is, the memory requirement of an application or a program if it needed all the memory at once. This is the total number of uniquely addressable memory locations required by the application, and *not* the amount of physical memory that must be dedicated to the application at any given time. All of the memory references within a process are *virtual addresses* that are dynamically translated into*physical addresses* at run time, and a process may be swapped in and out of the main memory such that it occupies different regions of main memory at different times during the course of its execution. The address translation is performed by the OS and/or CPU. Therefore, programs that require memory larger than the physical main memory can be executed without the programmer’s manually overlaying and swapping blocks of the large program.

PAGING

A process to be executed may be broken up into a several pieces (pages or segments), and these pieces need not be contiguously located in the main memory during execution. That is, it is not necessary for all parts of a process to be in the main memory during execution. Naturally, if a page or a segment is not available in the main memory during execution, a mechanism is needed to bring the piece from the disk, into the main memory. The mechanism to transfer pages between main memory and an auxiliary store, such as hard disk, is called *paging*. The bringing of a required part of a process incurs some performance penalty. This penalty may degrade the performance severely, since we need to bring the required page from a disk to a main memory, even to a cache. Instead of a programmer concentrating on how much memory an application needs to run and trying to manage the physical memory usage of the application manually, a virtual memory operating system continually attempts to find the answer to the minimum amount of memory space an application needs to execute. Because processes are broken into parts and only some parts are sent to the main memory, the amount of main memory required to execute an application at any given time is less than the size of the application/process, usually a lot less.

To apply paging, the physical memory is broken into fixed-sized blocks called *frames*. Although the virtual

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

memory is broken into blocks of the same size called *pages,* the virtual address generated by the CPU is divided into two parts: a page number and a page offset. The page number is the index in the page table. The page table contains the frame number of the block in the main memory, and the offset is used to then determine the position of the memory that was needed. Virtual memory systems initially load pages only as they are needed, and other pages may be demanded as the loaded pages are used and no longer needed. Pages that are never accessed are never loaded into the physical main memory. There are two common page fetch policies, and they are *demand paging* and *prepaging*. For the demand paging scheme, a page is brought to the main memory only when a reference is made to a location on that page. The prepaging scheme loads other pages including the page that is referenced into the main memory. Assuming a spatial locality (pages near the requested page in terms of space location may be accessed very soon), a prepaging scheme may effectively reduce the wait time when there is a page fault and a page must be loaded into the main memory as the expected page is already loaded. A page fault occurs when the requested page is not available in the main memory.

PAGE TABLE

The primary job of the page table is to translate the virtual memory addresses to physical memory addresses. There are other uses for the page table. Because only a subset of the total pages for a process is loaded to the main memory, the page table needs to maintain the information of which pages are present in the main memory. Another usage is to indicate whether the page was altered since it was last loaded into main memory. If a page was altered, then that page needs to be written to the hard disk when it comes time to replace the page in the main memory. If the page was not altered, there is no action to be done for the page.

In most computer systems, there is one page table per process. This may become problematic as some process can occupy huge amounts of virtual memory. If each process can have up to $2^{31} = 2$ Gbytes of virtual memory, using $2^{12} = 4096$ byte pages, this means that there can be as many as 2^{19} page table entries per process. This is clearly unacceptable. To overcome this problem, only some portion of the page table is stored in the physical memory. When a process is executing, a part of the page table resides inside the main memory that includes the page table entry of the pages currently executing. Therefore, the page table is also subject to paging. The size of the page tables for different processes is governed by the computer architecture and amount of main memory available. Also, since the size of the page table is large, we use multiple levels (a hierarchy) of page tables for size reduction. In a typical computer, the root page table (page directory) is an array of addresses and each entry points to a page table. The index into the root page table is determined by the highest order bits of the virtual memory address. The next bits in the virtual address are used to index the page table that is denoted by the first index. Typically, the maximum length of a page table is restricted to the size of one page and the Pentium processor uses this approach.

MEMORY MANAGEMENT UNIT

To implement virtual memory and map the virtual address to a physical address, a memory management module is necessary for the translation of addresses. The address translation hardware is often known as an *MMU* (Memory Management Unit). In some cases, the size of a physical and virtual memory space is the same, as in uClinux. In this case, when the processor accesses the main memory, the locations on the main memory never change. That is, an example memory address 00001 is always the same physical location inside the main memory.

With an MMU, memory addresses go through a translation step prior to each memory access. An intuitive virtual address to physical address is shown in Fig. 1, which means that a virtual address 00001 might be directed to physical address 24568 at one time, and to physical address 87006 at another time. The overhead of individually tracking the virtual address to physical address translations for billions of bytes of memory would be too great and costly. Instead, the MMU divides the main memory into *pages* or *segments*. These are contiguous sections of memory of a fixed size or variable size, respectively, which are handled by the MMU as single entities. Keeping track of these sections and their address translations is necessary in implementing virtual memory. For example, if the processor had stored data to the main memory in the past and wants to use that data again, it would have to know where the data were stored on the physical memory by performing the address translations from virtual to physical.

Similar to the cache, which stores recently accessed data from the main memory for the CPU, the translation lookaside buffer (TLB) is a cache/buffer that assists the virtual memory page table scheme (Fig. 2). The TLB contains the page table entries that were recently used. Given a virtual address, the processor will first examine the TLB rather than access the page table, which is typically larger than the TLB and may lead to performance degradation. If the desired page table entry is present in the TLB (called TLB hit), then the frame number is retrieved and the physical address is acquired. If the desired entry is not in the TLB (called TLB miss), the processor or the OS then accesses the page table.

PAGE SIZE

Several factors need to be considered when deciding on the size of the pages. One is internal fragmentation. This problem occurs when the page has unused portions. Thus, if the page size is small, there will be less internal fragmentation. Reducing the page size will, therefore, use the main memory more efficiently. However, smaller page sizes mean larger number of pages required for processes, and larger number of pages means larger page tables. Large page tables may mean that some part of the page table that maintains pages that are in the main memory can be in the virtual memory, and therefore, there can be a lot of

page faults occurring even when accessing the page table. The effect of page size on the page fault rate complicates the problem even more. If the page size is small, then a relatively large number of pages will be available for a process in the main memory. Thus, the page fault rate should be low. As the page size is increased, the individual pages will contain addresses that are further apart, weakening the principle of locality and the page fault rate begins to rise. And as the page size becomes as large as the process itself, the page fault rate decreases until the rate is 0 when the page size is the size of the entire process. The number of frames in the main memory allocated to a process also affects the page fault rate. Finally, the size of the main memory and the application or process size need to be considered when determining the page size.

SEGMENTATION

Segmentation allows a programmer to view memory as consisting of multiple address spaces or segments (1). This scheme is different from paging in that although pages are fixed in size, segments may vary in size, can be unequal, and the size can be dynamically changed. The virtual address for segmentation will consist of a segment number and an offset similar to pages. The segment table, however, is different in that there is the segment base address and a length associated with the segment. There are several advantages to the programmer over a nonsegmented address space. Segmentation simplifies the handling of dynamically changing data structures, sharing among processes can be easily done, and the programmer can

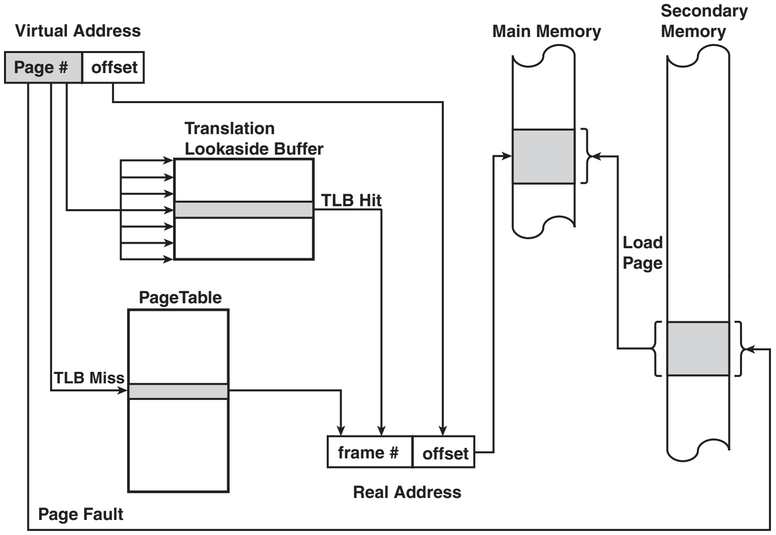

Figure 2. An intuitive representation of how the translation lookaside buffer (TLB) is used when accessing a page.

assign access privileges that can effectively protect a segment.

PLACEMENT

A placement policy determines where in the physical memory a page or a segment is stored. In a segmentation system, the placement policy is an important design issue and policies such as best-fit and first-fit methods are used. The best-fit scheme is a data placement scheme that places fetched data in an area where it would be "best" fit with smallest gaps between placements as possible. The first-fit scheme is a simpler method where the fetched data are placed in a large enough space that is discovered first. For a paging system, placement is usually irrelevant because the pages are usually of equal size; therefore, data can be placed in any page. However, there can be issues on which page to put data according to how the main memory is scanned for data.

REPLACEMENT

When all of the frames in the main memory are occupied and a page needs to be loaded into the memory to satisfy a page fault, this new page must replace an existing page in the main memory. The replacement policy determines which page in the memory can be replaced with the new page requested. There is one restriction on the replacement policy, and it is the frames that must not be replaced. These frames are used by the kernel of the operating system, I/O buffers, and other critical operations. Frames can be locked such that the replacement policy does not try to replace those frames. This can be achieved by introducing a lock bit or lock flag with each frame or include the frame into the page tables to indicate that the frame is occupied (or being executed) and must not be touched by the policy.

There are several basic algorithms for the replacement policy. These are the optimal, least recently used (LRU), first-in-first-out (FIFO), clock, and so on. The optimal policy selects the page that has the longest time to the next reference for replacement. Obviously, implementation of this policy is impossible because this policy assumes that the replacement module or the operating system has perfect knowledge of the future. The LRU strategy replaces the page that has not been referenced in the longest time. This scheme can be very costly to realize as each page needs a tag that indicates the last time it was referenced. For the FIFO policy, pages are replaced in a round-robin style. The clock policy combines the LRU and the FIFO methods. When a page is first loaded into a frame, in main memory, a use bit is set to 1 for that frame. Whenever the frame is referenced again, the bit is set to 1. When there is need to replace a frame, it starts as a round-robin-type scheme where a pointer goes around the frames to find the first frame with the use bit being 0. As the pointer encounters frames with use bit 1, it passes to the next frame but the use bit is set to 0. Therefore, if all of the pages have the use bit 1, then the very first frame that was checked for this use bit will be the page that will be replaced.

IMPLEMENTATION DETAILS: CASE STUDY OF AE32000C/LINUX

Here we introduce a case study of a virtual memory system implementation describing the workings of the processor and the operating system. Detailed implementation depends on the architecture of an operating system and MMU of a processor, because the design space is determined by architecture parameters. To provide intuitive insights on the implementation, the implementation section is based on how a virtual memory system is implemented with the Linux operating system on an embedded microprocessor, AE32000C (2), where the MMU provides simple straightforward features. These features are as follows:

- Separated On-Chip Instruction/Data TLB, 4-Way Set Associative, 32-Entries per TLB
- 4-KB page size
- Physically addressed Instruction/Data cache
- 8-bit ASN (Address-space number)
- Software page table walking

Linux supports up to a three-leveled page table in order to reduce the amount of memory occupied by page table entries anticipating virtual memory space lager than 4 GB (3). However, AE32000C/Linux uses a two-leveled page table as shown in Fig. 3. The first level is a page directory table that contains 1K number of entries to reference the second-level tables. The second level is the actual page table that contains 1K entries to reference physical pages. Therefore, the page table covers 4 GB of virtual address space; 1K (first level table) × 1K (second level table) × 4 KB (page size) = 4 GB. Since the second-level table is created only when the corresponding page is to be accessed, we can efficiently save memory occupied by the tables.

Figure 4 shows the structure of the page table entry. The primary field is a physical page number that is used in address translation. The others are used for access control and access tracking of the page. For instance, Linux provides writing permission on a page by setting the writable field. When the content of a page is modified or referenced, each field is set or unset to be used when the time comes to replace pages efficiently.

Usually the virtual address space is divided into user spaces and a kernel space. Although the user spaces are private address spaces for each process, the kernel space is a shared space for all processes. Moreover, Linux maintains the kernel space by dividing into two segments: an identity-mapped kernel segment and a page-table-mapped kernel segment (4). The identity-mapped segment is the space for allowing a kernel to be easily addressed virtually or physically where a direct translation relationship exists between virtual address and physical address. Most kernel objects, including the page tables, reside in this segment to avoid the overhead of a page table or to reduce implementation complexity such as handling nested TLB miss from kernel space and page-table swapping out. The page-table-mapped kernel segment is for dynamically allocated kernel objects especially requiring continuous address space such as kernel modules.

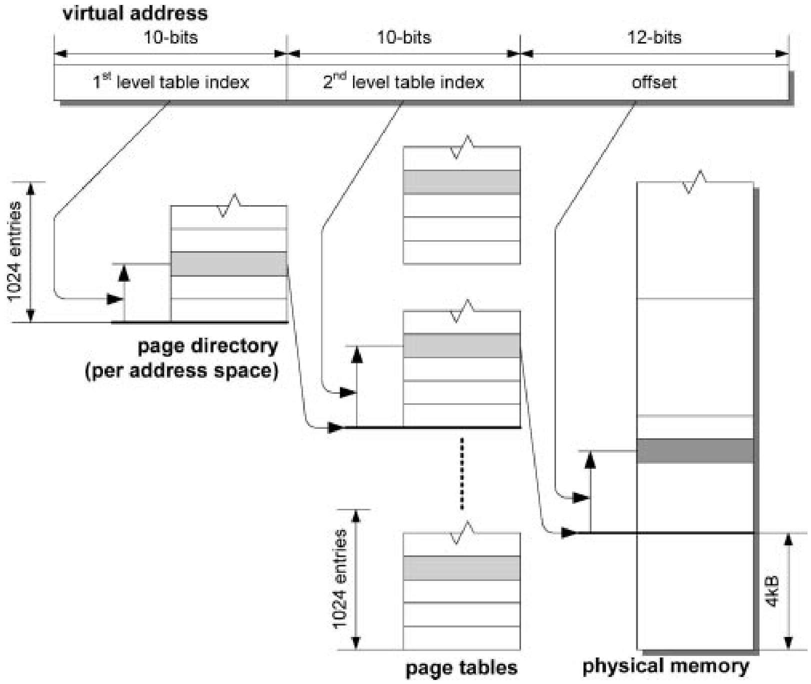

Figure 3. AE32000C/Linux page table.

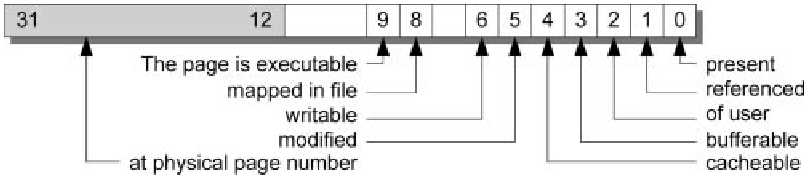

Figure 4. Structure of the page table entry.

In the case of AE32000C, the physical address of the SDRAM starts from 0xC0000000, which is the most popularly used start address of virtual kernel address space as shown in Fig. 5. Therefore, AE32000C/Linux sets the virtual address of the identity-mapped kernel segment the same as the physical address. This approach simplifies the kernel implementation and at the same time gets rid of any address translation mechanism for the segment.

Figure 6 depicts how the MMU translates a virtual address to a physical address. The MMU and the way of TLB management by the OS are highly dependent on the cache addressing scheme. Cache may be addressed by virtual address as well. The MMU for the cache does address translation only on a cache miss. The advantage of this scheme is fast cache access time due to no address translation on the cache hit. But, the drawback is the need for complicated cache coherence maintenance. For example, it should anticipate an alias/synonym problem since cache lines of several different virtual addresses, but of the same physical-address, can exist at the same instance. To alleviate this problem, the cache could contain tags as part of the physical address. But the cache size is restricted so that the cache index bits shall be part of page offset bits. The caches of AE32000C are physically addressed, and the MMU does virtual-to-physical address translation prior to every cache access. Although the drawback of this method is slower access time because it requires a TLB lookup before every cache access, the coherence maintenance is quite

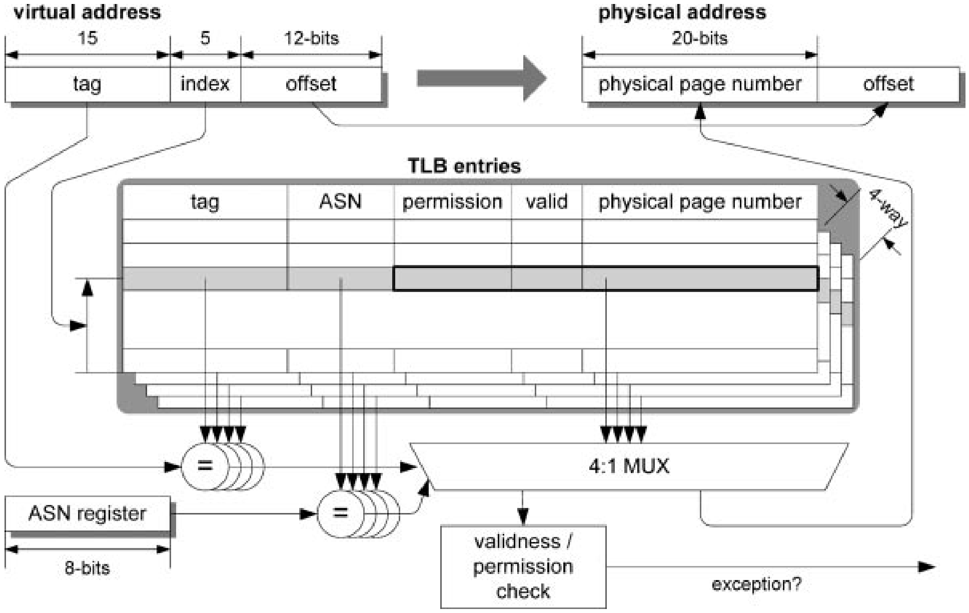

Figure 6. AE32000C MMU.

simple. To find the corresponding TLB entry for a virtual address, TLB entries are indexed by five bits of the address. From the indexed four entries, the MMU associatively finds out the right entry through matching tag field with the address and address-space number (ASN) with the current active address space. If the right entry is available, the MMU checks the validness of the entry, access permission for the corresponding page, and the presence of the page in the physical memory. Finally the physical address is obtained and then is used for accessing the cache memory, when all conditions are satisfied. Otherwise, an exception is generated in order to request the OS to handle it. As the MMU does not provide page table walking, the OS is responsible for the management of the TLB. Now, let's look at the OS implementation for TLB management.

Whenever no empty entries are available for a new translation, the TLB miss handler of the OS evicts an existing entry and inserts the new one with a carefully chosen TLB replacement policy. Popularly used policies are LRU (Least Recently Used) and NRU (Not Recently Used) for expecting recently used entry to be accessed in the near future in order to avoid frequent TLB misses. But, since it is difficult to implement such policies in software without any hardware help, AE32000C/Linux uses a round-robin/cyclic replacement policy for implementation simplicity.

The OS must maintain coherence between the page table and the TLB. In addition to the alias problem we discussed, the OS should be facilitated for supporting multiple address space. As an example, with the MMU that does not support multiple address space at a time, we should flush all the TLB entries whenever contexts are switched. To reduce the overhead from TLB flushing at the context switching, many processors, including AE32000C, provide address-space number (ASN) to keep TLB entries of multiple address space at a time (4). Each entry of TLB contains an 8-bit ASN field, and a the MMU has an ASN register indicating the address space of the current running process supporting up to 256 address spaces at a time. The ASN is extracted from the context information, which is platform-dependent. In the case of AE32000C/Linux, the context information is composed of an 8-bit ASN and a 24-bit ASN generation number. On every context switching, the validity of the context information of the process to be activated is checked by matching the ASN generation number with the current generation. The ASN is given in round-robin fashion for the context of old generation or a newly created context. When all ASNs are distributed for the current generation, the generation number increases and all TLB entries are flushed for coherence.

As mentioned, an exception is generated if there is no corresponding TLB entry for an access (TLB miss) or the access is not permitted on the page (access violation). On the exception from the MMU, the OS invokes an exception handler. The rest of this section describes how the handler works.

Figure 7 briefly illustrates an operation flow of the handler. There are four kinds of actions that the handler takes on an exception from the MMU. The first action is a TLB entry insertion/update where the exception is caused by a TLB miss, or when the page table entry is created or changed by other actions. If (*1*) MMU did not generate the exception due to access violation and the corresponding page table entry is already present, the exception was simply caused by absence of the corresponding TLB entry (i.e., TLB miss). Therefore, the handler inserts the TLB entry. Otherwise, (*2*) other actions may create a new page table entry or change the properties of an existing entry. In these cases, the handler inserts or updates the TLB entry. The second action is a copy-on-write for write access violation where the access is not illegal. All processes are created (i.e., forked) by their parent while inheriting memory space. The inheritance could be done by copying.

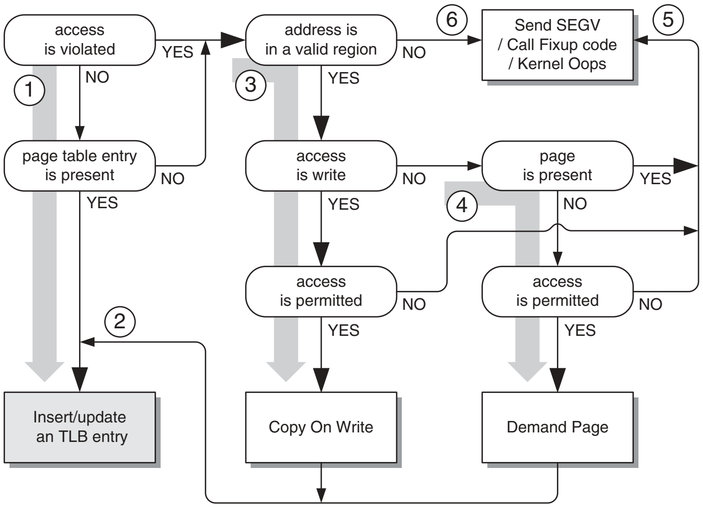

Figure 7. Operation flow of the exception handler.

But because child processes usually do not use or update all of the inherited pages, Linux avoids page copying by just sharing the pages unless there is a write access on them. The copying is done only on a write from either a parent or children. Hence, the access violation was caused by the purpose of this copy-on-write mechanism. To distinguish this violation from others, the handler checks (*3*) whether the write access violation was performed in a valid region and is actually permitted. The action, demanding page, is for a read access violation to allocate a physical page where there is no physical page corresponding to the virtual address because Linux allocates physical pages dynamically. A condition for triggering the demanding page is similar to that of the copy-on-write. But (*4*) the corresponding page table entry should not be present yet, because the presence of a page table entry implies that a physical page was already allocated. The last action is for accesses that (*5*) violate the permission or (*6*) reference an invalid memory region. If the access is from a user process (i.e., not kernel). Linux sends a segment violation signal (SEGV) to the process. If the kernel itself makes the violation, there is a handler (fixup code) to correct the access. The kernel sometimes accesses memory without checking its validness to reduce the overhead of checking code, because it is expected that the handler would be called if the access is illegal. The other exceptions are due to kernel errors. On the exception, Linux kills the current process and displays an error message. This is called Kernel Oops.

HISTORY

At the early stages of our computer era, the limited amount of physical memory caused a programmer to concentrate on a way to fit parts of a larger program or divide a large program into blocks and schedule the moves between the two levels of the memory hierarchy (i.e., between nonvolatile hard disks and main memory). The blocks are called pages or segments, and the movement operations are called swaps. The hard disks were slow; therefore, it was important to try and keep most of the executing applications in the fast main memory. A programmer's dream would be to have an unlimited amount of main memory, and thus, the concept of virtual memory was born (5).

It was obvious to the operating system designers in the early 1960s that automatic storage allocation could significantly unload the burden from the programmers. The first operating system design group to accomplish this was the Atlas team at the University of Manchester who, by 1959, had produced the first working prototype of a virtual memory system. They called it a *one-level storage system*. Their idea was to distinguish between "address" and "memory location." This distinction led them to three inventions: (*1*) a hardware that automatically translated each address generated by the processor to its current memory location; (*2*) demand paging, which is an interrupt mechanism triggered by the address translator that moved a missing page of data that is requested into the main memory; and (*3*) a replacement algorithm, a procedure to detect and move the least useful pages back to the secondary memory (5). In 1961, Burroughs released the B5000, the first commercial computer with virtual memory (6). It was based on segmentation, not paging.

Before virtual memory could be implemented in the mainstream operating systems, many models, experiments, and theories had to be developed to overcome numerous problems. Dynamic address translation required a specialized, expensive, and difficult-to-build hardware, which in early development made the access to the main memory slightly slow. More than anything, the consistent and robust address translation was a concern. By 1969, the debate over virtual memory for commercial computers was over (5). An IBM research team led by David Sayre showed that the virtual memory overlay system consistently worked better than the best manually controlled systems. Possibly the first minicomputer to introduce virtual memory was the

Norwegian NORD-1 (7). In 1972, virtual memory was announced for the IBM 370 series (8).

The difference between virtual memory implementations using pages or segments is not only about the fixed versus variable size memory division, respectively. In some systems, (e.g., Multics (9,10), the segmentation was actually visible to the user processes, as part of the semantics of a memory model. This is different from using pages, where the model is invisible to the process. In Multics, the segmentation method was used to provide a single-level virtual memory model, in which there was no differentiation between process memory and the file system. The active address space of a process consisted of only a list of variable segments (files) that were mapped into its potential address space, both code and data (9). This also worked when different processes mapped the same file into different places in their private address spaces (10). Today, most computer systems use virtual memory except for a few supercomputers and embedded CPUs and older personal computers (8).

VLSI CIRCUIT LAYOUT

INTRODUCTION

The significant achievement of integrated circuits (ICs) in the past half a century has driven the current revolution of computing and communication technologies. The applications of ICs have penetrated everywhere at work and at home, such as computer networking, switching systems, communication systems, vehicles, household appliances, and so on. As the IC technology itself has been experiencing rapid evolution with the number of transistors on a single chip growing from a few to over hundreds of million, the design and fabrication of very-large scale integration (VLSI) chips have developed beyond the capabilities of any number of humans without computer support. Thus, the trend toward automation will accelerate as improved circuit fabrication technologies permit higher levels of integration and as more powerful computers allow more sophisticated tools.

Integrated circuits consist of several electronic components, built by layering several different materials in a well-defined fashion on a silicon base called a *wafer*. The VLSI design cycle starts with a formal specification of a VLSI chip, follows a series of steps, and eventually produces a packaged chip. A typical design flow is depicted in Fig. 1. The first step is to lay down the *design specification*, i.e., a high-level presentation of the system. The considered factors in this stage include functionality, performance, physical dimensions, design techniques, and fabrication technology. As the second step, the *architectural design* is to determine the basic architecture of the system. Its output is a micro-architectural specification, by which performance, power, and die size of the design can be predicted. Then in the *behavioral design* step, the main functional units of the system and the requirements of interconnects between the units are identified. The system behavior is specified in terms of input, output, and timing of each unit without considering the internal structure. The output of the behavioral design is usually a timing diagram or other relationships between units. Then the design process comes to *logic design* and *circuit design*. In logic design, the control flow, word widths, register allocation, arithmetic operations, and logic operations are derived and verified by means of a Hardware Description Language (HDL). The purpose of the circuit design is to develop a circuit representation based on the output of the logic design by taking into account the speed and power requirements of the system.

Physical design is a process of converting the behavioral or structural representations from the previous phases into a geometric description, called *layout*, which is used in the fabrication of the system. A layout consists of a set of planar geometric shapes in several layers. It is created by converting each logic component (blocks, cells, gates, and transistors) into a geometric representation (specific shapes in multiple layers), which performs the intended logic function. Interconnects between different components are also expressed as geometric patterns in multiple layers. The exact details of the layout also depend on design rules, which are guidelines based on the limitations of the fabrication process and the electrical properties of the fabrication materials. Physical design is a very complex process and therefore usually broken down into various subprocesses. After layout design and verification, the design is ready for fabrication. Layout data are converted into photolithographic masks, one for each layer. Masks identify spaces on the wafer, where certain materials need to be deposited, diffused, or even removed. Finally, the wafer is fabricated and diced into individual chips in a fabrication facility. Each chip is then packaged and tested to ensure that it properly meets all the design specifications and functions.

To meet the quick time-to-market and high-yield requirements, restricted models and design styles are applied to reduce the complexity of physical design. The design styles can be classified to three categories: full-custom, semi-custom, and universal. In a full-custom layout, all circuitry and interconnect paths are designed. A circuit is partitioned into a collection of blocks according to certain criteria. The process is performed hierarchically, and thus, the full-custom design has several levels of hierarchy. Different blocks of any size can be placed at any location on a chip as long as all the blocks are non-overlapping. In a semi-custom layout such as standard cell and gate array, a library of predesigned cells is available and some parts of a circuit are predesigned/placed on a specific location of a chip. Standard cell layout consists of rectangular cells of the same height, whereas all the cells in the gate array layout are identical gates or cells. In the universal layout design style such as field programmable gate array (FPGA), the design is somewhat fixed and the designer programs the interconnections.

The choice of a layout style depends on many factors, including type of chip, cost, and time-to-market. Full-custom layout is a preferred style for complex and mass-produced chips, since the time required to produce a highly optimized layout can be justified. On the other hand, to design an application-specific IC (ASIC), a semi-custom layout style is usually preferred. Further more, FPGA can dramatically reduce manufacturing turn-around time and cost for low-volume production. Table 1 summarizes the differences of distinct layout design styles in multiple categories.

Physical design is an extremely tedious and error-prone process. VLSI physical design automation is essentially the research, development, and productization of algorithms and data structures related to the physical design process. Its objective is to investigate optimal arrangements of components on a plane (or in three dimensions) and efficient interconnection schemes between components to lower cost and improve yield without compromising

functionality and performance. In the following discussion, general physical design methodology mainly for digital VLSI systems is first discussed. Three major intermediate stages (i.e., partitioning, floorplanning and placement, and routing) in a typical physical design process are described one after another. Then the physical design techniques/features for the advanced technology and analog ICs are outlined. Finally, some emerging topics regarding the modern VLSI layout are presented.

PHYSICAL DESIGN METHODOLOGY

Layout is a process of translating schematic symbols into their physical representations (1). To design a large circuit, it is necessary to understand the layout of simple gates, which are the basic building blocks of any circuit. As an example, the layout of a CMOS inverter is depicted in Fig. 2. The inverter consists of two polysilicon (*poly*) regions overhanging a path in the diffusion layer that runs between VDD and GND. This forms pMos (within the region covered by the Nwell layer) and nMos, which act as pull-up and pull-down transistors, respectively. The transistors are shown by hatched regions in Fig. 2. The inverter input A is connected to the poly that forms the gates of both transistors, whereas the output B on the metal layer is connected to the source/drain terminals of pMos and nMos transistors. VDD and GND are laid out in a metal layer, and contacts are used to connect metal and diffusion layers.

For the physical design process of a VLSI circuit, the input is circuit netlist and the output is circuit layout as depicted in Fig. 3. The physical design automation is typically solved in a hierarchical framework. Each stage should be optimized, while making the problem manageable for subsequent stages. Typically, the following subproblems are considered:

1. Partitioning: The objective is to divide a circuit into smaller parts so that the size of each part is within prescribed ranges and the number of interconnections between parts is minimized.
2. Floorplanning and Placement: Floorplanning is the determination of the approximate location of each block in a rectangular chip area. The shape of each block and the location of the pins on the boundary of each block may also be determined in this phase. When each block is fixed, i.e., fixed shape and fixed pins, placement determines the best exact position for each block.
3. Routing: The objective is to complete the interconnections between blocks according to the specified netlist.
4. Compaction: As a postprocessing phase, compaction is simply the task of compressing the layout in all directions such that the total area is reduced.
5. Verification: It is the testing of a layout to determine whether it satisfies design and layout rules. Design rule checking (DRC) is a process that verifies that all geometric patterns meet the design rules imposed by the fabrication process.

Figure 3 shows the physical design flow with emphasis on timing constraints for VLSI digital systems. The timing performance is estimated after floorplanning and placement and routing, and these steps are iterated if some interconnections fail to meet the timing requirements. After the layout is complete, parasitics can be extracted and accurate timing can be calculated. If some interconnections or components fail to meet their timing requirements, some or all phases of physical design need to be repeated.

Table 1. Comparison of Distinct Layout Design Styles

	Style			
	Full-custom	Standard cell	Gate array	FPGA
Cell size	variable	fixed height	fixed	fixed
Cell type	variable	variable	fixed	programmable
Cell placement	variable	in row	fixed	fixed
Interconnection	variable	variable	variable	programmable
Cost	high	medium	medium	low
Area	compact	compact to moderate	moderate	large
Performance	high	high to moderate	moderate	low
Fabrication layers	all	all	routing layers only	none

PARTITIONING

In VLSI physical design, efficient handling of any complex system necessitates decomposition of the system into a set of smaller subsystems of manageable size. This process is called *partitioning*. If a system is divided into k partitions, the problem is called *k-way partitioning*. Two-way partitioning is called *bipartitioning*. In particular, if the two partitions have the same size, this bipartitioning problem is called *bisectioning*. The partitioning can be conducted in a hierarchical manner until each transformed subsystem is tractable. At any level of partitioning, the input to the partitioning algorithm is a set of components and a netlist. The output is a set of subcircuits and the affiliated terminals for interconnections between subcircuits.

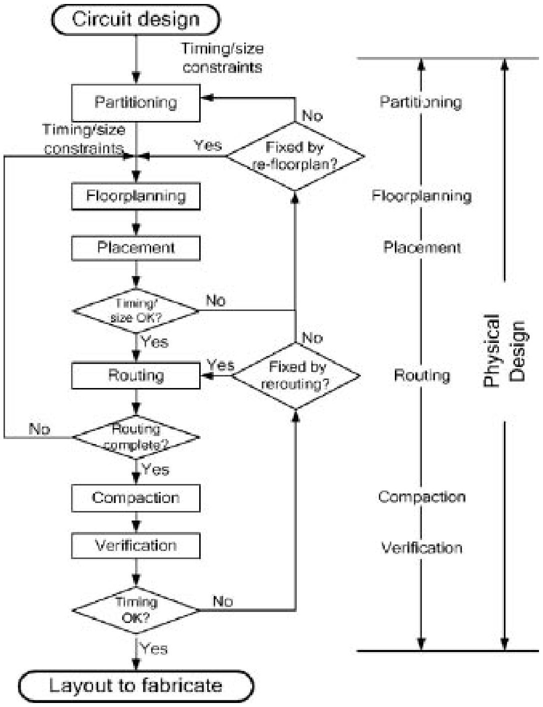

Figure 3. Complete physical design flow.

Problem Formulation

The partitioning problem can be modeled with the aid of hypergraph. Let $G = (V, E)$ be a hypergraph, where $V = \{v_1, v_2, \ldots, v_n\}$ is a set of vertices and $E = \{e_1, e_2, \ldots, e_m\}$ is a set of hyperedges. Each vertex represents a component. A hyperedge joins the vertices whenever the components corresponding to these vertices are connected. Thus, each hyperedge is a subset of the vertex set; i.e., $e_i \subseteq V, i = 1, 2, \ldots, m$. The area of each component is denoted as $a\ (v_i)$, $1 \leq i \leq n$. Fig. 4 depicts a hypergraph, where vertices from a to f represent circuit components, and three hyperedges (interconnecting a-b-c, c-d-e, and e-f, respectively) represent three distinct nets. The partitioning problem is to decompose V to $V_1, V_2, \ldots V_k$, where

$$V_i \cap V_j = \varnothing \quad (1 \leq i \leq n, 1 \leq j \leq n, i \neq j)$$
$$\cup_{i=1}^{k} V_i = V$$

Partition is also referred to as *cut*. The cost of partition is called *cut-size*, which is the number of hyperedges crossing the cut. Let c_{ij} be the cut-size between partitions V_i and V_j. Minimization of the number of interconnections between partitions is called the *mincut problem*, which is a very important objective function for any level partitioning algorithms. The number of interconnections between partitions represents the dependence of partitions. The least dependence of partitions is preferred so that the subsystem of one partition can be implemented without much concern of the other partitions. This strategy can also ease the following physical design stages, especially for complex systems. The objective function above can be stated as follows:

$$\sum_{i=1}^{k}\sum_{j=1}^{k} c_{ij}, (i \neq j) \quad \text{is minimized}$$

Another objective function might be the minimization of the maximum number of times a path crosses the partition boundaries. The constraints for the partitioning problem may include the following: area, terminal number, and partition number. The objective functions and constraints used in the partitioning problem vary depending on the

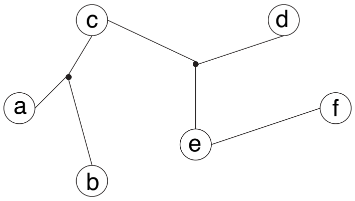

Figure 4. A hypergraph for modeling the partitioning problem.

partitioning level, the applied design style, and the specific problem.

Partitioning Algorithms

The partitioning problem is NP-complete. As a result, a variety of heuristic algorithms have been developed. The partitioning algorithms can be classified based on the process used for partitioning, including group migration algorithms, simulated annealing/evolution-based algorithms, and other partitioning algorithms.

The group migration algorithms start with some partitions, usually generated randomly, and then move components between partitions to improve the partitioning. They are deterministic algorithms, which can produce repeatable or deterministic solutions. One such algorithm is an iterative bipartition algorithm proposed by Kernighan and Lin (2). Based on graph, this algorithm starts with a random initial partition and then uses pairwise swapping of vertices between partitions, until no improvement is possible. Among a series of variant algorithms, Fiduccia and Mattheyses modified the Kernighan–Lin algorithm and reduced the time complexity to *O(t)*, where t is the number of terminals (3). The group migration algorithms are generally simple and efficient. However, the number of partitions, usually unknown when the partitioning process starts, has to be specified. And an algorithm used to find a minimum cut at one level may sacrifice the quality of cuts at the following levels.

Simulated annealing/evolution algorithms are the techniques used to solve general optimization problems, which include the partitioning problems. These techniques are especially useful when the solution space of the problem is not well understood. Simulated annealing is the simulation of crystal formation. The process starts with a random initial partitioning. An altered partitioning is generated by exchanging some elements between partitions. The resulting change in the cost, δ_c, is calculated. If $\delta_c < 0$ (representing lower energy), the move is accepted. If $\delta_c \geq 0$, the move is accepted with the probability of $e^{\frac{\delta_c}{kt}}$, where k is Boltzmann's constant and t is temperature. Thus, the probability of accepting an increased cost decreases with the decrease of temperature t, which allows the simulated annealing algorithm to climb out of local optimums in search of a global minimum. On the other hand, the simulated evolution algorithms simulate the biological process of evolution. The algorithm starts with an initial set of configurations, which is called *a population*. The simulated evolution algorithm is iterative, and each iteration is called a *generation*. The quality of generations is improved by using operators that imitate the biological events in the evolution process. For instance, the crossover operator is to generate offspring by combining schemata of two individuals at a time, whereas the mutation operator is to produce new offspring by causing incremental random changes. Simulated annealing/evolution algorithms allow a designer to come close to the optimal solution statistically, but the user needs to trade off quality and computation time.

Besides the group migration and simulated annealing/evolution methods, there are other partitioning algorithms such as the maximum-flow min-cut algorithm and eigenvector decomposition algorithm (4). The maximum-flow min-cut algorithm transforms the min-cut problem into the maximum flow problem. To separate a pair of nodes into two subsets, the minimum number of crossing edges is equal to the maximum amount of flow from one node to the other. Although this algorithm can find the optimal solution between any pair of vertices in a network, there is no constraint on the sizes of resultant subsets. The eigenvector decomposition algorithm finds an allocation by some metrics other than the graph structure. It requires the transformation of every multi-terminal net into several two-terminal nets first. The connections are represented in a matrix, and the eigenvectors of the matrix define the locations of all components and thus derive partitioning results.

FLOORPLANNING AND PLACEMENT

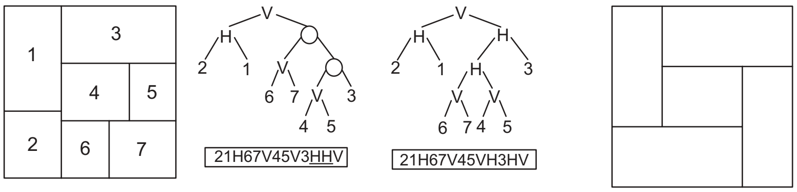
Once the partitioning phase is done, the next task is to assign a specific shape to each block and arrange the blocks on the wafer. This is done by floorplanning and placement phases. The blocks, whose dimensions are known, are called fixed blocks, whereas the blocks, whose dimension are yet to be determined, are called flexible blocks. The problem of assigning locations of any flexible blocks on a layout surface is called *floorplanning*, where the details, such as shapes of blocks, I/O pin positions, and so on., are not fixed yet. If all of the blocks are fixed, the positioning problem is called *placement*. Thus, the placement problem is a restricted version of the floorplanning problem.

Floorplanning

The floorplanning problem is to plan the positions and shapes of the blocks for optimizing the circuit performance. Some objectives, such as chip area, total wirelength, delay of critical path, routability, noise, heat dissipation, and so on., are normally considered in the floorplanning phase. Compared with the placement problem, floorplanning is more difficult. In floorplanning, several layout alternatives for each block are considered. Usually the blocks are assumed to be rectangular and the lengths and the widths of these blocks are determined besides their locations.

The input to the floorplanning problem is a set of blocks $(B_1, B_2, \ldots, B_n)$, the area of each block $(a_1, a_2, \ldots, a_n)$, possible shapes of each block, the number of terminals for each block, and the netlist. The aspect ratio of a block is the ratio of its width to its height. A_i^l and A_i^u (l ≤ z ≤ n) define the lower and upper bounds on the aspect ratio of each block. The floorplanning algorithm has to determine the width w_i and height h_i of each block B_i such that $A_i^l \leq \frac{h_i}{w_i} \leq A_i^u$. Finally the floorplanning algorithm has to generate a valid placement such that the area of the layout is minimized.

Floorplanning methods can be classified into two categories: slicing floorplanning and non-slicing floorplanning. A slicing floorplan is a floorplan that can be obtained by recursively partitioning a rectangle into two parts either by a vertical or horizontal line. The cut tree obtained by min-cut algorithm is known as *slicing tree*. A slicing tree is a binary tree in which each leaf represents a partition and



(a) slicing floorplan. (b) slicing tree. (c) slicing tree (skewed). (d) non-slicing floorplan.

Figure 5. A floorplan with slicing trees and a non-slicing floorplan.

each internal node represents a cut direction (or cut). A slicing floorplan is depicted in Fig. 5(a), and its corresponding slicing trees are shown in Fig. 5(b) and Fig. 5(c). Figure 5(d) shows a non-slicing floorplan.

Wong and Liu proposed a simulated annealing algorithm using a normalized Polish expression to tackle the slicing floorplanning problem (5). A Polish expression [as given in the blocks within Fig. 5(b) and Fig. 5(c)] is the postorder traversal of a slicing tree. By restricting a slicing tree [as depicted in Fig. 5(b) where one H node can have another H node as its son node on the right side] to a *skewed slicing tree* [i.e., no node and its son node on the right side in the slicing tree are the same as shown in Fig. 5(c)], a normalized Polish expression [i.e., no consecutive H's or V's as shown in Fig. 5(c)] can be obtained. And it can be proved that there is a 1–1 correspondence among slicing floorplan, skewed slicing tree, and normalized Polish expression. Thus, normalized Polish expressions can be used to represent slicing floorplans. And the slicing floorplan problem can be formulated as a state space search problem by defining a number of neighborhood structure move patterns within simulated-annealing optimization.

Compared with the slicing floorplan, the non-slicing floorplan is a more general form and thus much harder to handle. A conventional method for solving non-slicing floorplanning is mixed integer linear programming (6). This problem is formulated by a mathematical program, which includes a linear objective function and linear constraints. Each block is associated with four variables, including X/Y coordinates of the lower left corner and width and height. To keep blocks at non-overlap, linear inequalities can be set up to represent the location relationship of blocks. Finally the problem is solved with a linear programming (LP) package. However, because of the time-consuming feature of LP, practically this method can only solve small size problems. To explore more efficient solutions to the non-slicing floorplan, recently extensive research work has been conducted on non-slicing representations. These include sequence pair, bounded slicing grid, O-tree, B*-tree, corner block list, transitive closure graph, and so on. (7). Experimental results show that these non-slicing representations can generate efficient floorplan results.

Placement

The placement phase is very crucial in the overall physical design cycle. A problematic placed layout cannot be improved by high-quality routing in terms of area and performance. The placement problem can be formulated as follows. Let $B_1, B_2, \ldots, B_n$ be the blocks to be placed on a chip. Each $B_i 1 \leq i \leq n$, is associated with a height h_i and a width w_i. Let $N = \{N_1, N_2, \ldots, N_m\}$ be the set of nets representing the interconnection between different blocks. Let $Q = \{Q_1, Q_2, \ldots, Q_k\}$ represent rectangular empty areas allocated for routing between blocks. Let L_i denote the estimated length of net $N_u 1 \leq i \leq m$.

The placement problem is to find rectangles for each of these blocks on the plane denoted by $\mathcal{R} = \{R_1, R_2, \ldots, R_n\}$ such that (*1*) each block can be placed in its corresponding rectangle, that is, R_i has width w_i and height h_i; (*2*) no two rectangles overlap, that is, $R_i \cap R_j = \varnothing, \quad 1 \leq i \leq j \leq n$; (*3*) placement is routable, that is, Q_j, $1 \leq j \leq, k$ is sufficient to route all the nets; (*4*) the total area of the rectangle bounding $\Re$ and Q is minimized; and (*5*) the total wirelength is minimized, that is, $\sum_{i=1}^{m} L_i$ is minimized. In the high-performance-circuits, the length of the longest net (i.e., $\max\{L_i | i = 1, \ldots, m\}$) has to be minimized. A few popular methods for wirelength estimation exist, such as half bounding box of the interconnection (also known as half-perimeter method), complete graph, minimum spanning tree, minimum Steiner tree, squared Euclidean distance (squares of all pairwise terminal distances in a net using a quadratic cost function), and so on (8).

The general placement problem is NP-complete. Thus, the placement algorithms are generally heuristic in nature. Three types of the most popular techniques are used in the state-of-the-art placers (9): the simulated-annealing-based approach, the partitioning-based approach, and the analytical approach. Independent of the placement techniques used, most modern placers consist of three major steps: *(1)* global placement: determines the most desired position for each cell/block, which might results in cell/block overlaps; *(2)* cell legalization: removes the cell/block overlaps; and *(3)* detailed placement: refines the placement solution.

The simulated-annealing-based placement algorithm normally consists of two stages. At Stage 1, blocks are moved between different rows as well as within the same row. Block overlaps are allowed at this stage, and they will be removed at the second stage. When the temperature falls below a certain value, Stage 2 begins. At Stage 2, any overlaps are removed and only adjacent blocks are interchanged within the same row. The solution perturbations are based on certain predefined move patterns. The drawback of the simulated-annealing-based placement algorithm is the long running time.

Partition-based algorithms are designed to group closely connected blocks together. The idea is to repetitively divide a circuit into subcircuits such that the cut value is minimized. The placement region is partitioned by cutlines accordingly. Each subcircuit is assigned to one partition of the placement region. The partitioning methods normally apply the Fiduccia–Mattheyses algorithm or other variants with the multilevel capability. Some typical academic placement tools include Capo, Feng-shui, NTUplacer, and so on (9). The partition-based algorithms are normally fast in terms of execution time, but they are not stable.

Analytical placement algorithms represent the placement problem as an analytical mathematical problem. One example is quadratic placement algorithms (10). As sum of squared wire length is quadratic in the cell coordinates, the wirelength minimization problem can be formulated as a quadratic program. It can be proved that the quadratic program is convex; hence, a polynomial time solution can be derived. The force-directed method is another typical form of analytical placement algorithm (11). This method transforms the placement problem into the classic mechanics system of objects attached to springs. Circuit blocks are analogous to objects, whereas circuit nets can be seen as springs. If the net weights are treated as spring constants, an optimal placement is actually an equilibrium configuration of objects. To avoid overlapping of blocks, repulsive forces inversely proportional to distance and connections to the fixed I/O pins on the boundary of the placement region can be added. Compared with blind search of simulated annealing, the force directed methods use directions of forces to guide the search. Thus, it is usually much faster than simulated annealing. However, this method focuses on connections, not on shapes of blocks. As it is only a heuristic, an equilibrium configuration does not necessarily stand for a good placement.

ROUTING

Introduction to Routing

After placement, components are arranged on a plane and the task remains to insert the electrical interconnections among the components to make them function. The process of finding the geometric layout of all the nets is called *routing*. The input to the general routing problem is as follows: *(1)* netlist; *(2)* timing budget for nets, typically for critical nets only; *(3)* placement information including location of blocks, locations of pins on the block boundary, and location of I/O pins on the chip boundary; and *(4)* RC delay per unit length on each metal layer, as well as RC delay for each type of via.

The objective of the routing problem is dependent on the nature of the chip. For general-purpose chips, it is sufficient to minimize the total wire length, while completing all the interconnections. For high-performance chips, it is important to route each net such that it meets its timing budget. Usually routing involves special treatment of such nets as clock, power, and ground nets.

One approach to the general routing problem is called *Area Routing*, which is a single-phase routing technique. It routes one net at a time considering all the routing regions. However, because of the extremely large size of the modern VLSI chips, this technique is computationally infeasible for an entire chip and is typically used for specialized problems or smaller routing regions. The conventional approach is to divide the routing into two phases as represented in Fig. 6. The first phase is called *global routing*, which generates a loose route for each net. It assigns a list of routing regions to each net without specifying the actual geometric layout of wires. The second phase, which is called *detailed routing*, finds the actual geometric layout of each net within the assigned routing regions. Unlike global routing, which considers the entire layout, the detailed routing considers just one region at a time. The exact layout is produced for each wire segment assigned to a region, and vias are inserted to complete the layout. Both global routing and detailed routing are NP-complete.

Global Routing

The global routing consists of three distinct phases: region definition, region assignment, and pin assignment. The region definition is to partition the entire routing space into routing regions, which includes spaces between blocks and above blocks (due to over-the-cell routing). Each routing region has a capacity, which is the maximum number of nets that can pass through that region. The capacity of a region is a function of the design rules and dimensions of the routing regions and wires. As the second phase of global routing, region assignment is to identify the sequence of regions through which a net will be routed. This phase must take into account the timing budget of each net and the congestion of each routing region. After the region assignment, each net is assigned a pin on region boundaries. This phase is called pin assignment, which allows the regions to be somewhat independent. After global routing is complete, the output includes pin locations for each net on all the region boundaries it crosses. Using this information, the length of the net can be extracted and the corresponding delay can be estimated. If any net fails to meet its timing budget, it needs to be ripped-up or the global routing phase needs to be repeated.

The global routing problem is typically studied as a graph problem (12). As shown in Fig. 6, there are two kinds of approaches to solving the global routing problem: sequential and concurrent. In the sequential approach, nets are routed one by one. However, once a net has been routed, it may block other nets that are yet to be routed. As a result, this approach is very sensitive to the order in which the nets are considered for routing. Usually, the nets are sequenced according to their criticality, half perimeter of the bounding rectangle, and number of terminals.

As an important two-terminal routing algorithm, maze algorithms are used to find a path between a pair of points, called the source and the target, respectively, in a planar rectangular grid graph (13). The geometric regularity in the standard cell and gate array design style allow one to model the whole plane as a grid. The areas available for routing are represented as unblocked vertices, whereas the obstacles are represented as blocked vertices. The objective of a

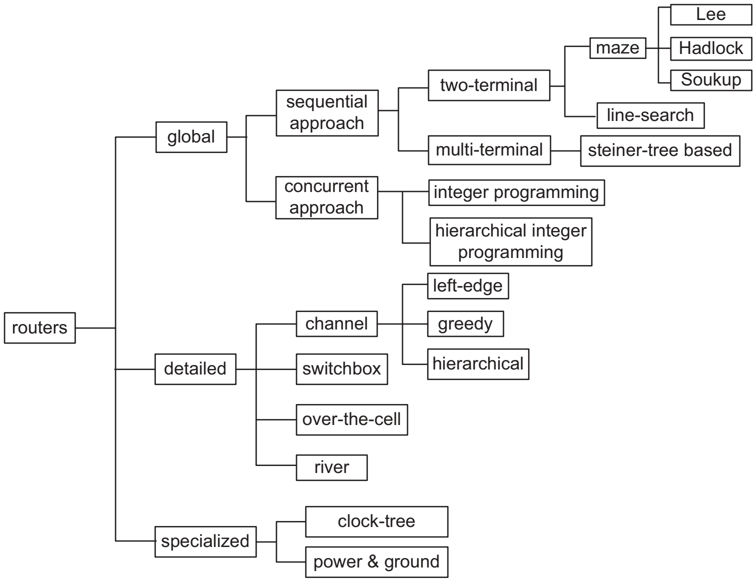


Figure 6. Classification of routing approaches.

maze routing algorithm is to find a path between the source and the target vertex without using any blocked vertex. The process of finding a path begins with the exploration phase, in which several paths start at the source and are expanded until one of them reaches the target. Once the target is reached, the vertices need to be retraced to the source to identify the path. The retrace phase can be easily implemented as long as the information about the parentage of each vertex is kept during the exploration phase.

The second global routing approach is concurrent approach, which avoids the ordering problem by considering the routing of all the nets simultaneously. The concurrent approach is computationally hard and no efficient polynomial algorithms are known even for two-terminal nets. As a result, integer programming methods as shown in Fig. 6 were proposed. The corresponding integer program is usually too large to be employed efficiently. Hence, hierarchical methods are employed to partition the problem into smaller subproblems, which can be handled by integer programming.

Detailed Routing

In a two-phase routing flow, detailed routing follows the global routing phase. The detailed router places the actual wire segments within the region indicated by the global router, thus completing the required connections between the terminals. The detailed routing has multiple forms, including channel routing, switch-box routing (2-D-switchbox and 3-D-switchbox), over-the-cell routing, and river routing. A channel is a rectangular area bounded by two opposite sides of blocks. A 2-D-switchbox is a rectangular area bounded all by block sides, whereas a 3-D-switchbox is a rectangular area with pins on all six sides. The detailed routing problem is usually solved incrementally. The ordering of the regions is determined by several factors, including the criticality of routing certain nets and the total number of nets passing through a region. Typically channel and 2-D-switchboxes should be routed first, since channels may expand. After channels and 2-D-switchboxes have been routed, the pin locations for 3-D-switchboxes are fixed and then their routing can be completed. After detailed routing is completed, exact wire geometry can be extracted and used to compute RC delays. The delay model not only considers the geometry (length, width, layer assignment, and vias) of a net, but also the relationship of this net with other nets. If some nets fail to meet their timing constraints, they need to be ripped-up or the detailed routing of the specific routing region needs to be repeated.

Different detailed routing strategies have been developed with a variety of objectives. A primary objective function of a detailed router is to meet the timing constraints for each net and to complete the routing of all the nets. Various secondary objective functions can also be considered, such as reducing total routing area, improving manufacturability by minimizing the number of vias and jogs, and improving performance by minimizing crosstalk between nets and delay for critical nets. Other objective functions may include minimization of the average or total length of a net or minimization of the number of vias per net.

The detailed routing algorithms can be classified in many different ways. Besides the classification method shown in Fig. 6, the algorithms can be categorized on the basis of the routing models used. Some routing algorithms use grid-based models, whereas others use the gridless models (14). The gridless models are more flexible as all the wires in a design need not have the same width. Another possible scheme is to classify the algorithms based on the strategy they use. Thus, we could have greedy routers, hierarchical routers, and so on. The number of layers used for routing can also be taken as a criterion to classify the algorithms. Thus, single-layer, two-layer, three-layer, and multilayer routing algorithms can be formed.

OTHER ISSUES IN VLSI PHYSICAL DESIGN

Design Techniques for the Advanced Technology

As the CMOS technology enters the deep submicron and nano design era, the interconnect density combined with the increase in wiring levels and the growth in chip size make the interconnect design become the most challenging area in the advanced technology. Wire delay and area tend to be the primary contributors to IC performance, power, and area. When using the conventional VLSI design, flow depicted in Fig. 1, the inaccuracy of wire modeling in the front-end design (including architectural design, behavioral design, logic design and circuit design) and the initial phases of the physical design often leads to long physical and timing closure periods to achieve a placement that is routable and meets timing requirements.

To overcome the inherent unpredictability of physical design in the preceding design process, floorplan-based design methodology, which takes into account the effect of floorplanning in the front-end design or initial phases of physical design, exhibits its promising applications especially in the advanced technology. For instance, chip floorplanning is performed continuously throughout the front-end process to discover physical design issues earlier and to impact register-transfer level (RTL) design decisions. Instead of relying on placement and routing results to correlate with prelayout models, floorplanning is deployed because of its relatively fast execution. Thus, an appropriate level of accuracy derived by floorplanning can guide the search in the front-end design process. This flow ensures rapid closure by characterizing netlist quality continuously during RTL implementation using iterative refinement of prelayout wire models.

In deep submicron and nano technology, the metal width tends to decrease with the length increase because of the complex system integration into single silicon. Therefore, the resistance along the power metal line increases. In addition, because of the nonlinear scaling of threshold voltage compared with power supply voltage in the advanced technology, IR-drop and clock skew issues become more crucial to the functionality of chip. As the design complexity exceeds millions of transistors on chip, it is reasonable to consider IR-drop and clock skew problems earlier in the design cycle. A floorplan-based planning methodology can be used for power network and clock network planning (15). From a floorplan, the power network size is determined at an early design stage based on the estimated power consumption. And even without a detailed gate-level netlist, clock interconnect sizing, the number and strength of clock buffers can be planned for balanced clock distribution. This early planning methodology at the full-chip level enables designers to fix the global interconnect issues by progressively refining the layout as the design proceeds for both the power and the clock distribution.

VLSI Physical Design of Analog ICs

The physical design methodologies discussed in the previous sections are mainly targeted to digital VLSI systems. Analog ICs have significantly different characteristics from digital circuits. These impose noticeable challenges on the physical design of analog circuits (16). In terms of the optimized parameters, digital ICs mainly consider the factors such as delay, area, power dissipation, and signal-to-noise ratio. On the other hand, for the analog circuits, there are numerous additional trade-offs among specifications, such as DC gain, bandwidth, offset voltage, 1/f noise, power supply rejection ratio, common mode rejection ratio, input swing, output swing, slew rate, and so on. Because of the considerable conflicts among these parameters, the optimization of analog ICs is a hard job requiring both knowledge and experience. In particular, the performance of analog circuits is strongly dependent on the detailed layout geometry and style.

Since the signal-to-noise ratio of digital circuits is large, over-the-cell routing is commonly used. However, this is not desirable in the analog layout because of the sensitive coupling effect of nets. Therefore, the structured custom layout approaches, which have been successful in speeding up the design of digital ICs, have difficulty in providing the same productivity gains to analog and mixed-signal ICs. A fixed library is unable to cover adequately the range of functions needed to construct arbitrary analog systems. Normally at least some fraction of an analog circuit on a mixed-signal chip must be full-custom designed at the considerable expense of time and skill.

In the view of layout, at least three distinctions exist between digital and analog ICs. First of all, analog blocks may have several alternative implementations, whereas digital blocks have only limited implementations. The transistors in digital circuits are always with the minimum size, whereas the transistors in analog circuits differ greatly in their width and length. Second, analog ICs are relatively small, which always include a limited number of blocks in all. In contrast, digital systems are very large (up to millions of transistors). Finally, lots of constraints are involved in the layout of analog circuits, such as parasitics, device matching, symmetric requirements, piezoelectric effects, and so on. For the layout of digital circuits, the constraints are limited.

The well-developed digital design tools/algorithms cannot be directly used for analog layout generation. In the following disussion, some typical methods used in the analog layout automation tools are described. Most of the existing analog layout automation tools apply a top-down design approach that takes the already optimized circuit netlist as the input and subsequently generates the layout (16). Meye zu Bexten et al. developed a rule-based analog layout system called ALSYN. The quality of the resulting layout greatly depends on the quality of the rule set, which is formulated in a context-dependent manner. The constructive technique proposed in Ref. 17 generates analog layouts by mapping features and special design constraints into an effective construction. A variety of interacting quality measures in the analog layout make this approach more suitable for layout generation at the device level. Algorithm-based tools, such as KOAN-ANAGRAM II (18), LAYLA (19), and ALADIN (20), can incorporate the analog layout knowledge into the design flow. These tools normally include complete placement and routing phases, which can handle special analog constraints. Recently, template-based layout automation, which retargets an existing analog layout to a different process or updated specification, was proposed (21). This technique, which is significant for supporting effective retargeting of analog intellectual properties, can produce good quality layouts in a reasonable amount of CPU time.

EMERGING TOPICS

The semiconductor industry has been driven by Moore's law for almost a half century. Device size miniaturization has allowed dense packing of transistors, whereas the improved transistor performance has led to significant increase in frequency. The VLSI physical design, which is closely related to performance requirements and high yield of ICs, has always faced new challenges posed by emerging technologies.

Among the grand challenges posted in the latest International Technology Roadmap for Semiconductors (ITRS, http://www.itrs.net/), layout design problems originating in state-of-the-art mask lithography and manufacturability take the lead. Of these, optical proximity correction of the mask and phase shift masking for enhancing sharpness are demanded. Dummy fill synthesis to achieve uniform density preferred for chemical-mechanical polishing needs to be realized.

Some research topics in deep submicron and nano regimes such as interconnect planning and synthesis, which involve interconnect architecture design, delay estimation, delay reduction by buffer insertion, and wire sizing, are attracting an increasing amount of attention. The resultant techniques are also pertinent to clock skew management in the clock-tree synthesis. Postplacement logic rewiring techniques for additional optimization of delay, power, and reliability are mandated.

Modern VLSI designers can integrate a whole system with large-scale logic/functional blocks on a single chip. This is called system-on-a-chip (SoC) design. The physical design for such a system needs to consider the integration of large-scale digital and analog (mixed-signal) circuit blocks, the design of system interconnections/buses, and the optimization of circuit performance, area, power consumption, and signal and power integrity. In addition, the highly competitive IC market requires faster design convergence, faster incremental design turnaround, and better silicon area utilization.

For modern VLSI circuits, more than half of the silicon area, power dissipation and delays are consumed by interconnects rather than devices. To tackle this issue, the 3D-Stacked IC (3D-SIC) technology aims to enable direct stacking of thinned ICs while realizing through-die area array interconnects (i.e., 3D vias) between them with an extremely high density. Thus, placing and wiring devices in the third dimension can promise higher clock rates, less power dissipation, and higher integration density. The physical design challenges of 3D-SIC include area, power and performance optimization, interconnect complexity, thermal distribution, process variations, signal integrity, and power/clock distribution.

Recently manufacturers of high-performance consumer electronics are turning to System-in-a-Package (SiP) design because it can provide a number of advantages over SoC. The SiP technology encompasses the packages with wire-bond die-stacks, or package-on-package 3D stacks. In addition to reduced cost, lower power, and higher performance, the SiP design offers the flexibility to mix RF and high-speed digital circuitry in the same package. It requires expert engineering talent in widely divergent fields (e.g., chip-package codesign).

As 3D packaging technology continues to advance, an emerging 3D system integration concept is to incorporate ultrathin films at microscale to embed both active and passive components (22). Besides the optimization of area, power and performance, the physical design of such a system needs to consider thermal distribution, mixed-signal substrate coupling and electromagnetic interference, power supply noise, and optical routing.

Furthermore, with the continued increase of on-chip packing density and the continued shrinking of device feature sizes due to the nanometer IC technologies, some other issues such as reliability (antenna effect, electrostatic discharge, electromigration, etc.), thermal, and yield (redundant via, process variation, etc.) will soon become first-order effects for VLSI physical design, as comparably important as the traditional design metrics—timing, power, signal/power integrity, and area. These effects have imposed tremendous challenges and opened many research opportunities to modern physical design.

COLLABORATIVE VIRTUAL ENVIRONMENT: APPLICATIONS

INTRODUCTION

As the Internet evolves, people realize that a more natural interaction and communication via local area network (LAN), wide area network (WAN), or Internet can improve the efficiency of their social activities and the productivity of their daily work. Rapid advances in networking technology in the past decade have offered the potential of achieving real-time collaborative applications via network connection, in which people are able to interact with each other and the virtual surrounding environment in a way that they experience in real life. Collaboration is part of basic communication form in human society. If a virtual environment or a cyberspace is connected by computer network to allow real-time sharing and exchanging of information by multiple users, efficient remote collaboration can be realized. Collaborative Virtual Environment (CVE) has been developed for such purposes. With the capability to support multiple geographically dispersed human-to-human and human-to-machine communication and interaction in a shared virtual environment, CVE opens a door to a broader spectrum of potential applications in various areas ranging from academic study to collaborative engineering to military war-game simulation applications. There are many scenarios that can significantly benefit from the solution presented by CVE over simply noncollaborative virtual reality (VR) or 3-D workstation computer graphics. An important pioneer application in this area, the SIMNET networked tank simulators (1) demonstrate the feasibility of a CVE system used for military training in a distributed interactive simulation environment. Besides military applications, CVE has also been applied in medical or industrial team training, collaborative design and engineering, collaborative scientific visualization, and social activity and entertainment-like multiuser VR games. Recently, the game industry has also adopted the findings in this field of research and developed new types of games based on CVE technology. Examples of these developments are the multiplayer games (2,3). These games aim to support very large user bases with massive multiplayer online role-playing interactions. This type of game has proven to be quite popular and a way of generating revenue for application and content providers.

In the following sections of this article, we discuss the CVE applications in the following four main categories: military applications, social interaction and entertainment, collaborative learning, and collaborative design and group work.

MILITARY APPLICATIONS

A military force must rehearse its options if it is to be prepared for a complex battlefield environment. However, battle training with troops and equipment in the real world is both expensive and dangerous. Thus, virtual military training using a computer-generated synthetic environment has an important role to play. Training individual soldiers with stand-alone equipment simulators using VR technology has achieved great success for many years. As modern warfare gets more complicated, it often requires joint force of Army, Navy, Marine Corps, and Air Force to accomplish a military task. Thus, individual stand-alone virtual training is no longer sufficient. It requires collaborative efforts of different military services. It becomes the natural need for CVE technology to construct a multi-user shared battlefield that supports simulation of various military weapons, realistic battlefield effects, and intelligent agent-controlled virtual soldiers called a computer-generated force (CGF) (4). The SIMNET networked tank simulator was the first such military application. It allows armor companies and mechanized infantry companies to practice fighting in cooperation against some foe in a LAN or WAN. A trainee in a tank simulator can see and interact with the avatar of a Bradley Fighting Vehicle located hundreds of kilometers away in the SIMNET war simulation.

Karr et al. (4) categorized military training simulation by the degree of human interaction as “live, virtual, and constructive.” In “live” simulation, data feeds from computers replace sensor information from real equipment. The simulated sensor readings are matched as closely as possible with physical cues such as 3-D imagery and realistic audio. Each of the services has programs incorporating live simulation. The Air Force has the Contingency Theater Automated Planning System, sailors aboard ships train in a simulated world using the Battle Force Tactical Training System, and Army reservists can train in M-60 tanks using the Guardfist Training System. In “virtual” simulation, the second category, the work environment is also simulated. The real trainee tank gunner, for example, is in a physical mockup of the inside of a tank, and when he looks into the gun sight, he sees a television screen displaying a computer-generated image. In the Army, the crews for hundreds of tanks, Bradley Fighting Vehicles, and helicopters are trained each year in their vehicles. In live and virtual simulation, the trainee is known as the man in-the-loop. In the third and last category of simulation, “constructive,” the man departs from the loop, and battles can be fought with no or minimal human intervention. CGF systems belong in this category. Entities in the virtual world—soldiers, ships, tanks, aircraft, and the like—also can be “manually” controlled by commanders undergoing training, just as scale models were pushed around large map tables in the old days. (In practice, the officer in training directs his commands to a specialist operator, who implements them on workstations.)

Besides battlefield training, CVE has also been used for military clinical therapy treatment for postwar personnel as reported by Rizzo et al. (5). The virtual environment of various war scenarios when combined with real-time clinician input via the “Wizard of Oz” clinical interface is

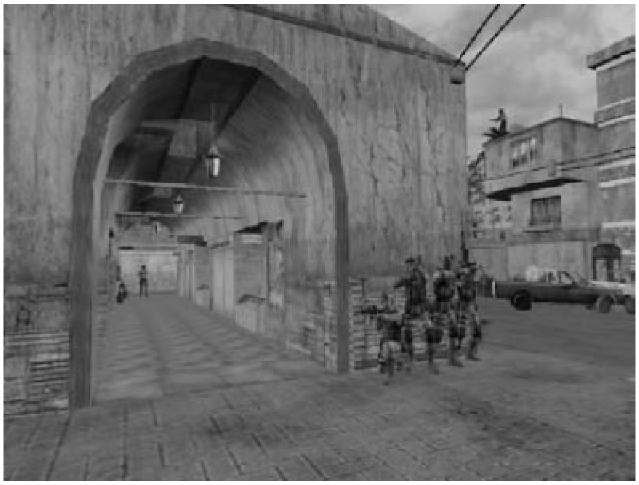

Figure 1. Flocking patrol (5).

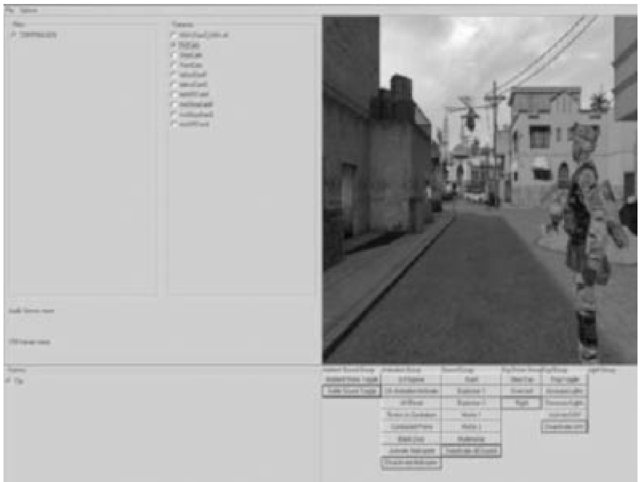

Figure 3. Clinical CVE postwar therapy interface (5).

envisioned to allow for the creation of a user experience that is specifically customized to the needs of the patient participating in treatment. It is designed such that clinical users can be teleported to specific scenario settings based on a determination as to which environment most closely matches the patient's needs, relevant to their individual combat-related experiences. These settings include city scenes, checkpoints, city building interiors, small rural villages, desert bases, and desert roads as illustrated in Figs. 1–3:

SOCIAL INTERACTION AND ENTERTAINMENT

CVE provides a virtual space to allow an electronic means of information exchange through network connections. In a CVE, a group of people can get together and communicate with each other, and they can gather information while freely moving about and engaging in a variety of activities. It provides a new information communications environment for people to exchange information, develop mutual understanding, interact freely with each other, and participate in entertainment activities (e.g., online multiplayer games, online digital community activities, etc.) in an enjoyable and efficient manner. It is a multiparticipant communication support platform that enables each participant's avatar to roam around freely in a 3-D virtual space. It also allows each avatar to engage in conversation with other avatars, with each avatar that may be mapped with facial image or live facial video image of the corresponding participant from a video camera mounted on his or her personal computer. This Feature enhances the feeling of presence in the shared social interaction and entertainment environment. Live audio and text chat in a shared 3-D environment engage online participants with easy communication and information exchange. For example, "There" see (http://www.there.com) (6) provides a persistent online environment for social interaction, as shown in Fig. 4. "There" shares many of the features of other online virtual environments and persistent role-playing games, such as Ultima Online (7), Everquest (2), Asheron's Call (8), World of Warcraft (9), and so on. Yet There is marketed as a "virtual getaway" for social interaction and exploration. Unlike online games, no overall goal exists to "There." Its

es, I've been watching them
Hey ... think those guys are pretty deep in conversation.
the case. They seem really closed off to the untrained eye.
I'm not sure if
maybe they need more structure
well ... if you have time get on the ... with some of
them and
let em know

Figure 4. Social interaction in "There" online environment (6).

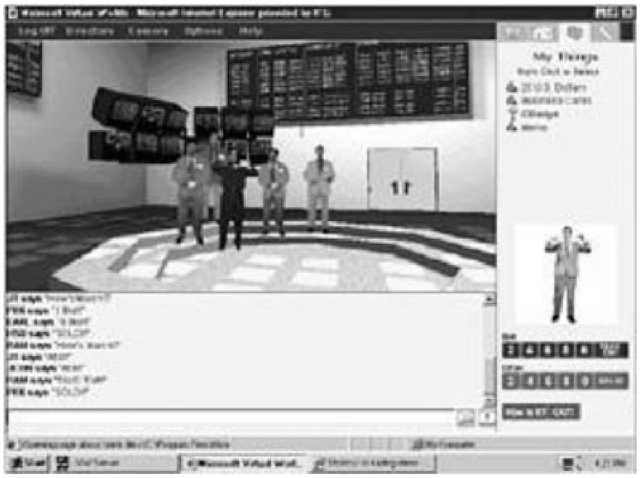

Figure 5. Virtual Worlds Platform-based-electronic mercantile exchange (10).

environment supports activities such as buggy races, paintball, flying jetpacks, treasure hunts, and even playing with virtual pets. Moreover, as with the real world, much attention is given to personal appearance, and one of the main activities in "There" is designing virtual clothes and selling them through in-game auctions. "There's" virtual world is augmented with support for instant messaging (both text and audio), forums, tools for organizing virtual "events," and forming groups. Specific attention has also been given to supporting social interactions in "There". Avatars can make emotional gestures, and chat is displayed in speech bubbles, within the game world, word by word, rather than in the complete lines of text displayed in instant messaging. Considerable attention has also been given to how avatars interact around objects. For example, unlike most games, the most commonly used camera angle is above the head and some distance back, which increases the field of view allowing easier interaction with objects that are close to the avatar. This view can also be turned with the mouse, an operation that is visible to others by the avatar turning its head.

Microsoft Research has also developed a Virtual Worlds Platform (10), which can be used for various social activity applications. The Electronic Mercantile Exchange, as shown in Fig. 5, is a prototype environment built by Acknowledge Systems using the Virtual Worlds Platform. It is an online environment for the financial services industry and a major futures exchange was consulted in the creation of this prototype. Among the features of the environment are a collaborative research center and a simulated trading floor that allows users to take part in a multi-user mock trading session, complete with 3-D graphics and audio. Used for marketing and education, the environment allows visitors to see, hear, and participate in simulations of these complex markets.

MusicWorld, as shown in Fig. 6, is another social interaction application built based on the Virtual World Platform. It is a graphical collaborative musical performance environment where avatars join together to explore a live, online "album" of multiple songs. Within each soundscape, avatars can mix sounds and compose their own musical patterns that are shared in real-time. Although all of the avatars can affect the music individually, all the changes they made are instantly updated across the network, guaranteeing that the music is truly collaborative and heard the same way for all participants. The space exemplifies the capabilities of V-Worlds to host a dynamically changing environment in which avatars could be expressive and change their world in real-time.

The Virtual World Platform has also been used to create a collaborative educational environment for exploring ancient Egyptian civilization and the crafts of archaeology and museum studies. It simulates the excavation of a new kingdom royal tomb in Egypt's Valley of the Kings. The tomb features a wide range of objects and artifacts representative of the late-eighteenth to early-nineteenth dynasties in ancient Egypt. It is intended as an educational simulation to be used by grade school students (age 9–12) in the classroom environment, and it is being developed in collaboration with teachers and museum educators. It features multi-user interaction in a 3-D virtual environment with rich textures, as shown in Fig. 7.

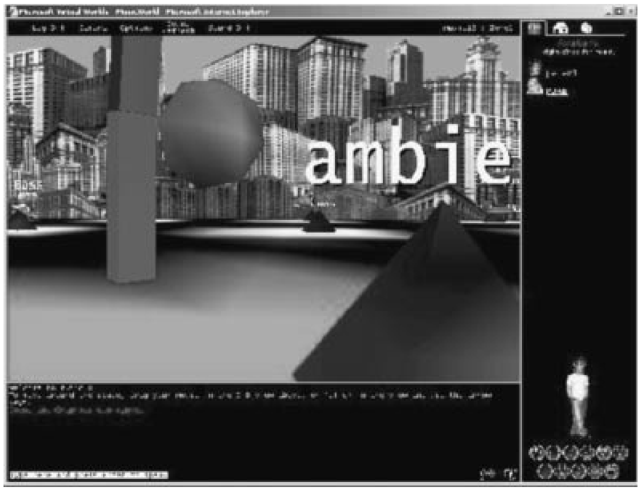

Figure 6. Virtual Worlds Platform-based MusicWorld (10).

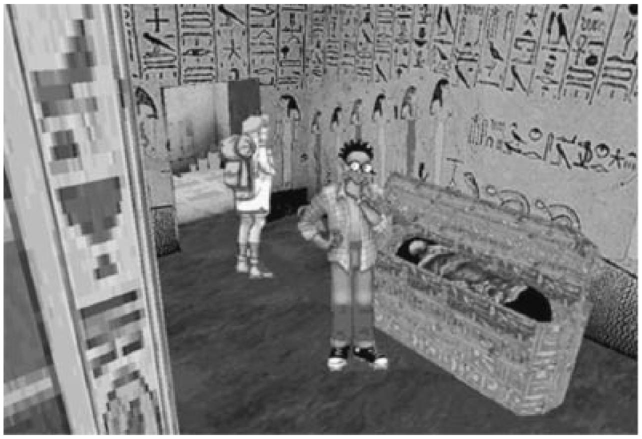

Figure 7. "Explorers of the Ancient World: Egypt" based on Virtual Worlds Platform (10).

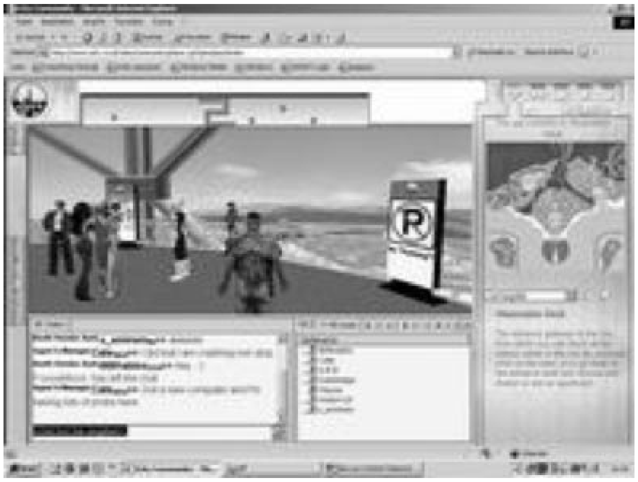

Figure 8. Blaxxun Shared Virtual Worlds (14).

Figure 9. MMORPG in Butterfly Grid (18).

There are also many other CVE-based social interaction applications, including Community Places (11) and Living Worlds (12) by Sony Research Laboratories, Diamond Park by Mitsubishi Electric Research Laboratories (13), Blaxxun Community Platform by Blaxxun Technologies (14), Virtual Playground by HITLab in Washington University (15), and VELVET in University of Ottawa (16). It provides facilities to allow users to create communities for various social interactions. For example, Blaxxun Community Platform allows users to set up homes, clubs, student dormitories, company offices, or other distinct locales on the Web, as shown in Fig. 8. These entities are divided into public and private spaces. For example, a community may have places like plazas, cafes, and offices where its members congregate. The community might also have neighborhoods devoted to members sharing special interests, like films, into which they can easily "homestead." Each member's home (complete with its own URL) can act as their personal communication center on the Web within which they can invite their friends, family, and other groups for scheduled or impromptu meetings and chats. Many present community members also attach this URL to their e-mail messages, which has the effect of promoting both the users' private home as well as the community URL. Homeowners receive all the tools required to maintain their places and can set up special access privileges to protect their privacy. The homes themselves can easily be built from one-click templates or designed more elaborately with objects like furniture, pets, and agent servants. Homes have all of the communication functionality delivered by the community manager.

MMORPG

Massively Multiplayer Online Role-Playing Games (MMORPGs) is another CVE application area. Recent developments on persistent MMORPGs, such as Everquest (2), allow game players to play in a persistent shared game world. It is a CVE type of game, which maintains a consistent game world for the game players so that they are given the feeling of playing in the same 3-D game scene while playing different game roles in a collaborative manner. In 2003, IBM and Butterfly launched a new network gaming environment for Sony Computer Entertainment, Inc.'s PlayStation2 that enables online video game providers to reliably deliver state-of-the-art games to millions of concurrent users (17). Traditionally, online video games have segmented players onto separate servers, limiting the number that could interact and creating reliability and support obstacles. In the first generation of online games, when one server is down, overloaded, or patches are being installed, game play comes to a halt. With Butterfly's grid technology, the server interaction is completely transparent and seamless to the user, delivering a resilient gaming infrastructure in which servers can be added or replaced without interrupting game play. In the Butterfly grid platform, game players can log on to the Grid through either a video game console, PC, set-top box, or mobile device running Butterfly Grid client software. During the course of a game, the Butterfly Grid divides the world into a series of mutually exclusive sectors known as "locales," each of which is assigned to a specific server. In the course of a game, a player may encounter areas of excessive activity within a locale—caused by factors internal to the game (such as a battle triggered by artificial intelligence systems) or simply large numbers of users—which increase the use of that locale's server. In such an instance, the Grid's "heartbeat monitoring" feature will flag the server as overutilized and move the high-activity locale to a less-utilized server on the Grid. Similarly, in the event a server goes down, game play is automatically and seamlessly routed to the nearest optimal server in the Grid using the same resource monitoring feature. Figure 9 shows a sample game screen from the Butterfly Grid platform.

COLLABORATIVE LEARNING AND TRAINING

Visualization has been used to enhance human understanding of conceptual work, from describing earth magnetic field (e.g., intensity and direction), to evaluating fighter jet design before prototyping, to aerodynamic study, to understanding of abstract fluid dynamic computation, to visualizing complex molecular structure. 3-D images bring better visualization of knowledge/information than any 2-D image does, whereas interactivity provided by a 3-D virtual environment makes the learning experience closer to real life than any animation technique offers. There is no dispute over the role of visualization in enhancing human understanding of abstract and complex concepts.

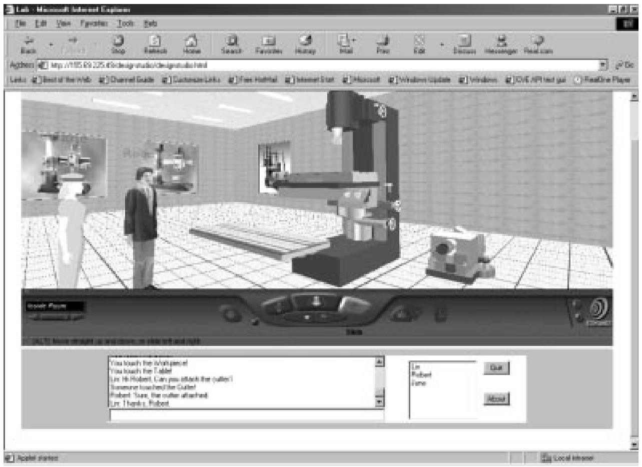
However, learning is contextualized in a social setting that may involve verbal interaction, collective decision making, conflict resolutions, peer teaching, and other group learning situations that are characteristic of a classroom setting (19). An engaging learning environment would stimulate learning interests and enhance students' knowledge acquiring performance. With CVE, the learning performance can be improved by providing intelligent and interactive learning contents in an engaging environment with multi-user participation and collaboration. A CVE-based learning system supports active exploratory and discovery learning (i.e., "learning by doing"), which is one of the most effective ways of learning. This method encourages the students' active thinking in every step of the learning process. One of the most important advantages is the computer supported collaborative learning that can model learning activities and interactions close to the traditional classroom, which is not possible in stand-alone visualization-based learning methods.

The NICE garden, as shown in Fig. 10, is one such CVE-based learning application. It was originally designed as an environment for young children to learn about the effects of sunlight and rainfall on plants, the growth of weeds, the ability to recycle dead vegetation, and similar simple biological concepts that are a part of the lifecycle of a garden. As these concepts can be experienced by most children in a real garden, the NICE garden provides its users with tools that allow its exploration from multiple different perspectives. In addition to planting, growing, and picking vegetables and flowers, the children have the ability to shrink down and walk beneath the surface of the soil to observe the roots of their plants or to meet other underground dwellers. They can also leap high up in the air, climb over objects, factor time, and experience first hand the effects of sunlight and rainfall by controlling the environmental variables that cause them. NICE supports real-time distributed collaboration. Multiple children can interact with the garden and each other from remote sites. Each remote user's presence in the virtual space is established using an avatar, a graphical representation of the person's body in the virtual world. The avatars have a separate head, body, and hand that correspond to the user's actual tracked head and hand motions, allowing the environment to record and transmit sufficiently detailed gestures between the participants, such as the nodding of their heads, the waving of their hand, and the exchange of objects. Additionally, voice communication is enabled by a real-time audio connection.

We have also developed a CVE-based learning system for collaborative learning. When the students work in multi-user collaborative mode, their interactions with 3-D objects are synchronized among all users in the same group. The student interface in multi-user mode also provides chat interface for students/lecturers in the group to communicate with each other in real-time. The students can learn/work collaboratively. For example, three students, Robert, Jane, and Lin, study collaboratively to learn assembling a milling machine in a shared 3-D virtual laboratory over the Internet, as shown in Fig. 11. The students can discuss and communicate with each other regarding the actions/tasks to be taken by each student to assemble the milling machine. Only after the students successfully assemble all components of the machine can its power be switched on. Then, its cutter can be tested, and so on. If it is needed, the course lecturer can also join the students in the virtual laboratory through the Internet and demonstrate to the students the correct procedures of assembling the milling machine before they practice themselves. This technology is an example we have created to illustrate the use of CVE in collaborative learning and training.

Our system experiment shows that the prototype learning system can successfully support multi-user collaborative learning in the CVE. It has the advantage of providing the students with active engagement in the learning

Figure 10. NICE project (19).



You touch the Workpiece!
You touch the Table!
Lin: Hi Robert, Can you attach the cutter?
Someone touched the Cutter!
Robert: Sure, the cutter attached.
Lin: Thanks, Robert

process. In particular, it promotes role-playing among students, which is important in creating a stimulating learning environment. It also allows students and lecturers to interact with each other in CVE where lecturers can demonstrate the learning contents to the students or the students can collaboratively study/work together to carry out one learning task, which would be particularly useful for those subjects that require multi-user collaboration.

Industrial Training

For similar motivation of using CVE in military training, industrial training looks to CVE as a cost-effective solution. Instead of working with physical equipment, they are modeled as virtual objects with relevant interactive behaviors in a virtual environment accessible to many users. The users, represented by avatars, can then manipulate and interact with the objects as in the real world, gaining valuable experience and training before using the real equipment, which is particularly useful for expensive and complex equipment. For example, Oliveira et al. (20) developed a multi-user teletraining application, which allows users, represented by avatars, to learn how to operate on a faulty asynchronous transfer mode (ATM) switch. The avatars repair the switch in steps that precisely reflect those necessary to perform the same actions in the real world. The prototype consists of two general modules: the user interface module and the network communication module. The user interface itself consists of a graphical interface (GUI), a 3-D interface (VR), and media interfaces (speech recognition, voice streaming, head tracking), as shown in Fig. 12. The upper-right area of the interface, which takes the largest part, is the *3-D environment*. On the left and below the 3-D environment are the *controls* used by the trainees to interact with objects and navigate in the environment. At the top left is the *head-tracking facility*. Below the head-tracking window is a *utility panel* that is used for different purposes as discussed later. There is also a *chat space* where users can exchange textual messages. To avoid navigation problems with inexperienced users, it is possible to view the world from a set of pre-defined camera views.

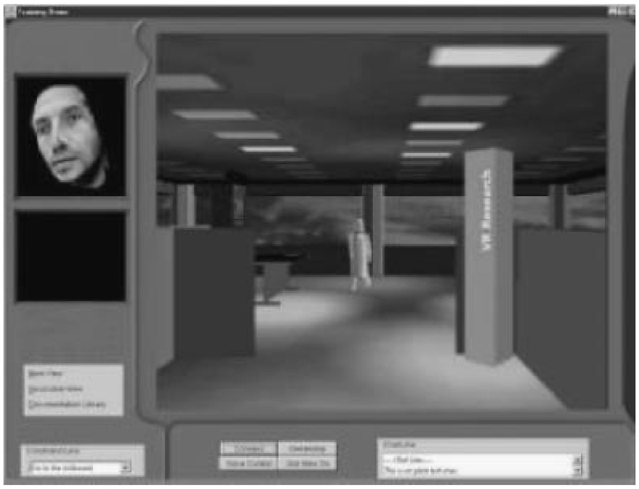

Figure 12. Training application's interface (19).

A user is able to approach and verify the operation of the switch and its cards, remove a faulty card and put it on the repair table, and replace it by installing a new card into the switch. Other parties will be able to watch that user's avatar taking such actions. All of the above actions can be performed by directly navigating in the scene and manipulating objects with the mouse or by selecting the action in a menu. A user can also view video segments showing the correct procedure for performing certain actions. The utility panel is used to display the video clips. If chosen by the trainer, the video will be displayed in every participant's screen. Another use for the utility panel is the *secondary view* feature, with which a user can simultaneously watch the current actions from an alternative point of view. In addition to the interfaces explained above, the prototype offers voice recognition technology whereby the user simply enters commands by talking into the computer's microphone. In this case, the user may simply speak pre-defined commands such as "Go to the table" for the avatar to perform, or may change views by saying "Table Top View," and so on, which enhances the effectiveness of collaborative training.

COLLABORATIVE DESIGN AND GROUP WORK

Randy Pausch at the University of Virginia suggested that the most promising use of CVE would be for applications in which people at different locations need to jointly discuss a 3-D object, such as radiologists using a VR representation of a CAT scan (21), the virtual medicine project developed by SRI International, a teleoperated laproscopic device uses force reflection to provide haptic feedback to a distant surgeon (22). And in the Microelectronics Center for North Carolina (MCNC), a virtual library, Cyberlib, is designed to allow patrons to venture into "the information space independently" or go to a "virtual reference desk" from anywhere across the United States via the Internet (23).

From a product design point of view, the traditional manner of collaboration is geographically limited. Colleagues are not easily able to collaborate and exchange their ideas if they are situated in different locations. Virtual collaboration is intended to solve this problem by incorporating CVE technology to facilitate the collaborative design for small-to medium-sized teams as demonstrated in VRCE (24). The collaborative design functions in VRCE multiview include collaborative design support, multiple opinions via collaborative, multilayer information exchange and experimenting with multiple designs. Daily et al. (25) also reported a system for Distributed Design Review In Virtual Environments (DDRIVE) by HRL Laboratories and General Motors Research & Development Center (GM R&D), as shown in Fig. 13. One important component of the DDRIVE system is the Human Integrating Virtual Environment (HIVE) collaboration infrastructure and toolset developed at HRL Laboratories to support research in multi-user, geographically distributed, 2-D and 3-D shared applications. The HIVE provides virtual meeting tools and high-fidelity multiway audio communication for heterogeneous interface environments. The HIVE is designed to work cooperatively with other applications to add collaboration

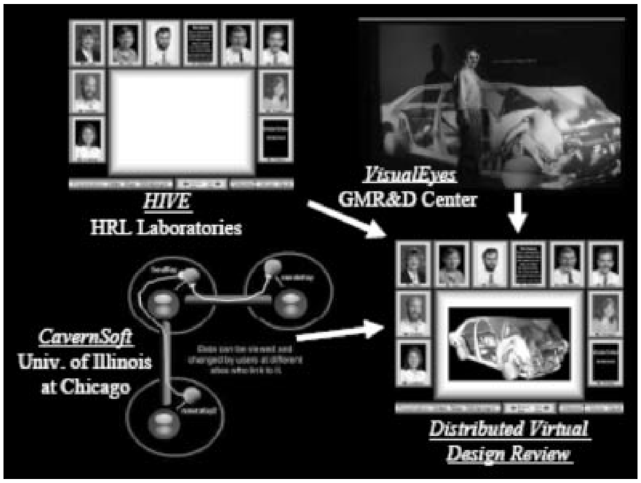

Figure 13. Components of the DDRIVE system (25).

capabilities. Another component is the VisualEyes, which provides a full-size immersive view of a shared model for high-quality visualization. VisualEyes is an interaction tool for visualizing data using mathematics and light. GM uses this tool for testing car designs and collaborating on projects in virtual environments. Imagine being able to sit in the driver's seat of a car before anything is built and change the placing of a dashboard control by a simple gesture because it is too difficult to reach. VisualEyes enables this kind of interactive design via an easy-to-use scripting language that allows control of the environment. Virtual environments can be built much more quickly than with other toolkits by merely bringing in models and applying simple rules.

Frederick et al. (26) also developed a collaborative virtual sculpting system to support a team of geographically separated designers/engineers connected by networks to participate in 3-D virtual engineering sculptures through a collaborative virtual sculpting framework, called VSculpt, as shown in Fig. 14. It provides a real-time intuitive environment for collaborative design. In particular, it addresses issues on efficient rendering and transmission of deformable objects, intuitive object deformation using the *CyberGlove*, and concurrent object deformation by multiple clients.

SUMMARY

In summary, CVE has vast potential for a wide spectrum of applications. It not only provides an engaging environment for social interaction and entertainment, but also offers cost-effective solutions for military/industrial training and collaborative group work in education, science, and engineering. The performance of CVE applications relies on the natural way of communication and interaction provided by a CVE system. As CVE applications may run in different devices such as desktop PCs, mobile devices like PDAs and wearable computers, and large display systems like CAVEs or HMDs, the advancement in computer processing power, network bandwidth, input devices, tracking and output of text, live voice/video, and so on will play important role in determining the performance of a CVE. The popularity of CVE applications will not only depend on the ease of use of such applications but also will depend on the cost of using them. As computer processors get faster, graphics techniques get more advanced, and the network connection gets faster and cheaper, we believe that CVE applications will be used by ordinary users in everyday life. For ordinary users, CVE applications will become a tool mostly for social interaction/communication, entertainment, distance learning, and working from home. At the same time, military and industrial CVE applications will focus more on visualization large-scale and complex data, decision-making training, task solving, and manipulating objects for training and collaborative work purposes.

In the future, the richness of CVE will be enhanced by new technologies under development. For example, intelligent recognition of faces, expressions, gestures, and speech and automatic detecting, accurate tracking, and localizing of human participants will allow CVE to be intelligent and responsive in nature. Responsive interfaces allow human actions and reactions to be sensed and interpreted by sensors embedded in an environment whereas a collaborative environment allows users to interact with each other through a network connection in a shared 3-D virtual space. Thus, a collaborative and responsive environment will be able to respond to the actions by mixing responses and interaction from other actors in a shared environment. The human participants can manipulate and interact with the environment for control and command as well as be presented with auditory and visual responses and displays in a mixed-reality environment with digital citizens, virtual entertainment, and so on, which will make the communication in CVE more intuitive and natural, thus improving its performance.

To make responsive interface possible, we need the technologies for sensing and interpreting human behavior and natural interaction through gesture, body language, and voice communication. To make collaborative environments with live auditory and visual representation of human participants possible, we need technologies for large-scale collaborative mixed reality, which allows a large number of users to interact with each naturally through the responsive sensing interface. There is no HMD, no body suit, not data glove, but pure human-to-machine and human-to-human interaction naturally in a comfortable and intelligent responsive room where users not only can have fun, like playing multi-user games, visiting places of interest, and meeting friends without any traveling, but also can conduct serious collaborative work like military warfare training, collaborative design and learning, and so on. Although such intuitive and intelligent interfaces will probably not be available and affordable in the near future, they will be necessary to take full advantage of the potential of CVEs.

COLLABORATIVE VIRTUAL ENVIRONMENT: SYSTEM ARCHITECTURES

INTRODUCTION

A collaborative virtual environment (CVE) is a shared synthetic space that provides users a shared sense of presence (or the feeling of "being there without physically going there") in a common context with natural interaction and communication. A CVE allows geographically dispersed users to interact with each other and virtual entities in a common synthetic environment via network connections. CVEs are normally associated with three-dimensional (3-D) graphical environments although it may be in the form of two-dimensional (2-D) graphics or may even be text-based. In a CVE, users, which are represented in the form of graphical embodiments called avatars, can navigate through the virtual space, meeting each other, interacting with virtual entities, and communicating with each other using audio, video, text, gesture, and graphics. For example, in a collaborative 3-D digital living community, every digital citizen with a unique digital identification number can create his/her own virtual house. People residing in the digital city can interact and communicate with each other naturally. Furthermore, each digital citizen may create and maintain communities such as a pet community for pet owners, a sports community for sports fans, an online gaming community, a music community, and so on. All real-life activities or pure imaginary activities like space travel or fiction games may be constructed in a collaborative digital living space where users can meet their friends and fans through a network connection from the comfort of their homes/offices. The human participants in a CVE can manipulate and interact with the environment for control and command as well as be presented with auditory and visual responses. Imagine you are flying in space with all the galaxies and clouds as you descend nearer over virtual London. You utter, "I like to see London," and there you are on the busy streets of London. You stroll along the streets and roam about the places with all the familiar sight and sound of London. You make a turn round a corner of a street, and there you are walking along Oxford Street with seas of virtual shoppers (or avatars representing the activities of other users in the collaborative virtual community) dashing around you. Or you can join your friends for a soccer game in the virtual sport community without traveling and physically meeting them. Yes, you can experience all these while you are immersed in your room at home with a network connection to the collaborative virtual community.

In a CVE, the behavior of an avatar acts as a visual description of a human player's movement or action or response to an event in the virtual world. The term "virtual entity" is used in CVE to describe any static or interactive virtual object in the form of text, 2-D/3-D graphics, audio/video streams, an agent, computer-controlled avatar, and those objects that may be invisible (graphically transparent) but will affect user interactions in CVE, for example, wind or transparent barriers. Static objects refer to those virtual entities whose states will not change as the CVE contents evolve. Background objects are often static. Whereas interactive objects refer to the virtual entities whose states will change based on a user's interaction with them; for instance, virtual doors are interactive objects as they can be opened or closed by users. Each interactive object may have several behaviors or animations associated with it. The behaviors may be triggered by the users when they interact with the object. Any changes to the states/behaviors of an interactive object triggered by one user are propagated via network connection to all other users in the same CVE to achieve the sense of sharing the same virtual environment by all users. The virtual entities, description files, sound files, texture images files, user state/interaction information data, and so on are usually stored in a database. The 3-D virtual entities may be stored in different formats, for example wrl, 3ds, obj, and nff. Users may interact with a CVE application through a user interface that could be in various forms ranging from a desktop with keyboard and mouse, to a game console with joystick or other game-playing devices, to mobile and wearable devices, to an immersive virtual reality head-mounted display with data glove and body suite depending on CVE application areas and their requirements.

SYSTEM ARCHITECTURES

One of the challenging tasks for the CVE creator is to determine where the data of the virtual world should be stored and how the data changes (e.g., interaction with an object by a user) should be propagated to all the users who share the same virtual world. When a user navigates in a virtual world, the movement of the avatar representing the user as well as his/her interaction with virtual entities should be perceived by other users in the same CVE. These require data communication among CVE users over the network. The design of system architecture centers around the choice of data communication models, database distribution models, and world consistency maintenance methods, which will have a direct impact on the CVE system performance. It is the core of a CVE design.

Client-Server System Architecture

The client-server architecture (also known as the centralized architecture), as illustrated in Fig. 1, has a server at the center of all communications. In this architecture, the server keeps a persistent copy of the virtual world database. To allow a user to interact with a CVE remotely through network connection, the user's computer ("Client") normally runs a client application program that can communicate with the CVE host computer ("Server") that runs a

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

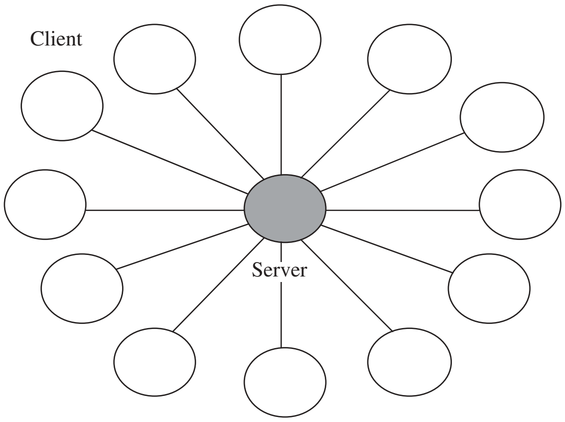

Figure 1. Client–server system architecture.

server program. The initial virtual environment data are first transmitted to the client computer and rendered into 3-D graphics using a client program. The user can then interact with the virtual environment through an input device, e.g., keyboard, joystick, 3-D space ball, or data glove. The user's interaction/navigation commands are captured by the client program. The user's commands may be processed locally by the client software or sent to the server program over the network depending on the computing power requirement. The virtual environment will then change according to the user's commands. The client program will also be responsible for updating CVE states changed by other users sharing the same virtual world. All clients pass their update messages to the server, which in turn distributes these messages to every other client. A database storing the current states of the VE is also kept in the server. When a new client joins a CVE, the server sends its world data to the new client program, which will update all virtual entities to their latest states. For example, RING (1) and Community Place (2) are typical client-server-based CVE systems.

Most small-scale CVEs are realized as client-server architectures because this is a conceptually and practically simple approach and are provided possibilities for accounting and security management. The scene database is centralized in one location: the server. Clients request CVE scene data from the server and update any relevant changes originated from each client end to the server. Because there is only one copy of the CVE scene data held at the server, then the issue of updating the data in a consistent manner is simple. Inconsistencies in the virtual world description can occur if the clients hold local caches of the world. If any changes to the cache should be necessary, the server has to invalidate the cached data and replace it by an up-to-date master copy.

The client–server architecture has the advantage of easy consistency control among all clients in the CVE. In addition, the server can tailor its communication to match the network and machine capabilities of each client. Empirical evidence suggests the scalability of sophisticated client/server systems to several hundred users. Many commercial CVEs use the client–server model, not only for technical but also for administrative and financial reasons: Clients are free, whereas servers and services are sold (4).

However, the problem with this model is the server will soon become the bottleneck when the number of user connections increases. The latency of the system also prolongs because the server basically does data storing and forwarding tasks. The two tasks will make the delay at least twice the time of sending data directly peer to peer.

Peer-to-Peer System Architecture

Peer-to-peer system architecture, as illustrated in Fig. 2, is a common CVE system architecture No server exists in peer-to-peer architecture. Thus, it requires the initialization of every peer host computer (also called the peer node) participating in the CVE with a homogeneous virtual world database containing information about the terrain, model geometry, textures, and behavior of all objects in the virtual environment. Since this architecture requires each peer node to establish a link to every other node in the system, there will be $n(\ n\ -\ 1)/2$ full duplex connections in the system for n participants. For each update, each node would have to send one packet for $n-1$ times, while receiving and processing another $n-1$ packets. This may be alleviated by the use of multicast. However, it is difficult to maintain the consistency of the data and conflicts between user interactions. Each peer host has to take part in this activity. Processes must run on each peer side to communicate with other peer processes and frequently exchange their latest updates to the VE database. Thus, a lot of computation has to be performed on the peer host computer. Furthermore, some peer hosts have to play the referee role to resolve the conflicts and inconsistency of the data replicated among all the participants. The peer nodes, however, may not be powerful enough to cope with the heavy traffic and computation load. This is especially true for Internet-based CVE. The slower peer nodes may soon become bottlenecks because the other peers have to reduce

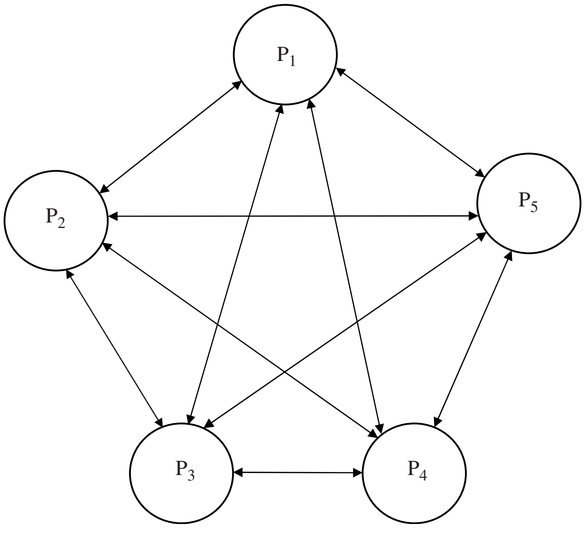

Figure 2. Peer-to-peer unicast architecture (P1 to P5 are indicative peers).

their speed to accommodate their slow peers. If any of the referee peer hosts crashes, it takes a long period before the CVE world state consistency is fully synchronized. Several existing CVE systems use peer-to-peer system architecture, e.g., NPSNET (5), MASSIVE (6), and DIVE (7). The peer-to-peer system architecture can be further classified into peer-to-peer unicast, peer-to-peer multicast, and distributed database with peer-to-peer communication based on data communication and database distribution models.

Peer-to-Peer Unicast. In peer-to-peer unicast architecture, each peer program sends information directly to other peer programs. Every peer has to establish a point-to-point connection of all other peers in a CVE This leads to the burst of the network traffic and to the burden on a single peer's processor (8). Typically, this is the most bandwidth-intensive of the three peer-to-peer approaches, but it avoids placing additional load on particular server computers and introduces lower network delays. This was used for communication in MASSIVE-1 (6). It is also commonly used to provide initial world state information to new participants.

Peer-to-Peer Multicast. Peer-to-peer multicast architecture, as illustrated in Fig. 3, is similar to peer-to-peer unicast except that the same information is not sent simultaneously and directly to many other peer hosts. It normally uses a bandwidth-efficient IP multicast network mechanism. This approach is used exclusively in NPSNET, and it is used for all updates in DIVE and MASSIVE-2. When an application subscribes to a multicast group, it can exchange messages with all applications subscribing to the same multicast group. It is also used for audio in many systems, e.g., SPLINE (9), even when a client/server approach is used for graphical data. However, multicast is not currently available on all networks, and wide-area availability is particularly limited. Consequently, some systems now include application-specific multicast bridging and proxy servers, which simplify use over wide-area and non-multicast networks.

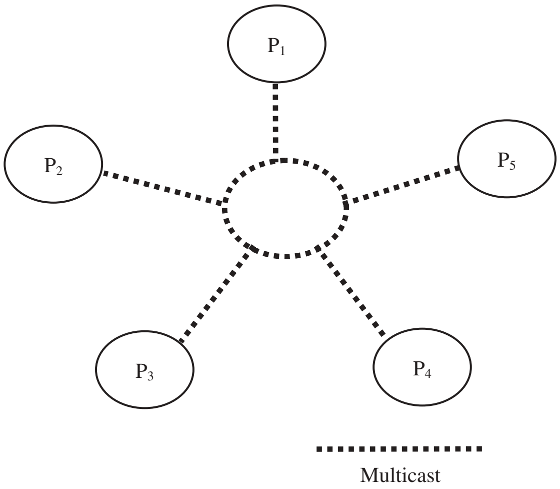

Figure 3. Peer-to-peer multicast architecture (P1 to P5 are indicative peers).

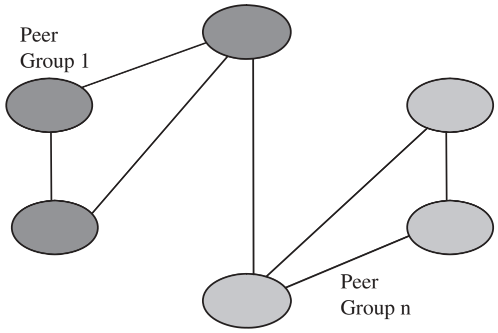

Figure 4. Distributed peer-to-peer architecture.

Distributed Database with Peer-to-Peer Communication. Distributed database with peer-to-peer communication architecture, as illustrated in Fig. 4. It is similar to peer-to-peer unicast/multicast architecture except that not all data of a virtual world are replicated on every CVE participating node. It attempts to segregate a large virtual world into smaller connected scenes so that a group of peer hosts who are close to each other will only update a database that is related to their area of interest. That database is replicated among this group of users.

The disadvantage with this approach is its high communication costs associated with maintaining reliability and consistent data across wide area networks. For example, if a client happens to belong to more than one interest group, it has to maintain multiple databases. Or if he goes across a boundary of groups, the computations and communications involved in reconstructing two areas will impose a significant burden on other peers and the network.

Hybrid Architecture

Hybrid system architecture, as illustrated in Fig. 5, attempts to take advantage of both client–server and peer-to-peer architectures. It merges client–server and peer-to-peer architectures. One approach is to replicate and update the world database on several servers while providing client–server service. The server is replicated or distributed. And server-to-server adopts the peer-to-peer communication model. By replicating the servers, this system can avoid the critical drawback of the client–server model in performance bottleneck and single point of failure due to the single server through which all communication goes. Many CVE systems adopt the hybrid architecture, such as BrickNet (10), RING (1), NetEffect (11), SpaceFusion (12), and CyberWalk (13). However, since every message still has to pass through the servers, certain servers are still possible to become a bottleneck and the breakdown of any server will cause services to the related clients to be shut down. In addition, since the packet pass through the servers, it will cause more delays for the packet.

Another approach is to use a variant form of the client–server model in which the database is partitioned among clients and communication is mediated by a central server.

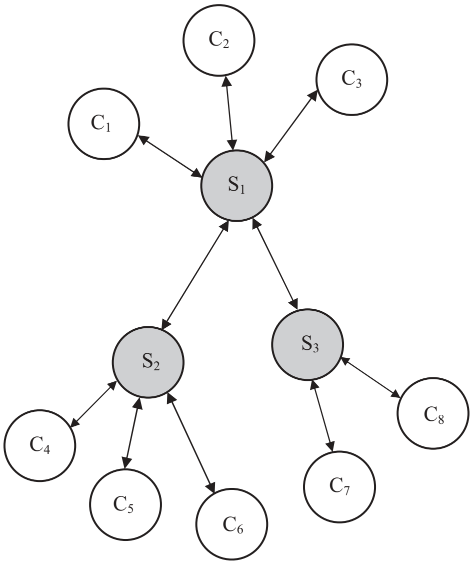

Figure 5. Hybrid system architecture (C1 to C8 are clients and S1 to S3 are servers, the number of clients and servers only serve an indicative purpose).

As an entity moves through the virtual environment, its database is updated by one of the servers, which maintain that part of the virtual world.

In hybrid architecture, the CVE system generally maintains client–server connections to provide the clients with a database of the initial virtual world. The clients will directly communicate with its peers when point-to-point communication appears to be more efficient. The advantage of this model is that it reduces the workload of a server computer. However, the effectiveness of this approach depends on a detailed design of the inter-server and client–server communication model, e.g., the role of servers, the types of data transmitted between client and server, and world consistency maintenance methods.

Mobile Agent-Based System Architecture

The mobile agent-based system architecture (14) models a CVE as a group of collaborative agents. Each agent is a software component to assume an independent task to provide a certain service for the system. Agents collaborate with each other to maintain the entire CVE system. To improve the system scalability, it allows all agents to be mobile without bonding with any fixed host. As the system scales up, agents will be able to clone or migrate to any suitable participating host (including trusted user nodes) to provide more CVE services, e.g., consistency maintenance, persistency maintenance, or scene data delivery. The mutual independence of services and hosts provides large flexibility to utilize the computing and network resources of the system efficiently.

The system architecture is divided into three layers: the resource layer for system resource management, content layer for VE content management, and gateway layer for VE directory management as illustrated in Figure 6. Each layer is composed of multiple collaborative mobile agents to achieve the management tasks.

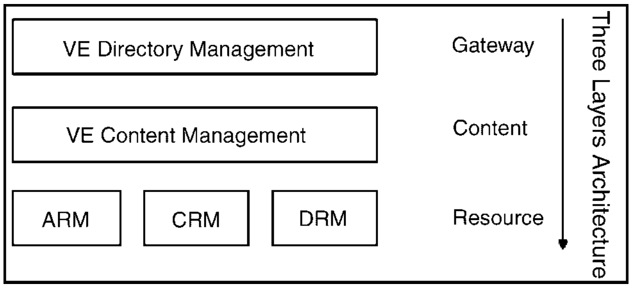

Figure 6. Mobile agent-based CVE architecture.

The resource layer manages the distribution of system resources. In this architecture, mobile agents, system computing nodes, and the data storage space are defined as system agent resource, system computing resource, and system database resource, respectively. Accordingly, the resource layer is further subdivided into three parts: agent resource management (ARM), computing resource management (CRM), and database resource management (DRM). This layer is independent with a different CVE application and scenario. It provides resource management services for the high layers and hides the complexity of the resource distribution. System scalability is further improved by adaptive data communication. The data communication in different parts of a CVE (e.g., region or cell) may adopt client–server, distributed multicast, peer-to-peer, or hybrid architecture depending on run-time activities and consistency requirements in each part of a CVE; for example, when a strict consistency is required for one activity (e.g., group work), then the cell consistent agent will enforce consistent data communication for the activity using client–server architecture (in which the cell consistent agent will act as the server); whereas in another activity that has less consistency requirements (e.g., individual animal hunting power gathering in a game), the cell consistent agent will activate multicast for such activity; or the system may adopt hybrid architecture for different data streams in one activity (e.g., peer-to-peer for audio/video data stream while using client–server for 3-D object interaction).

STANDARDS

Networked/distributed simulations are the ancestors of networked virtual reality/CVE. Thus the standards for networked/distributed simulations can be used as basic architecture for CVE. These standards include distributed interactive simulation and high-level architecture.

Distributed Interactive Simulation

Distributed interactive simulation (DIS) is an IEEE standard protocol for interoperability of distributed simulation. The heart of the DIS paradigm lies in establishing connectivity between independent computational nodes to create a consistent, time and space-coherent synthetic world environment with respect to human perception and behavior (15). This connectivity is achieved through a combination of network communication services, data exchange protocols, and algorithms and databases common to each. Local dead-reckoning is used to improve the DIS function as a standard to extend the SIMNET (16) underlying principle to heterogeneous simulation across local and wide area networks.

An advantage of the DIS-standard is that all DIS-compliant simulations, including CVE, can operate within one virtual environment. However, DIS's underlying data transport mechanism causes problems (17). First, messages may get lost or arrive in the wrong order due to the use of the UDP/IP protocol. Second, the messages sent are part of standardized, fixed-sized protocol data units (PDUs), although generic PDUs exist to communicate any type of data. Finally, because of the broadcast mechanism, the scalability is limited. In the case of CVE, reliable data transfer is crucial. Thus DIS using the UDP/IP protocol is suitable for CVE in a reliable and stable network environment like the local area network (LAN), but it may not be suitable for CVE in heterogeneous network like WANs and Internet.

High-Level Architecture

High-level architecture (HLA) (18) is a general architecture for simulation reuse and interoperability developed by the U.S. Department of Defense. The HLA architecture is an IEEE standard for distributed simulations. It provides a common architecture for reducing the cost and time required to create a synthetic environment for a new purpose. Two basic concepts have been proposed in the HLA: federate and federation. Federate is a software application participating in a federation, which may be a simulation model, data collector, simulator, autonomous agents, or passive viewer. Federation is a named set of federate applications that are used as a whole to achieve some specific objective. All federates incorporate specified capabilities to communicate through the runtime infrastructure (RTI), which is an implementation of a distributed operating system for the federation. The HLA runtime interface specification provides a standard way for federates to communicate with each other by interacting with the RTI. Routing spaces, which are a formal definition of a multidimensional coordinate space, is another important concept offered by HLA to standardize multicast schemes through the RTI. It uses federates' expressions of interest to establish the network connectivity needed to distribute all relevant data and minimal irrelevant data from producers to consumers. The HLA has the desirable features suitable for a basic CVE architecture (17).

CONSISTENCY MAINTENANCE IN CVE WORLD

To support massive interactions among the virtual entities in a CVE and maintain the consistent status of the interactions among the users, appropriate event detection and propagation mechanisms have to be provided to a CVE system. The task of detecting and propagating interactions is of order n-squared, where n is the number of entities in the VE. When the system is scaled up, this task may become too heavy to be handled. To improve the efficiency of world state consistency maintenance in CVE, various approaches have been developed by researchers in the field, including the broadcast method, distance-based method, acuity-based method, region/cell-based method, receiver interest method, peer/group-based method, sight view and spatial aura method, as well as behavior-based method.

Broadcast Method

The conventional approach maintaining the status consistency of a shared virtual world for distributed users is to update the status changes through central server broadcast, e.g., earlier version of aggregate level simulation protocol (ALSP)-based systems (19). In a client/server-based CVE system, when a user joins a virtual world maintained by a group of servers, the user's interaction with the virtual world will be captured and sent to the central servers. The servers then broadcast the interaction messages to all other users who share the same virtual world. The advantage of the broadcast method is that it has no computational cost for resolving the destinations for propagating the interaction messages. However, as the concurrent user number and VE size grows, the servers soon become a bottleneck. At the same time, the users are overwhelmed with the interaction messages that are not of interest, or even not relevant, to them. It results in unnecessary consumption of system network resource and processing power, and thus poor system scalability and performance.

Distance-Based Method

With the distance-based method, the distance between a user and the entities around him is used to decide the user's ability to know (see, hear, etc.) the entities. Only the states from the entities that are close enough to the user are actually sent to the particular user's host.

There are two ways of applying this method. The first one uses spatial distance to enable the interaction. Different mediums can have their corresponding spatial distance. For example, someone's voice could be heard before he is observed by others. Another form of the distance-based method is to enable interaction through the *horizon count* method. The horizon count indicates the maximum number of entities from which the user is prepared to receive updates. The system typically sorts the entities by distance from the virtual embodiment—the avatar—of the user, and only the closest ones can send their updates to the user. This is the approach of the interaction management used in Blaxxun's CyberHub (21). The distance-based method also uses spatial distance to calculate the level of detail (LOD) of the interaction information (22, 23). When the interaction is enabled, the distance between the two interaction entities will be used as the parameter to calculate the LOD of the interaction information sent between them.

The advantage of the distance-based method is that it considers the spatial distance as the dependent condition for enabling the interaction. That is very natural for some interactions occurring in a CVE. Another strength of this method is its simple logic for implementation. But it ignores the dependent conditions of the interaction entities to attract others' attentions other than the spatial distance. And it also has a high CPU requirement for the calculation of the distance among the interactive entities.

Acuity-Based Method

The distance-based approach works, but it can fail in some cases. A large object that is far away may be more relevant than a small object nearby. For example, a user in the VE may be able to see a tall building far away but not an insect nearby even though the insect is closer. To better reflect this scenario, the acuity-based method (24) is introduced. Acuity is a measure of the ratio between size and distance. In this model, every user has an acuity setting, which indicates the minimum size-over-distance ratio required in order for an entity to be known (seen, heard, etc.) to him. If the entity's acuity value is less than the acuity setting for the user, then the entity is too small or too far away for the user to see. In such a case, no updates from the entity are sent to the user. The acuity setting of the user is different for each type of medium. In this method, the ability of the entity to attract others is also considered.

The acuity-based method considers the size and the spatial distance of the interaction entities as the dependent condition to attract others' attentions. It also has a simple logic to implement. But it requires high CPU time for the calculation of the acuity among the interactive entities. The user's interest/intention is not taken into consideration, either.

Region/Cell-Based Method

In the region/cell-based method, the virtual world is partitioned into smaller pieces known as "regions" or "cells." The partition may be static (1) or adaptive (25). The system will decide which pieces are applicable to each particular user. Only the updating information from these pieces is transmitted to the corresponding user. The partition of the regions/cells is transparent to the users. Users can move among the regions/cells. When this kind of migration occurs, the LOD of the information between the user and other entities is dynamically changed accordingly. Bounding boxes and binary space partitioning (BSP) trees are used to define the region/cell partition in the VE.

The region/cell partition is widely used in CVE systems, such as the *locale* in Spline (3), and the *hexagonal cell* in NPSNET (5). It also appears as a third-party object in MASSIVE II (26). The advantage of this method is that it has a light computational load on CPU as multicast groups can be organized according to region or cell. It also reduces the interaction message propagation scope to a particular region or cell. However, this approach only provides a rough interaction message filtering for consistency maintenance of a CVE; more information may be received and processed than is needed. Another difficulty is that a VE can suffer from what is known as crowding or clumping. If many entities crowd, or clump, into one region, some entities that subscribe to the region may be overwhelmed by other entities not of interest to them.

Receiver Interest-Based Method

In the receiver interest-based method, the interaction messages are propagated to the interested users only. The interest management is accomplished by expressing the user's interest in a particular object to a server. The server in turn sends the updated state information of the objects whenever it is needed. Or the client application is required to subscribe to certain interest groups, i.e., to express the user's interests, before it can receive the status changes among the entities in those groups. Systems based on such a type of consistency maintenance method include the Minimal Reality (MR) Toolkit (27), Joint Precision Strike Demonstration (JPSD) (28), BrickNet (10), Close Combat Tactical Trainer (CCTT) (29), and Proximity Detection (30).

The advantage of the receiver interest-based method is that remote clients receive only messages of interest, and they never need to throw away information. But the sending entity, or the Interest Manager, needs to have knowledge of, as well as evaluate, the interests of all other entities in the virtual world. Thus, it has high CPU computation cost and increased latency and bandwidth requirement for a CVE system that supports a large number of concurrent users.

Peer/Group-Based Method

If a user does not wish to receive information from some entities, he could choose to "ignore" those entities. A variant on this "ignore" selection is the use of peers. By designating an entity as a peer, certain data streams are sent only to that peer. This provides a form of private communication, like whispering.

Grouping is another variation of this idea. By designating certain entities as part of a group, private conversation could be set up among the group members. The users out of the group will not receive the updating information of the entities in the group. Different from the region partition model, which divides the VE spatially, this approach partitions entities that could be involved in the interactions. The CyberSockets used in CyberHub (21), for example, supports the concepts of peers and groups.

Another example that uses the group-based method is the NPSNET (31). It partitions VE into associating spatial (hexagonal cell region division), temporal, and functionally related entity class to form network multicast groups. The Area of Interest Manager (AOIM) is used to identify the multicast groups that are potentially of interest to the users, and to restrict network traffic to these groups.

The main advantage of the peer/group-based consistency maintenance method is that it can reduce the network bandwidth consumption through the use of grouping methods. But virtual entity grouping computation in a large CVE requires high CPU processing power.

Spatial Aura Method

The distance-based method and the region-based method only propagate interaction information among the interaction entities according to the spatial distance among the entities, or the spatial position of the entities. However, more precise information filtering is needed when the system requires a more realistic spatial-based effect on the

Figure 7. Message routing in behavior based method for CVE consistency maintenance.

consistency maintenance. The spatial aura method is developed for this purpose in MASSIVE (6). The spatial interaction model is used to maintain users' awareness in the VE. Other systems, including DIVE (7) and the Community Place (2), also use the spatial aura interaction model.

The key concepts of the spatial model used in MASSIVE include *medium, aura, awareness, focus, nimbus*, and *adapters*. When a user's aura overlaps a virtual entity's aura, then interaction becomes possible. After the interaction is enabled by the aura collision, awareness is negotiated through combining the observer's focus and the observed entity's nimbus. A third-party object (26) is extended into the spatial model to allow for richer context-sensitive patterns of interaction.

The advantage of the spatial aura method is that it has a natural awareness model. It can support peripheral awareness. But it uses a passive view to the interaction. The intentions of the users are ignored. It has a high CPU requirement for the calculation of the Aura collision. To implement it, a server must perform an $O(N^2)$ collision detection between each entity within the virtual world.

Behavior-Based Method

The behavior-based method (32) incorporates a two-tiered architecture, which includes the high-level role of behavior-based interaction management and low-level message routing. In the high level, the interaction management is achieved by enabling the natural interactions based on the collaborative behavior definitions provided by CVE application developers. Thus, it extends the developer's management ability of the collaborations in the CVE application. In the low level, the message routing controls the propagation scope of the interaction messages according to the runtime status of the interactive entities, and hence reduces the network bandwidth consumption. The behavior-based interaction management supports routing of the interaction message via controlling the destination of the message and the LOD of the message. As illustrated in Fig. 7, the high-level interaction management serves as the first layer of interaction message filtering through identifying the virtual entities (human users, robot type intelligent agents, interactive objects, etc) involved in an interaction event, which is represented by a message received by the message router, based on role behavior definitions. The low-level message routing serves as the second layer of interaction message filtering based on the output from the first layer. This significantly reduces the number of virtual entities need to be evaluated for computing the low-level message routing. Accordingly, it greatly reduces the server computation time required to resolve the message routing destinations and LOD in the low-level message routing models, which are commonly used by existing interaction management approaches.

DESIGN ISSUES IN LARGE-SCALE CVE

CVE has drawn significant research interests in recent years. As CVE scales up in terms of the number of concurrent users and the complexity of a CVE virtual world, the greatest challenge for a large-scale CVE (LCVE) system design is not how to simulate the objects on individual client machine, but how to transfer the state changes of virtual entities (e.g., users or virtual objects) over the heterogeneous network like the Internet effectively, despite potentially vast variation in client machine computing powers. In constructing an LCVE, many issues need to be considered such as extensibility, scalability, consistency, and persistency issues. Extensibility refers to the ability to extend and evolve, in the sense that it can accommodate a dynamic number of users, dynamic number of 3-D virtual entities, as well as dynamic scope of the virtual world itself. Scalability is the capability to maintain the LCVE performance in the extended environment with a large number of virtual entities and concurrent users. To achieve scalability, the system has to make sure that the resources are not limited to certain scope and that the states of the virtual world are maintained persistent at all times. All LCVE participants also need to perceive the same state of virtual world at any point of time. In addition, fault tolerance, easy deployment, and configuration are also necessary.

Each of the issues mentioned above has its own challenge. The scalability of a system is limited by the available network bandwidth and processing power of participating computer hosts. To achieve scalability and maintain performance quality, the network load has to be divided carefully between machines. However, this will cause a challenge to the consistency and persistency issue because the need to synchronize every activity by the machines becomes higher.

Two general models are based on which LCVE can be built, a centralized system and distributed system. To build a scalable and extensible LCVE while maintaining the performance quality, a centralized system should not be used. A centralized system has a single controller that controls every data transmission and maintains the system database. Although this system will allow simple world consistency maintenance because of the single database that is only accessible by the central controller, the controller itself will become a bottleneck to the system. Thus, another option is the distributed or hybrid system. A distributed system does not have a central controller, and the network entities synchronize themselves by communicating with each other. Although good world consistency maintenance is crucial to a distributed system, this will provide a better load balancing to the system compared with the centralized system. However, because of the limitations of the distributed or hybrid approach discussed in previous section, to further enable the construction of a scalable and extensible LCVE, a mobile agents-based approach may be a good alternative.

A mobile agent is an autonomous network entity that can migrate between heterogeneous machines. Mobile agents can work independently to perform some tasks assigned to them. They can also work together with another entity, which requires them to have the capability to communicate using a definite communication protocol. Mobile agents can make runtime intelligent decision such that when overloaded, they can clone new agents to share their workload. They can also migrate to other machines or to terminate autonomously when their services are not needed. In short, mobile agent can have dynamic existence and provide a good load balancing, fault tolerance, and service deployment. Therefore, it can be observed how mobile agent mechanism can further contribute to the scalability and extensibility of LCVE.

COLLABORATIVE VIRTUAL ENVIRONMENT: WEB-BASED ISSUES

INTRODUCTION

With the Internet's exponential growth in the past decade, it has evolved from a repository of information to an interactive digital social world. Interactive multimedia contents can be embedded into Web pages to enrich the information presented in the cyberspace for enhanced social and business applications. Collaborative virtual environments (CVEs) function as a new type of interface that attempts to model the Internet into a real social world using the power of Internet communication and virtual reality. VRML/X3D has been developed as an International Standard Organization (ISO) standard to deliver three-dimensional (3D) interactive multimedia contents over the Internet as a 3-D extension to the World Wide Web (WWW). Java3D has also been developed to construct 3-D graphical applications for visualization and interaction over the Web. With VRML/X3D/Java3D, a Web-based CVE can be created using standard http protocol. However, due to heterogeneous nature of the Internet, special cares must be taken to address the Internet-related issues for CVE. In this article, we discuss the existing standards, methods for constructing Web-based CVE, and popular solutions to the Web-based CVE issues.

STANDARDS

Traditional CVEs are often application-based; i.e., the client or peer program communicates with each other or with the server directly for content delivery and virtual world states maintenance. Whereas a Web-based CVE requires the 3-D virtual world contents to be rendered and embedded in a Web page using a Web browser. The existing standards that can be used for such purposes include VRML, X3D, and Java3D.

VRML

Virtual Reality Modeling Language (VRML) (1) is an industrial standard file format for representing 3-D interactive vector graphics. The 3-D scene described by a VRML file is known as virtual world and can be distributed over the WWW and presented in special VRML browsers, most of which are plug-ins for the Web browsers. A reference to a VRML file can be embedded in a Hyper Text Markup Language (HTML) page, and hyperlinks to other media such as text, sounds, movies, and images can also embedded in VRML files. Thus, VRML can be seen as a 3-D visual extension of the WWW (2).

VRML originated in 1994 and the first official VRML 1.0 specification was released in 1995. The VRML 1.0 was a good start as an Internet-based 3-D graphics format, but it was a static scene description language, which cannot support user interactions. In 1996, VRML 2.0 was released that supports dynamic, interactive 3-D scenes. In 1997, VRML 2.0 was accepted by the ISO as ISO/IEC 14772 standard, also known as VRML97. It has the following main features.

Hierarchical Scene Graph. In VRML97, the basic element is the node that describes 3-D shape and geometry, appearance properties to be applied to the shape's geometry, light sources, viewpoint, and so on. Each node is typed and has a set of fields that parameterize the node. The 3-D scene consists of a set of nodes arranged in a hierarchical fashion. The hierarchy is built up by using a parent–child relationship in which a parent may have any number of children, some of whom may, in turn, be parents themselves. Scene graph refers to the entire ordered collection of these scene hierarchy.

Event Routing Mechanism. VRML97 provide an event routing mechanism to support a dynamic and interactive 3-D scene. Some nodes can generate events in response to environmental changes or user interaction, and other nodes can receive events to change the state of the node, generate additional events, or change the structure of the scene graph. These nodes may be connected together by ROUTE to achieve real-time animations, including entity behaviors, user–entity interaction, and inter-entity coordination.

Prototyping Mechanism. Prototyping provides a way to extend the build-in node types. It defined a new type of nodes, known as a prototype node, to parameterize the scene graph. Once defined, prototyped node types may be instantiated in the scene graph exactly like the built-in node types.

External Authoring Interface. External Authoring Interface (EAI) is an interface specification that allows an external program to manipulate the VRML scene graph while not directly being part of the scene graph. The implementation of EAI in Java is a set of classes with methods that can be called to control the VRML world to support dynamic scene changes.

However, VRML does not address any of the issues having to do with networking these worlds to enable multiple participants to interact with each other or distribute the workload associated with the simulation. Thus, developing Web-based CVEs using VRML requires network data communication support in order to allow multiple users to have collaborative interaction in a shared virtual world.

X3D

Extensible 3-D (X3D) (3) is an open standards Extensible Markup Language (XML)-enabled 3-D file format to enable real-time communication of 3-D data across all applications and network applications. It has a rich set of features for use in engineering and scientific visualization, CAD and

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

architecture, medical visualization, training and simulation, multimedia, entertainment, education, and more.

The X3D specification expressing the geometry and behavior capabilities of VRML using the Web-compatible tag sets of the XML. Scene graph, nodes, and fields, respectively, correspond to document, elements, and attributes in XML parlance. X3D is a more mature and refined standard than its VRML97 predecessor, so authors can achieve the behaviors they expect. X3D also provides compatibility with VRML97. In X3D, there is still a "Classic VRML" encoding that can play most nonscripted VRML97 worlds with only minor changes. None of the technology has been lost. It instead has evolved into X3D. Many features requested for VRML have been provided in X3D in a manner that is completely integrated into the standard. Thus, you can think of X3D as "VRML3"(4).

However, in contrast to the monolithic nature of VRML97, which requires the adoption of the entire feature set for compliance, X3D allows developers to support subsets of the specification ("Profiles"), composed of modular blocks of functionality ("Components") (3). A component-based architecture supports creation of different "profiles" that can be individually supported. Components can be individually extended or modified through adding new "levels," or new components can be added to introduce new features, such as streaming. Through this mechanism, advancements of the specification can move quickly because development in one area doesn't slow the specification as a whole. Importantly, the conformance requirements for a particular piece of content are unambiguously defined by indicating the profiles, components, and levels required by that content.

Java3D

Java3D (5) is an API released by Sun Microsystem, now a community source project developed on java.net. It provides methods for 3-D graphics application development. It is a standard extension to the Java 2 SDK. This would mean that Java3D removes the unreliability of communicating through an external program. Similar to all Java programs, Java3D is portable, robust, and platform independent.

Contrary to popular belief that it will replace VRML, Java3D and VRML are actually complimentary technologies. In terms of 3-D user interface support, VRML is Java3D's closest predecessor. VRML provides a standard 3-D interchange format that allows applications to save, transmit, and restore 3-D images and behaviors that are independent of application, hardware, platform, or programming language. Java3D provides a Java class library that lets an application developer to create, manipulate, and render 3-D geometry and portable 3-D applications and applets. In fact, Java3D provides support for runtime loaders that can load 3-D files of different formats such as VRML (.wrl), 3D Studio (.3ds), Lightwave (.lwo), and Wavefront (.obj).

Java3D provides a high-level, object-oriented view of 3-D graphics using a *scene graph*-based 3-D graphics model. It is designed to help programmers without much graphics or multimedia programming experience use 3-D in their applications. However, Jav3D is a high-level API and hides the rendering pipeline details from developers. This makes it unsuitable for several problems where such details are important. In addition, most Java3D components are heavyweight. They use native non-Java code to implement the actual rendering. This can complicate the Graphical User Interface development if a program uses Java Swing and its all-Java, or lightweight, components. In general, lightweight and heavyweight components do not mix well in the same container objects and windows.

CONSTRUCTING WEB-BASED CVEs

To embed CVEs in a Web page, which can be delivered via http protocol, and support collaborative interaction in a Web-based CVE, a 3-D modeling language is required to provide an interface that can capture local user's interactions with virtual entities and propagate the interactions to others through the network. At the same time, the interface should also be able to update the states of shared objects, which are changed by other users in the CVE, in the local virtual environment. To achieve this, EVENTS, ROUTES, and Sensors nodes in VRML (or X3D) can be used in combination to access a 3-D scene in the runtime, collect data from the scene, and change VRML nodes, properties of the scene.

Events. When one node needs to pass some information to another node, it creates an event. An event contains two pieces of information: the data and the timestamp. A timestamp is when the event was originally generated, not when it arrives at the destination. In VRML syntax, the behavior of events are defined by fields; three kinds of fields can be accessed: (1) eventIn, which is write-only and used to set value of a node; (2) eventOut, which is read-only and used to output data when there's an event; and (3) exposedField, which is both readable and writable.

Route. Route is used to pass information between nodes in the scene. It can be used to create an explicit connection between events. It can link an eventOut of a node to an eventIn of another node; for example, a statement "ROUTE node1.eventOutField TO node2.eventInField" results in the node1's evenOutField value to be sent to node2's eventInField.

Sensors. In normal cases, an eventOut field cannot generate events. VRML use sensors to get users' input and detect users' behavior/interaction or get time information. When the user interacts with a virtual entity in a CVE, a corresponding event will be generated. Table 1 defines the sensors in VRML and their functions.

CVE Scene Access

Besides generating interactive behaviors and capturing user interaction with VRML world, communication between the virtual environment and the network is further required to allow multiuser collaborative interaction. VRML's *External Authoring Interface* (EAI) (6) has been designed for such a purpose to allow communication between the VRML-based 3-D virtual world and its external environment. (Note: X3D uses Scene Access Interface (SAI) to achieve similar functionalities as VRML EAI.). It defines a set of functions on

Table 1. Sensors defined in VRML97

Name	Description
CylinderSensor	Translates user input into a cylindrical rotation. The CylinderSensor node maps pointer motion (e.g., a mouse or wand) into a rotation on an invisible cylinder that is aligned with the Y-axis of the local coordinate system.
PlaneSensor	Translate user input into a motion along the X–Y plane of the local coordinate system.
SphereSensor	Translates user input into a spherical rotation. It maps pointing device motion into spherical rotation about the origin of the local coordinate system.
ProximitySensor	Generates events when the viewer enters, exits, and moves within a region in space (defined by a box).
TimeSensor	Generates events as time passes. It can be used for driving continuous simulations and animations, controlling periodic activities (e.g., one per minute), and initiating single occurrence events such as an alarm clock.
TouchSensor	Detects when the user touches a given object. A TouchSensor node tracks the location and state of the pointing device and detects when the user points at geometry contained by the TouchSensor node's parent group.
VisibilitySensor	Detects if an object is currently visible to the user. The VisibilitySensor node detects visibility changes of a rectangular box as the user navigates the world.

the VRML browser that the external environment can perform to affect the VRML world. The external environment may take the form of a container application that holds a VRML browser, or a client/server style environment where the VRML browser forms the client and the application is a server program located on a remote computer. VRML EAI allows the developers to easily extend the functionality of the VRML 2.0 browser and thereby build the dynamic content of a 3-D application. In essence, EAI provides a set of methods for developing customized applications to interact with and dynamically update a 3-D scene so that the applications can "talk" to the VRML scene in real time. The EAI specifies the binding of its functions to Java, and hence, it can be considered a Java application programming interface. It defines a set of Java package and class for bridging Java applications to the VRML world. As a result, Java's strong ability in networking and multithreading can be used to establish the network connection and then achieve real-time collaboration among the users.

As illustrated in Fig. 1, by using VRML's EAI, together with Java Applet and Java networking capability, a VRML-based multi-user collaborative virtual environment can be built over the Internet. The VRML browser window generates and renders the 3-D geometry, whereas Java Applet delivers the control of the behavior and the logic of VRML scene graphical objects. EAI provides a two-way interface that lets VRML models and Java applets interact. It offers a set of functions of the VRML browser that the external program can call to control the content in the VRML scene. VRML EAI allows an external environment to access nodes in a VRML scene by using the existing VRML event model. In this model, an eventOut of a given node can be routed to an eventIn of another node. When the eventOut of a node generates an event, the eventIn (i.e., the receiver of the event generated by the eventOut node) is notified and its node processes that event.

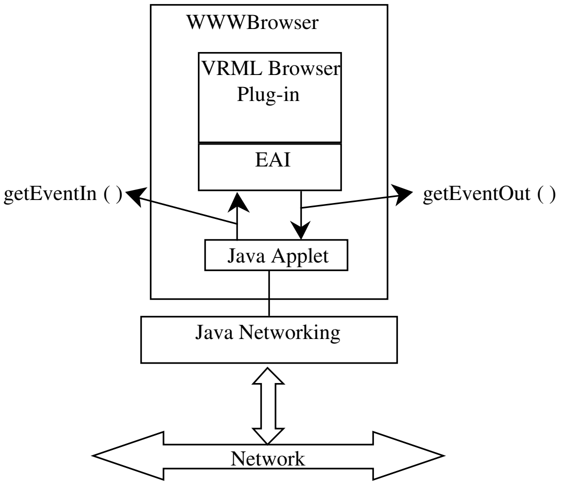

Figure 1. Communication between VRML world and the network through EAI.

Additionally, if a *script* in a Script node has a reference to a given node, it can send events directly to any eventIn of that node and it can read the last value sent from any of its eventOuts.

The Java implementation of the External Authoring Interface is specified in three Java *packages*: *vrml.external*, *vrml.external.field*, and *vrml.external.exception*. All members of package *vrml.external.exception* are classes derived from *java.lang.RuntimeException*; the rest of the members of the packages are specified as interfaces (with the exception of *vrml.external.field.FieldTypes*, which merely defines an integer constant for each EventIn/EventOut type). This allows the compiled Java applet to be used with any VRML browser's EAI implementation.

The EAI provides four types of accesses to a VRML scene:

1) Accessing the Browser
2) EventIn processing
3) EventOut processing
4) Getting notification from VRML scene

Accessing the Browser. The application communicates with a VRML world by first obtaining a reference to a browser object. This allows the application to uniquely identify a particular VRML scene in a computer where multiple scenes are active. To get a browser in Java applet, the following lines should be included in the applet program:

```
import vrml.external.Browser
Browser browser = Browser.getBrowser(this);
```

Once the Browser object is created, the Java applet can access scene nodes in the VRML Browser.

To gain access to a node (e.g., “ROOT” node), the Java applet needs to include the following codes:

import vrml.external.Node
Node rootnode = browser.getNode(“ROOT”);

Then, any or all events or leaf nodes of the Node can be observed and/or modified.

EventIn Processing. Once a node reference is obtained, all its eventIns are accessible using the *getEventIn()* method. This method is passed in with the name of the eventIn and returns a reference to an *EventIn* instance if an matching eventIn name is found. ExposedFields can also be accessed, either by giving a string for the exposedField itself (such as “*translation*”) or by giving the name of the corresponding eventIn (such as “*set_translation*”).

After an instance of the desired *EventIn* is obtained, an event can be sent to it. But *EventIn* has no methods for sending events. It must first be cast into the appropriate eventIn subclass, which contains methods for sending events of a given type.

Here is an example of sending an eventIn to a VRML scene containing a “House” node as follows:

DEF House Transform {. . .}

The Java codes for sending an event to change the *translation* field of the “House” node are as shown in Code Listing 1. (assume *browser* is the instance of a *Browser* class created from a previous call):

```
Node house = browser.getNode(“House”);

EventIn SFVec3f translation =

(EventIn SFVec3f)house.getEventIn(“set_translation”);

float value[3] = new float[3];
value[0] = 7;

value[1] = 8;

value[2] = 9;

translation.setValue(value);
```

Code Listing 1. EventIn processing.

In the above example, the translation value (7, 8, 9) is sent to the *translation* field of the Transform node of the “House.”

EventOut Processing. EventOut processing is similar to the EventIn processing. Once a node reference is obtained, all eventOuts of the node are accessible using the *getEventOut()* method. This method is passed in with the name of the eventOut and returns a reference to an EventOut instance if a matching eventOut name is found. ExposedFields can also be accessed, either by giving a string for the exposedField itself (such as “*translation*”) or by giving the name of the corresponding eventOut (such as “*translation_changed*”).

After an instance of a desired *EventOut* is obtained, two operations can be performed. The current value of the eventOut can be retrieved, and a callback can be setup to be invoked whenever the eventOut is generated. *EventOut* does not have any methods for getting the current value, so it must be cast into the appropriate eventOut subclass type, which contains appropriate access methods.

Similar to the eventIn example above, the current output value of the translation field can be read as follows:

```
float current[] = ((EventOut SFVec3f)
      (house.getEventOut(“translation_changed”))).getValue();
```

The array *current* now contains three floats with the x, y, and z components of the current translation value.

Getting Notification from VRML Scene. To receive notification when an eventOut is generated from the scene, the applet must first subclass the *EventOutObserver* class and implement the *callback()* method. Next the *advise()* method of *EventOut* is passed into the *EventOutObserver*. Then whenever an event is generated for that eventOut, the *callback()* method is executed and is passed the value and timestamp of the event. The *advise()* method is also passed a user-defined object. This value is passed to the *callback()* method when an event is generated. It can be used by the application author to pass user-defined data to the callback. It allows a single *EventOutObserver* subclass to handle events from multiple sources. It is a subclass of the standard java *Object* class; thus, it can be used to hold any data.

Using the above example again, the applet will be notified when the translation field of the Transform is changed, as shown in Code Listing 2.

```
public class MyObserver implements EventOutObserver {

  public void callback(EventOut value,

              double timeStamp,

              Object data)

   {

     //cast value into an EventOut SFVec3f and use it
       for intended operations

  }

}

  . . .

MyObserver observer = new MyObserver;

house.getEventOut(“translation_changed”).advise-
   (observer, null);
```

Code Listing 2. Getting notification from the VRML scene.

When the eventOut from the *translation* exposedField occurs, *observer.callback()* is invoked.

The EventOut class also has an *unadvise()* method that is used to terminate notification for that eventOut. The original *EventOutObserver* instance is supplied to distinguish which observer should be terminated if a single eventOut has multiple observers.

CVE Scene Construction

With the VRML EAI mechanism, we can construct a VRML-based CVE with avatars' representing users and shared objects with which users can interact.

Constructing Avatar. Avatar is a special shared object in a CVE virtual environment to represents the user's spatial location and interaction. It walks through the virtual space by following the user's navigation step, and it contains features to control the interaction between the user and the CVE, for example, mapping the user's viewpoint to the virtual world.

VRML's node mechanism can be used to support the concept of avatar. A VRML node is used to define an avatar, which includes the definition for the avatar's height, radius, and a 3-D model. A node is added into the CVE when the new user joins in the virtual environment. The two ways of node-creation methods provided by EAI: createVrmlFromString and createVrmlFromURL can be combined to embed the user's avatar into the virtual world. An avatar handler is created through a String, whereas the avatar's model is created through a URL and embedded into the avatar handler.

After creating avatar, its location and orientation in the virtual environment should be updated at run time to reflect the user's movement and interaction. EAI's VRML scene access mechanism can be used to update a user's avatar, i.e., by sending events to the eventIns of nodes inside a scene. From the process of creating an avatar node, the instance of the desired eventIn for setting avatar's location and rotation can be obtained. Once the instance of eventIn is created, an event can be sent to it.

To get an avatar's location and orientation, it requires a sensor to track the movement of a user's navigation in a CVE. As VRML ProximitySensor can output the changes of a viewer's position and orientation when the viewer is within the range covered by the ProximitySensor, a ProximitySensor node, with its size parameter to cover the whole CVE scene, can be used as the observer for the user's navigation. An EventOut Observer for the ProximitySensor and its callback function are used to get the notification when an eventOut is generated from the scene. Once a user moves, rotates, or enters/exits a defined region in the multi-user VRML world, two fields of the ProximitySensor node, one for location and the other for rotation, will reflect such movement by sending out the relative events.

But using only the ProximitySensor is not enough to define an avatar. NavigationInfo node should be used to define an avatar size, navigate speed, and type. We further use a Collision node to detect and to prevent two avatars from colliding. In the VRML file for the CVE, Code Listing 3 is added for the multi-user application.

```
NavigationInfo{

    avatarSize [0.25, 1.75, 0.75]

    headlight TRUE

    speed 2.0

}

Collision {

    collide TRUE

    children[

      DEF AvatarRoot Group{

        children[

        ]

      }

    ]

}

DEF LocalAvatarSensor ProximitySensor{

    center 0 0 0

    size 1000 1000 1000

}
```

Code Listing 3. Creating avatar nodes in VRML-based CVEs.

When a new user joins in, its avatar node will be added as a child to the AvatarRoot, which is a child of the collision node.

Creating Shared and Interactive Objects. In VRML, the fields of many nodes can be changed dynamically. These changes are made by routing events to the nodes. An event is a message sent to the node informing it that one of its fields should be changed. The process of the interactions on the 3-D interactive objects is illustrated in Fig. 2.

The VRML sensors provide a new level of user involvement with the virtual world. To interact with the virtual world, the sensor nodes are defined to monitor the inputs from the users. After the desired inputs were given, the sensor's eventOut will be routed to another sensor/script/interpolator's eventIn. Finally, the event will be routed to the animated object and the computed value will be set to the animated field. The VRML scene will be redrawn and show the animation of the objects to the user. In this

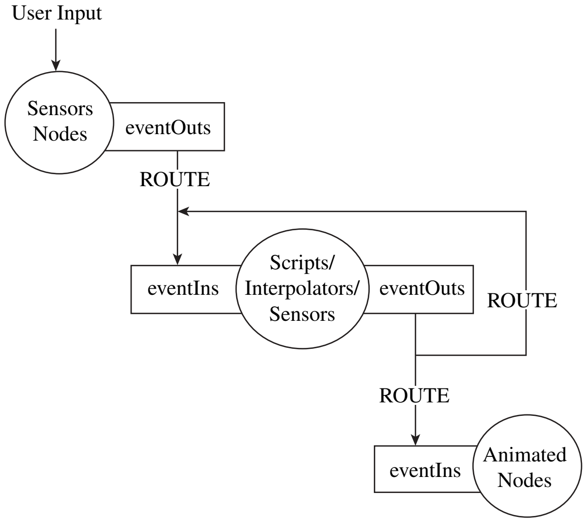

Figure 2. The process of interactions in VRML objects.

process, the routing requires that the eventOut and the eventIn have the same type.

For a multi-user collaborative virtual world, it is not enough to just allow an individual user to interact with the virtual objects or to allow the users to see each other's embodiment avatar. The CVEs also contain some shared interactive objects to make it more realistic and improve users' ability to interact with others as well as with the shared virtual world. For example, one user turns on a light and the other users should see the light in the virtual scene turned on. The states of these interactive objects are shared and can be changed by any user. It will be displayed locally, and the changes of the states will be propagated to other users through the network. Other more complex interactive objects are also required.

As discussed, the mechanism in EAI can be used to observe certain fields of a VRML node. As in the avatar node, it is also used to set parameters' values to the interactive objects. Once the value of the specified/affected field of the interactive object's VRML node is changed (an EventOut is sent from that field), the callback function will be called with the new value of that field. Hence, the system is notified when any changes happen and the operation to be carried out is implemented by the callback() function.

Although the basic idea is similar with creating avatar, implementing the interactive object is a little different. Because the interactive object and its behaviors have to be defined, the desired node can be obtained directly from the VRML scene. The node is designed in such a way that only one eventOut field is needed to be observed and only one eventIn field can trigger the status change of an interactive behavior. This will help to minimize the complexity of an EAI-aware Java applet because it only needs to observe one eventOut and set one eventIn.

To initialize the Event Observer in the client-side Java applet, information of the interactive objects has to be sent to the applet. The information includes the name of the Sensor node that will trigger the interaction, the name of the Script node that will carry out the operations for the interaction after it has been triggered, and the names of the fields in the Sensor and the Script that should be observed. A special Anchor node in the VRML file for the CVE can be defined for such a purpose as shown in Code Listing 4.

```
DEF InteractiveObjectsInfo Anchor{

    description

      "2/light/LightTS/isActive/lightScript/lightIsActive/

          door/DoorTS/isActive/DoorScript/doorIsActive/"

}
```

Code Listing 4. Creating sample shared interactive object information nodes in VRML-based CVEs.

The required information about the interactive objects in the CVE is provided by the description field of the node. In the above example, this Anchor node defines two shared interactive objects. One is the light, and another one is the door. With the techniques for creating avatar and synchronizing and maintaining a consistent virtual world among multiple users, 3-D VRML-based CVEs can be constructed. We have developed various Web-based CVEs using VRML to allow multi-user collaborative interaction, as shown in Figs. 3 and 4.

WEB-BASED CVE ISSUES

As discussed in the previous sections, a Web-based CVE can be constructed using VRML/X3D/Java3D. However, due to the heterogeneous nature of the Internet, system scalability, virtual world database delivery, and consistent world states maintenance across all participants in a Web-based CVE become more challenging issues than with its non-Web-based counterpart. This is particularly true if a Web-based CVE may have potentially a very large number of users at a time, which can easily overload a fast network. Real-time interactions require powerful networking capabilities to support large numbers of concurrent users. The underlying network support provided by Hyper Text Transfer Protocol (http) is insufficient for Web-based large-scale CVE. It is inadequate for supporting lightweight interactions and real-time streaming. To maintain collaboration, dynamic scene changes will need to be simulated by a variable combination of message passing, user commands, or entity behavior protocols. So Web-based CVEs will demand significant real-time data communication in addition to http-based client–server interactions.

As computing resources are limited, obvious problems will arise once the number of users in a Web-based CVE rises beyond a certain limit. One may expect a Web-based CVE to produce undesirable effects such as choppy rendering, loss of interactivity, and alike, due to lack of processing power to handle the ever-increasing load. If such a case

occurs, the collaboration will be lost. Thus, it requires a protocol designed for a Web-based CVE in addition to http. Virtual Reality Transfer Protocol (VRTP) (7) is designed for such a purpose. It is an application-level protocol that provides network capabilities for a large-scale interlinked VRML world. It provides additional capabilities, for many-to-many peer-to-peer communications plus network monitoring need to be combined with the client–server capabilities of http. To accomplish this task, VRTP is designed to support VRML worlds in the same manner as http was designed to support interlinked HTML pages.

VRTP define four basic components: client components, server components, peer-to-peer components, and monitoring components. By calling the services of these components, the CVE application can have the capability to act as a client to request 3-D world data from other application; act as a server to share its 3-D world data with others; act as peers to attend group communication; and act as a monitor to diagnose and correct the network problems. However, it should be noted that VRTP needs multicast-enabled network backbone services.

Besides providing an efficient protocol for Web-based CVEs, it is important that appropriate virtual world database delivery methods are used in combination to improve the system scalability. It is not practical to download and store an entire virtual world in the user's local machine each time and render the whole scene, because it will often lead to a long start-up time to wait for the whole database to be completely downloaded, and it could be unacceptably long due to Internet latency. This scenario is particularly

ICIS 3rd-generation Mobile Phone

Model SW2

Details :	
Product ID	20006
Manufacturer	NTU Pte Ltd
Our Price	S$1,000-
Size	3.2"L X 1.5"W X 0.5"T
Comment: One of the smallest GSM phones on the market. It is fully featured as a standard 3rd generation mobile phone and also has many additional features. Alphabet-numerical keyboard with 38 language options available.	

Figure 4. Web-based 3-D VRML virtual community CVE with live audio and video avatar face. (Note: Live audio and video data are transmitted in peer-to-peer.)

true for a large-scale CVE. Furthermore, all participants must maintain up-to-date object status, but updates for objects that they are not interested in waste processing power and network bandwidth (8). A popular solution to this issue is to partition the CVE into regions or cells. The virtual world partition may be static (9) or adaptive at run time (10). Once CVE is partitioned, each server may be assigned to provide service to a particular region. For example, in Spline (11), a region server maintains a record of all object models and states, as well as of interaction among all users in a given region. When a user enters a new region, the corresponding region server delivers object model data and initial information about the state of objects in the region to the user process. After this initial download, the user process obtains further object states' updates via group multicast communication. Algorithms may be introduced to achieve balanced workload for each server.

The virtual world database delivery may also be improved by an on-demand transmission approach as proposed in CyberWalk (12). It achieves the necessary performance with a multiresolution caching mechanism. First, it reduces the model transmission and rendering times by employing a progressive multiresolution modeling technique. Second, it reduces the Internet response time by providing a caching and prefetching mechanism. Third, it allows a client to continue to operate, at least partially, when the Internet is disconnected. The caching mechanism of CyberWalk tries to maintain at least a minimum resolution of the object models to provide at least a coarse view of the objects to the viewer.

Demand-driven geometry transmission (13) is another possible solution for improving content delivery performance. The proposed solution for content delivery includes area of interest (AOI) for delivering only part area of content; level of details (LOD) for delivering only given detailed data for an object; pre-fetching for hiding content delivery delay; and client memory cache management for improving client performance.

The virtual world content delivery and caching performance may further be improved by Pervasive Virtual Environment Scene Data Caching as proposed in MACVE (14). In traditional CVE systems, when a user navigates through a cell or region, it downloads the VE scene data of the cell/region and caches them for the possible future reloading. Whereas in MACVE, the cached virtual world data are used as an additional content delivery point if the caching user machine satisfies the Trusted User Node condition. Once a Trusted User Node caches virtual world data, it will be able to provide content delivery service to other users who are geographically located closer to the Trusted User. This process will be faster than downloading the same data from the server. Furthermore, it can reduce the workload and network bandwidth consumption on the server. MACVE achieves the Pervasive Virtual Environment Scene Data Caching by cloning Cell Agent and migrating it to the corresponding Trusted User Nodes. A Cell Agent may have multiple cloned ones running at different Trusted User Nodes. When a new user node needs to fetch the CVE scene data, it will be directed to the "nearest" Cell Agent.

To provide low latency interaction, world states synchronization methods should be carefully designed to incorporate with the corresponding world data delivery methods. For example, in Spline (11), world states changes are updated only to a small group of users in the region that are actually interested in it, rather than to all other concurrent users in the CVE via group multicast. Furthermore, Spline uses the "approximate database replication" idea on which DIS is founded (15). Spline world states are only approximately equal in the sense that different users observe events occurring at slightly different times. The time it takes to update a world model running locally in one user process with respect to changes made by a remote process depends on the network traveling time between the two user processes. The time difference is usually less than a couple of hundred milliseconds, which is still within the tolerance level for collaborative interactions. Further improvement may be achieved by fine-tuning the data communication approach based on the data type in the virtual world model. For example, state updates for small objects can be sent using multicast or unicast UDP or TCP packets, whereas graphic models, recorded sounds, and behaviors are identified by URLs and communicated using standard http protocols. And real-time streaming data, such as live audio/video, should be communicated using peer-to-peer direct transmission approach.

Another possible method that can be used to reduce user interaction (or world states changes) traffic is to use motion prediction (8) or dead reckoning (16). This method reduces network latency effects and improves the smoothness of collaborative interactions by extrapolating a virtual entity's next movement based on its history motion vector, thus reducing the number of states update packets required for synchronizing CVE states. However, it should be noted that this method does not work well with predicting user's movement in a CVE as users often have abrupt change in their motion.

To achieve good interactivity, data generated for scene consistency should be transferred as soon as possible to maintain the synchronization among remote users. This kind of data should have higher priority when communicating. Whereas persistent data are transparent to clients, it can tolerate a certain level of delay so long as the correctness of final virtual world states can be ensured. So, they can be queued and scheduled for processing at a lower priority. Thus, more bandwidth can be allocated for high-priority data.

SUMMARY

Similar to all other Internet applications, bandwidth is an important factor to be taken into consideration in Web-based CVEs. Because of limited bandwidth and appreciable network latency, Web applications have to be carefully constructed to avoid high bandwidth interaction between the client application on the user's machine and the server process on the other side of the Internet. For Web-based 3-D interactive CVEs, due to the heterogeneous nature of the Internet, the most challenging issues of system scalability, virtual world database delivery, and consistent world states maintenance across all participants should be addressed with efficient protocol and data communication architecture incorporated with appropriate virtual world partition, content delivery, and world states synchronization methods if it is intended for use by a large number of concurrent users over the Internet.

The WWW today is no longer just text and image displayed on the two-dimensional computer screen. The evolution of technology—higher computer processing speed and higher bandwidth—has enabled more interactivity, more content, and more realism on the Internet. Through the personal computers with network connections, Internet users can now "live" in three-dimensional worlds, where they can meet and interact with other users. They can now show their emotions and behavior through the representation of an avatar and communicate with each other using live audio and video streaming. With web3D, the future of the Internet will be an unlimited collaborative cyberspace where people can gain access to a shared 3-D interactive multimedia environment.

COMPUTER GAMES

INTRODUCTION

Computer (and video) games have gained significant interest in recent years, particularly the United States, where in total game sales for 2005 were over 10.5 billion US dollars, which repersented a 6% improvement over the game sales in 2004. Demographically, 69% of American heads of households play computer and video games. In the United Kingdom, which owns the world's third largest computer game market, 82% of 9- to 19-year-old youngsters own a game console. In this article, we discuss the existing technologies and the design issues of computer games. As computer and video games are closely related and technologically comparable, without loss of generality, our discussion will use the term *computer game* to also include video games.

GAME HISTORY

Computer game has a long history, in which we can trace back its root from 1947, when Thomas T. Goldsmith, Jr. and Estle Ray Mann designed the first game for playing on a cathode ray tube in the United States. Here, we are not intended to elaborate the full computer game history. Instead, we focus on the technological evolution of computer games and technical issues occuring throught the change. During the 1960s and 1970s, games developed were simple, primitive, and mainly in two dimensions. Many games of different types were developed. Two of the most unforgettable examples are Space Invaders and Pac-Man. In addition, handheld game devices were also developed, most of which were hard coded to run only a single game. For game playing, game players used simple button controllers, keyboards, or joysticks to control their game characters. The main forms of feedback were offered through screen displays with limited color and resolution as well as simple sound outputs. In the 1980s, there was a major growth in computer game technologies. For hardware, a variety of personal computers and game consoles were developed. For software, 3-D games and network games were first developed. In addition, different forms of input and output devices were developed, which included color monitors, sound cards, and various types of gamepads. They offer game players better game feedback and greater flexibility in controlling game characters. In the 1990s, games developed planted the seeds of today's game development. Many classic game types, including first-person shooters (FPS), real-time strategy (RTS), daily life simulators, and graphical multiplayer games, were developed during this period. Also, there was a trend for developing 3-D games. Nowadays, many new games are developed based on these classic games. The major difference of the new games from the classic ones is that the new games are mainly in three dimensions. Hence, hardware graphics accelerators were urged into development to support real-time rendering of 3-D game content. To take the advantage that human visual sense has a dominant influence of a game player to determine whether a game is good, game companies put their very first priority in enhancing the graphics output for their games. They put advanced graphics content, such as high detailed 3-D models, texture images, and various special effects, into the games. Multimedia elements, such as videos and songs, are also used to enrich the game content. However, such arrangements increase the complexity of the hardware requirement for running computer games. It also demands the development of efficient algorithms to manage such a variety of game content. To optimize both the manpower and time spent in game development, game developers begin to make use of ready-made game engines (please refer to the Game Engine section), which comprise many useful tools to support general game functions, to build their games.

When we go through the history of computer games, we note that, during the early stage, games were mainly simple and small. They could be generally handled by simple computation and graphics processing power. Hence, there were not really any stringent requirements put on the development of these games. Later, when game developers turned their focus to 3-D games, working out both hardware solutions and software solutions in supporting real-time rendering of 3-D graphics has subsequently become a critical part of game development. Besides, game physics and game artificial intelligence (AI) also played an important part of the games. Whereas game physics provides support to collision detection and motion control of game characters, game AI offers autonomy to the nonperson-controlled game characters to govern how these characters behave in the game environment. Recently, as multiplayer online games begin to dominate the game market, issues such as network latency, system scalability, and security are turned out consequently. Eventually, these issues make the game development face various technological design issues from different disciplines in computer sciences.

TYPES OF GAMES

2-D and 3-D Games

Technologically, computer games can be broadly categorized into 2-D and 3-D games. 2-D games generally manage the game environment into a logical 2-D space, where the game objects can be moving around and interacting. Practically. a majority of 2-D games, such as Pac-Man, Load-Runner, and Mario, can be implemented using a simple tile-based concept (1), which partitions the game environment into cells that are hosted in a 2-D array. Then different states can be assigned to an individual array element to logically represent different game objects and game scene elements in the game environment. When some objects are moving around in the game environment, the correspond-

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

ing elements of the 2-D array are then updated to reflect the change. To render game objects or game scene elements, it can be done as easy as using simple graphics primitives, such as line, point, and polygon, or alternatively using picture images to present the game objects or game scene elements in a more impressive and realistic way.

As the successor of 2-D games, 3-D games offer greater attractions to game players in terms of game interaction and visual effect. The game environment of such games is hosted in a 3-D space. As one more dimension is provided, game players have been offered a greater degree-of-freedom (DOF) in controlling their game characters and interacting with other game objects. They can also navigate and interact in the game environments with a variety of camera views. In addition, the 3-D setting of these games also gives a variety of advanced computer graphics effects a sufficient environment for implementation, which can then be visualized by the game players. Examples of the graphics effects range from some low level graphics techniques, such as lighting and shadowing, to some high level graphics techniques, which cover a wide variety of natural phenomenon simulations (2). In addition, computer animation techniques (3) can also be employed to make the game objects move in a realistic way. Unlike 2-D games, which can natively be displayed by most of the 2-D display controllers, 3-D games need a rendering process to convey 3-D game content to present on 2-D display devices. In light of supporting interactive game playing, the rendering process must be carried out with a frame rate of 25–60 frames per second, which means 25–60 pictures should be produced every second for the relevant portion of the game content for display purposes. To support such a performance, the rendering process is often needed to carry out by hardware graphics accelerators.

Multiplayer Online Games

Multiplayer online games have been developed as early as the late 1980s. The uniqueness of this game type is that it connects people from geographically dispersed locations to a common game environment for game playing. One of the early developed online games was the *Modem Wars,* which was a simple 2-D game designed for the personal computer—Commodore 64. The game connected two game players using modems into a shared game environment. During game playing, game players can interactively move the game items around the game environment to attack any enemy items located within a certain predefined range. Despite the game design being simple, it set a good foundation for the multiplayer online game development.

Nowadays, multiplayer online games have become one of the most popular game types. Unlike the old days, instead of running such games on peer computers and connecting the game machines through modems, the new online games are generally hosted in some server machines running on the Internet, which are referred as *game servers.* Game players from different geographical locations can connect to the games through some broadband network connections using their preferred game platforms, which can be a computer or a game console. Such game platforms are referred as *game clients.* The first commercial multiplayer online game of this type was, *Meridian 59,* published in 1996 by 3DO (4). Thereafter, some major game types, including FPS, RTS, and RPG, have dominated the market of multiplayer online games. Technically, the main responsibility of a game server is to keep track of the actions issued by the game clients and to propagate these actions and the state updates of the game environment to the relevant game clients. The game server also needs to build up a profile for each game player to store the game state and the possessions of the player, such that the players can keep on playing the game in future based on the saved profile. Today, most of the game developers focus on two major issues when developing multiplayer online games. First, they try to seek good game server architectures for hosting games to allow a larger number of game players to join and play their games. Second, to attract more people to play their games, the game developers take advantage of the advancement in computer graphics technologies to make their game have very impressive 3-D graphics presentations and visual effects.

Handheld Games

In contrast to computer-based or game console-based games, handheld games are run on machines with a small machine size. It allows people to carry it along anywhere and play around with it at any time when they are free. Generally, such machines can be referred to as dedicated handheld game consoles, personal digital assistants (PDAs), or mobile phones. Due to the hardware limitation, such game devices often suffer from small screen size and limited processing power and storage space, as well as the problem of short battery life. These problems do not only impose difficulties to handheld game development, they also make some people reluctant to play handheld games. Fortunately, these shortcomings have been addressed or have been worked around during recent years.

The first handheld game console is *Tic Tac Toe,* which was made in 1972. Similar to most of the early handheld game consoles, it came with one hard-coded game only. This limitation lasted until 1979, when the first handheld game console with changeable cartridges, *Microvision,* was developed. In general, as handheld game consoles at that period suffered from the small screen size and limited battery life problems, handheld games had not received great success. With the release of Game Boy (5) in 1989, which came with a monochrome display with improved resolution, used rechargeable batteries, and had a long list of game cartridges for game players to pick and play, handheld games began to attract a significant amount of game players. More importantly, Game Boy virtually set the "design standard" for today's game consoles. In addition, in 1998, the color display version of Game Boy was released to further improve the attractiveness of handheld game consoles. Nevertheless, up until the release of Game Boy and its color display version, as the processing power of the handheld game consoles was still quite limited, most of the games developed for the handheld game consoles were still essentially 2-D games.

Starting in 2000, there was a dramatic development in handheld game consoles, particularly in terms of computation and graphics processing power. In light of this improvement, 3-D games had been engaged to these devices, an example of which was in Game Boy Advance (5). On the other hand, useful accessories such as network connections, external memory storage and new types of input devices were added to the game consoles. Regarding the network capability, examples could be found in Nokia N-Gage (6) and Nintendo DS (5), which made multiplayer online games possible to be supported. Sony made use of UMD disks and Memory Stick Duo as a media to extend the amount of storage of its newest handheld game console, Sony PSP (7). For input device, Nintendo DS adopted a touch screen approach, where game players could use a stylus or even the player's finger as an input method to control the games objects.

On the other hand, similar to dedicated handheld game consoles, PDAs and mobile phones are also featured with high mobility, which makes such devices become alternate platforms for handheld games. More importantly, from the business point of view, putting games on essential devices, such as PDAs or mobile phones, is favorable as this frees people from investing or carrying addition game devices for entertainment. In addition, mobile phones and modern PDAs also natively come with network capability to provide a critical support for running online games. However, before PDAs and mobile phones become substantial handheld game devices, the technical problems of these devices, such as small screen size and limited storage space, which could also be found in dedicated handheld game consoles, must be solved.

GAME DEVELOPMENT PROCESS

Nowadays, making a game no longer focuses only on working out the game logic or game features and the graphical display for the game. Depending on the resource availability and the business strategy of a game company, a variety of associated tasks may also involve in the modern game development process. These tasks include game hardware and software development, media construction, localization, and even the handling of the cultural and social issues:

- **Game Hardware:** Gave hardware refers to the development of game consoles and game input/output devices. Such development may usually introduce new attractions to game players. It also offers game companies niches in developing proprietary hardware-specific games or obtaining license fees from developers who develop games on such game hardware. However, as developing game hardware usually requires quite a significant amount of investment in terms of manpower, time, and money, only large game companies can afford such development. More technical design issues on game hardware will be discussed in the Modern Game Design Issues Section.
- **Game Software:** Game software refers to the technical part of the game development process. It involves the development of various game software components, which may include some hard core game functionality, such as game content management and rendering, game animation, game AI, and game physics. In addition, it may also involve the development of game networking and game security, which depends on the type of the game for development. More details on this topic will be discussed in the next two sections.
- **Media Construction:** Media construction refers to the artistic part of the game development process. It involves the development of game content by using different types of media, which may include image, 2-D/3-D graphics model, audio, video, and motion capture information (8). As media offers the presentation of game content, which determines how game players perceive a game, media construction becomes an inevitable part of the game development process. Nowadays, many game companies have been investing a significant amount of resources in the media construction process.
- **Localization:** Localization is the process of turning a computer game into a country-specfic or a target-market-specific version, which helps a computer game broaden its market share and helps introduce country- or market-specific attractions to the game players. The localization process can be done as simple as by conveying the language of the user interface and the textual content of a game. In a more complicated way, we may further change the game characters or other game media content to country- or market-specific ones. Furthermore, we may even consider altering the storyline of a computer game to suit the culture or custom of the country-specific or target-market-specific game players.
- **Cultural and Social Issues:** During recent years, there has been a rising concern of the cultural and social effects of computer games on humans, especially on the youngsters. On the one hand, more and more people are getting addicted to computer game playing, particularly after the release of multiplayer online games, which likely has a bad effect to the academic performance of addicted student game players. It may also significantly reduce the amount of time for people to participate in social activities. On the other hand, the release of game titles with violent and sexual game content imposes negative ethical effect to the young people. Although there is not a consensus on the handling of the cultural and social issues of computer games, the game companies should try their best to maintain a good attitude in addressing these issues during the game development process.

GAME ENGINE

Making computer games is a complicated task. From the hardware perspective, when constructing a game, game developers may need to deal with a wide range of hardware and software platforms as well as work hard on a number of game components. More specifically, a computer game may need to be designed to run on different game platforms, including computers and game consoles, which are usually controlled by different operating systems. Even under the same hardware platform, the game may need to be rendered by different graphics accelerators and relied on different graphics application programming interfaces (APIs) to drive the graphics accelerators.

From the software perspective, when developing a computer game, game developers typically need to work on a number of game components, in which the most essential ones include game content management and rendering, game animation, game AI, and game physics. Working out these components generally involves much effort and is very time-consuming.

To minimize the complexity of game development by hiding the differences in various game platforms and to help game developers put their focus on developing high level game logics and game features, a game engine has been developed; it comprises a set of basic game building blocks and provides a high level and unified abstraction for both low level graphics APIs and hardware game platforms. With the help of a game engine, the investment of game development, in terms of time, manpower, and cost, can significantly be reduced. Reputable examples of game engines include Unreal Engine 3 (9) and RenderWare (10). In practice, there are not any standards or rules to govern the exact game components to be included in a game engine. Game engine developers have a great flexibility to select the appropriate set of components to make their own engines. However, there are some major game components that are essential to most of the games and, hence, should be included in the development of a game engine:

- **Game Content Management and Rendering:** Game content management and rendering is one of the most core parts of a computer game. It comprises techniques to manage game content in a way to support efficient content retrieval and processes for making the game content to be displayable on the output device of the game. For game content management, most of the game engines adopt a scene graph approach (11), where the game objects and the graphics primitives are hierarchically maintained with a tree structure. As such, tree structure implicitly links up the game objects according to their spatial relationship, it provides sufficient information for a game to pick out closely located game objects to support game rendering and game object interaction evaluation. On the other hand, for game content rendering, particularly when dealing with 3-D game content, there will be a significant amount of processes as well as a variety of options to go through for converting game content from the 3-D representation into the 2-D one for display. These processes and major options are shown as follows:
  1. *Standard graphics rendering processes*(12), such as perspective transformation, clipping, hidden surface, and back face removal, are fundamental to render 3-D game content into 2-D images for display. As these processes are usually natively come with the hardware graphics accelerators, game engine developers need not develop their own algorithm to support these processes. Instead, consider that the standard graphics rendering processes typically run on various hardware graphics accelerators, which are controlled by different low level graphics APIs, such as OpenGL (13) and DirectX (14), game engine developers may better work out high level unified abstraction on these graphics APIs and hardware to help reduce the effort of game developers to construct games for a variety of game platforms.
  2. *Shading and texturing* are the major processes to fix the appearance of individual game object. The shading process takes in the lighting and the object material information to evaluate the appearance of a game object by applying certain empirical lighting models. Common options of shading include flat shading, Gouraud shading, and Phong shading. They offer a different degree of realism to the rendered game objects. On the other hand, texture mapping adds or modifies detail on the game object surface. Basic options of texture mapping include basic texture mapping, multitexturing, and mipmapping, which arranges captured or artificial images to add on the surface of a game object. Advanced options of texture mapping include bumping mapping and displacement mapping. They make use of certain specially designed "texture maps," which comprise geometry modifiers rather than generic images, to modify the appearance of the geometric details over the surface of a game object.
  3. *Advanced rendering options* can be taken to further enhance the realism of the overall game environment. They include, but are not limited to, reflection, motion blur, and shadowing. Adopting these options definitely helps attract game players' interests as they make the rendered game environment look more realistic by adding details of some natural phenomenon to the game scene. However, as such rendering options generally require time-consuming add-on procedures to be executed on top of the standard graphics rendering processes, taking such options would likely degrade the rendering performance of a computer game significantly. Therefore, game developers should put these options as optional choices for game players to take rather than set them as mandatory game features.
- **Game AI:** Game AI (15) is a way to give "lives" to the nonperson-controlled game characters (NPCs) of the game environment, it directs the way of the NPC to interact with the game environment or other game objects. Putting different game AI to an NPC can assign different behaviors to the NPC. In fact, one of the major reasons for computer games to be so attractive is that game players can find different challenges and fun when they play against the NPCs inside the game environment. To implement game AI, two major options are available:
  1. *Reactive techniques* are widely adopted in many computer games, as they are fully deterministic. Examples of these techniques include scripts,

rule-based systems, and finite-state machines. Such techniques take in some given game parameters or game states, which are then evaluated through predefined rules to produce deterministic results. Practically, reactive techniques are good for implementing high level tactical decisions.

2. *Planning techniques*, in contrast, are nondeterministic. From a given situation, multiple actions can be taken depending on the current goal or some selected factors. A planning algorithm can scan through the possible options and find the sequence of actions that matches the goal or the selected factors. For instance, A^* is the most reputable example of planning techniques. Practically, planning techniques are good at helping to search the best possible path for a game object to navigate in the game environment.

- **Game Physics:** Game physics (16) is developed based on the laws of physics to govern how each individual game object reacts with the game environment or other game objects. It also offers a way to support the simulation of some natural phenomenon. Typically, the reaction of a game object can be determined using mass, velocity, friction, gravity, or some other selected physical properties. In practice, game physics can be natively applied to help generate a realistic response for the collision or interaction of the game objects. Alternatively, game physics can be applied to drive the motion of a large amount of tiny particles for simulating some natural phenomenon, such as the flow of smoke and water, fire blaze, snow, and cloud.
- **Animation:** Animation (3) is a technique to drive the motion of the body of the game characters. Typically, there are several ways to produce animation in computer games. They are shown as follows:

1. *Key-framing*(17) requires animators to define and draw key-frames of a motion sequence of the game character to be animated. However, manipulating and coordinating the limbs of a game character via key-framing is a complicated and tedious task. In addition, it is also difficult to produce realistic and natural looking motions with key-framing.
2. *Inverse kinematics*(18) computes the pose of a game character from a set of analytically constrained equations of motion. It can generally produce physically realistic motions.
3. *Motion capture*(8) acquires movement information from live objects. The captured position and orientation information from motion capture can then be applied to game characters to drive their motions. This approach has been widely accepted as it helps produce realistic and natural looking character animations.

MODERN GAME DESIGN ISSUES

Since the release of the first computer game, computer games have become one of our major entertainments. During the years, as game hardware becomes much more powerful, the game players' expectation on both the visual quality and the performance of computer games has then been increased significantly. Such expectation has partially been tackled by the release of new computer graphics algorithms and hardware. However, due to the advancement in computer network technologies and the popularity in multiplayer online games, game design issues are no longer restricted to computer graphics or input/output devices. Instead, the game design issues have become multidisciplined and are much more challenging than ever. The following shows the modern technical design issues that game developers should need to pay attention on when developing their new games:

- **Advancement in Hardware Graphics Accelerator:** Owning to the increase in the demand for high visual quality and high realism of the graphics output of computer games, a brand new type of hardware graphics accelerator—Graphics Processing Unit (GPU) (19) has been developing, which offers a dramatic improvement in the rendering performance at the game clients. Such improvement is due to the fact that GPU allows the major rendering tasks, including the standard and the advanced game rendering tasks as well as game physics, to be executed in parallel rather than carrying them out in a sequential manner as in the traditional hardware graphics accelerator. To take advantage of such advancement in hardware graphics accelerators, game engine developers should seek ways to parallelize the algorithms used for implementing the game engine components.
- **Game Controller (Input):** Game controller (20) is the primary input device for game players to issue commands or actions to drive game characters or interact in a computer game. Common game controllers include keyboard, joystick, and mouse. To use these controllers, game players need to convey their actions by getting in to their minds with controller-dependent operations. However, such operations may not always match well with the activities or interactions of one's game playing, especially for the games about human's real-life activities, such as driving, dancing, musical instrument playing, and shooting. Recently, game developers began to realize that the design of the game controllers could be one of the critical determinants for the success of a computer game. Hence, they have been working out many different game controllers to attract game players' interests and offer a better game playing experience. On the one hand, game-specific game controllers have been developed; examples include the steering wheel for driving or racing games, the dance platform for dancing games, and light guns for shooting games. Through these controllers, game players can act naturally as performing real-life activities during their game playing. On the other hand, game developers actively create new types of game controllers. Examples include the EyeToy of Playstations (21) and the wireless controller, Wii Remote by Wii (22).

Particularly, EyeToy makes use of a webcam to capture human motion, which virtually forms a game controller for a game player to control and interact with the game. Wii Remote is a wireless game controller with high degrees-of-freedom to let a game player generate a large variety of free motions or perform human's real-life actions for game playing. These game controllers also lead to the development of new game types.

- **Game Feedback (Output):** Game feedback is the way for a computer game to give game players responses to their actions. It is the one of the most direct ways for a game player to feel and to be impressed as to how good a computer game is. The primary ways for offering game feedback is to put different graphics effects on the screen and to generate sound effects for responding to game players' actions. However, as more game devices are released, a greater variety of game feedback is made available for game developers to consider putting in their games. Broadly speaking, we may have three methods of game feedbacks, includies tactile, audio, and visual feedbacks. For tactile feedback, the most common form can be found in most of the game pads of modern game consoles. It is typically done by generating vibrations to certain game events or game players' interaction. Another form is the resisting force used in the steering wheel for the car games. For audio feedback, as new sound compression and speaker technologies are emerging, multichannel sound feedback is now made available to provide higher sound quality and to support 3-D sound rendering. In particular, 3-D sound offers a new type of spatial feedback for objects or interactions in a game environment, which originally can be a provided by the visual feedback only. For visual feedback, a conventional approach focuses on rendering 3-D graphics and visual effects to display on a 2-D screen. But as stereo display technologies mature and become widely available, a 3-D display is made possible as an alternative option for visual feedback.
- **Scalability:** Multiplayer online games are the fastest growing game type in recent years. They allow a large amount of remote game players to get connected for playing in a shared game environment. Existing multiplayer online games have been implemented with distributed game servers. However, some of the games, such as Quake III Arena (23) and Diablo II (24), maintain an individual game state for each game server, which is not shared among the servers and is essentially a set of separated client–server systems running the same game and may not be considered as a real multiserver system. EverQuest (25), in contrast, divides the entire game environment into distinct zones and maintains these zones by individual game servers. EverQuest allows a client to travel from one zone (game server) to another freely. Ultima Online (26) and Asheron's Call (27) adopted an approach simlar to EverQuest, but they divided the entire game environment into visually continuous zones. The boundary of each zone is mirrored at a neighboring server to reduce the lag problem and to improve interactivity when a user crosses from one zone to another. In addition, Asheron's Call is technically more advanced in that it may dynamically transfer a portion of the zone controlled by a given game server to any other lightly loaded server. Unfortunately, game object coherency is not considered.
- **Network Latency:** A unique characteristic of multiplayer online games is that game updates are required to send to remote game players over the network throughout the game playing sessions to renew the states of the local copies of shared game objects at the game players. More than that, as multiplayer online games involve time-dependent game data and continuous user interaction, the state update events are therefore *continuous*(28) in nature. However, due to the existence of network latency, such updates are likely arrived at the remote game players after some delay, which leads to state discrepancy of the shared game objects among the game players. This fact opposes the sufficient condition for supporting game player interaction, in which the state updates need to be presented to remote game players either without any delay or at least within a very short period of time.

  To cope with the latency problem, adaptations could be performed at either the user side or the system side. For user-side adaptation, Final Fantasy XI (29), which is one of the popular online games currently available in the market, imposes restrictions to game player. In this game, a player usually receives position updates of other game players with almost a second delay. To reduce the effect of such delay, first, players can only attack enemy objects, but not each other. Second, the enemy objects are designed to move very little while they are under attack by a player. Such game rules significantly limit the game features and the type of games that can be developed. For system-side adaptation, a popular approach is to use dead reckoning (30). With this approach, the controlling game player of a game object runs a motion predictor for the object. Other game players accessing the object also run the same motion predictor to drive the motion of the local copies of the object. The controlling game player is required to keep track of the error between the actual and predicted motions of the object, and sends the updated motion information to the other game players when the error is higher than a given threshold. Although this approach is very simple, it does not guarantee that the state of a shared object could be synchronized among all game players.

  Recently, a trajectory preserving synchronization method (31) has been developed to tackle the problem. The method runs a reference simulator for each object on the game server. Each of the game players interested in the object, including those that access the objects as well as the owner of the object, will execute a gradual synchronization process on the local copy of the object to align its motion to that of the reference simulator running at the server. The method effectively reduces the discrepancy suffered by remote game players.

- **Game Cheating:** Game cheating generally refers to the activities that modify the game experience to give a game player an unfair advantage over the other players. Common ways of game cheating can be done in terms of user settings, exploits, and using external software. To cheat using user settings, one can change game data, game models, game environment, or game devices to make one to play a game in an easier way. Exploits, on the other hand, refer to the use of existing bugs of a game, or game features or tricks that are reserved for developers for testing purposes and are unintended to release to game players, to gain certain advantages for game playing. Other than the above, people may develop external software to help modify the normal behavior of a game to let a game player perform game cheating. To cheat in online games, packet tampering is common. It is performed by altering the game data sent between the game server and game clients. To prevent game cheating, game companies should take appropriate measures. Typical solutions may include the use of anticheating software and banning suspected cheaters from playing a game.

FUTURE TREND AND CONCLUSIONS

Based on the development in computer games, we enumerate and elaborate below a number of emerging issues on the future development of computer games, much of which serves the purpose of highlighting the direction for future research and development. In addition, it is anticipated that many new games will emerge in time as the technologies evolve. What we have pointed out here are only some important emerging issues and technologies, and we are leaving the readers to comment and decide which ones are the most important.

- **On-Demand Transmission:** Nowadays, multiplayer online games are usually set out with a large scale scene environment together with high quality game objects to attract more game players. A standard way to distribute such a large game content is to put it on CDROMs/DVDs for game players to purchase and subsequently install at their local machines. This scenario works fine if players' local machines have sufficient storage to hold the complete set of game content. Clearly, due to limited storage, it is difficult for handheld devices or portable game consoles to access multiplayer online games in this way. To loosen this limitation, a game-on-demand approach (32) can be adopted, which uses a prioritized content delivery scheme to help identify and deliver relevant game content in suitable quality to support users' game playing. In addition, the game-on-demand approach also serves games with very large scale game scenes and highly detailed game objects to be accessible to machines with any kind of network connection speeds. On the other hand, nowadays, game companies typically continue to develop new game scenes and game objects after they have released their games. It is not only because game companies want to gain revenue before they have finished developing their games, they also need to add new attractions to keep motivating people to play their games. With the game-on-demand approach, this process can be done totally transparently to the game players without requiring them to install patches as they do now, as new content can also be streamed progressively during game playing.
- **Web-Based Client Technologies:** Recently, there has been a dramatic development in client technologies for Web-based applications. Such technologies are emerging as important development tools and are critical for the future development of Web-based computer games. Typical examples include Flash, Java, and ActiveX. They help improve the user interface control of Web-based applications by getting through the problem of limited interaction control and web page reload when a user performs an action. More than that, client technology, like Flash, serves users with an interactive user interface as well as the multimedia support. The only requirement for adopting these client technologies is the preinstallation of application interpreters and plug-ins. In addition, a more advanced option, Asynchronous JavaScript and XML (AJAX) (33), has been made available since 2005 to provide more interaction control, such as context-sensitive menus and window interface, for developers to construct more serious Web-based application. AJAX also relaxes the need of preinstallation or maintenance of add-on plug-ins, and requires only a minimal amount of data transmission for application download, as they are driven by light-weighted JavaScript and XML codes. Finally, during run-time, AJAX can collect information from Web servers to update only a required part of the application content without the reloading web page.
- **Security Challenges:** Security control in existing computer games is partially addressed. However, as there is a trend that more and more computer games will be hosted on the Internet, the risk of these games being accessed by unauthorized people and being cracked for cheating will be increased as well. To address this problem, secure socket layer (SSL) could offer a good choice. It provides endpoint authentication and communications privacy over the Internet using cryptography. In particular, once a user has logged into a computer game, such data protection processes would be done transparently to the user.
- **Computer Games on Grid:** Grid Computing (34) is considered as a hot research area in recent years. Grid connects computers, storages, sensors, and services via fixed-line or wireless Internet (and other) networks. The goals of grid computing include resource sharing, coordinated problem solving, enabling dynamic virtual organizations/world, and thus service-oriented architecture is considered as a promising direction. Advantages of grid include data and performance reliability (avoid single point of failure), performance (avoid network and computation bottleneck), and resilience (guarantee existence of data and its

backup). In line with the change of new grid concepts, computer games can be considered as one important service to this emerging grid virtual world.

CROWD SIMULATION

Crowds are part of our everyday experience; nevertheless, in virtual worlds, they are still relatively rare. Despite achieving impressive levels of visual quality with nearly photorealistic look, virtual environments in many cases resemble "ghost towns," with a small number of virtual inhabitants in most cases only directly related to their scenarios. Computer graphics-generated crowds are rare in interactive virtual environments such as computer games or virtual reality educational and training systems.

The first generation of real-time virtual crowd simulations had to sacrifice both visual and behavioral details in order to increase the number of handled characters. Researchers, now, aim to go beyond earlier results to achieve high-fidelity believable groups and crowds integrated into complex virtual worlds, giving the user a possibility to interact with virtual characters. To achieve this goal, several topics have to be explored, including rendering, behavior computation, procedurally generated locomotion animation, interaction with objects, and scene management. New approaches taking into account requirements specific for crowd simulations, such as ability to produce variety and scalability, are needed. It is essential to investigate heterogeneous simulations where a smaller number of complex agents would coexist and interact with a less detailed larger crowd within the same virtual world. To optimize the amount of the computation needed for real-time crowd applications, levels-of-details techniques have to be explored taking into account the human perception in conjunction with an efficient scene management.

RELATED WORKS

Although collective behavior has been studied since as early as the end of the nineteenth century (1), attempts to simulate it by computer models are quite recent, with most of the work done only in the mid-and late-1990s. Recently, researchers from a broad range of fields such as architecture (2–4), computer graphics (5–8), physics (9), robotics (10), safety science (11, 12), training systems (13–15), and sociology (16) have been creating simulations involving collections of individuals.

We can distinguish two broader areas of crowd simulations. The first one is focusing on realism of behavioral aspects with usually simple two-dimensional (2D) visualizations like evacuation simulators, sociological crowd models, or crowd dynamics models. In this area, a simulated behavior is usually from a very narrow, controlled range (for example, people just flying to exit or people forming ring crowd structures) with efforts to quantitatively validate correspondence of results to real-world observations of particular situations (11). Ideally, simulation results would then be consistent with datasets collected from field observations or video footage of real crowds either by human observers (17) or by some automated image processing method (18). Visualization is used to help to understand simulation results, but it is not crucial. In most cases, a schematic representation, with crowd members represented by colored dots, or sticky figures, is enough, sometimes even preferable as it allows for highlighting important information.

In the second area, a main goal is high-quality visualization (for example, in movie productions and computer games), but usually the realism of the behavior model is not the priority. What is important is a convincing visual result, which is achieved partly by behavior models and partly by human intervention in the production process. A virtual crowd should both look well and be animated in a believable manner, the emphasis of the research being mostly on rendering and animation methods. Crowd members are visualized as fully animated three-dimensional figures that are textured and lit to fit into the environment (19). Here, behavior models do not necessarily aim to match quantitatively the real world; their purpose is more in alleviating the work of human animators, and to be able to respond to inputs in case of interactive applications.

SCALABILITY OF SIMULATION

Achieving high-fidelity crowds is a challenging task. All involved components such as behaviors, rendering, or animation should be able to run with a high level of detail. However, as there are always performance limits, only a smaller subset of the virtual population can be higher quality. Computational resources have to be distributed between a simulation of different parts of the population and a simulation of the environment.

Apart from high-level behavior, there are low-level consistency issues—for example, what should happen to parts of the scene that are not visible to the user? A common approach is to just ignore these parts of the scene; however, this causes inconsistent situations when the user's attention returns. As no simulation was done for this part, the system has to generate a new situation from scratch, which usually does not correspond to what the user remembers from his previous visit (e.g, a table was moved; however, when the user returns, the table is back in the original position and not where it was left before).

Of course, it is not desirable and often unfeasible to run a full simulation of the whole environment at all times. However, some minimal simulation has to be done to be able to maintain the consistency of the virtual world. This leads to the notion of levels of detail for simulation:

1) **Full simulation** for the parts of the scene, which are observed and being interacted with by the user(s).

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

2) **Simplified simulation** for the parts that are farther away and not well visible (some animations can be simplified, locomotion is less accurate, collision detection is less accurate, etc.).
3) **Minimal simulation** for the parts of the world that are not visible and not being interacted with. The entities should still keep their internal state, and movements have to be computed; however, there is no need to properly animate them.

The following sections will detail how rendering, animation, navigation, and behavior should be improved to allow for real-time, better, more realistic, and less costly crowd simulations.

HIGH-FIDELITY VISUALIZATION

We want to be able to have a full close-up zoom of a human with the highest possible level of detail in geometry, skin details, shadows, and facial animations, while still keeping a large crowd of humans.

All current crowd rendering methods use precomputation to speed up the rendering (8,20,21). The problem is how to balance the time used for each human to render it and how much will be stored in memory in the form of precomputed animations and behaviors. If all humans are computed and displayed dynamically on-the-fly, we can reach around 1000 humans with real-time performance (25 frames per second). On the other hand, if all animations are precomputed, we can render 10,000 humans with the same performance. With the precomputed approach, fewer animations can be stored because memory starts to become a concern when the number of possible animations grows. Dynamically created animation allows much wider variety of motions, especially for interactive applications where motions can depend on actions of the user. The animations can be then generated, for example, by using inverse kinematics, rag doll physics, or motion capture.

Other issues that need to be addressed are shadows cast by the humans, such as very detailed shadows when we have a close view and less detailed ones or no shadows when the user sees the crowd at a distance. High detail shadows, for example, are those in the face and those cast on the ground and onto other objects in the environment.

Rendering

Tecchia et al. (8) used billboards or impostors for crowd rendering. The main advantage is that impostors are very lightweight to render once they are in the memory of the graphics card. The method requires building of all animations from all possible camera angles and storing these pictures in a texture. One such texture can hold one frame of animation in very low-resolution billboards, where every individual subframe is about 16 pixels tall and wide. This process can give good visuals because it is basically an image-based rendering approach, so even pictures of real humans could be incorporated. However, zooming on these billboards will produce aliasing artifacts, because the images on the billboards have to be small to fit in the graphics card's texture memory. As a result, billboarded humans serve as a good approach for far-away humans that do not need detailed views. More sophisticated impostors have been also proposed by Aubel et al. (22).

Another approach that unifies image-based and polygonal rendering is found in Ref. 20. They create view-dependent octree representations of every keyframe of animation, where nodes store information about whether it is a polygon or a point. These representations are also able to interpolate linearly from one tree to another so that in-between frames can be calculated. When the viewer is at a long distance, the human is rendered using point rendering; when zoomed in, using polygonal techniques; and when in between, a mixture of the two. It does take large amounts of data per keyframe and needs long preprocessing times because of its precise nature, but also it gives near-perfect interpolation between detail levels without "popping" artifacts that otherwise occur if one uses discrete detail levels.

The third alternative is to use vertex shaders to deform a conventional mesh using a skeleton. The disadvantage is that the pipeline would be constrained to shaders, and every interaction such as lighting, shadows, and other standard effects would then have to be programmed with shaders.

In the last few years, rendering of virtual humans has been drastically improved. This improvement is due, for example, to variety in clothes and skin, which has been achieved through vertex and fragment shaders; many different levels of detail have been created and used; and computationally efficient fake soft shadows have been developed for the highest levels of fidelity.

Variety

Variety in rendering is defined as having different forms or types and is necessary to create believable and reliable crowds in opposition to uniform crowds. For a human crowd, variation can come from the following aspects: gender, age, morphology, head, kind of clothes, color of clothes, and behaviors. We create as many color variations as possible from a single texture.

One approach (23,24) to variety in rendering is an extension to Ref. 8 to create color variety from a single texture to dynamically animated three-dimensional (3-D) virtual humans. We obtain a wide variety of colors and appearances by combining our texture and color variety. Each mesh has a set of interchangeable textures, and the alpha-channel of each texture is segmented in several zones: one for each body part. This segmentation is done using a desktop publishing software. Using this alpha map to vary body part colors could be done with a fixed function pipeline approach, i.e., all the computation on the CPU. However, to improve the execution speed, it is possible to explore the performance of high-end consumer graphics cards, allowing for shader programming. This way, each character can have up to 256 different alpha key areas, corresponding to a certain body part. Using the fixed function pipeline approach, this is completely unreasonable, as it would require 256 passes.

In the process of designing human color variety, we have to deal with localized constraints: Some body parts need very specific colors. One cannot simply randomly choose any color for any body part. This would result in green skin, yellow lips, and other frightening results. With a graphics user interface, the designer can set intuitive color ranges in which a randomly chosen value will not produce unrealistic results. For instance, the color variety for the skin of a virtual human is defined in a range of unsaturated shades with red and yellow dominance, almost deprived of blue and green.

Levels of Detail

For the rendering part of crowds, levels of details are essential to lower the computational cost and allow for highly detailed virtual humans at the forefront of the scene. For example, we can consider three main levels of detail as introduced in Ref. 23:

- The highest level of detail of a virtual human is represented by a deformable mesh that can be deformed in real time to perform a skeleton-based animation. This deformable mesh can be divided into several different levels of fidelity; for example, we may consider the highest is composed of about 5000 vertices, and the next two have a smaller number of vertices, i.e., about 1000 and 200 vertices, respectively.
- The second level of detail of a virtual human could be a rigid mesh: a mesh whose deformation for a specific animation has been precomputed. The precomputed deformations allow substantial gains in speed; however, they require memory space to store the results and thus constrain the animation variety.
- The final rendering level of detail is the billboard model, which represents a virtual human as a textured rectangle that always faces the camera. To create these models, images are sampled around the waist level of the character at 20 different angles, for each keyframe composing an animation. Rendering such billboards is very fast; unfortunately, the memory requirements for each animation to sample are also very high.

Figure 1 shows an example with the three levels. Through these different levels of detail, we pass from a computationally expensive process to a very fast but memory requiring approach. One could ask if it is then worthwhile to use all these levels of details. The answer is yes, because the costly approaches in terms of memory are used for virtual humans that are far away from the viewer. For these models, only a few animations need to be sampled, because a varying speed or walk style is unnoticeable from afar. In terms of performances, with the three-level approach, it is possible to have a real-time crowd with about 40,000 individuals.

ANIMATION

While designing an animation engine usable in crowd simulations, several criteria have to be taken into account:

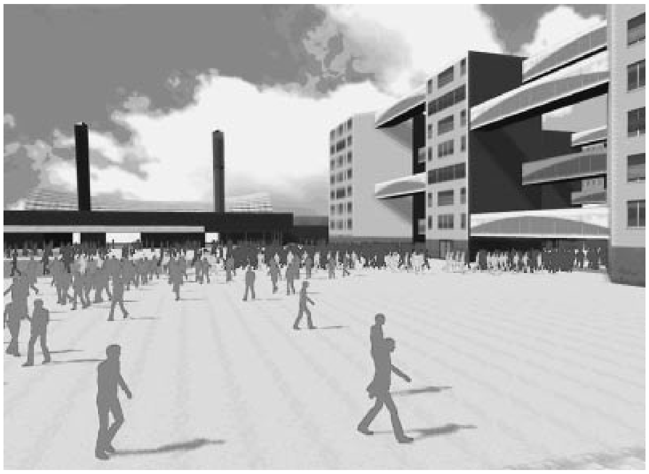

Figure 1. The three different rendering levels of detail: deformed meshes, rigid meshes, and billboards.

Animation computation should be efficient and scalable, it should also allow for variability, and it should be compatible with level-of-detail. To create flexible virtual humans with individualities, there are mainly two approaches:

- Motion capture and retargeting.
- Creation of computational models.

Motion Capture and Retargeting

The first approach consists in recording the motion using motion capture systems (magnetic or optical), and then trying to alternate such a motion to create this individuality. This process is tedious, and there is no universal method at this stage. Even if it is fairly easy to correct one posture by modifying its angular parameters (with an inverse kinematics engine, for instance), it becomes a difficult task to perform this over the whole motion sequence while ensuring that some spatial constraints are respected over a certain time range, and that no discontinuities arise. When one tries to adapt a captured motion to a different character, the constraints are usually violated, leading to problems such as the feet going into the ground or a hand unable to reach an object that the character should grab. The problem of adaptation and adjustment is usually referred to as the Motion Retargeting Problem.

Witkin and Popovic (25) proposed a technique for editing motions, by modifying the motion curves through warping functions, and produced some of the first interesting results. In a more recent paper (26), they extended their method to handle physical elements, such as mass and gravity, and described how to use characters with different numbers of degrees of freedom. Their algorithm is based on the reduction of the character to an abstract character, which is much simpler and only contains the degrees of freedom that are useful for a particular animation. The edition and modification are then computed on this simplified character and mapped again onto the end-user skeleton. Bruderlin and Williams (27) have described some basic facilities to change the animation, by modifying the motion parameter curves. They also introduced the notion of motion displacement map, which is an offset added to each motion curve. The Motion Retargeting Problem term was brought up by Michael Gleicher (28). He designed a space-time constraints solver, into which every constraint is added, leading to a big optimization problem. Bindiganavale and Badler (29) also addressed the motion retargeting problem, introducing new elements: using the zero-crossing of the second derivative to detect significant changes in the motion, visual attention tracking, and applying inverse kinematics to enforce constraints, by defining six subchains (the two arms and legs, the spine, and the neck). Finally, Lee and Shin (30) used in their system a coarse-to-fine hierarchy of B splines to interpolate the solutions computed by their inverse kinematics solver. They also reduced the complexity of the IK problem by analytically handling the degrees of freedom for the four human limbs.

Creation of Computational Models

The second approach consists in creating computational models that are controlled by a few parameters. One major problem is to find such models and to compose them to create complex motion.

The most important animation scheme used in crowd simulation, as well as games (31), is the locomotion, which is basically composed of walking and running motions.

The first idea is to generate different locomotion cycles online for each individual. Unfortunately, even though the engine could be very fast, we could not allow for spending precious computation time for such a task. Moreover, depending on the rendering levels of detail, e.g., billboards or rigid meshes, it is impossible to create an animation online.

A second approach is to use an animation database. At the beginning of a simulation, a virtual human walks at a certain speed. To find the corresponding animation, the framework formulates a request to the database. The database returns an animation at the closest speed. To create this database, we generate offline many different locomotion cycles, with varying parameters. A few representative locomotion cycles are selected to create the corresponding rigid mesh animations. An even smaller number of cycles are also selected to create billboard animations.

More recently, Glardon et al. (32) have proposed an approach to generate new generic human walking patterns using motion-captured data, leading to a real-time engine intended for virtual human animation. The method applies the principal component analysis (PCA) technique on motion data acquired by an optical system to yield a reduced dimension space where not only interpolation but also extrapolation are possible, controlled by quantitative speed parameter values. Moreover, with proper normalization and time warping methods, the generic presented engine can produce walking motions with continuously varying human height and speed with real-time reactivity.

This engine allows generating locomotion cycles, parameterized by a few user-defined values:

- Speed: the speed at which the human moves.
- Style: a value between 0 and 1, 0 being a walk motion, 1 being a run motion.
- Personification: a weight to blend among the five different locomotion styles of five different motions captured people.

Now when such a engine is fully integrated into a crowd framework, it is possible to generate many different locomotion cycles by simply varying the above parameters, thus, making each individual unique. This engine has been extended to curved walking (33) and dynamic obstacle avoidance (34).

NAVIGATION

The main goal is to simulate a large number of people navigating in a believable manner for entertainment applications. For this purpose, environments containing static obstacles are analyzed and preprocessed to identify collision-free areas (35,36). Collisions with dynamic obstacles, such as other pedestrians, are then avoided using local reactive methods based on a cell decomposition (37,38) or repulsive forces (9). Other approaches solve both navigation and pedestrian inter-collision problems simultaneously, using prioritized motion planning techniques (39, 40). In such approaches, navigation is planned successively for each entity, which then becomes a moving obstacle for the following ones—the growing complexity limits the number of people composing the crowd. The probabilistic roadmap (PRM) approach (41) can be adapted to plan individual locomotion (42,43). Recently, approaches tend to decompose environments in walkable corridors, whose width allows group navigation (44). None of these approaches automatically handle both uneven and multilayered environments, which are commonly encountered in virtual worlds. PRM-based approaches suit high-dimensional problems well. However, they are not the most efficient ones for navigation planning when the problem is reduced to three dimensions. Pettré et al. (23) propose a novel approach capable of decomposing such environments into sets of interconnected cylindrical navigable areas. Terrain analysis is inspired by Voronoï diagrams and by methods using graphics hardware to compute them (45). The resulting structure captures the environment topology and can be used for solving crowd navigation queries efficiently. To exploit the locomotion animations of the virtual humans, a navigation graph and path planner have been developed. The navigation graph supports both path planning and simulation by capturing the environment topology and by identifying navigable areas. These navigable areas (graph vertices) are modeled as cylindrical spaces with a variable radius. If two of these cylinders overlap, it is possible to pass from one to the other. A vertical gate (graph edge) is used to model each cylinder intersection as a connection. Figure 2 shows examples.

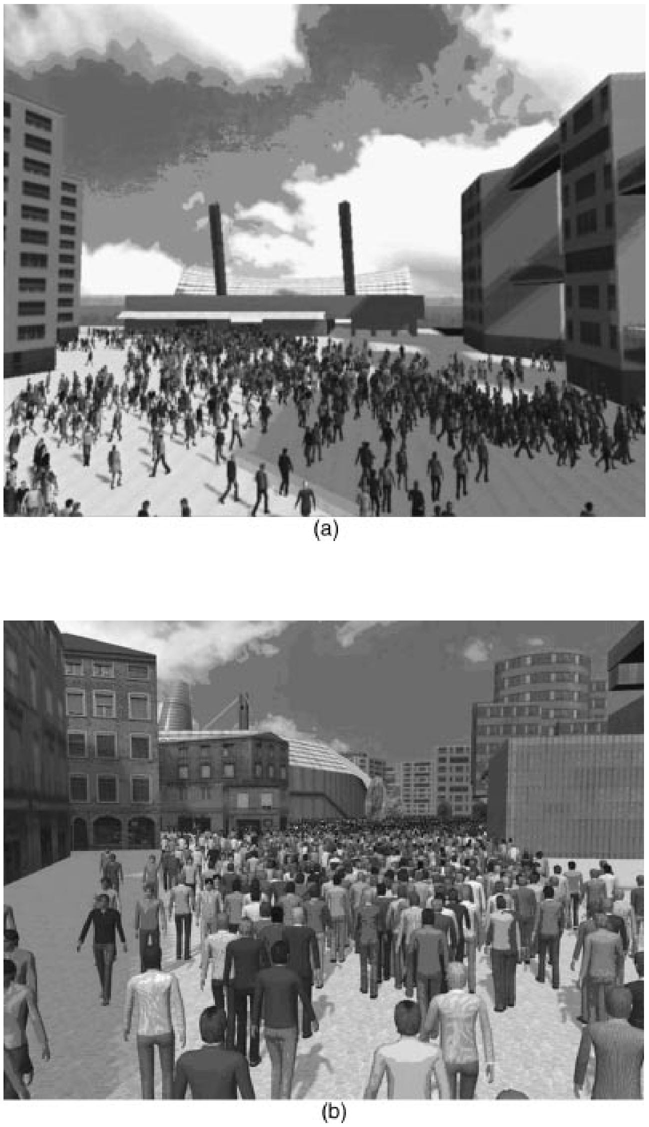

Figure 2. Two examples of large crowds.

HIGH-FIDELITY BEHAVIORS

To increase the number of simulated entities, the crowd simulation should be scalable. This function can be achieved, for example, by using behavior level-of-detail, where there are different computational demands for agents, depending on their relative position to the observer. The behavior model should then allow working with different fidelities, for example, by using iterative algorithms, or also heterogeneous crowds could be employed.

Behavior of animated characters has to obey some order. Humans have intentions and beliefs about their environment, and they almost never behave in a truly random manner. Most people plan their actions in advance with regard to the goal they are pursuing.

There are several possible approaches on how to simulate such behavior:

- **Scripting:** Scripting allows a very detailed level of control, but it is very inflexible. The virtual characters will not be able to react to the changes in their environment unless the scripts are extremely complex.
- **Reactive agents:** Virtual characters are not scripted, but they react to the changing environment according to the sets of rules (e.g., described by Badler in Ref. 46). There are few other popular techniques, e.g., BDI logic introduced by Bratman (47), cognitive modeling by Funge (48), or just simple finite state machines.
- **Planning:** Usually centralized, it tends to be inflexible in handling unexpected situations. To mitigate this to some extent, hierarchical planning is often used (49).

With the use of these three approaches, several difficulties arise: Scripting is problematic in the case of contingencies (e.g., unexpected obstacles in the path, objects being in unexpected places, etc.) and centralized planning tends to be complex, because it has to produce detailed plans for every character in the system and does not cope well with unexpected events. Reactive techniques perform usually well for single characters, but the lack of a global system state awareness hinders meaningful coordination if desired (e.g., a police squad).

These problems (contingencies, flexibility, and good level of control) can be addressed by a multilayered design, where:

- The low-level animation problems are handled by using state-of-the-art technology.
- The virtual characters have "brains," which handle the decision-making process by using classic planners. Planning on this level would allow for building goal-driven behaviors sensitive to the current situation.
- The virtual characters can communicate with each other by means of high-level communication primitives. The communication allows the virtual character to ask for help or for information. It also enables high-level communication with the user.

For example, in the ViCrowd system (50), crowds were modeled with various degrees of autonomy using a hierarchy of groups and individuals. Depending on the complexity of the simulation, a range of behaviors, from simple to complex rule-driven, were used to control the crowd motion with different degrees of autonomy (see Fig. 3). The crowd behavior is controlled in three different ways:

1) Using innate and scripted behaviors.
2) Defining behavioral rules, using events and reactions.
3) Providing an external control to guide crowd behaviors in real time.

To achieve the groups' and individuals' low-level behavior, three categories of information are used: knowledge that is used to represent the virtual environment's information; beliefs that are used to describe the internal

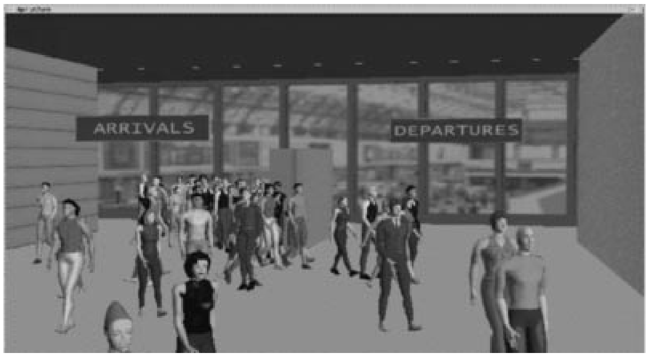

Figure 3. Crowd generated using the ViCrowd system.

status of groups and individuals; and intentions that represent the goal of a crowd or group.

Intelligence, memory, intention, and perception are focalized in the group structure. Also, each group can obtain one leader. This leader can be chosen randomly by the crowd system, defined by the user, or can emerge from the sociological rules. The crowd aims at providing autonomous, guided, and programmed crowds. Varying degrees of autonomy can be applied depending on the complexity of the problem. Externally controlled groups or guided groups no longer obey their scripted behavior, but they act according to the external specification. At a lower level, the individuals have a repertoire of basic behaviors that we call innate behaviors. An innate behavior is defined as an "inborn" way to behave. Examples of individual innate behaviors are goal-seeking behavior, the ability to follow scripted or guided events/reactions, and the way trajectories are processed and collision avoided. Although the innate behaviors are included in the model, the specification of scripted behaviors is done by means of a script language.

Perception

One key aspect in behavioral modeling is the perception of the virtual world by the virtual characters. For example, a decision should be based on the evaluation of the visual aspect of the scene as perceived by the virtual character. In a more general context, it is tempting to simulate perception by directly retrieving the location of each perceived object straight from the environment. This is of course the fastest solution (and has been extensively used in video games until the mid-1990s), but no one can ever pretend that it is realistic at all (although it can be useful, as we will see later on). Consequently, various ways of simulating visual perception have been proposed, depending on whether geometric or semantic information (or both) are considered. Conde and Thalmann (51) tried to integrate all multisensorial information from the virtual sensors of the virtual character.

Renault et al. (52) introduced first the concept of rendering-based vision, and then it was extended by several authors (53–57). In Ref. 52, it is achieved by rendering off-screen the scene as viewed by the virtual character. During the process, each individual object in the scene is assigned a different color, so that once the 2-D image has been computed, objects can still be identified: It is then easy to know which object is in sight by maintaining a table of correspondences between colors and objects' IDs. Furthermore, highly detailed depth information is retrieved from the view z-buffer, giving a precise location for each object. Rendering-based vision is the most elegant method, because it is the more realistic simulation of vision and addresses correctly vision issues such as occlusion, for instance. However, rendering the whole scene for each agent is very costly, and for real-time applications, one tends to favor geometric vision.

Bordeux et al. (58) have proposed a geometric vision consisting in a perception pipeline architecture into which filters can be combined to extract the required information. The perception filter represents the basic entity of the perception mechanism. Such a filter receives a perceptible entity from the scene as input, extracts specific information about it, and finally decides whether to let it pass through. However, the major problem with geometric vision is to find the proper formulas when intersecting volumes (for instance, intersecting the view frustum of the agent with a volume in the scene). One can use bounding boxes to reduce the computation time, but it will always be less accurate than rendering-based vision. Nevertheless, it can be sufficient for many applications, and as opposed to rendering-based vision, the computation time can be adjusted precisely by refining the bounding volumes of objects.

The most primitive approach is the database access. Data access makes maximum use of the scene data available in the application, which can be distributed in several modules. For instance, the object's position, dimensions, and shape are maintained by the rendering engine, whereas semantic data about objects can be maintained by a completely separate part of the application. Due to scalability constraints as well as plausibility considerations, the agents generally restrain their perception to a local area around them instead of the whole scene. This method is generally chosen when the number of agents is high, like in Reynolds' (7) flocks of birds or in Musse and Thalmanns (50) crowd simulation; human agents directly know the position of their neighbors and compute coherent collision avoidance trajectory.

AUTHORING

When increasing the number of involved individuals, it is becoming more difficult to create unique and varied content of scenarios with large numbers of entities. If we want to create or modify features of every individual one by one, it will soon become too laborious. If, on the other hand, we apply a set of features (either uniform or patterned) to many individuals at once, it could create unwanted artifacts on a larger scale, resulting in an "army-like" appearance with too uniform or periodic distributions of individuals or characteristics. Use of random distributions can alleviate such problems; however, it can be very difficult to capture the desired constraints into a set of mathematical equations,

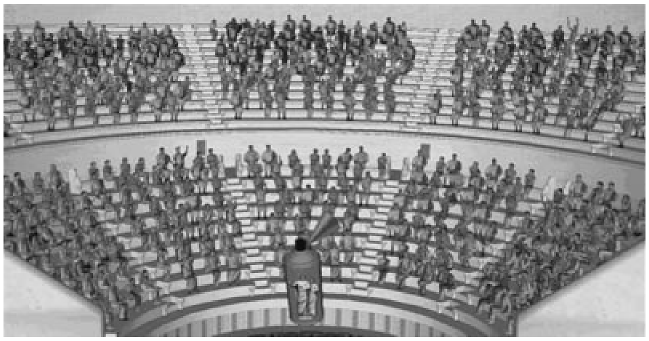

Figure 4. Crowdbrush application: The spray can is used to modify the class of Roman individuals.

especially considering integration into common art production pipelines.

Bottom-up approaches, such as local rule-based flocking (7), can create such complexity; however, they are difficult to control if we want to achieve particular end configurations (how to set local rules to get a global result). In the recent work, Anderson et al. (59) achieved interesting results for a particular case of constrained flocking animation. Nevertheless, the algorithm can get very costly when increasing the number of entities and simulation time.

Ulicny et al. (60) propose an approach that gives full creative power to designers using metaphors of artistic tools, operating on a 2-D canvas familiar from image manipulation programs working in WYSIWYG (What You See Is What You Get) mode, with a real-time view of the authored scene. The user controls the application using a mouse and a keyboard. These tools then affect the corresponding objects in a three-dimensional world space (see Fig. 4). Different tools have different visualizations and perform different effects on the scene, including creation and deletion of crowd members, changing of their appearances, triggering of various animations, setting of higher level behavioral parameters, setting waypoints for displacement of the crowd, or sending of events to a behavior subsystem. The mouse moves the visual representation of the brush tool (we used an icon of a spray can) on the screen, with the mouse buttons triggering different actions either on rendering or behavior subsystems. The keyboard selects different brushes and sets their parameters and switches between “navigate” and “paint” modes. In the “navigate” mode, the mouse controls position and orientation of the camera. In the “paint” mode, the camera control is suspended and the different areas on the screen are selected depending on the pressed mouse button. The selection areas can be, in principle, any arbitrary 2-D shape. This area is then further processed by the brush according to its particular configuration and a specific operator. For example, a stroke of the creation brush with the random operator would create a random mixture of entities or a stroke of the uniform color brush would set colors of affected individuals to the same value.

CONCLUSION

For many years, this was a challenge to produce realistic virtual crowds for special effects in movies. Now, there is a new challenge: the production of real-time truly autonomous virtual crowds. Real-time crowds are necessary for games, VR systems are necessary for training and simulation, and crowds are necessary in augmented reality applications. Autonomy is the only way to create believable crowds reacting to events in real time.

HIGH-QUALITY TEXTURE MAPPING AND RENDERING OF POINT MODELS

POINT-BASED RENDERING

For over a decade since their introduction, points have been explored as alternatives to triangle meshes for geometry modeling and rendering (1). They have recently received increasing attention from the computer graphics community and gained a lot of popularity because of the wider availability of three-dimensional (3-D) acquisition devices. Based on their fundamental simplicity, points have been shown to be flexible and efficient in representing highly detailed features on complex objects. Directly working on point-based geometries greatly simplifies content creation, surface reconstruction, and rendering, as no connectivity or topological constraints exist.

Many point-based rendering algorithms focus on efficiency using hardware acceleration. Emphasis has also been placed on high-quality rendering. The surface splatting technique (2) and differential points (3) techniques have been proposed for high-quality surface rendering. Alexa et al. (4) control the fidelity of the representation by dynamically adjusting the density of the points. Zwicker et al. (5) introduce the elliptical weighted average (EWA) filter to increase the rendering quality for point-based rendering. Recently Botsch et al. (6) proposed Phong splatting to generate superior image quality, which bases the lighting of a splat on an associated linearly varying normal field. Schaufler and Jensen introduced ray tracing of point-based geometry (7). Their approach renders high-quality ray-traced images with global illumination using unstructured point-sampled data, thus avoiding the time-consuming process of reconstructing the underlying surface or any topological information. Intersections with the point-sampled geometry are detected by tracing a ray through the scene until the local density of points is above a predefined threshold. They then use all points within a fixed distance of the ray to interpolate the position, normal and any other attributes of the intersection. A deferred shading technique (8) has been proposed for high-quality point-based rendering, providing per-pixel Phong shading for dynamically changing geometries and high-quality anti-aliasing.

As in triangle-based rendering, texture mapping can be an effective technique to enrich visual reality in renderings of point models. Textures can be directly generated by a 3-D painting and editing system (9). In 3-D scanning, high-resolution photos are often acquired when lower resolution scans are conducted. Existing approaches couple geometry and texture information at each point; a point has both geometry coordinates and a color. In Surfels (2), Pfister et al. store prefiltered texture colors of the Surfel mipmap in the layered depth cube (LDC) tree and perform linear interpolation during rendering. As existing methods assign one color to each point, photos (textures) are downsampled to match the resolution of the point set. In this process, high-frequency texture information is permanently lost.

Ren et al. (10) propose the use of textured polygons when textures are mapped to each point splat and are blended through splatting. The proposed object space EWA splatting uses a two-pass rendering algorithm. In the first rendering pass, visibility splatting is performed by shifting opaque surfel polygons backward along the viewing rays, whereas in the second rendering pass, surface polygons are texture mapped, deformed, and rendered through view-dependent EWA prefiltering.

MOTIVATION OF HIGH-QUALITY TEXTURE MAPPING ON POINT-BASED MODELS

Texture mapping enhances the visual richness of rasterized images with a relatively small additional computation cost. It has been one of the most successful techniques developed in computer graphics for high-quality image synthesis since its birth in 1970s.

Textures were originally developed for mesh or polygonal models. In its basic form, a texture (an image) is mapped to a simple geometry shape, which allows arbitrarily complicated color details of the surface to be rendered without additional mesh resolutions. One typical example is mapping a brick texture to a simple rectangle to resemble the details of a wall.

Besides color, other values can be mapped such as specular reflection, normal vector perturbation (bump mapping), and surface displacement. For additional reading on texture mapping topic, readers can refer to Heckbert's survey paper and Wolberg's book in the reading list.

With the recent rapid advancement of laser range scanning techniques, acquisition of real objects (both geometry and appearance) is becoming common, leading to an increasing number of point-based models. When scanning small-to middle-size objects, it is practical to scan a large number of points to densely sample the object details. In this case, the point density of scans can match up with the pixel resolution of photographs that represent the details of the objects. When scans and photographs are registered together, color information is assigned to each point. However, for large outdoor environment scanning, because of the limitations of the scanning device and the constraints of the scanning process, the acquired point resolution is usually far below the typical resolution of a digital photograph. For example, the resolution of a photo can be more than ten times higher than that of a laser scan. In these cases, it is more desirable to perform authentic texture mapping on point models, i.e., assigning texture coordinates to each point so that texture colors in between points can be looked up, instead of directly assigning a color to each point.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

INTERPOLATION VS. COMPUTATION ORDER

In computer graphics, interpolation is an important operation across the entire rendering pipeline. Interpolation can be performed either before or after a function evaluation (or table lookup), corresponding to either preinterpolation or postinterpolation, respectively. In the following discussion, we review several important graphical operations or visualization procedures that have featured alternative methods depending on when the interpolation is conducted. Within this framework, our TSplatting performs interpolation on texture coordinates before color lookup, which is an alternative to directly interpolating colors, as is performed in conventional point splatting.

Preshaded vs. Postshaded Volume Rendering

Volume datasets consist of sample points defined at 3-D grids. In volume rendering, volumes are resampled and each sample's color is computed and contributed to the final image through compositing. Volume rendering algorithms can be classified as preshaded and postshaded according to where the volume resampling (interpolation) takes place. In preshaded algorithms (11), original volume samples at grids are first classified (through transfer function lookup) and shaded before they are resampled. Instead, postshaded volume rendering algorithms (12,13) first resample (interpolate) raw volume samples and then perform transfer function lookup and shading using the resampled values. Thus, postshaded methods conduct preinterpolation, whereas preshaded methods conduct postinterpolation. Because both transfer function lookup and shading are nonlinear functions, the resulting images from the two approaches are different. Although consensus still does not exist on which method is superior, in general, images generated from the preshaded methods result in blurry images and loss of fine geometry details, whereas the postshaded methods produce sharper features in generated images. On the other hand, preshaded methods can be more efficient when super-sampling of volumes is performed for generating higher resolution images because less effort is spent on transfer function lookup and shading.

Gouraud vs. Phong Shading

When rendering polygon meshes, Gouraud shading (14) and Phong shading (15) are two major shading algorithms for local illumination. Gouraud shading performs a lighting calculation at each vertex and then interpolates among vertices to obtain pixel colors within the projection of each polygon. Instead, Phong shading first interpolates normals across the polygon facet and then a lighting calculation is performed based on the interpolated normal to obtain pixel color. Here, Phong shading does preinterpolation, whereas Gouraud shading does postinterpolation. Because of the normal interpolation before the lighting evaluation, Phong shading produces specular highlights that are much less dependent on the underlying polygons than Gouraud shading does. On the other hand, Phong shading is more expensive than Gouraud shading.

Surfels vs. Phong Splatting for Point-Based Rendering

Similar to polygon-based rendering, point-based rendering can also be classified as preinterpolation versus postinterpolation methods. In Surfels (2), each point is treated as a flat disk with a single normal direction. Points are first flat-shaded before composition. Alternatively, Phong splatting (6) generates superior image quality by first interpolating normals among points using point splatting and then deferred shading by evaluating lighting at each pixel using the interpolated normals. In this case, Phong splatting is a preinterpolation method, whereas Surfels is a postinterpolation method. An in-between method is rendering using differential points (16), in which normals in the vicinity of a point are extrapolated based on the local differential geometry of the point and are then used to calculate the lighting of the point disk; these shaded point disks are finally blended together as done in Surfels.

Color Splatting versus Texture Splatting for Texture Mapping Points

The operation of mapping textures on points can be achieved in alternative approaches falling in the preinterpolation and postinterpolation framework. In conventional methods of texture mapping points, the color of each point is first looked up using its predefined texture coordinates and is then splatted and composited with adjacent point splats similarly computed. This method is referred to as color splatting by us. In our texture splatting (TSplatting), texture coordinates, instead of color, are splatted and composited followed by a deferred texture lookup of each screen pixel to obtain pixel colors. Based on the interpolation order, TSplatting belongs to preinterpolation while color splatting belongs to postinterpolation. We will see that TSplatting produces superior image quality than that of color splatting.

We summarize the afore-mentioned methods in Table 1. In general, postinterpolation methods are computationally less expensive but generate lower image quality than do preinterpolation methods. Next, we provide additional discussion on our TSplatting algorithm, which is a preinterpolation method.

TSPLATTING—A POINT-BASED HIGH-QUALITY TEXTURE MAPPING FRAMEWORK

Motivated by the above requirements, a novel framework of high-quality texture mapping of point-based models, *TSplatting*, is developed (17). The general two-pass point-based rendering pipeline is modified into a three-pass pipeline. The first two steps are very similar to a conventional point-based rendering pipeline except that the color of each point is replaced with its texture coordinates. The texture lookup operation is deferred to a third pass through a per-pixel texture lookup for all screen pixels. In addition, advanced techniques like bump mapping and texture-based lighting can be implemented. This method is capable of rendering point models with much higher texture resolution than that of the point model itself without resorting to meshing or triangulation. As a result, a

Table 1. Comparison of Algorithms with Order Switch of Computation and Interpolation in Different Operations

Operation	Variable	Function	Postinterpolation	Preinterpolation
Volume rendering	Volume density	Classification	Preshaded	Postshaded
Polygon shading	Normal	Lighting	Gauraud shading	Phong shading
Point shading	Normal	Lighting	Surfels	Differential points Phong splatting
Point-based texture mapping	Texture Coordinate	Texture Lookup	Color splatting	TSplatting

significant improvement in rendering quality occurs. This decoupling of geometry and texture facilitates perceptually guided point simplification by leveraging texture masking effects in achieving uncompromised final image quality (18). These texture mapping results can be potentially achieved in Botsch et al. 's deferred shading framework (8) by encoding texture coordinate information in the attribute pass and performing a texture lookup in the shading pass. Here we describe the explicit design and implementation of this framework. We then point out several important issues raised in this seemingly straightforward process and describe solutions to them.

FRAMEWORK OVERVIEW

The *TSplatting* framework maps high-resolution textures onto point models of lower spatial resolution. The pipeline of the framework is illustrated in Fig. 1.

As mentioned, point-based models are rendered in two passes. In the first pass, points are rendered as opaque disks to obtain a visibility mask. The points that pass the visibility test are then rendered using splatting techniques in the second pass (2,10). Adjacent splats are overlapped to ensure no holes are on the rendered surface. The color of each splat is blended with that of its neighbors based on the opacity values modulated with a low-pass Gaussian filter.

In *TSplatting* framework, a three-pass rendering is employed to texture map point-based models. Instead of splatting colors for each point, texture coordinates are used in the second pass and one additional pass for texture lookup is added. The texture coordinate interpolation in the second pass is the key for mapping high-resolution textures onto sparse points. The three rendering passes are illustrated in Fig. 1 and are explained below.

Pass 1: Visibility Computation

In the first pass, a visibility mask is generated by rendering point splats as opaque disks. To ensure hole-free surfaces, the projection size of each point is suitably calculated.

Pass 2: Texture Coordinate Splatting

In this pass, each point is splatted by replacing color with texture coordinates. Texture coordinates between points are blended and automatically interpolated by graphics hardware.

Pass 3: Per-pixel Texture Look-up

In this pass, texture coordinates encoded in each screen pixel are used to look up the high-resolution texture image. Lighting can also be incorporated by modulating the texel color with the lighting coefficients.

TEXTURE COORDINATES SPLATTING

One of the main contributions of the *TSplatting* framework is the use of deferred shading for splatting in the second rendering pass and the subsequent texture lookup. In the following discussion, we provide an analysis and justification of using texture coordinates splatting in achieving high texture mapping quality.

In point splatting (5,10), objects are represented by a set of points $\{P_k\}$ in object space. Each point is associated with a radially symmetric basis function r_k and color coefficient w_k. With texture mapping, each point also has a texture coordinate coefficient v_k. Elliptical Gaussians are normally chosen as basis function r_k, and the prefilter is h. The

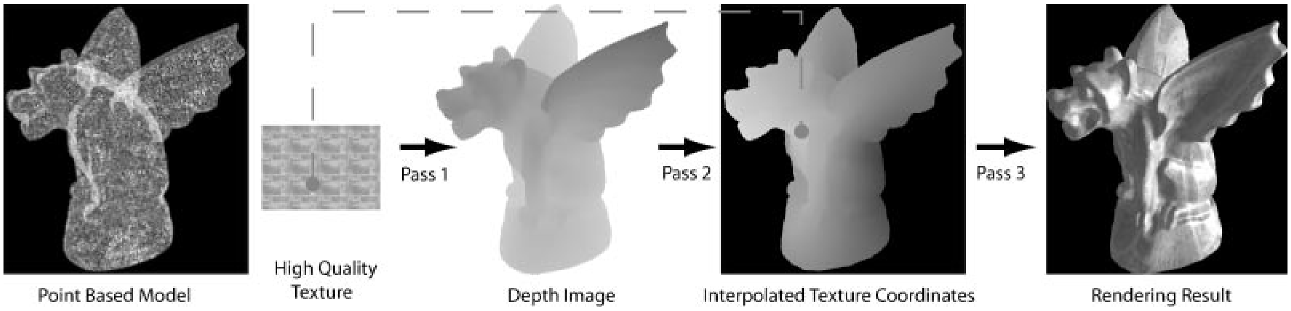

Figure 1. *TSplatting*. During rendering, texture coordinates between points are interpolated by graphics hardware. In the final step, a per-pixel texture look-up is performed to fetch colors from high-resolution textures.

splatting output $g_c(\mathbf{x})$ at screen position $\mathbf{x}$ can be expressed as a weighted sum of resampling filters $\rho_k(\mathbf{x})$:

$$g_c(\mathbf{x}) = \sum_{k \epsilon N} w_k \rho_k(\mathbf{x}) \tag{1}$$

$\rho k(\mathbf{x})$ is a convolution of the basis function r_k and prefilter h. The detailed definition of $\rho_k(\mathbf{x})$ can be found in Ref. 10. Color w_k is precomputed by texture prefiltering (5). According to the Nyquist theorem, the prefiltering results in a loss of texture details with frequency higher than the point model sampling rate.

Although the texture coordinate coefficient v_k normally varies gradually over the points, their corresponding textures may contain high-frequency details. In *TSplatting*, a reconstruction of texture coordinates $g_t(\mathbf{x})$ is first computed in the screen space (pass 2):

$$g_t(\mathbf{x}) = \sum_{k \epsilon N} v_k \rho_k(\mathbf{x}) \tag{2}$$

As the local parameterization is normally smooth, the loss of $g_t(\mathbf{x})$ during the splatting reconstruction is minimal.

In the subsequent stage (pass 3), each screen pixel obtains its color information through a resampling of the texture, in contrast with color splatting where each pixel color is obtained by a direct interpolation among colors of an adjacent point.

In the second rendering pass, texture coordinates are rendered as color attributes for each point. As the point size increases, texture splats overlap and smooth interpolation between splat centers is performed by assigning a Gaussian kernel (representing opacity) to each splat and the adjacent splats are composited together. Smoothly interpolated texture coordinates ensure a faithful mapping of the high-resolution texture. Note that, along boundaries, textures are deformed because of a lack of neighboring points for blending. A solution to this issue will be discussed later in this article.

Various experiments show that the *TSplatting* method (TS) provides much higher quality texture mapping than the normal color splatting methods (CS). In Fig. 2, a texture is mapped to point-based vase models with various resolutions. Figure 2(a) and (b) are vase models, with 10K and 35K points, respectively, rendered by the TS method. Figure 2(c)–(e) are rendered by traditional CS, with model sizes ranging from 10K to 560K. The rendering quality of the point model with only 35K points using the TS method [Fig. 2 (a)] is comparable with that of the 560K point model rendered with CS [Fig. 2 (e)]. Images in the second row are the close-ups (128×128) of the corresponding first row images. The last row shows the individual points of each model. Only when the point resolution is close to the image pixel resolution does the rendering quality of CS start to match up with the quality of the TS.

Figure 3 demonstrates the TS results by applying various high-resolution textures to a torus model. This torus model has 22,321 points. The texture resolutions are around 1024×1024. Per-pixel lighting is applied in the rendering. Figure 4 shows applying bump mapping with TS. The bump map shown in the upright corner is created using the NVIDIA Normal Map Filter.

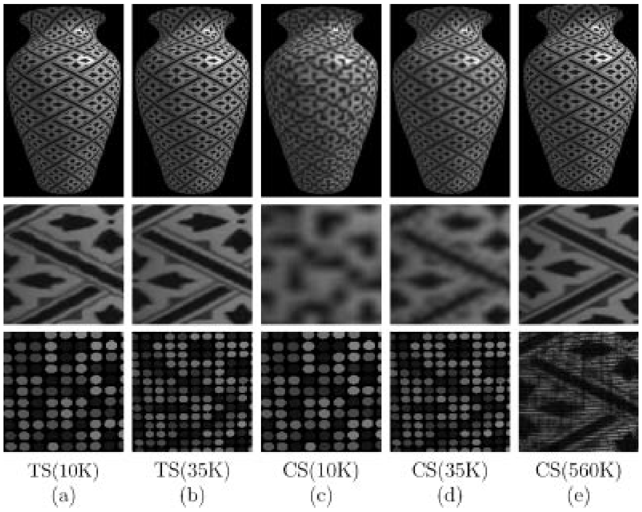

Figure 2. Comparison of *TSplatting* with traditional color splatting on points. Images (a) and (b) depict models rendered by the TS method and have 10K and 35K points, respectively. Images (c)–(e) are rendered by traditional CS. The image quality resulting from color splatting increases when the number of points increases (from 10K to 560K). Images in the second row are the corresponding close-ups of the rendered images in the first rows. The last row shows individual points in each model.

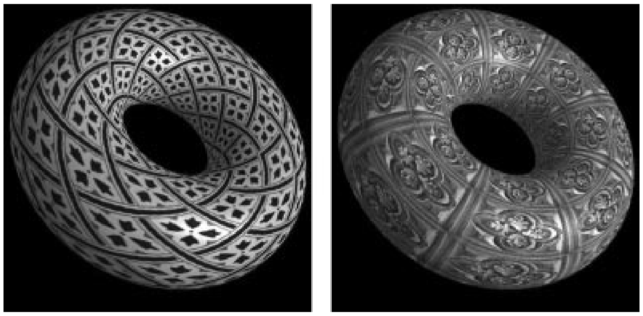

Figure 3. Various textures are applied to a torus model with the *TSplatting* method.

ADVANCED RENDERING ISSUES

We discuss solutions to several issues to achieve high-quality texture mapping on points at different viewing resolutions and texture/object boundaries.

Anti-aliasing—Mipmapping

Similar to mesh rendering, aliasing occurs when texels are minimized (i.e., one texel projects to less than one pixel size on screen) during texture mapping. The rendering must be appropriately anti-aliased to achieve high-quality results.

In the TS framework, conventional anti-aliasing methods can be naturally integrated. The mipmapping function (19) supported by OpenGL is used to achieve anti-alaising. To this end, an image pyramid is created for each input texture using the OpenGL command **gluBuild2DMipmaps** without explicit computation in the shader. In the last rendering pass, for each fragment, the appropriate level

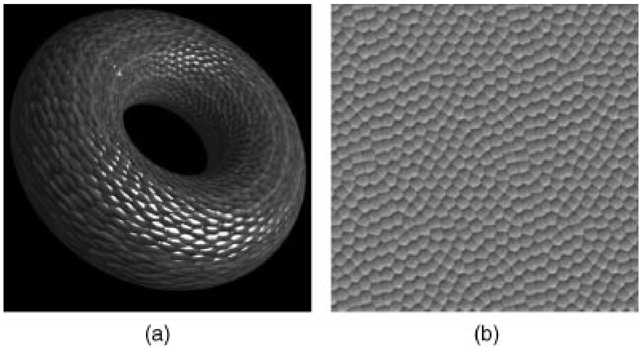

Figure 4. Bump mapping by *TSplatting*. (a) Rendered image. (b) Bump map texture.

of textures will be computed automatically by hardware and used for look-up. Effectively, no extra coding is needed for the anti-alisasing except changing the OpenGL status and building the texture pyramid.

Boundary Issues

When directly applying texture coordinate interpolation to a point model at the object boundaries, artifacts may appear in two situations: along the model boundaries because of lack of texture blending and at the locations where the texture coordinates change discontinuously [Fig. 5(b), marked by a yellow rounded rectangle]. Texture coordinates may be inappropriately interpolated along the discontinuity (boundary) of texture coordinates. Direct interpolation between the splats on the opposite sides of the texture coordinate discontinuity will result in a blur of the whole spectrum of the texture coordinates along the boundary.

To remove such rendering artifacts, it is necessary to limit the footprint of the boundary splats. We adapt the techniques to render sharp features by explicitly representing boundaries or discontinuity features as clip lines (20).

The mathematical setup of a clipping scheme is illustrated in Fig. 5(a). For each point, at most two clipping lines in each point's local texture coordinate are specified in the form of

$$A_i x + B_i y + C_i = 0 \tag{3}$$

A_i, B_i, and C_i (i = 1,2) are line parameters. The local texture coordinate is defined by the two-texture parameter vector du and dv. The point's center is the origin. Each line divides a plane containing the point splat into two parts. The region where

$$A_i x + B_i y + C_i < 0 \tag{4}$$

is defined to be clipped. Line parameters are passed to hardware together with other attributes of each point. During rendering, each fragment is checked with its value according to Equation (4). Figure 5(a) shows an example with two types of boundaries. The first is the point model boundary. The second is the texture coordinate discontinuity. Without clipping [Fig. 5 (b)], texture coordinates are blended across the boundary and artifacts are introduced. With clipping [Fig. 5 (c)], points along boundaries are represented as clipped points and are free from artifacts. With the solution for boundary problems, TS framework can also accommodate texture atlases.

CONCLUDING REMARKS

TS provides a novel framework for high-quality texture mapping on point-based models without connectivity information. It is capable of mapping a low-resolution point-based model with high-resolution textures. The texture coordinates of neighboring splats are interpolated, and the resulting smooth texture coordinate field in the screen space is used to look up the pixel colors. In this way, point

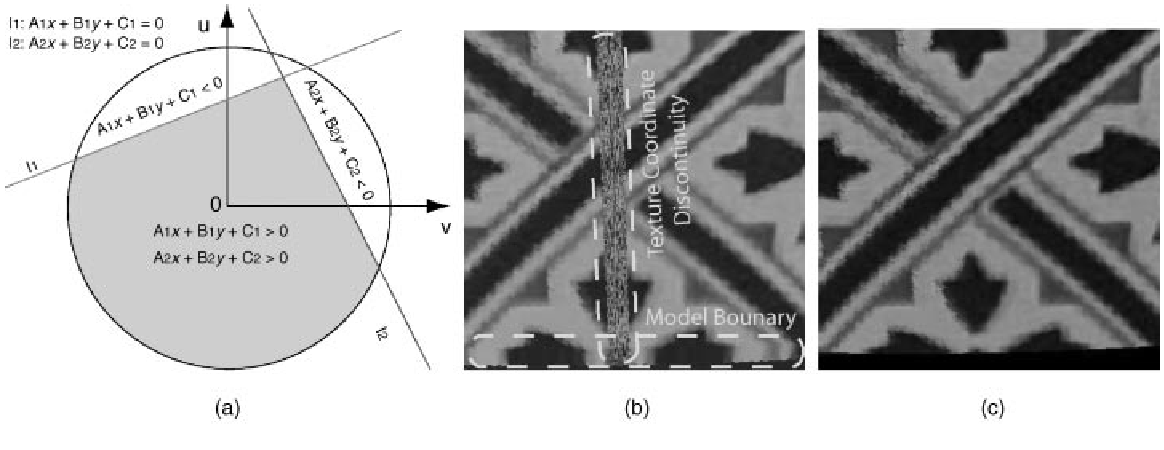

Figure 5. Clipping for points along boundaries. (a) For each point splat, up to two optional clipping lines are specified. Artifacts are marked by dotted yellow rectangles. (b) Clipping disabled. (c) Clipping enabled.

models with much higher texture resolution than that of the point model can be rendered.

LIGHTING

All we see around us is due to light. If we want to generate synthetic images that look like reality with a computer, we need to simulate how light behaves: How it leaves its sources, how it is reflected on objects, and how it is attenuated in the fog before it finally enters the eye and lands on the retina or enters the camera lens and excites the film. We need to perform *lighting* simulation. Studying the interaction of light with objects for the purpose of image generation has a long history in art and has been experiencing a huge revival in the last 40 years in the field of computer graphics. The more realistic and more quickly generated the synthetic images are, the more applications they find. Computer graphics is being used in instruction and training, industrial and artistic design, architectural walkthroughs, video games, the film industry, and scientific visualization.

The goal of lighting simulation is to generate images that look like reality. To achieve this effect, one needs to start with a faithful description of the environment being simulated, which is the stage of *modeling*, in which one has to specify the geometry of all objects in the scene (objects' shapes, positions, and sizes), optical properties of their surfaces (reflection, transmission, etc.), positions and emission properties of light sources, and, finally, the position and properties of the virtual camera. After the modeling stage, the virtual scene is ready for simulation of light transport (i.e., for simulation of the way light propagates in the scene). After simulation is done, we can take the scene's synthetic snapshots, which is also called image rendering. Often, the rendering stage and light transport simulation steps are combined into a single stage. In this case, the light simulation is restricted to finding how much light from the visible scene is ultimately reaching the sensors in a virtual camera.

The distribution of light in space, generated by various light sources, may vary significantly. Sun gives very intense rays of light originating from a single point. Such light will cause very definite shadows with hard edges. An overcast sky emits a very different light field—the light rays originate from all the positions over the sky dome and is distributed more or less uniformly in space. If such light generates any perceptible shadows at all, they will not manifest themselves as more than a dark and blurry smudge on the ground around an object.

Light goes through many interactions with scene objects before it reaches our eyes. Depending on the object shapes and their reflectance properties, light propagation creates various patterns and phenomena so well known from our everyday life. A matt wall reflects light *diffusely*, which means that it scatters light in all possible directions. Diffuse reflections often lead to the phenomenon called *color bleeding* (Fig. 1a, see the reddish tinge on the left part of the dragon's body), when a diffuse object lends its color tone to another diffuse object. *Caustics* are another well-known phenomenon, most often seen on a table under an interestingly shaped glass (Fig. 1b). It is formed by a light reflected by a shiny (specularly reflecting) object or refracted by a transparent object and focused on a diffuse receiver.

The goal of lighting is to simulate the light propagation in the scene to be able to reconstruct all the aforementioned phenomena such as hard and soft shadows, mirror reflections, refractions, color bleeding, and caustics. Today a large variety of lighting algorithms is available in computer graphics, differing by the degree to which they can faithfully simulate those phenomena. This article will give a short overview of those algorithms. Nowadays, there is a strong trend toward using physically plausible (or at least physically motivated) algorithms for lighting simulation. Therefore, before we delve into the workings of those algorithms, we will have to be more formal and define some physical quantities related to light propagation.

Lighting simulation is one of the tools used in a subfield of computer graphics called *image synthesis* or *rendering*. There are rendering techniques that do not use lighting simulation at all. Those techniques try to render objects in an expressive, artistic way, artificially stressing some of the objects' features. They are usually referred to as *non-photorealistic rendering* (NPR) techniques. Computer software for image synthesis is called a *renderer*.

A thorough treatment of lighting simulation with the focus on the underlying physics is given in Ref. 1. A more easily accessible, implementation-oriented description of lighting simulation is given in Refs. 2 and 3.

RADIOMETRY

Light is a form of energy. The amount of light energy in unit time is described by *radiant flux* Φ measured in Joules per second or Watts (W). To better localize the radiant flux in space, we use *irradiance* $E(P) = \frac{\mathrm{d}\Phi(P)}{\mathrm{d}A}$, which describes flux per unit area arriving at an infinitesimal surface area *around point* P from all possible directions. Irradiance is measured in Watts per square meter [$\mathrm{W{\cdot}m^{-2}}$]. *Radiant exitance* (or *radiosity*) B is the same as irradiance but describes the light *leaving* an infinitesimal surface area.

To be able to localize the flux not only in space but also in directions, we need to define solid angle and differential solid angle. Similar to its counterpart in plane, *solid angle* measure the span of a set of directions in space. Formally, the solid angle subtended by an object from a point P is the area of the projection of the object onto the unit sphere centered at P. *Differential solid angle* $\mathrm{d}\omega$ is an infinitesimally thin cone of directions around a considered direction. Radiant flux density in directions is given by *radiant intensity*, $I(\omega) = \frac{\mathrm{d}\Phi(\omega)}{\mathrm{d}\omega}$. Intensity, flux per unit solid angle, is mostly used to describe light leaving a point light source.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

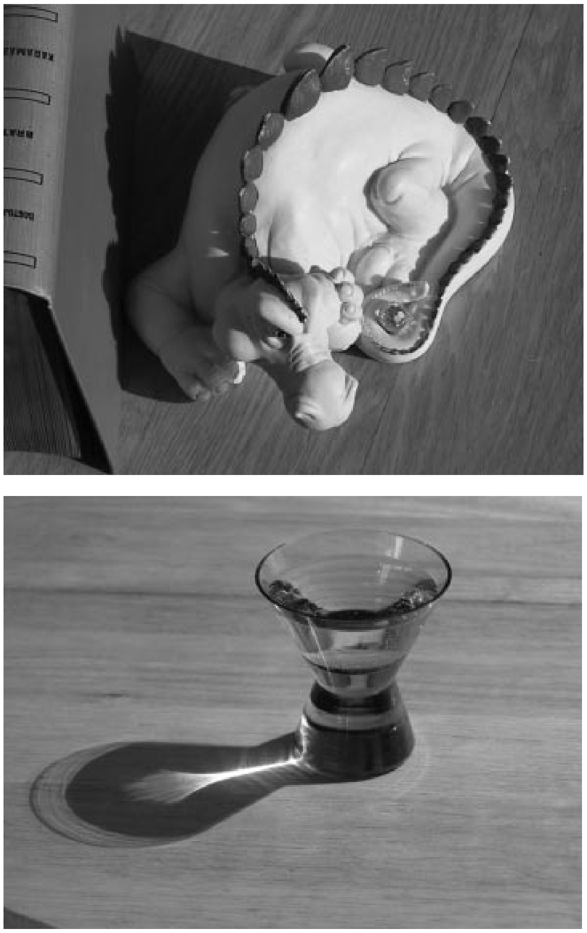

Figure 1. Complex light phenomena. *Color bleeding* (a) is due to diffusely reflected light landing on another diffuse surface. Here, the red book reflects light onto the dragon, effectively "transferring" the red color from the book to the back side of the dragon. *Caustics* (b) are patterns of light focused by reflections or refractions on a specular surface, landing on a diffuse object. Here, the green glass focuses the light onto the wooden table.

The physical quantity used to describe light energy distribution in space and in directions is *radiance* (Fig. 2), defined as $L(P,\omega) = \dfrac{\mathrm{d}\Phi(P,\omega)}{\mathrm{d}A\cos\theta\mathrm{d}\omega}$, that is radiant flux per unit *projected* area perpendicular to the considered direction, per unit solid angle. θ is the angle between the surface normal of the surface and the given direction. The term $\cos\theta$ in the denominator of the radiance equation converts the differential area to the *projected* differential area and makes a unit amount of radiance represent the same amount of light power reaching a surface independent of the surface's orientation.

Radiance is the most important quantity for lighting simulation for two reasons. First, it is the value of radiance and not any other radiometric quantity, which directly determines the intensity of light perceived by human observer or recorded on a photographic film.

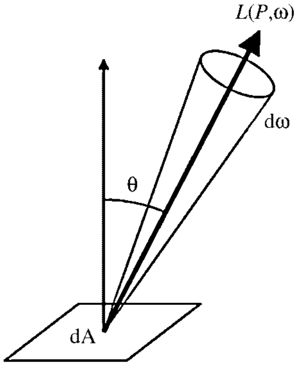

Figure 2. Radiance is radiant flux per unit projected area perpendicular to the considered direction per unit solid angle.

> *The ultimate goal of lighting simulation is to determine the value of outgoing radiance in the direction of the virtual camera for all visible points in the scene.*

Second, radiance is constant along rays in space (see Fig. 3).

> *The value of incoming radiance arriving at a point P from the direction ω is the same as the value of outgoing radiance leaving point Q (directly visible from P along ω) in the opposite direction $-\omega$.*

For these reasons, radiance is the most suitable quantity for computing energy transfer between surfaces in terms of straight rays transferring the light energy, which corresponds to the treatment of light propagation in *geometric optics* adopted by the vast majority of lighting simulation

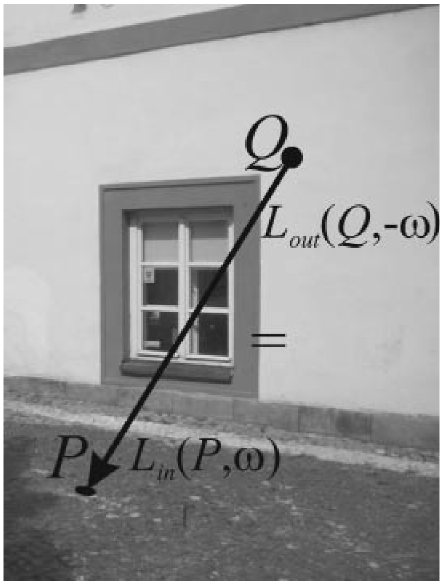

Figure 3. Radiance is constant along rays in space. The value of incoming radiance arriving at a point P from the direction ω is the same as the value of outgoing radiance leaving point Q (directly visible from P along ω) in the opposite direction $-\omega$.

algorithms: *Light propagates along straight lines until it hits an object and gets reflected*.

COLOR TREATMENT

Radiometric quantities are, in general, functions of light wavelength λ—they are spectral quantities. A spectrum of visible light is perceived as a color. The tri-chromatic nature of the human visual system (HVS) allows us to reproduce this color by a linear combination of three spectrally independent primary colors that are termed red, green, and blue (RGB) color (see the article on Color). In a lighting simulation software, the value of a radiometric quantity is thus represented by a 3-D vector corresponding to the three primary colors. This description of the spectral distribution of light energy is sufficient for simulating most of the perceivable lighting phenomena. However, some phenomena, such as dispersion, require performing the lighting simulation with the full spectrum representation and converting to RGB at the end of the simulation before the image display.

LIGHT SOURCES

Several different light source models are used for lighting simulation, some are completely abstract, others correspond to physical light emitters (see Fig. 4). *Point light*, a commonly used light source, emits all the light energy from a single point. The emitted light is expressed by *radiant intensity I*, which is the flux per unit solid angle in a given direction. The emission of a point light source is fully described by the *goniometric diagram*, a diagram of radiant intensity as the function of direction. An *omnidirectional point light* emits light equally in all directions (the goniometric diagram is constant). *Spot light* is a special type of point light source that emits only in a cone of directions around an axis. Even though point light sources do not exist in reality, they are very popular in lighting simulation, because they are very simple to handle and hence make the lighting simulation efficient. Another abstract light source type is *directional light*, which emits the light in parallel rays. It can be considered a special case of point light source where the point is at infinity. Point and directional light sources cast very sharp shadows.

Area light source refers to a 3-D object emitting light, a model that directly corresponds to physical luminaires. Emission of an area light source is described by the *emission distribution function* (EDF), which describes the outgoing radiance as a function of position on the light source and outgoing direction. Most common area light sources are rectangular or spherical lights with constant radiance over the surface position and direction. Area lights provide softer shadows than point light sources but are computationally more demanding.

Light probe image or *environment map* is a record of real world illumination at a point from all directions that can be used as a light source. Acquisition and illumination by light probe images is called image-based lighting and is described in a separate paragraph below.

LIGHT REFLECTION, BRDF, SHADERS

Light rays travel in straight lines in space until they hit the surface of an object, when the light gets either absorbed (changes into heat) or reflected. The way an object's surface reflects light defines the object's appearance: apparent color, glossiness, roughness, and so on. The color is a result of the spectral composition of the reflected light—some wavelengths get reflected more than others. Glossiness, roughness, specularity, and so on depend on the angular characteristics of the reflected light. Some materials reflect light in preferred directions (e.g., a mirror reflects only according to the Law of Reflection), others scatter the light in all directions (e.g., matte paints). The reflection behavior of a surface is described by the *bidirectional reflectance distribution function* (BRDF), which, for a given incoming direction ω_{in} and an outgoing direction ω_{out}, is the ratio of the differential irradiance due to the light incident from ω_{in} and the radiance reflected to ω_{out}, (Fig. 5a). Formally

$$f_r(P, \omega_{in}, \omega_{out}) = \frac{\mathrm{d}L_{out}(P, \omega_{out})}{L_{in}(P, \omega_{in}) \cos\theta_{in} d\omega_{in}}$$

In general, the BRDF is different for each point on a surface; it is a function of position: $f_r(P, \omega_{in}, \omega_{out})$. The position dependence of the BRDF creates the surface's characteristic visual texture.

BRDF defines the surface appearance and, therefore, it is at the heart of all rendering algorithms. It has to be evaluated for each visible point in the scene because it converts the light arriving at that point from the light sources (direction ω_{in}) into the light directed toward the eye (direction ω_{out}). Renderers make use of a small routine, called a *shader*, which uses the BRDF to compute the

amount of light reflected along an outgoing direction due to the light incident from one or more directions. Each object in the scene has a shader assigned to it depending on the desired reflectance properties.

BRDF Properties

A physically plausible BRDF must satisfy three fundamental properties. First, BRDF is a non-negative function. Second, BRDF is reciprocal, that is to say the BRDF value does not change if the incoming and outgoing directions are interchanged [i.e., $f_r(\omega_{in}, \omega_{out}) = f_r(\omega_{out}, \omega_{in})$]. Third, BRDF is energy conserving (i.e., a surface cannot reflect more than the amount of incident light).

BRDF Types

The BRDF functions are as wildly varying as are the appearances of objects in the real world. A *diffuse (Lambertian) BRDF* describes matte objects that reflect light uniformly in all directions. No matter where the light comes from, it is reflected uniformly along all directions in the hemisphere above the surface point. Diffuse BRDF is constant, $f_r^{diffuse}(\omega_{in}, \omega_{out}) = \frac{k_d}{\pi}$, where $0 \leq k_d \leq 1$. *Specular BRDF* describes a mirror surface, which only reflects light according to the Law of Reflection (angle of reflection is equal to the angle of incidence) and the reflected radiance is a constant fraction of the outgoing radiance. Apart from those two special cases, there is a wide range of *glossy* or *directional diffuse* BRDFs that can have completely arbitrary properties. Most commonly, the light is directed around the direction of perfect specular reflection, but it can also be reflected back toward the direction of incidence (retro-reflective materials). Real BRDFs are usually modeled by a sum of diffuse, specular, and glossy components (Fig. 5b).

BRDF Models

For the purpose of lighting simulation, general BRDFs are usually described by a mathematical model, parameterized by a small number of user settable parameters. The most common is the *Phong model*, whose physically plausible form is $f_r^{phong}(\omega_{in}, \omega_{out}) = k_d + k_s \cos^n \alpha$, where α is the angle between the mirror reflection direction ω_r of ω_{in} and outgoing direction ω_{out}. The user sets k_d (diffuse reflectivity—determines the surface color), k_s (specular reflectivity—determines the intensity of specular highlights), and n (specular exponent, or shininess—determines the sharpness of specular highlights). Many other BRDF models exist, see Refs. 1 or 3 for some examples.

BRDF Extensions

BRDF describes the reflection of light at one point. The model assumes that all light energy incident at a point is reflected from the same point, which is not true in the case of *subsurface scattering*, where the light energy enters the surface at one point, is scattered multiple times inside the material and leaves surface at a different point. This reflection behavior is exhibited by human skin (think of the frightening red color in one's face if he or she positions a flashlight under his or her chin), marble, milk, plant tissues, and so on. Reflection behavior of those materials is described by the *bidirectional surface scattering (reflectance) distribution function* (BSSDF).

DIRECT ILLUMINATION

Once the emission, geometry, and reflection functions of scene objects are specified, the light transport in the scene can be simulated. Real-time graphics (e.g., in video games) use the lighting simulation that disregards most of the interactions of light with scene objects. It only takes into account the so-called *direct illumination*. For each visible surface point in the scene, only the light energy coming *directly* from the light source is reflected toward the view point. The direct lighting simulation algorithm proceeds as follows.

For each image pixel, the scene point visible through that pixel is determined by a hidden surface removal algorithm [most commonly z-buffer algorithm (4)]. For a visible surface point P, the outgoing radiance $L_{out}(P, \omega_{out})$ in the direction of the virtual camera is computed by summing the incoming radiance contributions from the scene light sources, multiplied by the BRDF at P:

$$L_{out}(P, \omega_{out}) = \sum_{i=1}^{\#lights} L(Q_i \to P) \cdot f_r(P, Q_i \to P, \omega_{out}) \cdot \cos\theta_{in} \tag{1}$$

In this equation, Q_i is the position of the ith light source, $Q_i \to P$ denotes the direction from the ith light source toward the illuminated point P, and $L(Q_i \to P)$ is the radiance due to the ith light source, arriving at P. The equation assumes point light sources. Area light source can be approximated by a number of point lights with positions randomly picked from the surface of the area light source.

In the specific example of physically plausible Phong BRDF, the direct illumination would be computed using a formula similar to the following:

$$L_{out}(P,\omega_{out}) = \sum_{i=1}^{\#lights} I_i \cdot A_i \cdot [k_d + k_s \cos^n \alpha] \cdot \cos\theta_{in}$$

Here, I_i denotes the intensity of the light source. A_i is the light attenuation term, which should amount to the squared distance between the light source position and the illuminated point. In practical rendering, the attenuation might be only linear with distance or there might be no attenuation at all. The cosine term, $\cos\theta_{in}$, is computed as the dot product between the surface normal and direction ω_{in} (i.e., a unit vector in the direction of the light source).

In the basic form of the algorithm, all the light sources are assumed to illuminate all scene points, regardless of the possible occlusion between the illuminated point and the light source. It means that the determination of the outgoing radiance at a point is a local computation, as only the local BRDF is taken into account. Therefore, the algorithm is said to compute *local illumination*. All surfaces are illuminated exclusively by the light coming *directly* from the light sources, thus *direct illumination*. Direct illumination is very fast; using today's graphics hardware, it is possible to generate hundreds of images per second of directly illuminated reasonably complex scenes.

To include shadow generation in a direct illumination algorithm, the occlusion between the light source and the illuminated point has to be determined. To detect possible occluders, one can test all the scene objects for intersection with the ray between the illuminated point and the light source. However, this process is slow even with a specialized spatial indexing data structure. For real-time lighting simulation, shadows are generated using *shadow maps* or *shadow volume* (4).

GLOBAL ILLUMINATION

The simplistic direct illumination algorithm is generally not capable of simulating the interesting lighting effects mentioned in the introduction, such as specular reflections, color bleeding or caustics. The two main reasons are as follows. First, those effects are due to light reflected multiple times on its way from the source to the camera. In direct illumination, however, only a single reflection of light is taken into account (the reflection at the visible point P). Second, the point P under consideration is not only illuminated by light sources but also by the light reflected from all other surfaces visible from P. The light arriving at a point from other scene surfaces is called *indirect illumination* as opposed to direct illumination, which arrives directly from the light sources.

The total amount of light reflected by a surface at a point P in the direction ω_{out} is given by the following hemispherical integral referred to as the *Reflectance Equation* or *Illumination Integral*.

$$L_{out}(P,\omega_{out}) = \int_{\Omega_{in}} L_{in}(P,\omega_{in}) \cdot f_r(P,\omega_{in},\omega_{out}) \cdot \cos\theta_{in}\, \mathrm{d}\omega_{in}$$

Note the similarity between this equation and the direct illumination sum in Equation (1). The direct illumination sum only takes into account only those directions leading to the point light sources, whereas the Reflectance Equation takes into account all direction in the hemisphere, thereby translating the sum into an integral.

To compute the outgoing radiance L_{out} at the point P using the Reflectance Equation, one has to determine the incoming radiance L_{in} from every incoming direction ω_{in} in the hemisphere above P, multiply L_{in} by the BRDF and integrate over the whole hemisphere. The incoming radiance L_{in} from the direction ω_{in} is equal to the radiance leaving point Q (visible from P in direction ω_{in}) in the direction $-\omega_{in}$. That is to say, the incoming radiance at the point P from a single direction is given by the outgoing radiance at a completely different point Q in the scene.

The outgoing radiance at the Q is computed by evaluating the Reflectance Equation at Q, which involves evaluating the outgoing radiance at many other surface points R_i for which the Reflectance Equation has to be evaluated again. This behavior corresponds to the aforementioned multiple reflections of the light in the scene. The light transport is *global* in the sense that illumination of one point is given by the illumination of all other points in the scene.

By substituting the incoming radiance $L_{in}(P,\omega_{in})$ at P by the outgoing radiance L_{out} at the point directly visible from P in the direction ω_{in}, we get the *Rendering Equation* describing the *global light transport* in a scene:

$$L(P,\omega_{out}) = L^e(P,\omega_{out}) + \int_{\Omega_{in}} L(\Psi(P,\omega_{in}), -\omega_{in}) \cdot f_r(P,\omega_{in},\omega_{out}) \cdot \cos\theta_{in}\, \mathrm{d}\omega_{in}$$

The self-emitted radiance L^e is nonzero only for light sources and is given by the Emission Distribution Function. $\Psi(P,\omega_{in})$ is the ray casting function that represents the surface point visible from P in the direction ω_{in}. As all radiances in the Rendering Equation are outgoing, the subscript "out" was dropped. Global illumination algorithms compute an approximate solution of the Rendering Equation for points in the scene.

RAY TRACING

The simplest algorithm that computes some of the global illumination effects, namely perfect specular reflections and refractions, is ray tracing (5). The elementary operation in ray tracing is the evaluation of the ray casting function $\Psi(P,\omega)$ (also called *ray shooting*): Given a ray defined by its origin P and direction ω, find the closest intersection of the ray with the scene objects. With an acceleration space indexing data structure, the query can be evaluated in $O(\log N)$ time, where N is the number of scene objects.

Ray tracing generates images as follows. For a given pixel, a *primary ray* from the camera through that pixel is cast into the scene and the intersection point P is found. At the intersection point, *shadow rays* are sent toward the light sources to check whether they are occluded. Incoming radiance contributions due to each unoccluded light source are multiplied by the BRDF at P and summed to determine direct illumination. So far we only have direct illumination as described above. The bonus with ray tracing is the treatment of reflection on specular surfaces.

If the surface is specular, a *secondary ray* is cast *in the direction of the perfect specular reflection* (equal angle of incidence and reflection). The secondary ray intersects the scene at a different point Q, where the outgoing radiance in the direction $\omega = P - Q$ is evaluated and returned to the point P, where it is multiplied by the BRDF and added to the pixel color. The procedure to compute the outgoing radiance at Q is exactly the same as at P. Another secondary ray may be initiated at Q that intersects the surface at point R and so on. The whole procedure is recursive and is able to simulate multiple specular reflections. Refractions are handled similarly, but the secondary ray is cast through the object surface according to the index of refraction. This algorithm is also referred to as *classical* of *Whitted* ray tracing.

Ray tracing is a typical example of a *view-dependent* lighting computation algorithm—light, to be precise, the outgoing radiance, is computed only for the scene point visible from the current viewpoint of the virtual camera. In this way, ray tracing effectively combines image generation with lighting simulation.

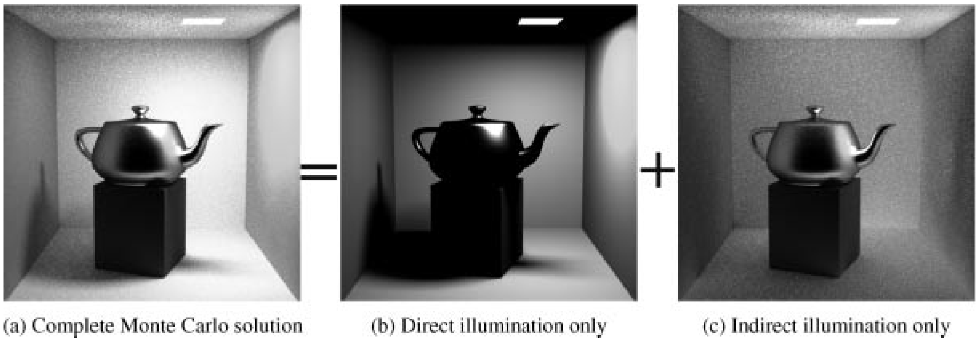
MONTE CARLO

Ray tracing as described in the previous section handles indirect lighting on perfectly specular or transmitting surfaces, but still is not able to compute indirect lighting on diffuse or glossy ones. On those surfaces, one really has to evaluate the Reflectance Equation at each point. The problem on those surfaces is how to numerically evaluate the involved hemispherical integral. One possibility is to use Monte Carlo (MC) quadrature. Consider MC for evaluating the integral $I = \int_0^1 f(x)\mathrm{d}x$. It involves taking a number of uniformly distributed random numbers ξ_i from the interval $\langle 0, 1\rangle$, evaluating the function f at each of those points, and taking the arithmetic average to get an unbiased estimator of the value of integral $\langle I\rangle = \frac{1}{N}\sum_i f(\xi_i)$. The unbiased nature of the estimator means that the expected value of the estimator is equal to the value of the integral. The larger the number of samples $f(\xi_i)$, the more accurate the estimate is, but the expected error only decreases with the square root of the number of samples.

MONTE CARLO RAY TRACING

To apply MC to evaluating the hemispherical integral in the Reflectance Equation, one generates a number of random, uniformly distributed directions over the hemisphere. For each random direction, a secondary ray is cast in that direction exactly in the same way as in classic ray tracing. The secondary ray hits a surface at a point Q, the outgoing radiance in the direction of the secondary ray is computed (recursively using exactly the same procedure) and returned back. The contributions from all secondary rays are summed together and give the estimate of the indirect lighting. MC is only used to compute indirect illumination (the light energy coming from other surfaces in the scene). Direct illumination is computed using the shadow rays in the same way as in classic ray tracing. Figure 6 shows an image rendered with MC ray tracing.

Simply put, MC ray tracing casts the secondary rays in randomized directions, as opposed to classic ray tracing, which only casts them in the perfect specular reflection direction. By sending multiple randomized rays for each pixel and averaging the computed radiances, an approximation to the correct global illumination solution is achieved. A big disadvantage of MC ray tracing is the omnipresent noise, whose level only decreases with the square root of the number of samples.



=
+
(a) Complete Monte Carlo solution
(b) Direct illumination only
(c) Indirect illumination only

Figure 6. Global illumination (a) is composed of the direct illumination (b) and indirect illumination (c). The indirect illumination is computed with MC quadrature, which may leave visible noise in images. Overall, 100 samples per pixel were used to compute the indirect illumination.

Classic ray tracing was able to compute indirect lighting only on specular surfaces. By applying MC to evaluating the Reflectance Equation, MC ray tracing can compute indirect lighting on surfaces with arbitrary BRDFs.

IMPORTANCE SAMPLING

Consider again evaluating the integral $I = \int_0^1 f(x)\mathrm{d}x$, but imagine this time that function *f* is near zero in most of the interval and only has a narrow peak around 0.5. If MC quadrature is run as described above by choosing the samples uniformly from the interval $\langle 0, 1\rangle$, many of the samples will not contribute to the integral estimate because they will miss the narrow peak, and the computational power put in them will be wasted. If no information is available about the behavior of *f*, if is probably the best one can do. However, if some information on the behavior of the integrand *f* is known, concentrating the samples around the peak will improve the estimate accuracy without having to generate excessive samples. *Importance sampling* is a variant of MC quadrature that generates more samples in the areas where the integrand is known to have larger values and reduces the variance of the estimate significantly. If the samples are generated with the probability density $p(x)$, the unbiased estimator is $\langle I\rangle = \frac{1}{N}\sum_i \frac{f(\xi_i)}{p(\xi_i)}$, where ξ_i's are the generated random numbers. Importance sampling significantly reduces the estimator variance if the probability density $p(x)$ follows the behavior of the integrand *f*(*x*). Going back to evaluating the Reflectance Equation, the integrand is $f_r(\omega_{in}, \omega_{out})L_{in}(\omega_{in})\cos\theta_i$. Incoming radiance $L_{in}(\omega_{in})$ is completely unknown (we are sending the secondary rays to sample it), but the BRDF is known. The direction ω_{out} is fixed (the integration is over the incoming directions), so we can use the known function $f_r^{\omega_{out}}(\omega_{in})\cos\theta_i$ as the probability density for generating the samples. For highly directional (glossy) BRDFs, the noise reduction is substantial, as shown in Fig.7.

PHOTON MAPS

Although importance sampling reduces the image noise a great deal, MC ray tracing still takes too long to converge to a noise-free image. Photon mapping (6) is a *two-pass* probabilistic lighting simulation method that performs significantly better.

In the first (photon tracing) pass, light sources emit photons in randomized directions. Brighter lights emit more photons, whereas dimmer ones emit less. Each time an emitted photon hits a surface, the information about the hit (hit position, photon energy, and incoming direction) is stored in the *photon map*, which is a spatial data structure specifically designed for fast nearest-neighbor queries. After storing the photon in the map, the tracing continues by reflecting the photon off the surface in a probabilistic manner (mostly using importance sampling according to the surface BRDF). The result of the photon tracing pass is a filled photon map, which roughly represents the distribution of indirect illumination in the scene.

In the second pass, lighting reconstruction and image formation are both done together. For each pixel, a primary ray is sent to the scene. At its intersection with a scene surface, the direct illumination is computed by sending the shadow rays as described above. Indirect illumination is reconstructed from the photon map. The map is queried for *k* nearest photons ($k = 50-200$), and the indirect illumination is computed from the energy and density of those photons with a procedure called *radiance estimate*. In this maner, the incoming radiance $L_{in}(\omega_{in})$ in the reflection equation is determined from the photon map without ever having to send any secondary rays.

Unlike ray tracing, photon mapping separates the lighting simulation stage from image generation. The first, photon tracing, pass is an example of a *view-independent*

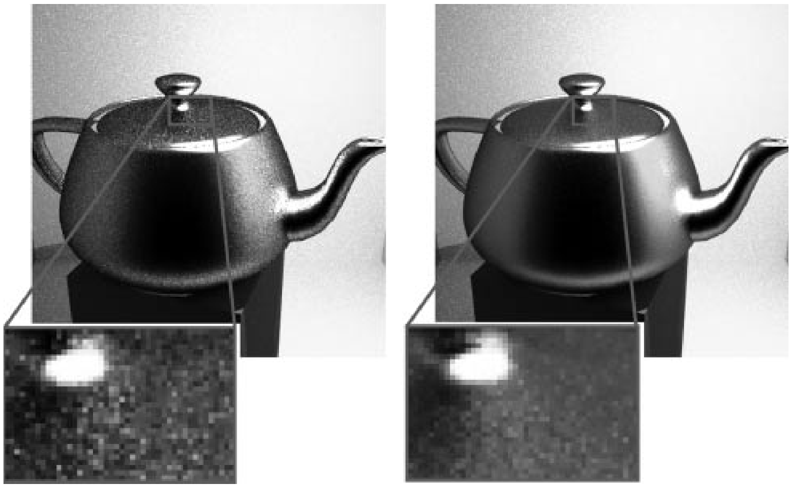


Figure 7. Importance can substantially reduce the noise level in the image. Both the left and right images were computed with MC ray tracing using 100 samples per pixel. Uniform hemisphere sampling was used for the image on the left; importance sampling was used for the image on the right.

lighting computation algorithm. The photons are traced and stored independently from the position of the camera. The image generation itself is performed in the second pass.

FINAL GATHERING, IRRADIANCE CACHING

As the photon map holds a very rough representation of illumination, the images generated with the reconstruction pass as described above do not usually have good quality because the indirect illumination randomly fluctuates over surfaces. Final gathering inserts one level of MC ray tracing into the lighting reconstruction pass of photon mapping and achieves high-quality images. For each primary ray hitting a surface, many secondary rays are sent (500–6000) to sample the indirect incoming radiance. At the points where the secondary rays hit a scene surface, the radiance estimate from the photon maps is used to determine indirect illumination. Because as many rough radiance estimates as there are secondary rays are averaged for each pixel, the image quality is good (the uneven indirect radiance is averaged out).

Final gathering is still very costly, because many secondary rays have to be sent for each pixel. However, on diffuse surfaces, the surface shading due to indirect illumination tends to change very slowly as we move over the surface, which is exploited in the *irradiance caching*(7) algorithm, where the costly final gathering is computed only at a few spots in the scene and interpolated for points in a neighborhood. Photon mapping with a form of final gathering is currently the most commonly used method for computing global illumination in production rendering software.

PARTICIPATING MEDIA—FOG, CLOUDS, AND SMOKE

All methods in the previous sections were built on one fundamental assumption—the value of radiance along a straight ray does not change until the ray hits a surface. However, if the space between the scene surfaces is filled with a volumetric medium like fog, cloud, or smoke, radiance can be altered by the interaction with the medium.

At each point of the medium the value of radiance along a straight line can be modified by a number of events. *Absorption* decreases the radiance due to conversion of the light energy into heat and is described by the volume absorption coefficient $\sigma_a[m^{-1}]$. *Scattering*, described by the volume scattering coefficient $\sigma_s[m^{-1}]$, is a process where a part of light energy is absorbed and then re-emitted in various directions. The angular distribution of the scattered light is described by the *phase function*. Scattering in a volume element is similar to reflection on a surface and the phase function corresponds to a surface BRDF. The total radiance loss due to absorption and scattering is described by the Beer's exponential extinction law: Radiance decreases exponentially with the optical depth of the medium. The optical depth is the line integral of $\sigma_a + \sigma_s$ along the ray. The value of radiance in a volume element does not only decrease, it can be increased due to emission and in-scattering. *In-scattering* is the radiance gain caused by the energy scattered into the ray direction from the neighboring volume elements. By integrating all the differential radiance changes along the ray, we get the integral form of the *Volume Light Transfer Equation* (see Ref. 3).

The light transfer in volumes is much more complicated than on surfaces and takes longer to compute. Fortunately, humans are not very skillful observers of illuminated volumes and large errors can be tolerated in the solution, which is often exploited by simplifying the transport—the most common simplification is the *single scattering* approximation, where only one scattering event is assumed on the way between the light source and the eye. It corresponds to direct illumination in surface lighting.

RADIOSITY METHOD

Radiosity (8) is a very different approach to computing global illumination on surfaces than MC ray tracing. It is based on the theory of radiative heat transfer and the solution is found with a finite element method. In the basic radiosity method, the scene surfaces are discretized into small surface elements (patches) of constant radiosity. Only diffuse BRDFs are considered. The energy exchange in the scene is described by the radiosity equation

$$B_i = B_i^e + \rho_i \sum_{j=1}^{N} F_{i,j} B_j$$

where B_i is the total radiosity of the ith patch, B_i^e is the radiosity due to self emission (non zero only for light sources), ρ_i is the surface reflectance, and $F_{i,j}$ is the form (or configuration) factor. The *form factor* $F_{i,j}$ is the proportion of the total power leaving the ith patch that is received by the jth patch. The whole radiosity equation means that the radiosity leaving the ith patch is the sum of the patch's self emitted radiosity and the reflection of the radiosities emitted by all other surface patches toward the ith patch. The radiosity emitted by a surface patch j toward the patch i is form factor $F_{i,j}$ times its total radiosity B_j. Knowing the form factors, the radiosity equations corresponding to all the patches of the scene can be cast in a system of linear equations with unknown patch radiosities and solved by standard linear algebra techniques. The details of the algorithm are given in a separate article.

In spite of a great deal of research that has gone into radiosity, the method did not prove to be practical. The most important disadvantage is that the method works correctly only with "clean" models (no overlapping triangles, no inconsistent normal, etc.), which is rarely the case in practice. Among computational disadvantages are large memory complexity due to the surface discretization, difficulty of computing form factors, and inability to handle general BRDFs.

Similar to the first pass of the photon mapping algorithm, radiosity gives a view-independent solution. It computes radiosity values for all surface patches regardless of the position of the camera. To generate the final image from a radiosity solution, final gathering is used because it masks the artifacts due to discretizing surfaces into patches.

IMAGE-BASED LIGHTING, HIGH DYNAMIC RANGE IMAGES

In spite of the success of modeling and rendering techniques to produce many realistic looking images of synthetic scenes, it is still not possible to model and render every naturally occurring object or scene. A compromise to this problem is to capture the real-world images and combine them with computer-rendered images of synthetic objects. This approach is commonly used for special effects in movies, in high-quality games, and in contents created for simulation and training. To achieve a seamless and convincing fusion of the virtual object with the images of the real world, it is essential that the virtual object be illuminated by the same light that illuminates other objects in the real scene. Thus, the illumination has to be measured from the real environment and applied during the lighting simulation on the synthetic object.

Image-based lighting (9) is the process of illuminating objects with images of light from the real world. It involves two steps. First, real-world illumination at a point is captured and stored as a *light probe image* (also called an *environment map*) (Fig. 8), an omnidirectional image in which each pixel corresponds to a discrete direction around the point. The image spans the whole range of intensities of the incoming light—it is a *high dynamic range (HDR) image*. An omnidirectional image can be taken by photographing a metallic sphere reflecting the environment or with a specialized omnidirectional camera. Multi-exposure photography is used to capture the high dynamic range. Each exposure captures one zone of intensities, which are then merged to produce the full dynamic range.

Once the light probe image is captured, it can be used to illuminate the object. To this end, the light probe might be replaced by a number (300–1000) of directional lights corresponding to the brightest pixels of the probe image.

IMAGE DISPLAY, TONE MAPPING

Once the physical radiance values are computed for a rectangular array of pixels, they have to be mapped to image intensity values (between 0 and 1) for display. One of the main problems that must be handled in this mapping process is that the emitting ranges of display pixel are limited and fixed, whereas the computed radiance values can vary by orders of magnitude. Another problem is that the displayed images are normally observed in illumination conditions that may be very different from the computed scene. *Tone reproduction* or *tone mapping* algorithms attempt to solve these problems. Reference 10 describes a number of such algorithms.

DISCUSSION

Lighting computation is an important branch of computer graphics. More than 30 years have been devoted to the research in lighting computation. Lighting engineers are

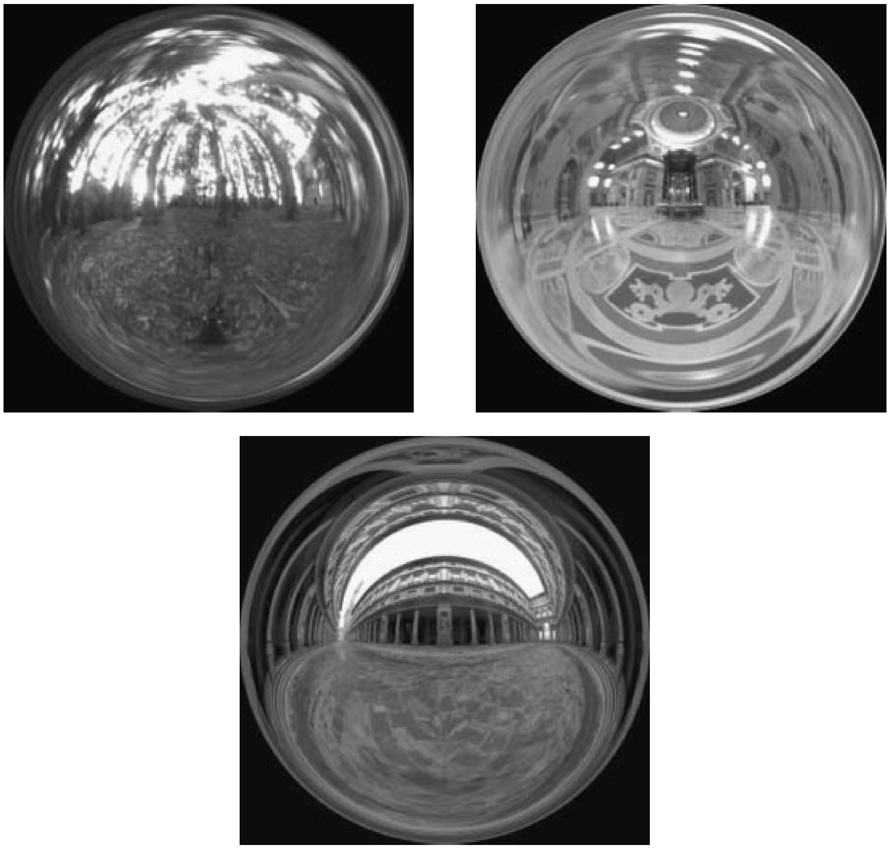

Figure 8. Example light probe images from the Light Probe Gallery at http://www.debevec.org/Probes. (Images courtesy of Paul Debevec.)

regularly using lighting computation to accurately predict the lighting distribution in architectural models. The entertainment industry is using lighting computation for producing convincing computer-generated images of virtual scenes.

Unfortunately, the computation time for global illumination simulation is still very high, prohibiting its full use in the entertainment industry, where thousands of images must be rendered within tight deadlines. Still, the industry is able to create images of stunning quality, mostly thanks to artists who know how light behaves and use their knowledge to “fake” the global illumination. As the indirect lighting would be missing in a direct illumination-only solution, lighting artists substitute indirect lighting by a number of *fill lights* to achieve a natural look of the object without having to resort to computationally expensive global illumination techniques. However, it takes a great deal of expertise to achieve a natural looking “global illuminated” scene using direct illumination-only techniques, and sometimes it is not possible at all. It is, therefore, desirable to make the global illumination available to all computer graphics artists. To that end, most of the current lighting research is being devoted to developing approximate but very fast global illumination algorithms, accurate enough to be imperceptible from the correct global illumination solution.

In the research community, MC techniques have been established as the method of choice for computing global illumination. Still, there are some important topics for future work. Efficient handling of light transport on glossy surfaces, adaptive sampling techniques exploiting a priori knowledge such as illumination smoothness are some examples. Finally, the computer-generated images will continue to look “computer generated” unless we start using reflection models that closely match reality. For this reason, more accessible and precise acquisition of BRDFs of real-world objects will be a topic of intensive research in future.

PARAMETRIC SURFACE RENDERING

INTRODUCTION

Parametric surface (1) is a surface defined by a tensor-product of parametric curves, which are represented by parametric equations. As such a surface comes with a well-defined mathematical definition, it becomes one of the most common geometric tools for computer-aided geometric design and for the object modeling aids of many computer graphics applications. Typical examples of such a surface include Bézier surfaces (1) and non-uniform rational B-Spline (NURBS) surfaces (2). Unfortunately, because most existing graphics hardware only handle polygons, extra procedures must be carried out to convert a parametric surface into a polygon representation for rendering. This process introduces a significant bottleneck to graphics applications, which involve parametric surfaces, to assure interactiveness in terms of rendering performance.

ABOUT PARAMETRIC SURFACES

In the past, many different parametric surfaces have been developed. They include Bézier surfaces and NURBS surfaces, Bézier triangle, and multivariate objects. Such surfaces are mainly used to model smooth and curved objects, and particularly, to provide a good support for modeling deformable objects. For instance, Bézier surfaces and NURBS surfaces are typically used in computer-aided geometric design, whereas multivariate objects are mainly used in scientific visualization and in free-form deformation (3). A unique feature of the parametric surface is that its shape can be changed by modifying the position of its control points.

A parametric surface is modeled by taking a tensor-product on some parametric curves, which are formulated by parametric equations. In a parametric equation, each three-dimensional coordinate of a parametric curve is represented separately as an explicit function of an independent parameter u:

$$C(u) = (x(u), y(u), z(u)) \tag{1}$$

where $C(u)$ is a vector-valued function of the independent parameter u in which $a \leq u \leq b$. The boundary of the parametric equation is defined explicitly by the parametric intervals [a, b].

Bézier Surface

The Bézier surface (1) was developed by a French engineer named Pierre Bézier and was used to design Renault automobile bodies. The Bézier surface possesses several useful properties, such as endpoints interpolation, convex hull property, and global modification. Such properties make the Bézier surface highly useful and convenient to design curved and smooth objects. Hence, this surface is adopted widely in various CAD/CAM and in animation applications, and in general graphics programming packages, such as OpenGL and Performer. A Bézier surface is defined as

$$S_{Bez}(u,v) = \sum_{i=0}^{n}\sum_{j=0}^{m} B_i^n(u) B_j^m(v) P_{ij} \quad \text{for} \quad 0 \leq u, v \leq 1 \tag{2}$$

where n and m are the degrees of the Bézier surface along u and v parametric directions, respectively. P_{ij} forms the control net. $B_i^n(u)$ and $B_j^m(v)$ are the basis functions, in which each is defined by a Bernstein polynomial:

$$B_i^n(u) = \frac{n!}{i!(n-i)!} u^i (1-u)^{n-1} \tag{3}$$

To evaluate a Bézier surface, we can apply the de Casteljau subdivision algorithm (4) to its Bernstein polynomials in both u and v parametric directions. For instance, in the u direction, we have

$$P_i^r(u) = (1-u) P_i^{r-1}(u) + u P_{i+1}^{r-1}(u) \tag{4}$$

for $r = 1, \ldots, n, i = 0, \ldots, n-r$ where n is the degree of the surface. Bernstein polynomials of the other parametric direction also are evaluated through a similar recursion process.

Although the Bézier surface provides a powerful tool in shape design, it has some limitations. Particularly, when modeling an object with complex shape, one may either choose to use a Bézier surface with prohibitively high degrees or a composition of pieces of low-degree Bézier surface patches by imposing an extra continuity constraint between the surface patches.

B-Spline Surface

The B-Spline surface (2) is formed by taking a tensor-product on B-Spline curves in two parametric directions, in which each of the B-Spline curves is a combination of several piecewise polynomials. The connecting points of the polynomial segments of a B-Spline curve are maintained automatically with C^{p-1} continuity, where p is the degree of the B-Spline curve. In addition, a B-Spline curve is composed of several spans. In the parametric domain, these spans are defined by a *knot vector*, which is a sequence *of knots*, or parameter values u_i, along the domain. A B-Spline polynomial is specified by a scaled sum of a set of basis functions. A B-Spline surface is defined as follows:

$$S_{Bsp}(u,v) = \sum_{i=0}^{n}\sum_{j=0}^{m} N_i^p(u) N_j^q(v) P_{ij} \tag{5}$$

where n and m are the numbers of control points, and p and q are the degrees of surface in the u and v parametric

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

directions, respectively. P_{ij} forms the control net. $N_i^p(v)$ and $N_j^q(v)$ (v) are the basis functions. A basis function is defined by

$$N_i^p(u) = \begin{cases} 1 & \text{for} \quad (u_k \le u \le u_{k+1}) \\ 0 & \text{otherwise} \end{cases} \quad \textit{for} \quad p = 1 \tag{6}$$

$$N_i^p(u) = \frac{u - u_i}{u_{i+p} - u_i} N_i^{p-1}(u) + \frac{u_{i+p+1} - u}{u_{i+p+1} - u_i} N_{i+1}^{p-1}(u) \text{ for } p > 1 \tag{7}$$

The knot vectors of the B-Spline surface are defined as follows:

$$U = \{\underbrace{0, \ldots, 0,}_{p+1} u_{p+1}, \ldots, u_{r-p-1}, \{\underbrace{1, \ldots, 1,}_{p+1}\} \text{ for } r = n + p + 1 \tag{8}$$

$$V = \{\underbrace{0, \ldots, 0,}_{q+1} u_{q+1}, \ldots, u_{s-q-1}, \underbrace{1, \ldots, 1}_{q+1}\} \quad \text{for} \quad s = m + q + 1 \tag{9}$$

where U and V are the knot vectors along the u and v parametric directions, respectively. U has r knots, and V has s knots. The de Boor algorithm (5) was proposed to evaluate a B-Spline surface in parameter space with a recurrence formula of B-Spline basis functions. Other methods are proposed to accelerate the evaluation process, such as Shantz's adaptive forward differencing algorithm (6) and Silbermann's high-speed implementation for B-Splines (7).

Generally speaking, the B-Spline surface has similar properties to the Bézier surface. In addition, both surfaces are tightly related. For instance, a B-Spline surface can be reduced to a Bézier surface if it has both knot vectors in the following format:

$$\{\underbrace{0, \ldots, 0,}_{p+1} \underbrace{1, \ldots, 1}_{p+1}\} \quad \text{for} \quad p = \text{degree of B-Spline} \tag{10}$$

In addition, a B-Spline surface can be converted into several of Bézier surface patches through knot insertion (8).

NURBS Surface

A NURBS surface (2) is a rational generalization of the tensor product nonrational B-Spline surfaces. They are defined by applying the B-Spline surface Equation 5 to homogeneous coordinates rather than to the normal 3-D coordinates. The equation of a NURBS surface is defined as follows:

$$S_{Nrb}(u, v) = \frac{\sum_{i=0}^{n} \sum_{j=0}^{m} w_{i,j} P_{i,j} R_{i,j}(u, v)}{\sum_{i=0}^{n} \sum_{j=0}^{m} w_{i,j} R_{i,j}(u, v)} \tag{12}$$

where $w_{i,j}$ are the weights, $P_{i,j}$ form a control net, and $R_{i,j}(u,v)$ are the basis functions. NURBS surface not only shares all properties of nonrational B-Spline surface, but in addition, they possesses the following two useful features:

- They produce correct results under projective transformations, whereas nonrational B-Spline surfaces only produce a correct result under affine transformations.
- They can be used to represent lines, conics, planes, quadrics, and tori.

Similar to the Bézier surface, the NURBS surface is used widely in various CAD/CAM and animation applications, and in common graphics programming packages, such as OpenGL (9) and Performer (10), because such a surface can represent both analytic shapes and free-form surfaces with a common mathematical form. In addition, it comes with many useful geometric modeling toolkits, which include knot insertion, knot refinement, knot removal, degree elevation and degree reduction. Moreover, one can use a much smaller number of NURBS surface patches to construct objects with complex shapes in comparison with using a Bézier surface of the same degree, which helps to reduce effectively the effort in maintaining the visual continuity between surface patches.

Multivariate Objects

Bézier and B-Spline surfaces are used commonly in existing modeling and animation applications, because they are simple in geometric definition and possess a regular shape. In addition, their evaluation cost is low. However, such surfaces are difficult to use in modeling higher dimensional volumes or objects with very complicated shapes. Therefore, research has been conducted to explore higher dimensional multivariate objects (3,11,12), such as parametric volumes and hypersurfaces in R^n, n>3. The multivariate objects can be categorized mathematically into two major types. They are the multivariate objects formed by the multidimensional tensor-product of univariate Bernstein polynomials (S_A) and the generalized Bernstein polynomials over the barycentric coordinates (S_B). The defining equations of these two kinds of multivariate objects are shown as follows:

$$S_A(u, v, w, \ldots) = \sum_{i=0}^{l} \sum_{j=0}^{m} \sum_{k=0}^{n} \ldots B_i^l(u) B_j^m(v) B_k^n(w) \ldots P_{ijk\ldots} \tag{13}$$

$$S_B(u, v, w, \ldots) = \sum_{i+j+k\ldots=n} B_{ijk\ldots}^n(u, v, w, \ldots) P_{ijk\ldots} \tag{14}$$

where $B_i^l(u) B_j^m(v) B_k^n(w) \ldots$ and $B_{ijk\ldots}^n(u, v, w, \ldots)$ are the basis functions. $P_{ijk\ldots}$ form the control net. Note that the Bézier surface can be treated as a special case of the multidimensional tensor-product of univariate Bernstein polynomials, whereas the B-Spline surface or the NURBS surface can be represented in terms of the tensor-product of univariate Bernstein polynomials after applying appropriate knot insertion operations.

To evaluate a multivariate object defined by the multidimensional tensor-product of univariate Bernstein polynomials, we may subdivide it into a polygon model by applying the de Casteljau subdivision formula to all Berstein polynomials of different parametric directions. For example, in the u direction, we have

$$P^{rjk\ldots}_{ijk\ldots}(u) = (1-u)P^{r-1,j,k,\ldots}_{ijk\ldots}(u) + uP^{r-1,j,k,\ldots}_{i+1,j,k,\ldots}(u) \qquad (15)$$

for $r = 1, \ldots, l, i = 0, \ldots, l-r$ and all $j,k,\ldots\ldots$, where $(l, m, n,\ldots)$ is the degree of the surface. The other parametric directions have similar recursions. On the one hand, a multivariate object defined by the generalized Bernstein polynomials can be evaluated by applying the generalized de Casteljau subdivision formula. The generalized polynomials of degree n in generalized de Casteljau form are

$$P^{r}_{\mathrm{I}}(\mu) = uP^{r-1}_{\mathrm{I}+e1}(\mu) + vP^{r-1}_{\mathrm{I}+e2}(\mu) + wP^{r-1}_{\mathrm{I}+e3}(\mu) + \ldots \qquad (16)$$

for $r = 1,\ldots,n$ and $|\mathrm{I}| = n - r$, where $e1 = (1,0,0,\ldots)$, $e2 = (0,1,0,\ldots)$, $e3 = (0,0,1,\ldots)$, and $\mu = (u,v,w,\ldots)$.

On the other hand, multivariate objects may offer support to edit shapes of objects with arbitrary geometric representation. As a result, free-form deformation (FFD) (3) should be applied. It embeds an object to edit shapes in a regularly subdivided parallelepipedical 3-D parametric solid lattice, which is defined by a trivariate Bézier volume (a kind of multivariate object formed by the multidimensional tensor-product of univariate Bernstein polynomials). The solid lattice is referred to as the FFD lattice. Each sample point of the embedded object should be mapped to a parametric coordinate set of the FFD lattice. Shape editing of the embedded object can then be performed by moving the control points of the FFD lattice, in which the change in shape of the lattice would then be passed automatically to the embedded object. Based on FFD, extended free-form deformation (13) was proposed to relax the shape of the FFD lattice to arbitrary ones rather than sticking to the parallelepipedical one.

Properties of Parametric Surfaces

To examine the major properties of parametric surfaces that affect significantly the object modeling process, we broadly divide the parametric surfaces into two high-level classes by considering whether one is formulated by taking the tensor-product of just one polynomial or a several piecewise polynomials in each parametric direction. If just one polynomial is used in each parametric direction, the surfaces defined fal into the class of Bézier surfaces; otherwise, they belong to the class of B-Spline surfaces. The properties of these surfaces are depicted and compared as follows:

Local Modification Property. Local modification is proprietary to surfaces defined under the class of B-Spline, because any basis function $N_{i,p}(u)$ of a one-dimensional B-Spline would be evaluated as zero if we consider a parametric range outside the interval $[u_i, u_{i+p+1})$. Effectively, this approach implies a local control of each control point P_i of B-Spline surfaces. In other words, moving the control point P_k would only change a one-dimensional B-Spline within the parametric interval $[u_i, u_{i+p+1})$. For instance, in the case of a B-Spline surface, the control point $P_{i,j}$ affects only the shape of the surface within the parameter region $[u_i, u_{i+p+1}) \times [v_j, v_{j+q+1})$, where p and q are the degrees of the surface along u and v parameter directions, respectively.

Dependency between the Surface Degree and the Number of Control Points. Such dependency exists only on the surfaces defined under the class of Bézier surfaces, where the number of control points of a degree p Bézier curve is equal to $p + 1$. Essentially, when conducting object modeling using Bézier surfaces, if more control points are needed to model complex shapes, the degrees of such Bézier surfaces should then be increased accordingly. By doing this, the complexity in evaluating or in tessellating the Bézier surfaces would be increased significantly, which eventually leads to an undesired poor rendering performance. In contrast, surfaces defined under the class of B-Spline do not have such restriction. Effectively, the number of control points n depends on both the number of knots r and the degree p of a B-Spline, which equals

$$r = n + p + 1 \qquad (11)$$

whereas the degree of a B-Spline is fixed, one is allowed to choose any number of knots to define the B-Spline, which implies that the number of control points of a B-Spline is governed primarily by the number of knots. As the complexity in evaluating a B-Spline surface is mainly caused by the increase in the degree of the surface rather than in the increment in the number of knots, this property relaxes a B-Spline from experiencing very poor evaluation performance even if a lot of control points are added to the B-Spline to facilitate the modeling of complex shapes.

Continuity. Continuity (1,14) is a common property of both surfaces defined under the class of Bézier and B-Spline surfaces. It describes the smoothness at the junction of composite surface patches. Two types of continuity descriptors exist, namely *parametric continuity* C^n and *geometric continuity* G^n, where n typically indicates the level of continuity. Parametric continuity requires all derivatives of order 0 to $n-1$ at the junction of composite surface patches to be agreed, whereas geometric continuity imposes such agreement by considering the derivatives evaluated with respect to the arc-length around the junction, rather than to the parameterization at the junction. Parametric continuity suffers from the problem that it may not be held if the parameterization of the composite surface patches is changed, despite that the smoothness of the surface patches still is kept unchanged. In contrast, geometric continuity is appropriate for dealing with shape modeling as it allows one to modify the parameterization of a surface without affecting the smoothness of the surface. with regard to both classes of parametric surfaces, a B-Spline surface with degree (p,q) automatically maintains C^{p-1} and C^{q-1} continuity between polynomial patch segments in u and v directions, respectively. Comparing this with the composite

Bézier surface patches where an additional intersurface continuity constraint is required to be imposed, the B-Spline surface is thus preferred over the Bézier surface in the applications involving piecewise composite surface patches.

Degree Elevation and Reduction. Degree elevation and reduction (2) are tools used to adjust the degree of the parametric surfaces. They are applicable for both classes of Bézier and B-Spline surfaces. By altering the degree of a surface, the number of control points is increased or decreased. Hence, the degree of freedom for shape manipulation of the surface is adjusted as well. The most important feature of degree elevation and reduction is that both operations will not alter the shape of a surface, which provides the sufficient condition for one to freely change the degrees of parametric surfaces in an application, which is very useful. For instance, one may apply these tools to make all parametric surfaces in a modeling environment have the same degree. These surfaces can be stitched together to form a complex object, and the continuity condition of the object can be maintained.

GENERIC RENDERING METHODS

Pixel-Based Rendering

During the last two decades, various rendering methods have been developed for parametric surfaces. In the earlier stage, researchers focused on generating accurate images of parametric surfaces. Most methods developed were performed generally too slowly to support rendering parametric surface in real time. Catmull (15) presented a pixel-level subdivision method to render parametric surface by recursively subdividing a surface into smaller subpatches not bigger than a single screen pixel. Although Catmull derived an efficient subdivision algorithm for bicubic patches, the performance still is too slow to support an interactive display of surfaces because of the depth of subdivision. A more efficient method called scan-line display was developed and improved by several researchers (16–18). This method processes the screen pixels in the scan-line order. For each scan-line, the intersection of the scan plane with the surface forms a span. In practice, most scan-line based methods take advantage of spatial coherence to speed up the span computation. However, because of the inherent complexity of calculating scan-line intersections, these methods still do not perform fast enough for real-time display of large models. Whitted in Ref. 16 presented a method to render photo-realistic images of bicubic surfaces using ray tracing. The method subdivides repeatedly a surface intersected by a ray using Catmull's scheme (15) until the subpatch is small enough to approximate the point of intersection. This method was speed up by Kayjiya's numerical solution (19), where the calculation of ray patch intersection is reduced. Moreover, the performance can be additionally enhanced by Nishita et al.'s Bézier clipping algorithm (20), where the portion of a surface that does not intersect a ray is eliminated. However, the expensive ray intersection operations still make the interactive display of parametric surface difficult.

Polygon-Based Rendering

To speed up the rendering of parametric surface, many polygon-based rendering methods (5–8,21) have been developed. These methods subdivide a surface recursively into smaller patches until each patch is flat enough to be approximated by a polygon. Once the approximating polygons are computed, they can then be passed to and rendered by the hardware graphics accelerators. In contrast to the pixel-based methods, these methods use the polygon rendering capability available in existing graphics systems and hence may approach real-time rendering. The polygon-based rendering methods can be categorized into the *polynomial evaluation method, subdivision method*, and *frame-to-frame coherence method*, which are shown as follows:

- **Polynomial Evaluation Method:** A direct way to tessellate a parametric surface into polygons for rendering is performed by evaluating the surface equation for a succession of parametric pairs (u, v). The points obtained then form a set of polygons to approximate the parametric surface. The set of polygons is then passed to and processed by the hardware graphics accelerator. For example, the de Boor algorithm (5) was proposed to evaluate NURBS surfaces in the parameter space by using a recurrence formula of B-Spline basis functions. It is very useful for computer implementation, as one can implement this directly using a simple recursive function. An alternative approach to evaluate parametric surfaces is the Horner's algorithm (1). Instead of evaluating the surface equation along the (u, v) pairs in succession, it evaluates the surface polynomials in the form of a nested multiplication of monomials, which is generally faster. However, this method is numerically unstable because of the monomial form. Other methods are proposed to accelerate the evaluation process, such as Shantz's adaptive forward differencing algorithm (6) and Silbermann's high-speed implementation of NURBS (7). They propose alternative solutions to simplify the evaluation process of the parametric surface.
- **Subdivision Method:** Subdivision can be performed adaptively or uniformly. Adaptive subdivision subdivides recursively a parametric surface into surface patches until each patch is sufficiently flat or small enough to meet the screen-space projection threshold to assure a good display quality to the rendered surface. The surface patches created are held in a tree structure to ease the maintenance and tracing of the surface patches during the subdivision process. This approach can produce an optimized number of polygons for parametric surfaces with highly varying curvatures. Methods of this approach include those proposed by Clark (22), Barsky et al. (23) and Forsey et al. (21). However, extra care must be taken when using adaptive subdivision methods, as cracks may

appear in the generated polygon model. This problem occurs because resulting neighboring polygons may not be at the same resolution level. Hence, an additional crack prevention process is required to fix the cracks in the generated polygon model to ensure its visual continuity.

Uniform subdivision computes a constant step size along each parametric direction of a surface to generate a regular grid of polygons to represent a surface. Unlike adaptive subdivision, the polygon model created by uniform subdivision can be stored in an array instead of a tree structure, and the subdivision therefore is nonrecursive. On the other hand, although uniform subdivision can tessellate surfaces more efficiently than adaptive subdivision, usually it produces more polygons than necessary. Rockwood et al. (25) and Abi-Ezzi et al. (21,26) propose methods on uniform subdivision. In particular, Rockwood et al.'s method (25) subdivides a surface into a set of simple surface segments and tessellates these segments into a regular grid of polygons. A Coving and tiling process will then be conducted to handle the tessellation of the boundaries between the surface segments and that of the trimming regions of the surface. In practice, a variant of Rockwood et al.'s method (25) has been implemented in SGI GL and OpenGL libraries. Abi-Ezzi et al. (21,26) enhances this method by improving the computation of step size of polygonization and separating the compute-intensive and algorithm-intensive procedures.

- **Frame-to-Frame Coherence Method:** Kumar et al. (27) proposed a method to keep track of the user's viewpoint on a surface and to tessellate the surface according to the change of this viewpoint between successive frames. Similar to Rockwood et al.'s method, which subdivides a surface into a set of simple surface segments to facilitate additional processing, this method is based on the visibility of each surface segment in every next frame during run time and performs incremental tessellation on a surface segment or deletes one accordingly. Because there is usually only a small change in the viewpoint between two consecutive frames, this method minimizes the number of polygons generated within a given time frame.

Issues in Polygon-Based Rendering

The issues for applying the polygonal approximation methods to render parametric surfaces are summarized as follows:

- **Trimmed Surfaces:** If we restrict the domain of a parametric surface to a subset of its parametric space, the resultant surface is called a *trimmed surface*. We can trim a surface by enclosing a subset of area of the surface by a set of closed loops of directed curves called *trimming curves*. The enclosed area is called a *trimming region*. For rendering, a special triangulation procedure should be carried out around the boundary of the trimming region. Existing works for tackling this issue include Ref. 25 and 27.
- **Efficiency:** The method used to tessellate a parametric surface must be capable of calculating efficiently both the surface points and their corresponding normal vectors. The surface points form the vertices of the polygon model approximating the parametric surface. The normal vectors are used to shade and to support surface culling.
- **Display Quality:** The display quality is a very important criterion in surface rendering. To increase the display quality, one may generate a lot of polygons to represent the surface, although this is traded for the rendering performance. Nevertheless, generating a lot of polygons may not be necessary to correspond to a good visual quality for displaying a surface. Hence, to guarantee the display quality of a parametric surface, one needs to determine an optimal number of polygons based on some viewing criteria, such as the screen-space projection (25), to obtain a smooth image of the surface according to the current user's view point.
- **Sampling Distribution:** In addition to determining the number of polygons to represent a parametric surface, the method also should determine the distribution of these polygons. Two ways to handle this issue are *uniform tessellation* and *adaptive tessellation*. Uniform tessellation subdivides a surface evenly with a predetermined sampling size. Adaptive tessellation subdivides a surface with nonuniform resolution according to the local geometry, such as the curvature, to optimize the total number of polygons generated. In general, uniform tessellation produces more polygons for rendering than adaptive tessellation. However, extra computational time is needed for adaptive tessellation to determine the distribution of the polygons.
- **Crack Prevention:** When the adaptive tessellation is used, cracks may appear from the different sizes of neighboring polygons as shown in Fig. 1. Additional procedures must be performed to ensure the visual continuity of the image by removing the cracks (28).
- **Frame-to-Frame Coherence:** To accelerate the rendering of a parametric surface, the frame-to-frame coherence could reduce significantly the number polygons that are generated between successive frames. This coherence is helpful to accelerate the rendering performance when the viewing parameter to the surface is changing continuously.

RENDERING OF DEFORMABLE SURFACES

In real life, many objects are deformable, in which their shapes could be changed. Examples include human or animal characters, facial expressions, and soft objects such as clothes. The incorporation of such objects in computer graphics applications is particularly attractive as it is useful to enhance the realism of such applications. However, the rendering process of such objects generally is expensive. When an object deforms, a rendering process for the object is needed to re-run repeatedly from frame to frame to produce appropriate pixels or polygons for

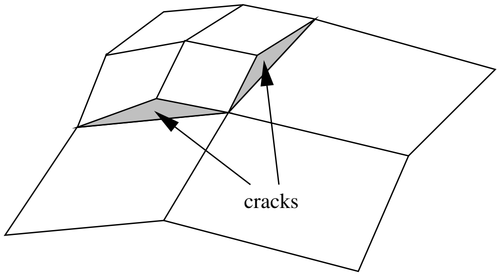

Figure 1. Cracks from adaptive tessellation.

graphics hardware to display the object. This process poses a significant computation burden on the graphics applications, which makes the real-time rendering of deformable objects difficult. Hence, deformable objects are seldom incorporated in interactive types of graphics applications.

To address this problem, an incremental surface rendering method (28,29) has been proposed, which is based on two fundamental techniques, *incremental polygon updating* and *resolution refinement*. The basic idea of incremental polygon model updating is to maintain two data structures of a deformable surface, the surface model and a polygon model representing the surface model. As the surface deforms, the polygon model is not regenerated through polygonization. Instead, it is updated incrementally to represent the deforming surface. This updating accelerates the rendering process of deformable surfaces by concerning the incremental evolution of such surfaces in successive frames. More specifically, we consider whenever a control point $P_{ijk}\ldots$ of a surface is moved to $\overline{P}_{ijk\ldots}$ with a displacement vector $\vec{V} = \overline{P}_{ijk} - P_{ijk\ldots}$, the incremental difference between two polygonal representations for a parametric surface before and after the control point movement can be represented as follows. For the multidimensional tensor-product of univariate Bernstein polynomials:

$$\overline{S}_A(u,v,w,\ldots) - S_A(u,v,w,\ldots)$$
$$= B(B_i^l(u)B_j^m(v)B_k^n(w)\ldots)(\overline{P}_{ijk\ldots} - P_{ijk}) = \alpha_{ijk\ldots}\vec{V} \quad (17)$$

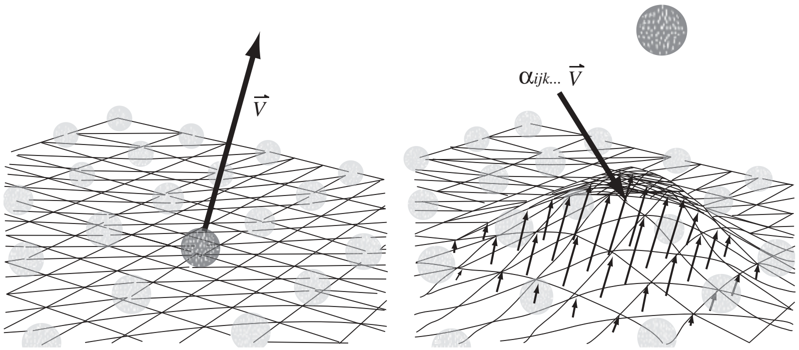
where $\alpha_{ijk\ldots} = B_i^l(u)B_j^m(v)B_k^n(w)\ldots$. For the generalized Bernstein polynomials over the barycentric coordinates:

$$\overline{S}_B(u,v,w,\ldots) - S_B(u,v,w,\ldots)$$
$$= (B_{ijk\ldots}^n(u,v,w,\ldots))(\overline{P}_{ijk\ldots} - P_{ijk\ldots}) = \beta_{ijk\ldots}\vec{V} \quad (18)$$

where $\beta_{ijk\ldots} = B_{ijk\ldots}^n(u,v,w,\ldots)$ It is obvious that the two deformation coefficients $\alpha_{ijk\ldots}$ and $\beta_{ijk\ldots}$ are constants for each particular set of $(u,v,w,\ldots)$ parameter values. Hence, if the resolution of the polygon model representing the surface remains unchanged before and after deformation, one may precompute the deformation coefficients and update the polygon model incrementally by the deformation coefficients and the displacement vector of the moving control point. In the implementation, the incremental polygon model updating is carried out in two stages: the *preprocessing* stage and the *run-time* stage. In the preprocessing stage, a surface is tessellated to obtain a polygon model and a set of deformation coefficients $\alpha_{ijk\ldots}$ or $\beta_{ijk\ldots}$ for each control point is evaluated. As the surface deforms during run time, the polygon model is updated incrementally with the set of deformation coefficients and the displacement vector of the moving control point. Figure 2(a) shows a surface deformation by moving a control point with displacement $\vec{V}$. Figure 2(b) shows the incremental updating of the affected polygon vertices. With the incremental polygon model updating technique, a surface point on the deformed surface $\overline{s}_{ijk\ldots}$ can be calculated by

$$\overline{s}_{ijk\ldots} = s_{ijk\ldots} + \alpha_{ijk\ldots}\vec{V} \quad (19)$$

where $s_{ijk\ldots}$ and $\overline{s}_{ijk\ldots}$ are the surface points before and after deformation, respectively. $\vec{V}$ is the displacement vector of the current moving control point, and $\alpha_{ijk\ldots}$ is the deformation coefficient associating with the surface point s and the current moving control point. This technique is efficient. First, only one vector addition and one scalar-vector multiplication are found on each affected vertex of the polygon model to produce the deformed one. Second, the precomputed deformation coefficients are constant, and hence, no recomputation is needed. Second, since a surface point on the deformed surface is calculated by Equation (19) regardless



(a) (b)

Figure 2. Incremental polygon model updating.

of the type of deforming surfaces to handle, the computational complexity is therefore independent of the complexity of the defining equation of the deforming surface. In other words, this technique has a constant and low computational complexity for all types of deformable parametric surfaces.

On the other hand, when a surface deforms, its curvature also is changed. If the curvature is increased or decreased by a large amount during the deformation process, the resolution of the corresponding polygon model may become too coarse or too high to represent the deformed surface, respectively. To overcome this problem, a resolution refinement technique has been proposed to refine incrementally the resolution of the polygon model and to generate the corresponding deformation coefficients according to the change in the local curvature of the surface and some animation parameters, such as the viewer-object distance or the screen projection size of the object. More specifically, resolution refinement considers the fact that either a surface is modeled by the multidimensional tensor-product of univariate Bernstein polynomials or the generalized Bernstein polynomials over the barycentric coordinates, and it can be subdivided through de Casteljau formula as shown in Equations (15) and (16), respectively. By subtracting a subdivided deformed surface generated by the de Casteljau formula with its nondeformed counterpart, one can easily deduce that deformation coefficients incrementally can also be generated through de Casteljau formula. As a result, the de Casteljau formula provides a means to refine incrementally the polygon model representing the deformable surface and to generate corresponding deformation coefficients for newly added polygon vertices to support incremental polygon model updating.

All in all, the incremental surface rendering method (28,29) provides a unique solution to allow deformable parametric surfaces to be rendered interactively. Rendering deformable parametric surfaces with this method can be roughly 3 to 15 times faster than applying generic rendering methods. In addition, an extended version of this method has been published in Ref. 30 to cover trimmed parametric surfaces.

CONCLUSION

In conclusion, a parametric surface offers several advantages for object modeling. First, it has a well-defined mathematical definition, which provides a concise and systematic way to represent objects. Second, a parametric surface produces scalable geometry; i.e., all fine detailed features of the modeled object could be reserved without any loss even if the object is undergoing arbitrary zooming. Third, the control points provide a native aid to support object–shape modification. Despite the advantages, the rendering process of parametric surfaces is typically time consuming, as such a process is not natively supported by existing hardware graphics accelerators. Another major obstruction to providing native hardware support in rendering parametric surface is that several different kinds of parametric surfaces exist, each of them should be evaluated differently. To date, a unified way for surface evaluation still is not yet available. Another factor that hinders the rendering performance of parametric surface is that if a parametric surface is deforming, a generic rendering process must be re-run for every time frame to generate the updated pixel- or polygon-based representation to render the shape changed surface.

To improve the rendering performance, incremental update always is an effective approach, which helps to minimize the computational overhead for surface rendering. For instance, one can refine or prune only certain subregions of a parametric surface. More specifically, the subregions should be those experiencing visibility changes or undergoing deformation. On the other hand, incremental polygon updating, as in Refs. 28 and 29, accelerates the rendering of a deformable parametric surface by maintaining a set of deformation coefficients and uses the coefficients to update incrementally the polygonal representation of the surface. In the future, a major effort will be focused on the development of new surface rendering methods by taking advantage of the parallel processing power of the graphics processing unit to accelerate significantly the surface rendering process. Developing such methods, however, is not straightforward. In particular, the irregularity of trimming curves/regions makes parallelizing the rendering method for trimmed parametric surfaces difficult. A preliminary attempt to address this issue can be found in Ref. 31. On the other hand, the methods developed also should take care of the handling of object deformation. To this end, when supporting object deformation, one should minimize the memory usage and the amount of data transfer to and from the texture memory or to other kinds of memory storages.

RADIOSITY

INTRODUCTION

Radiosity, a radiometric quantity, is the amount of light flux leaving unit surface area.[1] The unit of this quantity is watts/m^2. In the computer graphics field, the radiosity is mostly used to describe an object-space method for computing accurate radiosities on the object surfaces in a synthetic environment. In the rest of the article, we will describe this radiosity method.

Radiosity method is the very first physically based global illumination computation method. It was introduced into the computer graphics field by the researchers from Cornell University in 1984 (1). The basic idea is to first discretize the scene into patches, then set up a linear system for unknown radiosities of the patches, and finally solve the linear system to compute these radiosity values. The linear system describes the radiosity propagation between patches in equilibrium. Once the computation is done, it is possible to render the scene from any viewing point using any of the standard rendering techniques with radiosity[2] as the color of the patch. Radiosity is widely used in realistic rendering and real-time visualization of synthetic scenes.

Radiosity method is mostly used to compute global illumination solution in scenes containing diffusely reflecting surfaces and illuminated by diffuse light sources. It successfully simulates multiple inter-reflections. Such inter-reflection between diffuse surfaces is very difficult to simulate using other methods, like ray tracing. Radiosity method provides a solution for every surface patch in the scene, and the solution is independent of the viewer position, thus called a *view-independent object-space* technique.

To get a general idea about radiosity, it is helpful to observe how light propagates in a simple scene. Figure 1 shows an intuitive scenario of light propagation in a very simple scene made up of three patches. Light propagates between every pair of patches. In Fig. 1, patch 1 illuminates patch 2 and patch 3; patch 2 illuminates patch 1 and patch 3; patch 3 illuminates patch 1 and patch 2. Concave patches will also illuminate themselves. One can see from Fig. 2 that, during this light propagation process, only a fraction of light flux leaving patch *i* reaches another patch *j*. For diffuse surfaces, this fraction depends only on the form (size, orientation, and distance) of the pair of patches and hence is known as form factor. Form factor is denoted by $F_{i\to j}$, where subscript $i\to j$ represents light reaching patch *j* from patch *i*. A total of nine form factors are needed to describe the light propagation in the scene in Fig. 1. They are shown in Fig. 3. When the light propagation between the patches in Fig. 1 reaches equilibrium (i.e., light flux leaving or reaching each patch remains unchanged), the light flux leaving a patch can be expressed as the light flux emitted from the patch plus the reflected part of the light flux incident on the patch. The incident flux is the sum of the flux arriving from all other patches in the scene. Thus, we can write an expression for the equilibrium flux leaving a patch in terms of the light flux leaving all other patches of the scene. In Equation (1), we give the expressions for the three patches of the scene shown in Fig. 1.

$$\begin{aligned}\Phi_1 &= \Phi_{e,1} + \rho_1\Phi_1 F_{1\to 1} + \rho_1\Phi_2 F_{2\to 1} + \rho_1\Phi_3 F_{3\to 1}\\ \Phi_2 &= \Phi_{e,2} + \rho_2\Phi_1 F_{1\to 2} + \rho_2\Phi_2 F_{2\to 2} + \rho_2\Phi_3 F_{3\to 2}\\ \Phi_3 &= \Phi_{e,3} + \rho_3\Phi_1 F_{1\to 3} + \rho_3\Phi_2 F_{2\to 3} + \rho_3\Phi_3 F_{3\to 3}\end{aligned} \tag{1}$$

Each of these equations is linear, and together they form a linear system. A general form of the light flux equation in an arbitrary scene is given in Equation (2).

$$\Phi_i = \Phi_{e,i} + \rho_i \sum_{j=1}^{n} \Phi_j F_{j\to i} \text{ for } i = 1\ldots n \tag{2}$$

where Φ_i, $\Phi_{e,i}$, and ρ_i are the equilibrium light flux, the emitted light flux, and the diffuse reflectance of the surface patch *i*, respectively; $F_{j\to i}$ is the form factor between patch *j* and patch *i*; and *n* is the total number of patches in the scene.

Equation (2) is known as the light flux transport equation. $\Phi_{e,i}$ and ρ_i in the equation are the surface properties and are known quantities. $F_{j\to i}$ depends only on the geometry of surface patches *i* and *j*, and hence can be computed independent of the lighting condition. Given the values of $\Phi_{e,i}$, ρ_i, and $F_{j\to i}$, the unknown Φ_is can be computed by solving the linear system formed from Equation (2).

FORM FACTOR

The form factor $F_{i\to j}$ is defined as the fraction of light flux leaving patch *i* and reaching patch *j*. Equation (3) provides a mathematical expression of the form factor between two diffuse surfaces with uniform light flux over their area.

$$F_{i\to j} = \frac{1}{A_i}\int_{A_j} dA_y \int_{A_i} dA_x \frac{\cos\phi_x \cos\phi_y}{\pi r_{xy}^2} V(x,y) \tag{3}$$

where ϕ_x and ϕ_y are the angles between the normal's of differential patches dA_x and dA_y, respectively with the line connecting the two differential patches; r_{xy} is the distance between dA_x and dA_y; and A_i and A_j are areas of patches *i* and *j*. Figure 4 illustrates these parameters. *V(x,y)* is the visibility between the two differential patches and is

3	$F_{3\to1}$	$F_{3\to2}$	$F_{3\to3}$

Figure 3. Form factors.

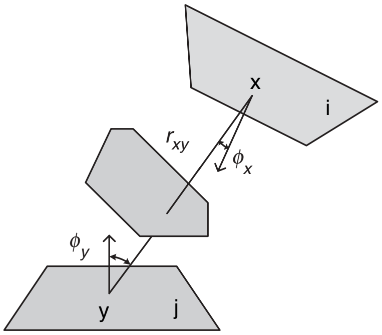

Figure 4. Form factor parameters.

expressed in Equation (4).

$$V(x,y) = \begin{cases} 0, \text{ if there is occlusion between } dA_x \text{ and } dA_y \\ 1, \text{ otherwise} \end{cases} \tag{4}$$

If we change the relationship between the patches i and j and wish to write an expression for $F_{j\to i}$, then it will be as follows:

$$F_{j\to i} = \frac{1}{A_j}\int_{A_j} dA_y \int_{A_i} dA_x \frac{\cos\phi_x \cos\phi_y}{\pi r_{xy}^2} V(x,y) \tag{5}$$

From these two form factor equations we can derive a useful property of form factor:

$$A_i F_{i\to j} = A_j F_{j\to i} \text{ or } \frac{F_{i\to j}}{F_{j\to i}} = \frac{A_j}{A_i}$$

In other words, the ratio of the two form factors between any two patches is inversely proportional to the ratio between the areas of the two patches.

From the definition of the form factors itself, we get another property: The sum of all form factors from any patch is no greater than 1 (i.e., $\sum_j F_{i\to j} \leq 1$).

RADIOSITY EQUATION

In the beginning of this article, we defined radiosity as the flux per unit area. If we use symbol B to denote radiosity and assume that the light is distributed uniformly over the area of the patch, then we have $B_i = \frac{\Phi_i}{A_i}$. Using this definition of radiosity and the property of form factor, we derive the radiosity transport equation (or *radiosity equation* for short) in Equation (6) from the flux transport equation given in Equation (2).

$$\begin{aligned}\frac{\Phi_i}{A_i} &= \frac{\Phi_{e,i}}{A_i} + \rho_i \sum_{j=1}^{n} \Phi_j \frac{F_{j\to i}}{A_i} = \frac{\Phi_{e,i}}{A_i} + \rho_i \sum_{j=1}^{n} \frac{\Phi_j}{A_j}\frac{A_j F_{j\to i}}{A_i} \\ &= \frac{\Phi_{e,i}}{A_i} + \rho_i \sum_{j=1}^{n} \frac{\Phi_j}{A_j} F_{i\to j} B_i = E_i + \rho_i \sum_{j=1}^{n} B_j F_{i\to j}\end{aligned} \tag{6}$$

The derivation of Equation (6) uses the inverse area form factor relationship $\frac{A_j F_{j\to i}}{A_i} = F_{i\to j}$ described in the previous section.

Figure 5 summarizes the various steps for the radiosity computation algorithm. The process begins by inputting the model, followed by computing form factors and solving a linear system, and finally by displaying the scene from any arbitrary viewpoint. The input geometry is often discretized into smaller patches in the first step. The last step is often a hardware walk-through in the scene. Note that in this walk-through step, the change in view direction does not require the re-evaluation of any other step of the algorithm. Change in the surface property (diffuse reflectance and emissivity), however, does require repetition of the linear system solution step. But, form factors are not

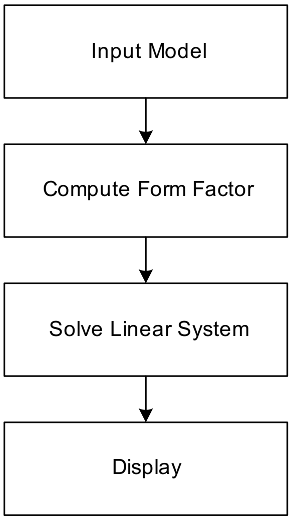

Figure 5. Radiosity algorithm.

affected by this change and hence they do not have to be recomputed.

SOLVING RADIOSITY EQUATION

By rearranging Equation (6), we can get the following matrix form of the radiosity system:

$$(I - M)B = E \tag{7}$$

where; I is the identity matrix, M =

$$\begin{bmatrix} \rho_1 F_{1\to 1} & \rho_1 F_{1\to 2} & \cdots & \rho_1 F_{1\to n} \\ \rho_2 F_{2\to 1} & \rho_2 F_{2\to 2} & \cdots & \rho_2 F_{2\to n} \\ \vdots & \vdots & \ddots & \vdots \\ \rho_n F_{n\to 1} & \rho_n F_{n\to 2} & \cdots & \rho_n F_{n\to n} \end{bmatrix}, B = \begin{bmatrix} B_1 \\ B_2 \\ \vdots \\ B_n \end{bmatrix}, \text{ and}$$

$$E = \begin{bmatrix} E_1 \\ E_2 \\ \vdots \\ E_n \end{bmatrix}.$$

For convenience, we may denote (I–M) in Equation (7) with K, a square matrix with coefficients k_{ij}.

$$K \equiv I - M = (k_{ij})_{n\times n} \tag{8}$$

where

$$k_{ij} = \begin{cases} 1 - \rho_i F_{ii}, & \text{for } i = j \\ -\rho_i F_{ij}, & \text{for } i \neq j \end{cases}$$

With this change, the radiosity system is now represented by Equation (9), as follows:

$$KB = E \tag{9}$$

Given this matrix formulation, the radiosity system can be solved by inverting K and computing $B = K^{-1}E$. However, the size of the linear system of the radiosity equations for any nontrivial scene makes inverting the matrix K impractical. A common environment could have tens of thousands or millions of patches.

From the law of conservation of energy, $\rho_i \leq 1$, and the property of the form factor mentioned in the earlier section, we get the relation $\sum_{j=1}^{n}\rho_i F_{ij} \leq 1$, or in other words $\sum_{j=1,j\neq i}^{n}\rho_i F_{ij} \leq 1 - \rho_i F_{ii}$. Thus, each row of the matrix K satisfies the property $\sum_{j=1,j\neq i}^{n}|k_{ij}| \leq |k_{ii}|$, which makes K a diagonally dominant matrix, and hence guarantees that the radiosity equation has a unique solution, which also guarantees that an iterative method will finally converge to this unique solution. Hence, iterative methods or relaxation methods are commonly used for the radiosity solution. We describe two popular solution methods in the next section.

Two different classes of iterative methods have been used to solve the radiosity system [Equation (9)]. They include: *gathering methods* and *shooting methods*. These methods start from an initial estimation for the unknowns, and then they are iteratively updated based on the previous estimation until the linear system reaches convergence. To describe these methods, we go back to the original radiosity equation given in Equation (6).

Gathering Methods

A basic gathering method for solving the radiosity system is the iterative refinement of the radiosity values of the patches from the values computed at the previous iteration. The iteration scheme is shown in Equation (10). It is a reformulated version of Equation (6).

$$B_i^{k+1} = E_i + \rho_i \sum_{j=1}^{n} F_{ij} B_j^k \tag{10}$$

where $B_j^0 = E_j$ and B_j^k is the result after evaluating Equation (10) for k iterative steps.

This iterative method is the same as the well-known *Jacobi* iteration method for solving a linear system. A simple extension of this method is to always compute B_i^{k+1} using the latest values of B, as shown in Equation (11).

$$B_i^{k+1} = E_i + \rho_i \sum_{j=1}^{i-1} F_{ij} B_j^{k+1} + \rho_i \sum_{j=i+1}^{n} F_{ij} B_j^k \tag{11}$$

This method is well known as the *Gauss–Seidel* method. It converges faster than the *Jacobi* method. An additional advantage of this method is that it is no longer required to maintain the previous and current sets of B values.

Both the *Jacobi* and *Gauss–Seidel* methods seem to be gathering radiosity values from all the patches of the scene to compute the radiosity of a single patch, which is why these methods are known as *gathering methods*.

Shooting Methods

This class of methods is based on another iterative reformulation of Equation (6). The reformulation is given in Equation (12). In this reformulation, the radiosity of a patch j is distributed or shot to all other patches i of the scene to update their radiosity values.

$$\begin{aligned} B_i^{k+1} &= B_i^k + \Delta Rad \\ \Delta B_i^{k+1} &= \Delta B_i^k + \Delta Rad \end{aligned} \tag{12}$$

where $\Delta Rad = \rho_i \Delta B_j^k F_{ij} = \rho_i \Delta B_j^k \dfrac{A_j}{A_i} F_{ji}$ and is the *unshot* radiosity.

This method starts with $B_i^0 = \Delta B_i^0 = E_i$. A patch j with maximum unshot flux (i.e., $\Delta B_j^k A_j = \max\limits_{1 \le m \le n} \{\Delta B_m^k A_m\}$) is chosen to shoot the radiosity to all other patches. After the shooting is done, the patch's unshot radiosity ΔB_j^k is set to zero. This process of choosing the patch and shooting its unshot radiosity is repeated until converged.

The total number of iterative steps required using iterative shooting methods is not any less than that required for the gathering method. However, in the shooting method, the radiosity values of the patches approach faster to the equilibrium value. Both the iterative methods are rarely run to achieve the full convergence of the solution. They are only computed for a fixed number of iterations in practice. Thus, the shooting method often creates a solution closer to the equilibrium solution, hence the rendering created from the partial radiosity solution obtained using a reasonably small number of iterations is visually preferable. Cohen et al. (2) first proposed this method for solving the radiosity system and called it the progressive refinement method. They computed a display radiosity value $B_i^{display}$ from the partial iterative solution, as shown by the equation

$$B_i^{display} = B_i^k + B_{ambient}^k \tag{13}$$

where $B_{ambient}^k$ is the ambient radiosity approximated by multiple bounces of average radiosity $\overline{\Delta B}^k$ with average diffuse reflectance $\bar{\rho}$, and their expressions are shown below.

$$B_{ambient}^k = \sum_{j=0}^{\infty} \bar{\rho}^j \overline{\Delta B}^k = \frac{1}{1-\bar{\rho}} \overline{\Delta B}^k \tag{14}$$

where

$$\overline{\Delta B}^k = \sum_{j=1}^{n} \Delta B_j^k A_j \Big/ \sum_{j=1}^{n} A_j \text{ and } \bar{\rho} = \sum_{j=1}^{n} \rho_j A_j \Big/ \sum_{j=1}^{n} A_j$$

FORM FACTOR COMPUTATION

Form factor must be computed before solving the radiosity system. Form factor computation is the most complex step of the radiosity method. In general, it takes 60–80% of the computation time in total. There are two classes of methods to compute form factors: analytical methods and numerical methods.

Analytical Methods

The analytical methods are useful only in the absence of the occlusion between two patches. The most often used analytical method is from Nishita and Nakamae (3). It formulates the form factor between a differential patch dS_i of the patch S_i to patch S_j as a line integral. The formulation is given in Equation (15). This method does not consider occlusion between dS_i and S_j.

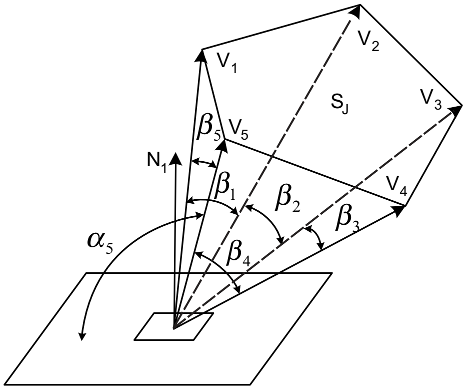

Figure 6. dS_i and S_j.

$$F_{dS_i \to S_j} = \frac{1}{2} \sum_{k=1}^{m} \beta_k \cos \alpha_k \tag{15}$$

where $\cos \beta_k = \dfrac{QV_{k+1}}{|QV_{k+1}|} \cdot \dfrac{QV_k}{|QV_k|}$, $\cos \alpha_k = \dfrac{N_i}{|N_i|} \cdot \dfrac{QV_k \times QV_{k+1}}{|QV_k \times QV_{k+1}|}$, and V_k-s are the vertices of patch S_j and Q is the center of the differential patch dS_i (see Fig. 6 for illustration).

Numerical Methods

Numerical methods are often used in the form factor computation. Hemicube method (4) is one of the first proposed and most popular numerical methods. This method also computes form factor $F_{dS_i \to S_j}$ between a differential patch dS_i to all the patches S_j in the scene. In this method, a virtual unit hemicube is set up around dS_i. The faces of the hemi-cube are discretized into a number of rectangular pixels (See Fig. 7 for illustration). The form factors ΔF_q of pixel q from dS_i to the pixel q on the virtual hemicube is precomputed analytically. All the patches of the scene are scan converted with visibility resolution onto the five faces of the hemicube. $F_{dS_i \to S_j}$ is finally computed by summing up the ΔF_q-s of all the pixels on the hemicube that are occupied by the patch S_j.

This method can take advantage of hardware Z-buffer rendering to speed up the form factor computation. Z-buffering allows for handling the visibility of patches.

The patch-to-patch form factor $F_{i \to j}$ is either approximated to be equal to $F_{dS_i \to j}$ computed from the center of the patch S_i or approximated as an average of the $F_{dS_i \to j}$-s at the vertices of the patch S_i.

ΔF_q-s are precomputed analytically using the equations given below.

For a pixel q on the top face of the hemicube, the following is the equation for ΔF_q:

$$\Delta F_q = \frac{\cos \phi_i \cos \phi_j}{\pi r_{ij}^2} \Delta A_{top} = \frac{1}{\pi (1 + x^2 + y^2)^2} \Delta A_{top} \tag{16}$$

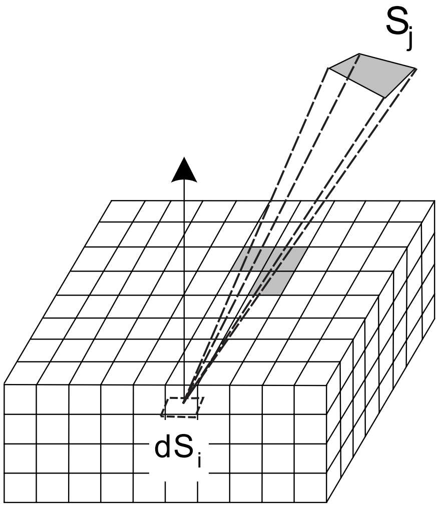

Figure 7. Hemicube.

In this equation, ΔA_{top} is the area of the pixel. Given the local coordinate system setup as shown in Fig. 8, the coordinate of the center of the pixel is $(x,y,1)$, and we also have $\cos\phi_i = \cos\phi_j = 1/r_{ij}$ and $r_{ij} = \sqrt{1+x^2+y^2}$.

For a pixel on the left side face of the hemicube, its ΔF_q is computed as follows:

$$\Delta F_q = \frac{1}{\pi(1+y^2+z^2)^2}\Delta A_{side} \tag{17}$$

where $(-1, y, z)$ is the coordinate of the center of the pixel and ΔA_{side} is the area of the pixel. Equations for the pixels on the other side faces are similar to Equation (17), except for the denominator, which depends on the coordinate of the pixel.

EXTENSIONS TO CLASSIC RADIOSITY

Classic radiosity methods assume that the radiosity is uniform over the area of the surface. This condition is rarely true over larger surfaces of the scene. So the very first step of the radiosity method is scene discretization. Regular discretization of scene surface causes light and shadow leakage at discontinuities due to shadow boundaries and touching objects. A discontinuity meshing technique (5) has been proposed to address this issue. This technique identifies discontinuities and splits the surfaces along the discontinuities first. The split surfaces are further discretized to smaller patches.

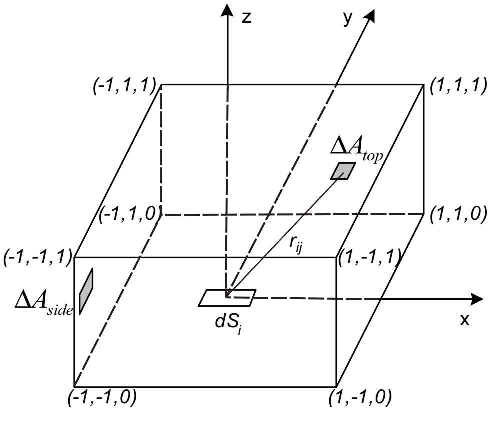

Figure 8. Coordinate system of ΔF_q.

The radiosity computed for patches of a surface gives discrete approximation of a smooth radiosity function over the surface. Direct rendering of such a function gives a faceted appearance to the surface. Hence, a smooth reconstruction of the radiosity function over the surface is desirable before it is used for display. A commonly used reconstruction method is to first compute the weighted average radiosity on vertices of the scene using radiosity of adjacent patches. Weights are the relative areas of the patches. The radiosity on any point on a patch is then interpolated from the vertices of the patch giving a smooth appearance to the scene surfaces.

The assumptions imposed in radiosity formulation often limit the application of the classic radiosity method. The assumptions are: Lambertian surface, uniform light distribution over the patch, planar patches, nonparticipating medium, and so on. There has been much research aimed at overcoming the limitations. Wavelet (6) and finite element methods (7) have been proposed to remove the uniform light distribution assumption and thus to reduce the amount of discretization. The hierarchical radiosity method (8,9) has been proposed to accelerate the computation by reducing the number of form factor computations with very little loss of accuracy. Extensions to support nondiffuse surfaces (10), textured surfaces (11), curved surfaces (12), nondiffuse light sources (13), participating media (14), furry surfaces (15) and fractals (16) have also been proposed.

The radiosity method will remain the primary physically based method for computing realistic lighting in synthetic scenes. More than 15 years of research has been devoted to solving problems related to this method. Findings of this research are being used regularly in many rendering software solutions developed for commercial and noncommercial use. Despite so many years of research efforts, the scene discretization and the extension to nondiffuse environments remain hard problems.

RENDERING

INTRODUCTION

In the real world, light sources emit photons that normally travel in straight lines until they interact with a surface or a volume. When a photon encounters a surface, it may either be absorbed, reflected, or transmitted. Some of these photons may hit the retina of an observer where they are converted into a signal that is then processed by the brain, thus forming an image. Similarly, photons may be caught by the sensor of a camera. In either case, the image is a 2-D representation of the environment.

The formation of an image as a result of photons interacting with a 3-D environment may be simulated on the computer. The environment is then replaced by a 3-D geometric model and the interaction of light with this model is simulated with one of a large number of algorithms. The process of image synthesis by simulating light behavior is called *rendering*.

As long as the environment is not altered, the interaction of light and surfaces gives rise to a distribution of light in a scene that is in equilibrium (i.e., the environment does not get lighter or darker).

As all rendering algorithms model the same process, it is possible to summarize most rendering algorithms by a single equation, which is known as the *rendering equation*. The underlying principle is that each point x on a surface receives light from the environment. The light that falls on a point on a surface may be coming directly from a light source, or it may have been reflected one or more times by other surfaces.

Considering a point x on some surface that receives light from all directions, the material of the surface determines how much of this light is reflected, and in which directions. The reflective properties of a surface are also dependent on wavelength, which gives each surface its distinctive color. A material may therefore be modeled using a function that describes how much light incident on a point on a surface is reflected for each incoming and each outgoing direction. Such functions are generally known as *bidirectional reflectance distribution functions* (BRDFs), and are denoted here as $f_r(\mathrm{x}, \Theta_i, \Theta_o)$. This function is dependent on the position on the surface x, as well as the angle of incidence Θ_i and the outgoing direction Θ_o.

To determine how much light a surface reflects into a particular direction, we can multiply the BRDF for each angle of incidence with the amount of incident light $L_i(\mathrm{x}, \Theta_i)$ and integrate these pairwise multiplications, which yields a quantity for one specific outgoing direction.

A point on a surface may also emit light, which is denoted with a non-zero term $L_e(\mathrm{x}, \Theta_o)$. This term is dependent on position on the surface (e.g., a television screen emits light that is spatially varying in intensity), and may also be directionally varying (e.g., spot lights emit more light in some directions than in others).

Thus, the amount of light that leaves a point x on a surface in a particular direction Θ_o may be modeled as follows:

$$L_o(\mathrm{x}, \Theta_o) = L_e(\mathrm{x}, \Theta_o) + \int_{\Omega_i} g(\mathrm{x}, \Theta_i, \Theta_o) d\omega_i \tag{1}$$

$$g(\mathrm{x}, \Theta_i, \Theta_o) = f_r(\mathrm{x}, \Theta_i, \Theta_o) L_i(\mathrm{x}, \Theta_i) \cos \Theta_i \tag{2}$$

This equation is known as the *rendering equation*. To compute how much light is reflected into a particular direction, we need to integrate over all incident directions (a hemisphere of directions Ω_i if we assume that the surface is not transparent). Thus, the above equation will have to be recursively evaluated for each point in the environment that is visible from x.

To compute an image by simulating light in the above manner, we would have to evaluate the rendering equation for each pixel separately (multiple times if we were to apply *antialiasing* in the process). It should be clear that the number of computations required to evaluate this equation even once is astronomical. For practical problems, the computational cost of evaluating the rendering equation directly is too high. However, there are many ways to simplify this equation, for example, by removing parts of the computation that do not contribute significantly to the final solution.

It is, for instance, possible to only account for the direct contribution of light sources, and ignore all reflected light. Such algorithms fall in the class of *local illumination* algorithms. If indirect illumination (i.e., illumination after one or more reflections or transmissions) is accounted for, then we speak of *global illumination* algorithms.

Finally, the rendering equation is known as a Fredholm equation of the second kind, which implies that no analytical solutions are known. We, therefore, have to resort to numerical approximations to evaluate the rendering equation. In particular, this equation is routinely discretized, turning its evaluation into a sampling problem.

In summary, rendering involves the creation of images by simulating the behavior of light in artificial scenes. Such scenes consist of descriptions of surfaces and light sources (the *geometry*). In addition to having a position in space and a particular shape, surfaces are characterized by the manner in which they interact with light (*material properties*). In the following sections, geometry and materials are discussed in greater detail, followed by a brief explanation of the more prominent local and global illumination algorithms.

GEOMETRY

The shape of an object can be modeled with a collection of simple primitives, including polygon and triangle meshes, spline surfaces, and point-based representations.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

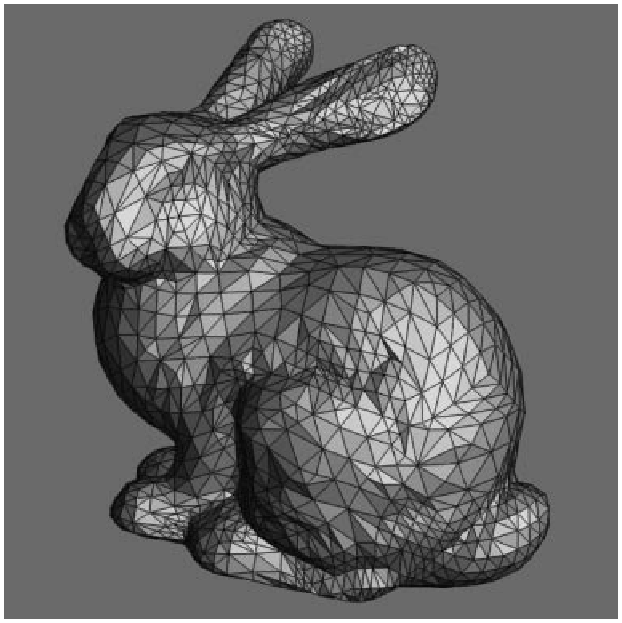

Figure 1. Mesh representation of a model of a bunny. Image courtesy of Hugues Hoppe (1).

Geometric representations can either be modeled by hand using modeling software, such as Alias Wavefront, or objects can be scanned with a laser scanner.

A frequently used representation is a mesh (Fig. 1). A mesh is made up of one or more simple polygonal shapes, for example, triangles. Some polygons share boundaries with other polygons in the mesh and together produce the structure of the object. Of course, polygons will only approximate the shape of the actual object. The larger the number of polygons used (and therefore the smaller their size), the closer the approximation will be to the actual shape of the object. The number of polygons also determines the time it takes to render the object, thereby affording a trade-off between quality and computation time.

For efficiency purposes, large meshes may be reduced in size. One technique to reduce the number of polygons representing an object's surface is *displacement mapping*. In this technique, the surface of the object is represented by fewer, larger polygons, and the small-scale features are captured in a depth map. Points on the surface, which is represented by polygons, are then displaced according to the displacement map. In this way, the object shape retains fine features, but the number of polygons used to represent the object is smaller.

Another way of reducing rendering time is to use *level of detail* algorithms. These algorithms ensure that the object is represented by as many primitives as necessary, dependent on distance to the viewer. If the object is far from the viewpoint, most of the fine details will not be visible, and thus the object's shape may be represented by fewer polygons. If the viewpoint approaches the object, the object needs to be represented by a larger number of polygons so that the fine-scale features, which are now visible, are adequately visualized.

The shape of an object may also be described by parametric equations such as Bézier curves and B-splines. The parametric surface has certain advantages over the simpler polygonal model. First, the representation is much more concise. If an object has fine features, the mesh will require many polygons to represent the object. However, patches of the same surface, when represented paramet-rically, will be fewer, which is because each patch can represent a curved surface segment, whereas triangles and polygons are flat.

Scanners can be used to determine the shape of existing objects. The output from a scanner is a dense set of points. Typically-these points define the vertices of a triangle mesh. Relatively recently, algorithms have been developed to render point clouds directly, obviating the need for triangulation. This approach also lends itself to a simpler level of detail algorithms because altering the number of points is more straightforward than altering the number, size, and shape of polygons or patches representing the object shape.

MATERIALS

The micro-structure of the object determines the way light interacts with it, and hence it determines the appearance of the object. This micro-structure is represented by a material description, such as the BRDF f_r introduced in the Introduction.

If a surface scatters light equally in all directions, we call the material *diffuse* or *Lambertian*, leading to a BRDF that is a constant function (i.e., $f_r = \rho/\pi$) where ρ is a measure of how much light is reflected. Other materials may reflect light more in some directions than others, which is a function of the direction of incidence. For instance, a mirror reflects almost all light in the reflected direction. In between lie glossy materials that scatter light into a cone centered around the direction of mirror reflection.

The angles Θ_i and Θ_o can each be decomposed into an elevation angle ϕ and an azimuthal angle θ in the plane of the surface, for instance, $\Theta_i = (\phi_i, \theta_i)$. If the material's reflective properties depend only on ϕ_i, ϕ_o, and $\theta_i - \theta_o$, then reflections are invariant to rotation around the surface normal, and the material is called isotropic. On the other hand, if f_r depends on $\theta_i, \theta_o, \phi_i$, and ϕ_o independently, then rotation around the surface normal will alter the reflection, and the material is called anisotropic (brushed aluminium is an example).

Real materials can be measured, or BRDFs may be modeled empirically. In the latter case, reciprocity and conservation of energy are considered important features of any plausible BRDF. Reciprocity refers to the fact that f_r should return the same result if Θ_i and Θ_o are reversed. Conservation of energy means that light is either reflected or absorbed, but not lost in any other way.

Extensions to basic BRDFs include models for transparency (e.g., glass), translucency, and spatial variance. Translucency stems from light scatter inside a surface, as shown in Fig. 2. Wax, skin, fruit, and milk all display some degree of translucency. An example of a spatially varying material is woodgrain, which is normally modeled using texture mapping. A texture map can be created by taking a photograph of the desired material, and then

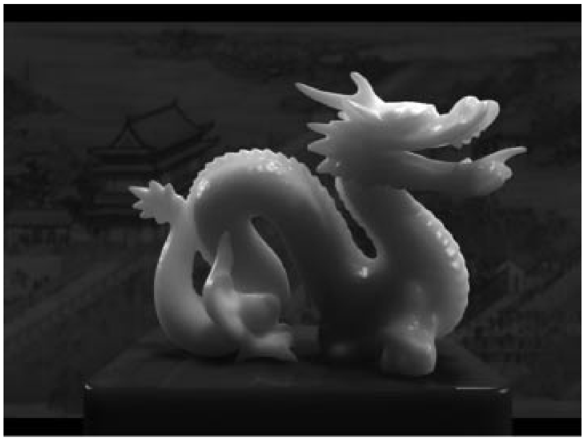

Figure 2. An example of an object rendered with a translucent material. Image courtesy of Rui Wang, university of Massachusetts, Amherst.

mapping it onto the surface of the object. Texture maps and BRDFs may be combined to yield spatially variant BRDFs, or *bidirectional texture functions* (BTFs).

LOCAL ILLUMINATION

Images may be rendered by projecting all the geometry onto a plane that represents the screen in 3-D space, thus implementing a local illumination model. For each pixel, the nearest object may be tracked using a *z-buffer*. This buffer stores for each pixel the distance between the view point and the currently nearest object. When a new object is projected, its distance is tested against the distances stored in the z-buffer. If the new object is closer, it is drawn and the z-buffer is updated. The color assigned to the pixel is then derived from the object's color using a simple shading algorithm.

The simplicity of projective algorithms makes them amenable to hardware implementation. As a result, most graphics cards implement a graphics pipeline based on z-buffering. To maximize performance, geometry is typically limited to simple shapes such as triangle and polygonal meshes. Only simple materials are supported.

However, modern graphics cards incorporate two programmable stages that allow vertices and pixels to be manipulated respectively, providing flexibility in an otherwise rigid hardware environment. Programming these two stages is achieved through APIs such as *OpenGL* or *DirectX*. The (limited) ability to program graphics cards has given rise to many extensions to the basic z-buffer algorithm, such as *shadow maps*, which compute shadows.

RAY TRACING AND RAY CASTING

One of the basic operations in rendering is to compute which (part of an) object is visible from a given point in space and a given direction. Such sampling of the scene is often accomplished with a technique called *ray casting*. A ray is a half-line starting at a specified point in space (its *origin*) and aimed at a particular *direction*. There may be many objects located along the line of sight of such a ray, and to compute which object is closest to the ray origin, the ray is intersected with each object. The point on the surface of the nearest object where the ray intersects, is called the *intersection point*. Functions for ray intersection calculations are available for a wide variety of geometric primitives, including triangles, polygons, implicit surfaces, and splines—a distinct advantage of any ray casting-based algorithm.

An image of a scene may be created by specifying a camera position, and casting (primary) rays starting at this position into different directions associated with the pixels that make up the image. This process computes for each pixel the nearest object. The color of the nearest object is then assigned to its corresponding pixel. Such a ray caster may be extended to a full ray tracer by also shooting secondary rays. These rays start at the intersection points of the primary rays and are aimed into specific directions based on which type of lighting effect is desired.

For instance, rays may be traced from an intersection point toward the light sources. Such shadow rays are useful for computing shadows, because the shading of the intersection point can be adjusted based on whether it was in shadow or not.

If an intersection point belongs to an object with a specular material, an additional ray may be shot into the reflected direction. This direction is computed by mirroring the incident ray into the *surface normal*, a vector that specifies the surface orientation at the intersection point. The reflected ray is then recursively traced and its returned color is assigned to the intersection point, which is in turn used to color a pixel. The same procedure is followed for transmitted rays in the case of transparent objects. A typical ray tracing example is shown in Fig. 3.

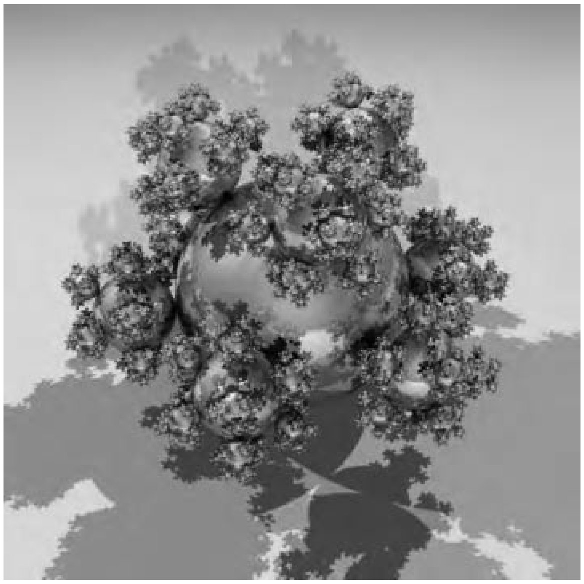

Figure 3. A typical ray traced image, consisting of reflective spheres and sharp shadows. Image courtesy of Eric Haines. The model is part of the Standard Procedural Database, as set of models for testing rendering algorithms; see *http://www.acm.org/tog/resources/SPD/*.

Thus, ray tracing is a recursive algorithm based on casting rays. Starting from the view point, it is called *eye ray tracing*. It is a relatively straightforward way to evaluate a simplified version of the rendering equation [Equation (1)], known as the ray tracing equation:

$$\begin{aligned} L_o(\mathrm{x},\Theta_o) = {} & L_e(\mathrm{x},\Theta_o) \\ & + \sum_{L} \int_{x_i \in L} v(\mathrm{x},\mathrm{x}_i)\, f_{r,d}(\mathrm{x}) L_e(\mathrm{x}_i,\Theta_i) \cos\Theta_i d\omega_i \\ & + \int_{\Theta_s \in \Omega_s} f_{r,s}(\mathrm{x},\Theta_s,\Theta_o) L(\mathrm{x}_s,\Theta_s) \cos\Theta_s d\omega_s \\ & + \rho_d(\mathrm{x}) L_a(\mathrm{x}) \end{aligned}$$

The four terms on the right-hand side are the emission term, followed by a summation of samples shot toward the light sources. The visibility term $v(\mathrm{x},\mathrm{x}_i)$ is 1 if position x_i on the light source is visible from point x and 0 otherwise. The integration in the second term is over all possible positions on each light source. The third term accounts for specular reflections, and the fourth term is the *ambient term*, which is added to account for everything that is not sampled directly.

Thus, in ray tracing, only the most important directions are sampled, namely the contributions of the light sources and mirror reflections, which represents a vast reduction in computational complexity over a full evaluation of the rendering equation, albeit at the cost of a modest loss of visual quality. Finally, ray tracing algorithms can now run at interactive rates and, under limited circumstances, even in real-time.

RADIOSITY

Both ray tracing and the local illumination models discussed earlier are view-point-dependent techniques. Thus, for each frame, all illumination will be recomputed, which is desirable for view-point-dependent effects, such as specular reflection. However, diffuse reflection does not visibly alter if a different viewpoint is chosen. It is therefore possible to preprocess the environment to compute the light interaction between diffuse surfaces, which may be achieved by employing a radiosity algorithm (Fig. 4). The result can then be used to create an image, for instance, by ray tracing or with a projective algorithm.

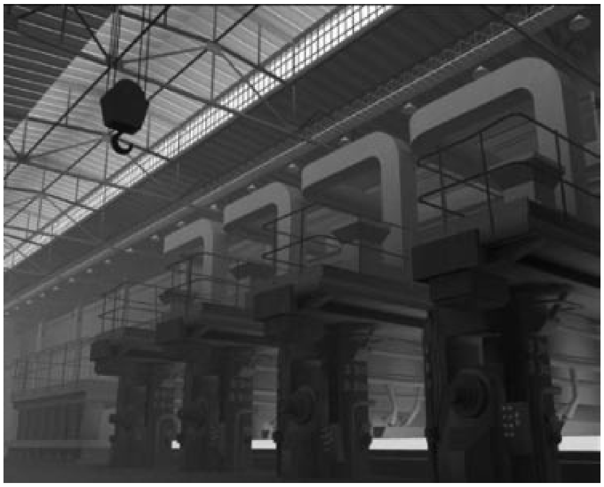

Figure 4. An early example of a scene preprocessed by a radiosity algorithm. Image courtesy of Michael Cohen (2).

The surfaces in the environment are first subdivided into small patches. For computational efficiency, it is normally assumed that the light distribution over each patch is constant. For small enough patches, this assumption is fair. Each patch can receive light from other patches and then diffusely reflect it. A common way to implement radiosity is to select the patch with the most energy and distribute this energy over all other patches, which then gain some energy. This process is repeated until convergence is reached. As all patches are assumed to be diffuse reflectors, the rendering equation [Equation (1)] can be simplified to not include the dependence on outgoing direction Θ_o:

$$L(\mathrm{x}) = L_e(\mathrm{x}) + \rho_d(\mathrm{x}) \int_{\mathrm{x}} L(\mathrm{x}') \frac{\cos\Theta_i \cos\Theta_o'}{\pi \|\mathrm{x}' - \mathrm{x}\|^2} v(\mathrm{x},\mathrm{x}') dA'$$

where $v(\mathrm{x},\mathrm{x}')$ is the visibility term, as before. This equation models light interaction between pairs of points in the environment. As radiosity operates on uniform patches rather than points, this equation can be rewritten to include a *form factor*F^{ij}, which approximates the fraction of energy leaving one patch and reaching another patch:

$$L^i = L_e^i + \rho_d^i \sum_j L^j F^{ij}$$

$$F^{ij} = \frac{1}{A^i} \int_{A^i} \int_{A^j} \frac{\cos\Theta_i \cos\Theta_j}{\pi r^2} \delta^{ij} dA^j dA^i$$

where the visibility term v between points is replaced with δ^{ij}, which denotes the visibility between patches i and j. The form factor depends on the distance between the two patches, as well as their spatial orientation with respect to one another (Fig. 5). In practice, the computation of form factors is achieved by ray casting.

The radiosity algorithm can be used to model diffuse inter-reflection, which accounts for visual effects such as

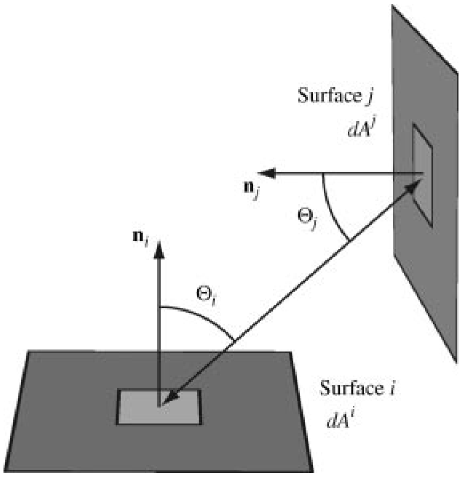

Figure 5. Geometric relationship between two patches.

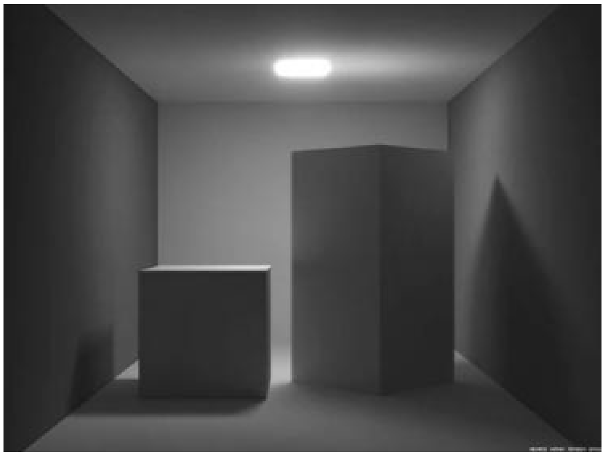

Figure 6. Example of color bleeding. In particular, the gray object on the right has a tinge of yellow and blue, caused by light that was first reflected off the yellow and blue surfaces. Image courtesy of Henrik Wann Jensen.

color bleeding (the colored glow that a surface takes on when near a bright surface of a different color, as shown in Fig. 6).

MONTE CARLO SAMPLING

The integral in the rendering equation [Equation (1)] may be evaluated numerically. However, as both the domain Ω_i and the integrand [Equation (1)] are complex functions, a very large number of samples would be required to obtain an accurate estimate. To make this sampling process more efficient, a stochastic process called Monte Carlo sampling may be employed. The environment is then sampled randomly according to *a probability density function* (pdf) $p(\omega_i)$:

$$\int_{\Omega_i} g(\omega_i, \Theta_i, \Theta_o) d\omega_i \approx \frac{1}{N} \sum_{i=1}^{N} \frac{g(\omega_i, \Theta_i, \Theta_o)}{p(\omega_i)}$$

The number of sample points N can be set to trade speed for accuracy. Typically, to evaluate each $g(\omega_i, \Theta_i, \Theta_o)$, a ray is traced into the environment. For efficiency, the pdf should be chosen to follow the general shape of the integrand $g(\omega_i, \Theta_i, \Theta_o)$. There are many ways to choose the pdf, a process known as *importance sampling*.

In addition, it is possible to split the integral into disjunct parts for which a simpler pdf may be known. This process is called *stratified sampling*. One could view ray tracing as a form of stratified sampling, because instead of sampling a full hemisphere around each intersection point, rays are only directed at the light sources and the reflected and transmitted directions. Both importance sampling and stratified sampling will help reduce the number of samples N required for an accurate evaluation of the rendering equation [Equation (1)].

PHOTON MAPPING

Certain complex types of illumination such as the caustic patterns created by light refracted through transparent objects are not efficiently sampled by Monte Carlo sampling alone. Rendering algorithms, such as ray tracing, radiosity, as well as local illumination models, expressly omit the sampling that would be required to capture caustics.

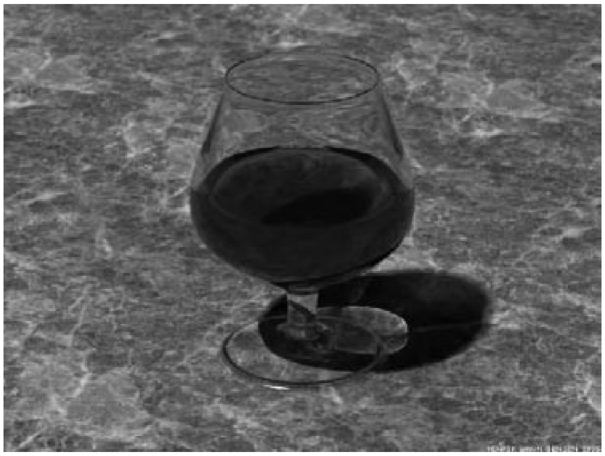

Figure 7. Light refracted through the transparent glass creates a caustic on the table. Image courtesy of Henrik Wann Jensen.

To enable the rendering of caustics, as shown in Fig. 7, as well as make rendering of other light interactions such as diffuse inter-reflection more efficient, photons may be tracked starting at the light source (known as *photon ray tracing*), rather than tracing photons backwards starting at the viewpoint (as in eye ray tracing). They can then be deposited on diffuse surfaces after having undergone one or more refractions through dielectric (transparent) objects. Thus, photons are stored in a data structure called *a photon map*, which represents the distribution of light over the surfaces in an environment.

An image may then be created using conventional ray tracing. Whenever an intersection with a diffuse surface is detected, the photon map is used to determine how much light is present at the intersection point. The photon map may therefore be seen as a data-structure to connect the initial light pass with the subsequent rendering pass.

Regarding efficiency, photon maps need to be created only once as long as the scene is static. The rendering pass can be repeated for any desired viewpoint.

IMAGE-BASED RENDERING

To avoid the expense of modeling a complicated scene, it is sometimes more convenient to photograph a scene from different viewpoints. To create images for novel viewpoints that were not photographed, an interpolation scheme may be applied. Rendering using images as a modeling primitive is called *image-based rendering*. Such techniques attempt to compute a continuous representation of the *plenoptic* function, given some discrete representation of it. The plenoptic function is defined as the intensity of light rays passing through the camera center at every camera location (V_x, V_y, V_z), orientation (θ, ϕ), and for every wavelength (λ) and time (t), that is:

$$P_7 = P(V_x, V_y, V_z, \theta, \phi, \lambda, t) \tag{3}$$

Thus, the plenoptic function may be considered a representation of the scene, such that, when input parameters like camera location and orientation are altered, the scene represented by the function changes accordingly. Simplified versions of the plenoptic function exist. For instance, if we assume that the environment is constant, we may remove the parameter t. The simplest plenoptic function is a 2-D panoramic view of the scene with a fixed viewpoint. θ and ϕ are the only two input parameters in this case.

If instead of a full panoramic view, we captured several images that are a part of this panoramic view, then these images would be a discrete representation of the plenoptic function. Image-based rendering techniques take these discrete representations as input and provide a continuous representation, for example, the complete panoramic view in the above case. A technique might take two images with different viewpoints as input and produce a set of images that have viewpoints that lie in between the two original viewpoints.

There are many image-based rendering techniques, and they may be broadly classified into three groups. The first group requires complete information of scene geometry, for example, in the form of a depth map of the scene. This information along with one or more images is sufficient to render scenes from a viewpoint close to the viewpoint of the given image(s). 3-D warping techniques belong to this category.

The second group of image-based rendering techniques uses only input images of the scene to render another image of the same scene from a different viewpoint. There is no reliance on any given information of the scene geometry. Examples include *light field rendering* and *lumigraph* systems.

The third group lies somewhere in between the previous groups. This group requires several input images as well as further geometric information in the form of correspondence features in the two images (for example, points). Given this correspondence, the scene may be rendered from all viewpoints between the two viewpoints of the original input images. *View morphing* (Fig. 8) and *interpolation* techniques fall under this category.

Images may also be used to represent the lighting of the scene alone, whereas geometry and materials are represented directly. This process is called *image-based lighting* (IBL, see Fig. 9). Here, the first step is to create the image that will represent the lighting of the scene. An image of a mirrored ball placed in the scene may be used to represent this lighting. Images typically have a limited range of pixel values (0 to 255), which cannot represent the lighting of an arbitrary scene. *High dynamic range* (HDR) images are used instead as their pixel values are not limited to 256 values and are proportional to the actual illumination of the scene. The captured image is then mapped to a sphere and the object is placed within it before rendering.

FURTHER READING

Rendering is an important part of the field of computer graphics. There are many excellent books, as well as a vast number of papers. Examples of general graphics books are in Refs. (5–9). References (10–13) are books specifically for ray tracing. Global illumination is covered in Ref. 14. Radiosity is explained in detail in Refs. 15–17. Photon mapping is described in Ref. 18. For local illumination models as well as using the OpenGL API, see Ref. 19. Image-based lighting is a relatively new rendering technique, described in Ref. 20. For real-time rendering, see Ref. 21. Parallel rendering is covered in Ref. 22. The notation used for the equations in this article are based on Arjan Kok's thesis (23).

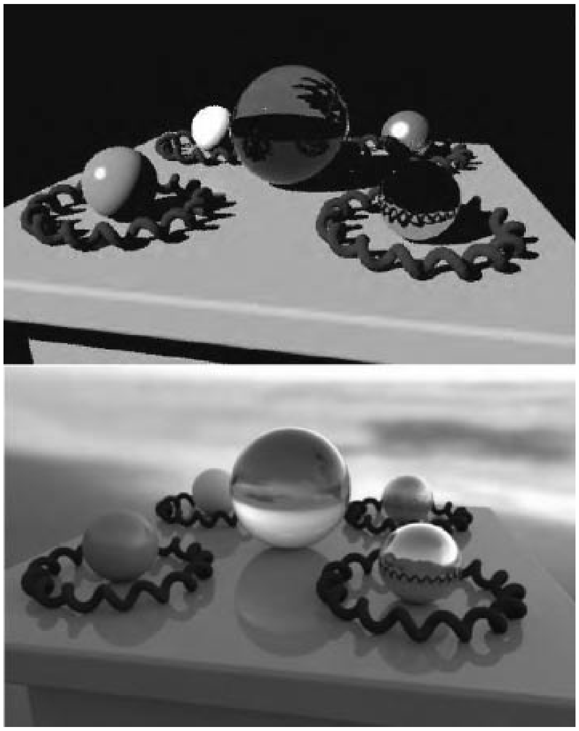

Figure 9. Scene rendering without image based lighting (top), and with image-based lighting (bottom). Image courtesy of Paul Debevec (4).

The latest research on rendering is published in a variety of forums. The most relevant conferences are *ACM SIGGRAPH*, the *Eurographics Symposium on Rendering*, and the *Eurographics main* conference. In addition, several journals publish rendering papers, such as *ACM Transactions on Graphics*, *IEEE Transactions on Visualization and Computer Graphics*, *Eurographics Forum*, and the *Journal of Graphics Tools*.

SOLID MODELING

Solid modeling is the technique for representing and manipulating a complete description of physical objects. A complete description of a solid object is a representation of the object that is sufficient for answering geometric queries algorithmically. This requires a mathematical formulation that defines rigorously the characteristics of a solid object. Based on this mathematical formulation, different schemes for representing physical objects are developed.

MATHEMATICAL FORMULATION

A solid is described using the concept of point-set topology, whereas the boundary of a solid is characterized by using the concept of algebraic topology as discussed below. A solid is a closed point set in the three-dimensional Euclidean space E^3. For example, a unit cube is denoted as $S = \{\mathbf{p} : \mathbf{p} = (x,y,z),$ such that $x \in [0,1], y \in [0,1], z \in [0,1]\}$. A point set in E^3 denoting a solid is rigid and regular (1). A point set is rigid, which implies that it remains the same when being moved from one location to another. A point set is regular, which implies that the point set does not contain isolated points, edges, or faces with no material around them. To ensure a point set is regular, a regularization process is applied to a point set as defined below.

Definition 1. Regularization of a Point Set. Given a point set S, the regularization of S is defined as $r(S) = c(i(S))$, where $c(S)$ and $i(S)$ are, respectively, the closure and interior of S

The regularization process discards isolated parts of a point set, which is then enclosed with a tight boundary resulting in a regular point set. A point set S is regular if $r(S) = S$, and a regular set S is usually referred to as an r-set.

BOOLEAN OPERATIONS ON POINT SETS

Boolean operations on r-sets may result in a nonregular point set. For example, if $A = \{\mathbf{p} : \mathbf{p} = (x,y,z),$ such that $x \in [0,1], y \in [0,1], z \in [0,1]\}$ and $B = \{\mathbf{p} : \mathbf{p} = (x,y,z),$ such that $x \in [1,2], y \in [1,2], z \in [1,2]\}$, then,

$$A \cap B = \{\mathbf{p} : \mathbf{p} = (x,y,z), \text{ such that } x \in [0,1] \cap [1,2], y \in [0,1] \cap [1,2], z \in [0,1] \cap [1,2]\}$$

or,

$$A \cap B = \{\mathbf{p} : \mathbf{p} = (x,y,z), \text{ such that } x = 1, y = 1, z = 1\},$$

$A \cap B$ is thus a single point and is not regular. To ensure the result of Boolean operations on point sets are regular point sets, the concept of regularized Boolean operation is adopted. In the above example, $A \cap B = (1,1,1)$, the interior of $A \cap B$ is empty; i.e., $i(A \cap B) = \phi$. As the closure of $i(\phi)$ is empty, applying a regularization on $A \cap B$ gives $r(A \cap B) = c(i(A \cap B)) = \phi$. Based on the concept of regularization on point sets, regularized Boolean operation is defined as follows.

Definition 2. Regularized Boolean Operations. Denote $\cup^*$, $\cap^*$, and -* as the regularized union, intersect, and difference operations, respectively. They are defined as follows:

$$A \cup^* B = c(i(A \cup B) \tag{1a}$$

$$A \cap^* B = c(i(A \cap B) \tag{1b}$$

$$A -^* B = c(i(A - B) \tag{1c}$$

A point set describing a solid must be finite and well defined. The surfaces of a solid are thus restricted to be algebraic or analytic surfaces.

THE BOUNDARY OF A SOLID

The boundary of a solid is a collection of faces connected to form a closed skin of the solid. The concept of algebraic topology (2) is usually adopted for characterizing the boundary of a solid.

The surface composing the boundary of a solid is a 2-manifold in the two-dimensional space E^2. A 2-manifold is a topological space in which the neighborhood of a point on the surface is topologically equivalent to an open disk of E^2. However, there are cases when the boundary of a solid is not a 2-manifold as shown in Fig. 1. In addition, some 2-manifolds do not constitute a valid object in E^3 (e.g., the Klein bottle). To ensure the boundary of an object encloses a valid solid, the faces of the boundary must be orientable with no self-intersection. An object is invalid (or is a nonmanifold object) if its boundary does not satisfy the Euler–Poincare characteristic as described below.

THE EULER–POINCARE CHARACTERISTIC

The Euler–Poincare characteristic states that an object is a nonmanifold object if its boundary does not satisfy the equation

$$v - e + f = 2(s - h) + r$$

where v-number of vertices, e-number of edges, f-number of faces, s-number of shells, h-number of through holes, and r-number of rings.

The Euler–Poincare formula is a necessary but not a sufficient condition for a valid solid. An object with a boundary that does not satisfy the Euler–Poincare formula is an invalid solid. On the contrary, an object satisfying the Euler–Poincare formula may not be a valid solid. Figure 2

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

illustrates an invalid solid satisfying the Euler–Poincare formula.

REPRESENTATION SCHEMES

Denote M as the modeling space of solids. That is, a solid X is an element of M. A solid representation (1) of an object is a collection of symbols specifying the solid object. There are various representation schemes for modeling solids defined as point sets in E^3. In general, the properties of a solid representation scheme can be described as follows:

Geometric coverage — the objects that can be described using the representation scheme.

Validity — a representation scheme must designate a valid solid (Fig. 3)

Completeness — a representation must provide enough data for any geometric computation. For example, given a point **p**, an algorithm must exist for deciding if **p** is *in, on,* or *out* of the solid.

Uniqueness — a representation scheme is unique if there is only one representation for a given solid object.

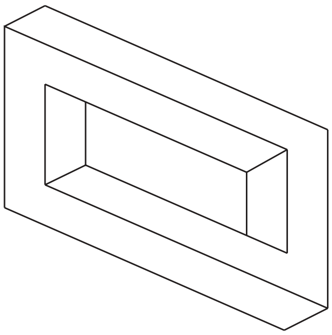

Figure 3. An invalid solid.

Unambiguous — a representation scheme is unambiguous if a representation designates exactly one solid object.

Conciseness — the space (computer storage) required for a valid representation.

Closure of operation — whether operations on solids preserve the validity of the representation.

Computational requirement and applicability — the algorithms that can be applied to the representation scheme and the complexity of these algorithms.

Among the various solid representation schemes, the constructive solid geometry and the boundary representation are the most popular schemes as discussed in the following.

CONSTRUCTIVE SOLID GEOMETRY (CSG)

Constructive solid models consider solids as point sets of E^3. The basic elements of CSG model are simple point sets that can be represented as simple half-spaces. Given a mapping $f : E^3 \rightarrow R$ that maps the Euclidean space to the real axis, the function $f(\mathbf{p})$, where $\mathbf{p}$ is a point in E^3, divides the three-dimensional space into two halves. They are the space $f(\mathbf{p}) > 0$ and its complement $f(\mathbf{p}) \leq 0$. More complex objects are obtained by combining half-spaces with Boolean operations. Figure 4 shows a cylinder constructed with three half-spaces. An object modeled with constructive solid geometry can be represented with a CSG tree. A CSG tree is a binary tree structure with half-spaces or primitive solids at the leaf nodes. Figure 5 shows a set of solid primitives commonly used in a CSG modeler. All internal nodes are Boolean operations or transformations. An example is shown in Figure 6, where an L-shaped block is constructed with a CSG modeler. Figure 7 gives an example for modeling a more complicated object using a CSG modeler.

POINT MEMBERSHIP CLASSIFICATION AND BOOLEAN OPERATIONS

A basic characteristic of a solid representation scheme is to be capable of providing sufficient information for deciding

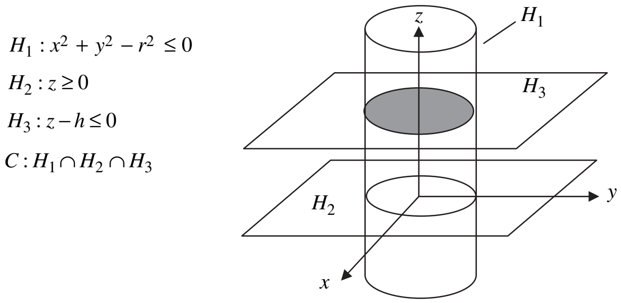

Figure 4. A cylinder constructed with three half-spaces.

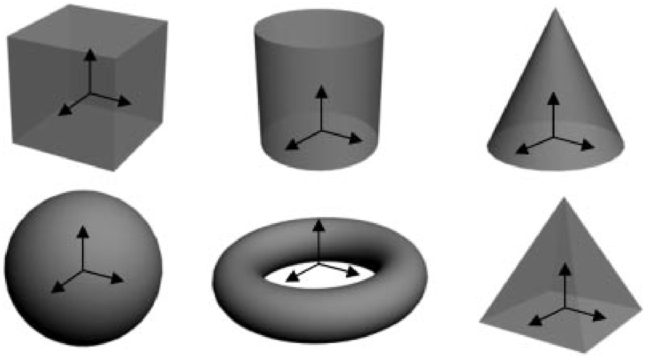

Figure 5. Commonly used solid primitives.

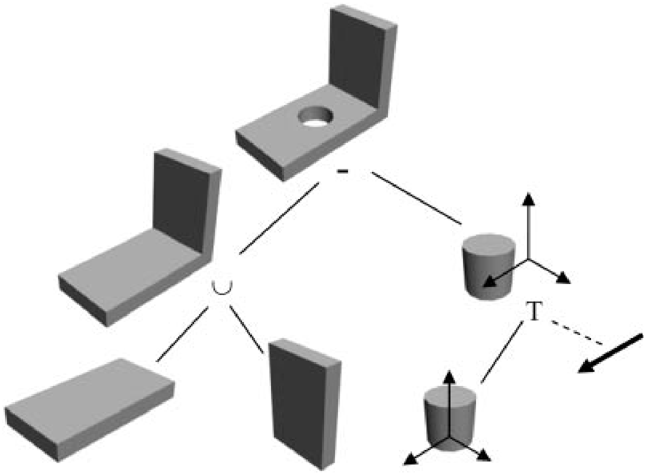

Figure 6. The CSG tree of an L-shaped block.

if a given point **p** is *in*, *on*, or *out* of a solid using a suitable point membership classification (PMC) (3,4) algorithm. Using a CSG representation scheme, point membership classification is performed with a divide-and-conquer approach. Starting from the root node of the CSG tree, the point **p** is passed down the tree. Whenever a Boolean operation node is encountered, **p** is passed to both the left and right subnodes of the current node. If a transformation node is encountered, an inverse transformation is applied to **p** and the result is passed to the left subnode. Whenever a leaf node is encountered, the point (possibly transformed) is classified against the half-space or primitive solid of the node. The result is propagated upward to the parent node. In this upward propagation, the results of the left and right subtree of a Boolean operation node are combined. The upward propagation ends at the root node where the result obtained will be the result of classifying p against the whole object.

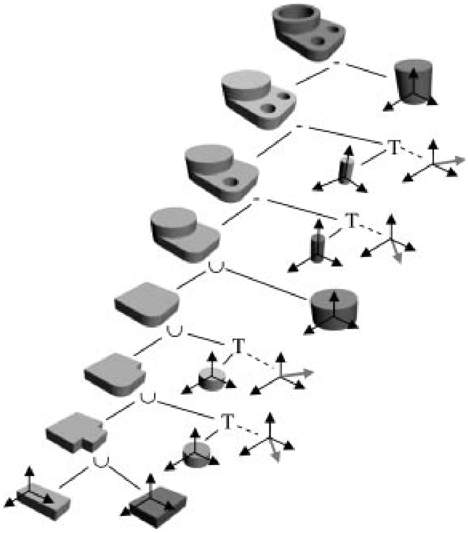

Figure 7. Object modeling with constructive solid geometry.

Combining the PMC results at a Boolean operation node requires special consideration. Assume R_L and R_R as the PMC results of the left and right subtrees, respectively. If $R_L \neq \text{on}$ or $R_R \neq \text{on}$, then the result of R_L *.op.* R_R (where $op \in \{\cup, \cap, -\}$) can be easily obtained according to Table 1. In all three cases, if a point is *on* both A and B, the classification result is undetermined. For instance, in Fig. 8, the point **p** is *on* both A and B. However, **p** may be *in* or *on* $A \cup B$ depending on the relative position of A and B. To obtain an accurate classification result, information regarding the local geometry of the solids in the vicinity of the point is required for the classification.

NEIGHBORHOOD

The Neighborhood $N(\mathbf{p}, S)$ of a point $\mathbf{p} = (x, y, z)$ with respect to a solid S is the intersection of an open ball with S, where the open ball is a sphere with an infinitesimal

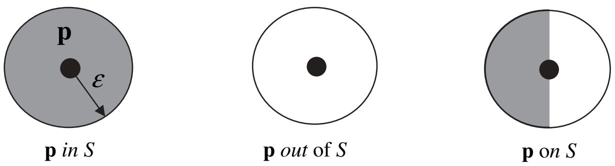

Figure 9. Three possible cases of the neighborhood at a point.

radius ε centered at **p**; i.e.,

$$N(\mathbf{p}, S) = S \cap \{(x\prime, y\prime, z\prime) | (x\prime - x)^2 + (y\prime - y)^2 + (z\prime - z)^2 < \varepsilon^2\} \qquad (2)$$

Using the notion of neighborhood, the following three cases can be established (Fig. 9):

1. A point **p** is *in* S iff N(**p**, S) is a full ball.
2. A point **p** is *out* of S iff N(**p**, S) is empty.
3. A point **p** is *on* S iff N(**p**, S) is not full and not empty.

If **p** lies in the interior of a face, its neighborhood can be represented by the equation of the surface and is oriented such that the face normal points to the exterior of S (Fig. 10a). If **p** lies in the interior of an edge, the neighborhood is represented by a set of sectors in a plane containing **p** that is perpendicular to the edge at **p** (Fig. 10b). A vertex neighborhood is inferred from the set of face normals of the faces incident at **p** (Fig. 10c). In a Boolean operation between two objects A and B, the neighborhoods of a point **p** relative to A and B are combined. Whether the combined neighborhood is full, empty, or not full nor empty determines whether **p** is *in, out*, or *on* the combined solid. In addition, by interpreting whether the neighborhood is a face neighborhood, edge neighborhood, or vertex neighborhood, the point **p** can be classified to be lying on a face, an edge, or is a vertex. For example, in a union node, if the neighborhood N_L, N_R of **p** relative to both the left and the right subtrees are face neighborhoods with face normals $\mathbf{n}_L$ and $\mathbf{n}_R$, respectively, then the union N of N_L and N_R is an edge neighborhood when $|\mathbf{n}_L \bullet \mathbf{n}_R| \neq 1$. If $\mathbf{n}_L \bullet \mathbf{n}_R = 1$, then N is a face neighborhood. If $\mathbf{n}_L \bullet \mathbf{n}_R = -1$, N is full (Fig. 11). If N_L and N_R are edge neighborhoods, the union of N_L and N_R may be a vertex neighborhood, an edge neighborhood, a face neighborhood, or it is full (Fig. 12).

BOUNDARY EVALUATION

CSG representation provides a concise description of a solid. However, there is no explicit information for display purposes. To obtain this explicit information, a boundary evaluation process is required. This requires classifying all edges and faces of all primitive solids (or half-spaces) against the CSG representation of the solid. These are performed with the edge-solid classification and the face-solid classified algorithms.

In the edge-solid classification process, an edge L is partitioned into segments by intersecting L with all primitives of the solid. These segments are then classified against the given solid. A simple approach for classifying segments is to apply a point membership classification at the midpoint of each segment. Segments that are classified as lying *on* the solid are combined to give edges of the solid (Fig. 13).

In the face-solid classification process, a face is intersected with all primitives of the solid. The intersection edges and the boundary edges of the face are then classified against the given solid using the edge-solid classification algorithm. Edges lying on the solid are then connected to form boundaries of the face (Fig. 14).

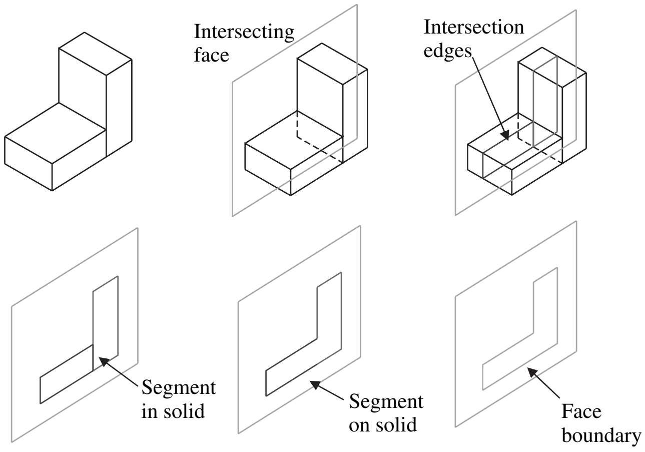

Figure 14. Face-solid classification.

PROPERTIES OF CSG MODELS

The geometric coverage of a CSG modeler depends on the type of primitive solids and half-spaces used. Provided all primitives are *r*-sets, and regularized set operations are adopted for the construction of more complex solids, CSG models are always valid solids. CSG models are unambiguous but not unique. A CSG model can be described precisely using a binary tree. CSG representations are thus relatively concise. Algorithms for manipulating CSG models (e.g., boundary evaluation) may be computationally expensive. With suitable algorithms, CSG models can be converted to other types of solid representations.

BOUNDARY REPRESENTATION

A boundary representation (B-Rep) of a solid describes a solid by its boundary information. Boundary information in a B-rep includes the geometric information and the topological relationship between entities of the boundary. Geometric information refers to the vertices, positions, surfaces, and curves equations of the bounding faces and edges. Topological relationship refers to the relationship among the faces, edges, and vertices so that they conform to a closed volume. For instance, the boundary of an object can be modeled as a collection of faces that forms the complete skin of the object. Each face is bounded by a set of edge loops, and each edge is, in general, bounded by two vertices. The boundary of an object can thus be described as a hierarchy of faces and edges as depicted in Fig. 15.

B-REP DATA STRUCTURE

Among the various data structures for implementing B-Rep, the most popular one is the winged-edge structure (5), which describes a manifold object with three tables of vertices, faces, and edges. In the winged-edge structure, each face is bounded by a set of disjoint edge loops or cycles. Each vertex is shared by a circularly ordered set of edges. For each edge, there are two vertices bounding the edge, which also defines the direction of the edge. There are two

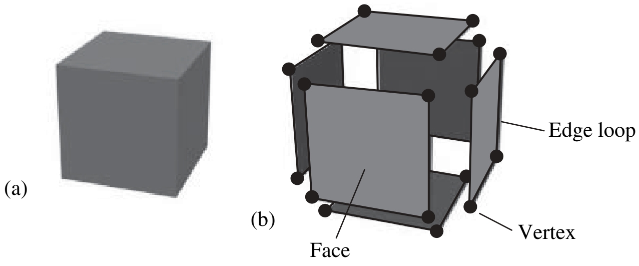

Figure 15. Boundary data: (a) A cube and (b) boundary data of a cube.

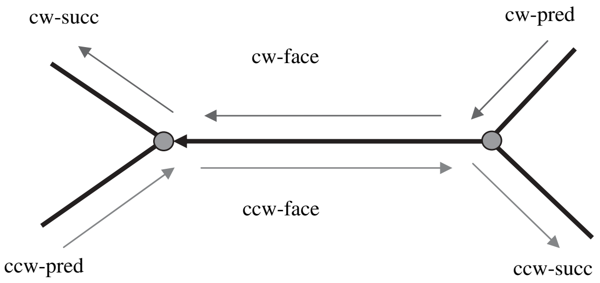

Figure 16. The winged-edge data structure.

faces, the left and the right adjacent faces, sharing an edge. There are two edge cycles sharing an edge. One edge cycle is referred to as in the clockwise direction, and the other is in the counterclockwise direction. The edge cycle on a face is always arranged in a clockwise direction as viewed from outside of the solid. In each direction, there is a preceding and a succeeding edge associated with the given edge. Figure 16 illustrates the relations among vertices, edges, and faces in a winged-edge structure. Table 2 gives an example of a winged-edge representation of the tetrahedron shown in Fig. 17.

VALIDITY OF B-REP SOLID AND EULER OPERATORS

Given a boundary representation specifying a valid solid, the set of faces of a boundary model forms the complete skin of the solid with no missing parts. Faces of the model do not intersect each other except at common vertices or edges. Face boundaries are simple polygons or closed contours that do not intersect themselves. To avoid the construction of invalid B-Rep solid, Euler operators (4,5) are usually employed in the object construction process. Euler operators keep track of the number of different topological entities in a model such that it satisfies the Euler–Poincare characteristic. Euler operators are functions defined as strings of symbols in the character set {M, K , S, J, V, E, F, S, H, R}. Each of the symbols M, K, S, and J denotes an operation on the topological entities V, E, F, S, H, and R. Descriptions of these symbols are listed below:

M—make, K—kill, S—split, J—join,
V—vertex, E—edge, F—face, S—solid, H—hole, R—ring.

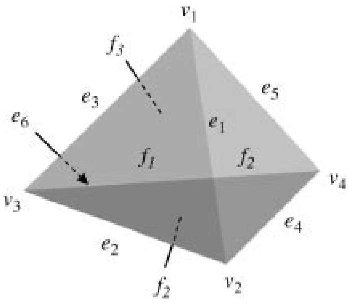

Figure 17. A tetrahedron.

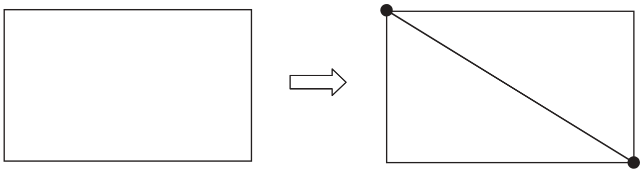

Figure 18. The MEF operator.

For example, an operator MEF denotes a function to "Make Edge and Face." As shown in Fig. 18, inserting an edge in the model also creates another face at the same time. In Fig. 19, the operator KEMR removes an edge while creating a ring in the object. The use of Euler operators always produces topologically valid boundary data. However, an object with a topologically valid boundary may be geometrically invalid. As shown in Fig. 20, moving the vertex **p** of a valid solid upward causes the interior of the object to be exposed and thus becomes an invalid object.

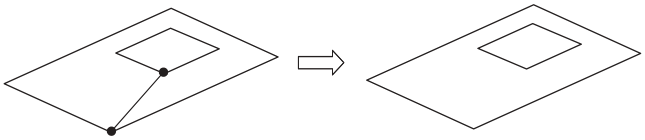

Figure 19. The KEMR operator.

e_6	v_4	v_3	f_4	f_3	e_3	e_5	e_4	e_2

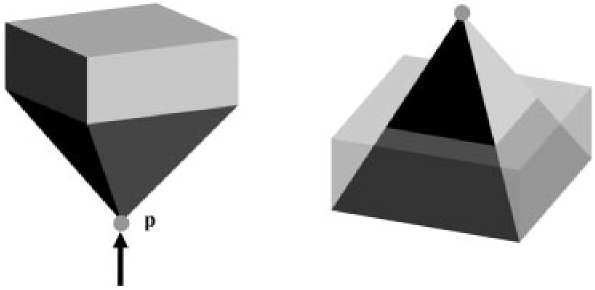

Figure 20. A topologically valid solid becomes geometrically invalid.

PROPERTIES OF B-REP

The geometric coverage of the boundary representation is determined by the types of surfaces being used. Early works in boundary representation are mainly confined to the manipulation of polyhedral solid models (6). Contemporary B-Rep modelers adopt trimmed NURBS surfaces for describing the geometry of an object boundary. This allows freeform solids to be modeled. B-Rep is unique but ambiguous; that is, one representation always refers to one solid. However, there may be more than one representation for one object. For example, a cube can be represented by 6 squares, or it can be represented by 12 triangles. As vertices, edges, and faces information are readily available, fast interactive display of B-Rep solid can be achieved. However, a complex data structure is required for maintaining a B-Rep. Nevertheless, B-Rep is attractive as it allows local modifications of objects. Local modification refers to a change in the geometry of an object. For instance, a change in the position of a vertex of a cube causes a plane of the cube to become a bilinear surface (Fig. 21).

HYBRID REPRESENTATION

As there is no single representation scheme that is superior, hybrid representation is usually adopted. In most popular hybrid representation schemes, objects are represented basically in B-Rep. Boolean operations are allowed for constructing solids. In some cases, sweep operations (7) are also adopted for constructing solids. A history of operations is recorded that is an extension of a CSG representation. The history of operations allows the modeled object to be modified by adjusting the location or shape parameters of the primitive solids. It also serves as the basis for implementing the “Undo” operation. As a B-Rep exists for each object, local modifications can be performed on the solid, whereas set operations may also be applied on objects. This provides a basis for the parametric or constraint-based modelers (8), which are widely adopted in commercial CAD systems.

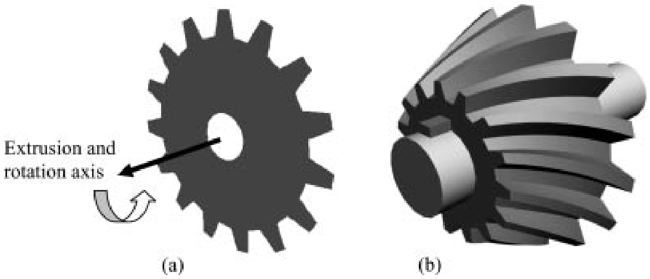

Figure 22. A bevel gear created with a sweep operation: (a) The gear contour, the extrusion, and rotation axis for the sweep. (b) Union of the swept solid, a cylinder, and a block.

OTHER REPRESENTATION SCHEMES

Besides the most popular CSG and B-Rep representation schemes, other representation schemes help to widen the geometric coverage or the scope of applications of solid modelers. Schemes that widen the geometric coverage of CSG modeler include the Sweep-CSG (7) and the Constructive Shell Representation (9). Sweep-CSG technique allows objects created with sweep operations to be used as primitives in a CSG modeler. An example is shown in Fig. 22 where a bevel gear is created by sweeping a planar contour as shown in Fig. 22a. The sweep operation is an extrusion of the contour, whereas the contour is being rotated and scaled. The Constructive Shell Representation adopts truncated tetrahedrons (Trunctet) as basic primitives. A trunctet is a tetrahedron truncated by a quadric surface. By maintaining continuity between trunctets, free-form solids can be modeled with CSG representation (Fig. 23).

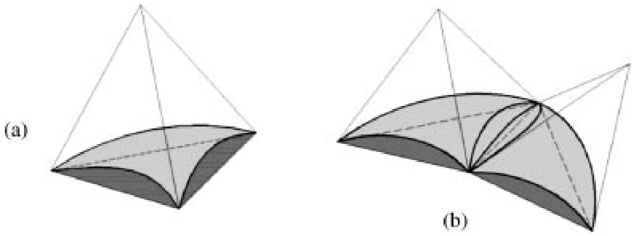

Figure 23. Trunctet and the Constructive Shell Representation: (a) A trunctet and (b) an object constructed with four smoothly connected trunctets.

Applications such as various stress and heat analysis using the finite element method requires an object to be represented as a collection of connected solid elements. This solid representation scheme is usually referred to as Cell Decomposition (10). Spatial Enumeration and Octree (10) are solid representation schemes widely used in applications where only a coarse representation of an object is required (e.g., collision detection). Although the most popular B-Rep and CSG schemes may not be suitable for these applications, algorithms exist for converting B-Rep and CSG models into other representation schemes, and hence, they remain a primary representation in existing solid modeling systems.

REMARKS

Solid modeling is a technique particularly suitable for modeling physical objects and is widely adopted in most commercial CAD systems. A product model built on top of a solid model provides the necessary information for the design analysis and production of the model. For instance, the rapid prototyping process requires an object to have a closed boundary for its processing. Manufacturing process planning of a product requires identifying the manufacturing features of the object. This can be obtained from the CSG tree of the object or the topological relationship between the entities in a B-Rep model. The bills of materials for a product require volumetric information of the product, which is readily available in the solid model of the product. A major limitation of solid modeling is its complexity in terms of storage and the algorithms required for its processing.

SURFACE DEFORMATION

Surface deformation is a fundamental tool for the construction and animation of three-dimensional (3-D) models. Deforming a surface is to adjust the shape of surface, which requires adjusting the parameters in the representation of a surface. As the defining parameters of different types of surfaces are different, different shape control techniques are available for different surface types. Alternatively, general deformation tools can be used for deforming surfaces. However, the deformation effect depends on how these tools are applied to the surfaces. In general, deformation tools can be classified into the geometric- and physics-based approaches. The geometry-based approach refers to the deformation of surfaces by adjusting geometric handles such as lattices and curves. The physics-based approach associates material properties with a surface such that the surface can be deformed in accordance with physical laws. They are discussed in detail in the following sections.

REPRESENTATION AND DEFORMATION OF SURFACE

The early work on the deformation technique developed by Alan Barr (1) uses a set of hierarchical transformations (stretching, bending, twisting, and tapering) for deforming an object. This technique determines the surface normal of a deformed object by applying a transformation to the surface normal vector of the undeformed surface. It requires a representation of the surface of which the Jacobian matrix can be determined. In fact the representation of a surface determines how a surface can be deformed. For surfaces that are represented in terms of geometric entities such as points and curves, deformation of the surface can be easily achieved through adjusting the locations of the points or modifying the shape of the curves. However, for surfaces where there is no direct geometric interpretation for the defining parameters, special techniques have to be employed to associate geometric entities with its representation. In order not to restrict the pattern of deformation on a surface, free-form surfaces or surfaces that can be used to model arbitrary object shapes are usually considered for surface deformation.

Deforming Algebraic Surfaces

An algebraic surfaces *f* is a function of the mapping *f*: $E^3 \rightarrow R$, such that all points **p** in E^3 satisfying *f*(**p**) = *k* lie on the surface, where *k* is a constant. Deforming an algebraic surface is to modify the function *f* such that a different set of points satisfies the modified function. As the defining parameters of an algebraic surface are the coefficients of the function *f*, they do not provide intuitive control over the shape of the surface. Alternative means are adopted for deforming algebraic surfaces. One approach to provide intuitive shape control on algebraic surface is to express an algebraic surface with a set of control points (2–4). Consider a tetrahedron T with vertices $\mathbf{v}_1$, $\mathbf{v}_2$, $\mathbf{v}_3$, $\mathbf{v}_4$; a point **p** lying within T can be expressed as

$$\mathbf{p} = s\mathbf{v}_1 + t\mathbf{v}_2 + u\mathbf{v}_3 + v\mathbf{v}_4, \qquad s + t + u + v = 1 \tag{1}$$

where (*s, t, u, v*) is the barycentric coordinate of **p** relative to the vertices $\mathbf{v}_1$, $\mathbf{v}_2$, $\mathbf{v}_3$, $\mathbf{v}_4$. The barycentric coordinates of $\mathbf{v}_1$, $\mathbf{v}_2$, $\mathbf{v}_3$, $\mathbf{v}_4$ are thus (1, 0, 0, 0), (0, 1, 0, 0), (0, 0, 1, 0), and (0, 0, 0, 1), respectively. Using Gua's approach (3), a quadric algebraic patch interpolating three vertices of T is given by

$$\begin{aligned} a_b(s,t,u,v) &= w_{2000}s^2 + w_{0200}t^2 + w_{0020}u^2 + w_{0002}v^2 \\ &\quad + 2w_{1100}st + 2w_{1001}sv + 2w_{0011}uv + 2w_{0110}tu \\ &\quad + 2w_{1010}su + 2w_{0101}tv \\ &= 0 \end{aligned} \tag{2}$$

where w_{ijk} are the weights associated with the control points on the tetrahedron as shown in Fig. 1. Assuming the surface passes through the vertices $\mathbf{v}_1$, $\mathbf{v}_2$, $\mathbf{v}_3$, the weights w_{2000}, w_{0200}, w_{0020} are zero. Normalizing Equation 2, or setting w_{0002} to 1, gives

$$\begin{aligned} a_b(s,t,u,v) &= v^2 + 2w_{1100}st + 2w_{1001}sv + 2w_{0011}uv \\ &\quad + 2w_{0110}tu + 2w_{1010}su + 2w_{0101}tv \\ &= 0 \end{aligned} \tag{3}$$

The shape of a surface ·patch is thus defined by the weights w_{1100}, w_{0110}, w_{1010}, w_{1001}, $w_{0101,}$ w_{0011}, which are determined by the surface normals $\mathbf{n}_{\mathrm{i}}$ of the surface at the base vertices of the tetrahedron as given by the equations (3).

$$\begin{aligned} &w_{1100} = \frac{1}{2}(\mathbf{v}_2 - \mathbf{v}_1)\cdot\mathbf{n}_1,\ w_{0110} = \frac{1}{2}(\mathbf{v}_3 - \mathbf{v}_2)\cdot\mathbf{n}_2, \\ &w_{1010} = \frac{1}{2}(\mathbf{v}_1 - \mathbf{v}_3)\cdot\mathbf{n}_3, \\ &w_{1001} = \frac{1}{2}(\mathbf{v}_4 - \mathbf{v}_1)\cdot\mathbf{n}_1,\ w_{0101} = \frac{1}{2}(\mathbf{v}_4 - \mathbf{v}_2)\cdot\mathbf{n}_2, \\ &w_{0011} = \frac{1}{2}(\mathbf{v}_4 - \mathbf{v}_3)\cdot\mathbf{n}_3, \end{aligned} \tag{4}$$

The shape of an algebraic surface can thus be changed by adjusting the locations of the control points on the tetrahedron.

Deforming Tensor Product Surfaces

Parametric surfaces are usually represented with a set of geometric entities. Consider a tensor product surface $\mathbf{s}(u, v)$ expressed in terms of a set of control polygon vertices (e.g., Bezier surface and NURBS surfaces) (5)

$$\mathbf{s}(u,v) = \sum_{i=0}^{n}\sum_{j=0}^{m}\alpha_{i,k}(u)\beta_{j,l}(v)\mathbf{b}_{i,j} \tag{5}$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

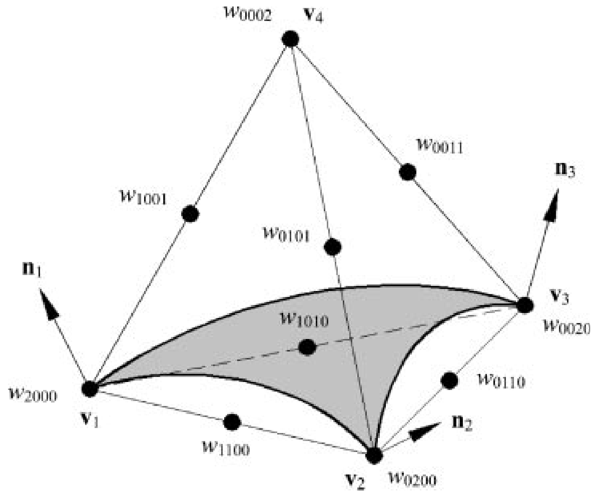

Figure 1. An algebraic surface patch.

where $\alpha_{i,k}(u)$, $\beta_{j,l}(v)$ are blending functions or basis functions associated with each control polygon vertices of the surface and k and l are orders of the basis functions in the u and v directions, respectively. The shape of the surface $\mathbf{s}(u, v)$ can be easily modified by adjusting the location of the control polygon vertices $\mathbf{b}_{i,j}$. For tensor product surfaces, $\mathbf{s}(u, v)$ approximates the control points except at the corners where $\mathbf{s}(u, v)$ interpolates the corner vertices. By subdividing $\mathbf{s}(u, v)$ into a set of C^{k-1}, and C^{l-1} continuous surface patches $\mathbf{s}_i(u, v)$ along the u and v directions, deformation of $\mathbf{s}(u, v)$ can be controlled by adjusting the corner vertices of $\mathbf{s}_i(u, v)$. This allows points on the surface to be used as handles for the deformation. However, special consideration has to be taken to maintain the continuity of the surface at these corner vertices (5). This is also true for surfaces that are defined by its corner vertices and tangents, e.g., parametric cubic surfaces; deformation of the surface can be achieved through adjusting the corner vertices and tangents.

Trimming Tensor Product Surfaces

In general, adjusting the control polygon vertices or surface points of a surface modifies the curvature of a surface. Although the boundary of a surface can be adjusted by modifying the control vertices on the boundary of a surface, this may also affect the curvature of a surface. To adjust the boundary of a surface without affecting the surface curvature, the concept of trimmed surface is usually adopted.

A trimmed surface is a surface with irregular boundaries. Consider a region of a surface defined by a series of trimming curves on a surface $\mathbf{s}(u,v)$ as shown in Fig. 2. A popular approach for representing trimming curves of a surface is to specify the curves on the parametric space of $\mathbf{s}(u, v)$. For example, in a trimmed NURBS surface, a trimming curve is expressed as

$$\mathbf{c}(t) = (u(t), v(t)) = \sum_{i=0}^{n} R_{i,k}(t)\mathbf{b}_i \tag{6}$$

where $\mathbf{b}_i = (u_i, v_i)$ are points on the parametric space of $\mathbf{s}(u, v)$,

$$R_{i,k}(t) = \frac{w_i N_{i,k}(t)}{\sum_{j=0}^{n} w_j N_{j,k}(t)}$$

$$N_{i,k}(t) = \frac{(t - t_i)N_{i,k-1}(t)}{t_{i+k-1} - t_i} + \frac{(t_{i+k} - t)N_{i+1,k-1}(t)}{t_{i+k} - t_{i+1}},$$

$$N_{i,1}(t) = \begin{cases} 1 & \text{if } t_i \le t \le t_{i+1} \\ 0 & \text{otherwise} \end{cases}$$

and w_i are the weights associated with $\mathbf{b}_i$. The trimmed curve in 3D space is thus $\mathbf{s}(u(t), v(t))$. Trimming curves are closed loops in the parametric space of $\mathbf{s}(u, v)$. To identify the valid region of the trimmed surface, a popular approach is to use the direction of the trimming curve loop to indicate the region of the surface to be retained (6). For instance, a counter-clockwise loop denotes the outer boundary of the surface, whereas a clockwise loop indicates a hole of the surface.

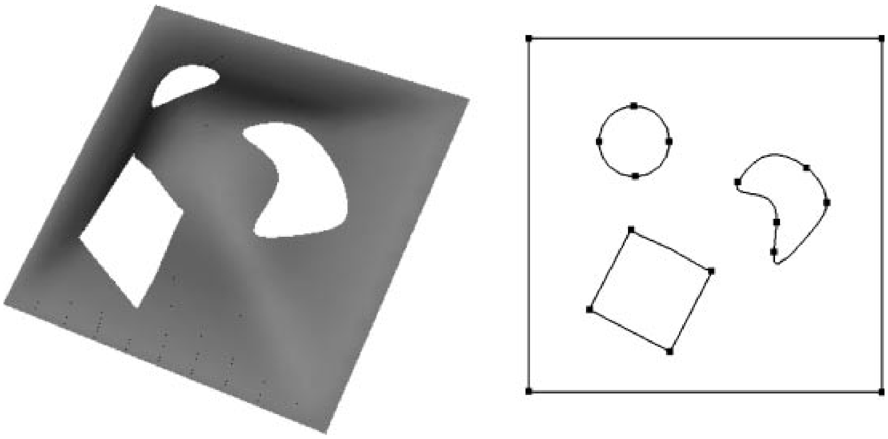

Figure 2. A trimmed surface and its trimming curves in the parametric space.

Deforming Subdivision and Mesh Surfaces

Subdivision surfaces and simple polygon meshes are also popular choices for deformable surfaces as they are defined by a set of points $\mathbf{b}_{i,j}$ constituting the base mesh or polygon mesh of the surface. Deformation can thus be achieved through adjusting the locations of $\mathbf{b}_{i,j}$. However, manipulating individual vertices of a polygon mesh is a tedious process especially for surfaces with a high mesh density. Deformation tools are thus usually adopted for this purpose as discussed below.

GEOMETRY-BASED DEFORMATION TOOL

Popular tools for geometry-based deformation include the lattice-based deformation, the curve-based deformation, and the constraints-based deformation.

Free-Form Deformation (FFD)

The free-form deformation technique introduced by Thomas W. Sederberg and Scott R. Parry (7) deforms an object by embedding the object in a parallelepiped region. Defining a local coordinate system at a point $\mathbf{p}_0$ in the parallelepiped region as shown in Fig. 3, a point $\mathbf{p}$ of the object can be expressed as

$$\mathbf{p} = \mathbf{p}_0 + s\mathbf{l} + t\mathbf{m} + u\mathbf{n} \tag{7a}$$

where $\mathbf{l}$, $\mathbf{m}$, $\mathbf{n}$ are the coordinate axes at $\mathbf{p}_0$ and their corresponding coordinates are

$$s = \frac{(\mathbf{p}-\mathbf{p}_0)\cdot\mathbf{l}}{|\mathbf{l}|^2}, \quad t = \frac{(\mathbf{p}-\mathbf{p}_0)\cdot\mathbf{m}}{|\mathbf{m}|^2}, \quad u = \frac{(\mathbf{p}-\mathbf{p}_0)\cdot\mathbf{n}}{|\mathbf{n}|^2} \tag{7b}$$

so that $0 \le s \le 1$, $0 \le t \le 1$, and $0 \le u \le 1$ for $\mathbf{p}$ lying in the parallelepiped. By imposing a grid of control points $\mathbf{q}_{ijk}$ on parallelepiped, where

$$\mathbf{q}_{ijk} = \mathbf{p}_o + \frac{i}{l}\mathbf{l} + \frac{j}{m}\mathbf{m} + \frac{k}{n}\mathbf{n}, \tag{8}$$

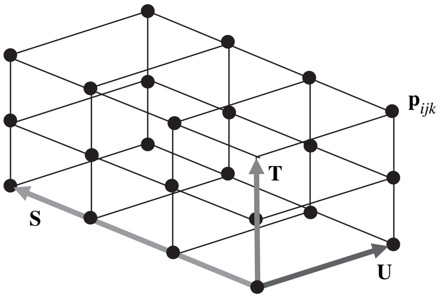

Figure 3. An FFD lattice.

and l, m, n are the dimensions of the grid in the $\mathbf{l}$, $\mathbf{m}$, $\mathbf{n}$ direction respectively, the point $\mathbf{p}$ can be expressed as

$$\mathbf{p} = \sum_{i=0}^{l}\sum_{j=0}^{m}\sum_{k=0}^{n}\binom{l}{i}\binom{m}{j}\binom{n}{k}(1-s)^{l-i} \times s^i(1-t)^{m-j}t^j(1-u)^{n-k}u^k\mathbf{q}_{ijk} \tag{9}$$

A change in the location of the control points $\mathbf{q}_{ijk}$ thus causes the point $\mathbf{p}$ and hence the object to be deformed. Denote F_1 as a mapping $F_1\colon E^3 \to R^3$, such that $\mathbf{p} \in E^3$, $\mathbf{p}_L \in R^3$, and $\mathbf{p}_L = (s, t, u)$, so that $\mathbf{p}_L = F_1(\mathbf{p})$ is the function in Equation 7b. Define F_2 as the mapping $F_2\colon R^3 \to E^3$, where F_2 is the function in Equation 9. A free-form deformation is a mapping $F = F_1 \circ F_2$, where $F : E^3 \to E^3$ transforms every point of an object S to that of the deformed object $F(S)$. As F is independent of the representation of S, the deformation can be applied to an object irrespective of its representation. However, applying the deformation to surface points or the control points of the surface may result in different surfaces as shown in Fig. 4. An example illustrating the application of FFD on the algebraic surface (8) discussed in Section 2.1 is shown in Fig. 5.

Extended Free-Form Deformation

The control lattice as constructed with Equation 8 is parallelepiped. This contrained the shape and size of the region to be deformed by FFD. Coquillart (9) proposed an Extended FFD that allows the use of a non-parallelepiped or non-prismatic control lattice. Predefined lattices in EFFD include the parallelepipedical and cylindrical lattices (Fig. 6). These lattices can be edited and combined to give more complex lattices. An EFFD lattice thus consists of a set of standard FFD lattices that may include degenerated vertices. A surface or a region of a surface is associated with the EFFD lattice. Given a point $\mathbf{p}$ in the region of a surface to be deformed, the corresponding FFD lattice

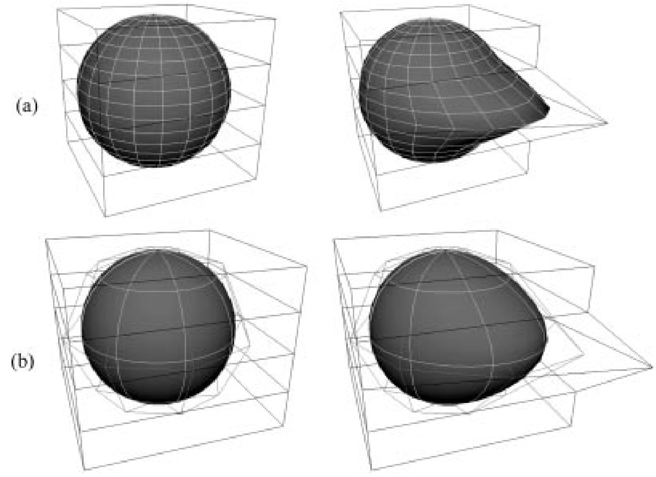

Figure 4. Deformation of a sphere using FFD. (a) Applying the deformation to the polyhedral model of a sphere. (b) Applying the deforming to the control polygon of a NURBS sphere.

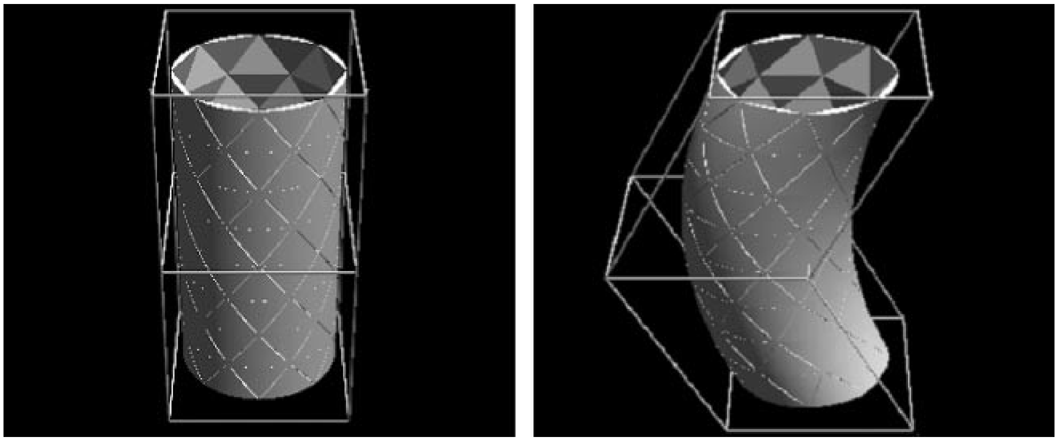

Figure 5. Applying FFD on an algebraic surface.

containing **p** is located. The lattice coordinate (s, t, u) of **p** relative to the corresponding FFD lattice is then determined using Newton approximation. Whenever there is a change in the locations of the lattice vertices, the position of **p** in E^3 can be computed using Equation 9. This allows the shape of the surface covered by the lattice to be modified by adjusting the EFFD lattice control points.

Direct Free-Form Deformation

Free-form deformation allows an object to be deformed by adjusting the lattice control points. A more intuitive approach for controlling the deformation is to allow object points to be adjusted directly. The corresponding positions of the lattice control vertices are then determined (10). This in turn is used to determine the deformation of the other object points. According to Equation 8, a deformed object point **p** can be expressed as **p** = **BQ**, where **Q** is the column matrix of the lattice control points and **B** is a function of s, t, u. Assuming a deformation of the lattice control points $\Delta\mathbf{Q}$ causes a deformation of the object point by $\Delta\mathbf{p}$, then

$$\Delta\mathbf{p} = \mathbf{B}\Delta\mathbf{Q} \tag{10}$$

Given $\Delta\mathbf{p}$, the deformation of the lattice control points $\Delta\mathbf{Q}$ is to determined by solving Equation 10. As there are $(m+1)(n+1)(l+1)$ control points in the FFD lattice, $\Delta\mathbf{Q}$ is thus a $(m+1)(n+1)(l+1)$ by 3 matrix and **B** is a row matrix with $(m+1)(n+1)(l+1)$ elements. As **B** cannot be inverted, the pseudoinverse $\mathbf{B}^+$ of **B** can be used to obtain $\Delta\mathbf{Q}$, i.e.

$$\Delta\mathbf{Q} = \mathbf{B}^+\Delta\mathbf{p} \tag{11}$$

where $\mathbf{B}^+ = (\mathbf{B}^T\mathbf{B})^{-1}\mathbf{B}^T$.

Using the pseudoinverse for solving Equation 10 gives the best solution, in a least-squares sense, for the required deformation.

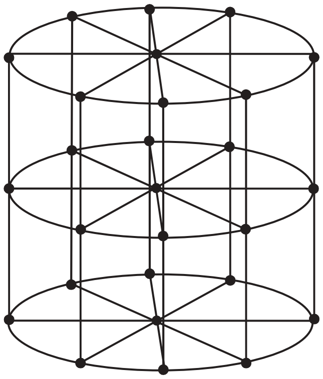

Figure 6. A cylindrical lattice.

Other Free-Form Deformation Techniques

There are several other variations of FFD, including the use of non-uniform rational B-splines for the control lattice, which provides more control on the deformation (11). The use of lattice with arbitrary topology constructed with subdivision surfaces (12) or triangles (13) allows irregularly shaped lattice to be used for the deformation. Free-form deformation is also applied for animation (14). A more recent study on geometric wraps and deformation can found in Ref. 15.

Axial Deformation

Axial deformation (16) deforms an object by associating a curve with an object. Deformation of the object can be achieved by manipulating the curve. Axial deformation is a mapping α: $E^3 \to E^3$, and $\alpha = f \circ g$, where $g: E^3 \to R^4$, and f: $R^4 \to E^3$, where the function g converts an object point **p** in E^3 to the axial curve space defined by a given curve $\mathbf{c}(t)$. The function f maps a point in axial space to E^3. Converting a point in E^3 to the axial space of a curve is to specify the given point relative to a local coordinate frame on $\mathbf{c}(t)$. The local coordinate frame of a curve is a set of normalized orthogonal vectors $\mathbf{u}(t)$, $\mathbf{v}(t)$, and $\mathbf{w}(t)$ defined at the point $\mathbf{c}(t)$. A popular approach is to specify the local coordinate frame using the Frenet Frame, which is expressed as

$$\mathbf{w} = \frac{\mathbf{c}'(t)}{|\mathbf{c}'(t)|} \tag{12a}$$

$$\mathbf{u} = \frac{\mathbf{c}'(t) \times \mathbf{c}''(t)}{|\mathbf{c}'(t) \times \mathbf{c}''(t)|} \tag{12b}$$

$$\mathbf{v} = \frac{\mathbf{w} \times \mathbf{u}}{|\mathbf{w} \times \mathbf{u}|} \tag{12c}$$

The Frenet Frame of a curve is defined by the tangent, normal, and binormal of $\mathbf{c}(t)$. The local coordinate frame is thus completely defined by the curve $\mathbf{c}(t)$, and there is no user control on the orientation of the frame, which may not be desirable. In addition, $\mathbf{c}''(t)$ may vanish so that the normal and hence the coordinate frame is not defined. An alternative is to use the rotation minimizing frame (17).

$$\mathbf{w} = \frac{\mathbf{c}'(t)}{|\mathbf{c}'(t)|} \tag{13a}$$

$$\mathbf{u}'(t) = -\frac{(\mathbf{c}''(t) \cdot \mathbf{u}(t)\mathbf{c}'(t))}{|\mathbf{c}'(t)|^2} \tag{13b}$$

$$\mathbf{v}'(t) = \frac{(\mathbf{c}''(t) \cdot \mathbf{v}(t))\mathbf{c}'(t)}{|\mathbf{c}'(t)|^2} \tag{13c}$$

Given an initial coordinate frame, the set of differential equations (13a–13c) can be solved to obtain a rotation minimized frame along the curve $\mathbf{c}(t)$. As only one local coordinate frame is specified, this technique cannot be used for obtaining a smooth transition between user-defined local coordinate frames. That is, the twist of a curve and hence the twist of the object cannot be fully controlled.

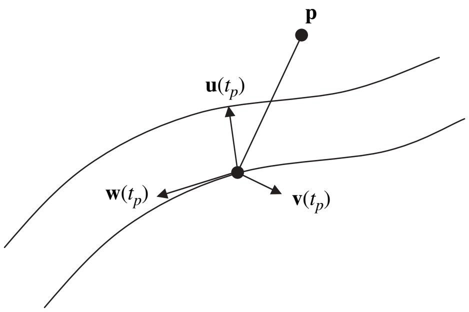

Figure 7. Axial curve pair.

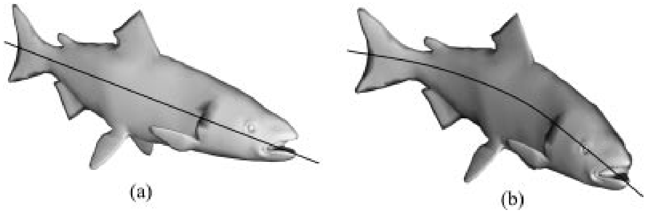

Figure 8. Axial deformation. (a) Object with an undeformed axial curve. (b) Object with the deformed axial curve.

The use of a curve-pair (18) for specifying the local coordinate frame provides complete control over the twist of a curve. A primary curve specifies the location of the local coordinate frame, and an orientation curve is used to define the rotation of the frame relative to the curve (Fig. 7). In this case, a special technique is required for synchronizing the change in shape of both the primary and the orientation curve. With a well-defined local coordinate frame on an axial curve $\mathbf{c}(t)$, and a given point $\mathbf{p}$ on an object, $\mathbf{p}$ can be expressed relative to the curve $\mathbf{c}(t)$ as

$$\mathbf{p} = \mathbf{c}(t_p) + \lambda\mathbf{u}(t_p) + \beta\mathbf{v}(t_p) + \gamma\mathbf{w}(t_p) \tag{14}$$

where

$$\lambda = (\mathbf{p} - \mathbf{c}(t_p)) \cdot \mathbf{u}(t_p) \tag{15a}$$

$$\beta = (\mathbf{p} - \mathbf{c}(t_p)) \cdot \mathbf{v}(t_p) \tag{15b}$$

$$\gamma = (\mathbf{p} - \mathbf{c}(t_p)) \cdot \mathbf{w}(t_p) \tag{15c}$$

and $\mathbf{c}(t_p)$ is the point on $\mathbf{c}(t)$ corresponding to $\mathbf{p}$. Usually, $\mathbf{c}(t_p)$ is the point on $\mathbf{c}(t)$ closest to $\mathbf{p}$. A point in the axial space of $\mathbf{c}(t)$ corresponding to $\mathbf{p}$ is thus $(t_p, \lambda, \beta, \gamma)$. By specifying object points in the axial space of $\mathbf{c}(t)$, the shape of the oe deformed by adjusting $\mathbf{c}(t)$. Figure 8 shows an example of applying an axial deformation to an object. Figure 9 shows the bending and twisting of an object using the curve-pair approach. A zone of influence can be associated with the axial curve to constraint the region of influence of the axial curve. The zone of influence is defined as the region between two general cylinders around the axial curve. Denote $r_{\min}$ and $r_{\max}$ as the radii of the zone of influence; an object point $\mathbf{p}$ will only be deformed if $r_{\min} \leq |\mathbf{p} - \mathbf{c}(\mathbf{t_p})| \leq r_{\max}$. This allows an object to be

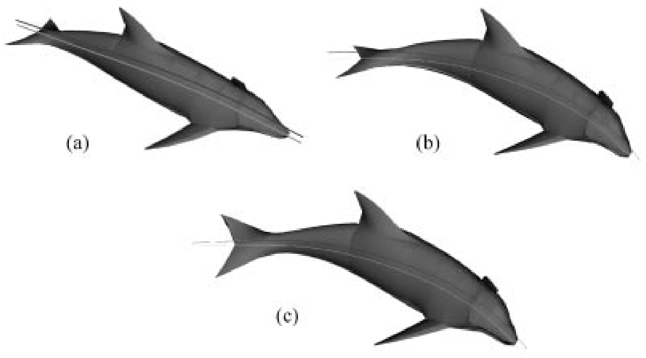

Figure 9. Curve-pair based axial deformation. (a) Object with an undeformed axial curve-pair. (b) Effect of bending an axial curve-pair. (c) Effect of twisting an axial curve-pair.

deformed locally as all object points lying outside of the zone of influence are not deformed.

The curve-based deformation technique also includes the "Wire" deformation technique (19) in which a deformation is defined with a tuple (*W*, *R*, *s*, *r*,*f*), where *W* is the wire curve, *R* is a reference curve, *r* specifies the zone of influence (the distance from the curve), and *s* is the scale factor. By adjusting the wire curve *W*, the shape of *W* relative to the reference curve *R* determines the deformation on the associated object.

Constraint-Based Deformation

The constraints-based approach (20) deforms a surface by defining a set of point displacement constraints. Deformations satisfying these constraints are determined by solving a system of equations satisfying the constraints. Given a point $\mathbf{u} = [u_1, u_2, \ldots, u_n]^{\mathrm{T}}$, and its displacement $d(\mathbf{u}) = [d_1(\mathbf{u}), d_2(\mathbf{u}), \ldots, d_n(\mathbf{u})]^{\mathrm{T}}$, the deformation at a point can be expressed as

$$d(\mathbf{u}) = \mathbf{M}\, f(\mathbf{u}) \tag{16}$$

where *f* is a function of the mapping $f: R^n \to R^m$, $m \geq n$, and $\mathbf{M}$ is the matrix of a linear transformation $T : R^m \to R^n$. Assume there are n_c constraint points, then $d(\mathbf{u}_i) = [d_1(\mathbf{u}_i), d_2(\mathbf{u}_i), \ldots, d_n(\mathbf{u}_i)]^T$, $j = 1, \ldots, n_c$. With a given function *f*, the matrix $\mathbf{M}$ is obtained by solving the system of $n \times n_c$ equations

$$[d(\mathbf{u}_1) \quad \ldots \quad d(\mathbf{u}_{n_c})]^T = \mathbf{M}[f(\mathbf{u}_1) \quad \ldots \quad f(\mathbf{u}_{n_c})]^T \tag{17}$$

In general, n may not be the same as n_c, and $\mathbf{M}$ is obtained using pseudoinverse. Once $\mathbf{M}$ is obtained, the displacement of any point of the object can be computed using Equation 16. Based on the same concept, the Simple Constrained Deformation (21) associates a desired displacement and radius of influence for each constraint point. A local B-spline basis function centered at the constraint point is determined that falls to zero for points beyond the radius of influence. The displacement of an object point is obtained by a linear combination of the basis functions such that all constraints are satisfied.

Physics-Based Deformation

Physics-based deformation techniques are deformation methods based on continuum mechanics, which accounts for the effects of materials properties, external forces, and environmental constraints on the deformation of objects.

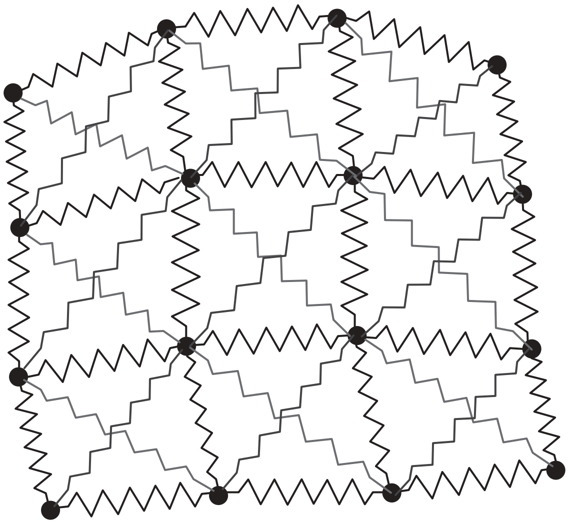

Figure 10. A surface modeled with a mass-spring system.

Mass-Spring Model

The mass-spring model is one of the most widely used techniques for physics-based surface deformation (22). A surface is modeled as a mesh of point masses connected by springs as shown in Fig. 10. The springs are usually assumed to be linearly elastic, although in some cases, nonlinear springs are used to model inelastic behavior. In general, a mass point at the position $\mathbf{x}_i$ in a mass spring system is governed by the Newton's Second Law of motion

$$m_i \underset{i}{\ddot{\mathbf{x}}} = -\gamma_i \underset{i}{\dot{\mathbf{x}}} + \sum_{j=0}^{n_g} \mathbf{g}_{ij} + \mathbf{f}_i \tag{18}$$

where m_i is the mass of the mass point, $\gamma_i \dot{\mathbf{x}}_i$ is the velocity-dependent damping force, $\mathbf{g}_{ij}$ are the spring forces acting at m_i, and $\mathbf{f}_i$ is the external force at m_i. Assuming there are n mass points in the system, applying Equation 18 at each of the mass points gives

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{f} \tag{19}$$

where $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ are the $3n \times 3n$ mass, damping, and stiffness matrices, respectively, and $\mathbf{f}$ is a $3n \times 1$ column vector denoting the total external forces on the mass point. Equation 19 describes the dynamics of a mass-spring system and is thus commonly used for modeling surfaces that are deformed dynamically. Given the initial position $\mathbf{x}$ and velocity $\mathbf{v}$ of the mass points, and expressing Equation 19 as

$$\mathbf{v} = \mathbf{M}^{-1}(-\mathbf{C}\mathbf{v} - \mathbf{K}\mathbf{x} + \mathbf{f}) \tag{20a}$$

$$\dot{\mathbf{x}} = \mathbf{v} \tag{20b}$$

the velocity $\mathbf{v}$ of the mass point at subsequent time instances can be obtained. The corresponding location of the mass point can be obtained with various numerical integration techniques. Mass-spring systems are easy to construct and can be animated at interactive speed. However, it is a significant simplification of the physics in a continuous body. A more accurate physical model for surface deformation is to use the finite/boundary element method.

Deformation using Finite/Boundary Element Method

Using the finite element method (FEM), an object is approximated with a set of discrete elements such as triangles, quadrilaterals, tetrahedrons, and cuboids. Solid elements (e.g., tetrahedrons and cubes) are used for closed surfaces, whereas plate or shell elements are used for nonclosed surfaces. As an object is in equilibrium when its total potential energy is at a minimum, an equilibrium equation is established by considering the total strain energy of a system and the work due to external forces. The boundary element method (BEM) approximates the closed surface of a volume with a set of elements such as triangles and quadrilaterals. No solid element is thus required for BEM. Assuming the deforming object is linearly elastic, both FEM and BEM result in a simple matrix equation

$$\mathbf{F} = \mathbf{K}\mathbf{U} \tag{21}$$

where $\mathbf{F}$ denotes the external forces acting on element nodes of the object, $\mathbf{U}$ is the displacement at the element nodes, and $\mathbf{K}$ is the stiffness matrix. Detailed discussion on the derivation of Equation 21 can be found in Refs. 22 and 23 and in standard texts on FEM/BEM. Given the material properties of an object, the variables at an element node are the external force acting on the node and the corresponding displacement. In general, one of the variables is known, whereas the other one is unknown. By partitioning $\mathbf{F}$ and $\mathbf{U}$ into known and unknown elements, Equation 21 can be rewritten as

$$\begin{bmatrix} \mathbf{F}_k \\ \mathbf{F}_u \end{bmatrix} = \begin{bmatrix} \mathbf{K}_{00} & \mathbf{K}_{01} \\ \mathbf{K}_{10} & \mathbf{K}_{11} \end{bmatrix} \begin{bmatrix} \mathbf{U}_k \\ \mathbf{U}_u \end{bmatrix} \tag{22}$$

where $\mathbf{F}_k$, $\mathbf{F}_u$ denotes the known and unknown nodal forces and $\mathbf{U}_k$, $\mathbf{U}_u$ denotes the known and unknown nodal displacements.

Hence,

$$\mathbf{F}_k = \mathbf{K}_{00}\mathbf{U}_k + \mathbf{K}_{01}\mathbf{U}_u \tag{23a}$$

$$\mathbf{F}_u = \mathbf{K}_{10}\mathbf{U}_k + \mathbf{K}_{11}\mathbf{U}_u \tag{23b}$$

In general, for graphics applications, the diplacement at certain nodes is specified or constrained, and the forces at the free or unconstrained nodes are zero (i.e., $\mathbf{F}_k = 0$). Assume there are n nodes in the object with known displacement at k of the nodes. The free boundary will be composed of $n - k$ nodes. The dimensions of $\mathbf{K}_{00}$ and $\mathbf{K}_{01}$ are thus $(n - k) \times k$, and $(n - k) \times (n - k)$. Equation 23a gives

$$\mathbf{U}_u = -\mathbf{K}_{01}^{-1}\mathbf{K}_{00}\mathbf{U}_k \tag{24}$$

Given the deformation at certain nodes of a surface, the deformation of the other nodes can be obtained using Equation 24.

In general, FEM and BEM technique can only be applied for solid objects or closed surfaces. Standard plate or shell elements can be used for open surfaces by assuming a constant thickness for the surface. By considering the potential energy in the stretching and bending of a surface, an energy functional can be established for a surface (24,25). Minimizing the energy functional gives an equation in the form of Equation 21. Standard FEM techniques can then be used for deforming the surface. A mass and a damping term can also be incorporated into Equation 21 to allow for the simulation of dynamic effects.

REMARKS

Geometry-based deformation tools are usually employed for deforming surfaces in the object construction process in which the deformation does not need to obey the laws of physics. For the purposes of animation, the use of geometry-based deformation for generating realistic motions relies very much on the skill and experience of the animator in using the deformation tool. On the contrary, physics-based deformation is capable of generating an animated surface deformation with little user interactions and thus plays an important role in animation.

SURFACE MODELING

INTRODUCTION

Surface is a fundamental element in describing the shape of an object. The Classic method for specifying a surface is to use a set of orthogonal planar projection curves to describe the surface. With the advance of computer graphics and computer-aided design technologies, the wire frame models has evolved and is now capable of describing three-dimensional (3-D) objects with lines and curves in 3-D space. However, the wire frame model is ambiguous and does not provide a complete 3-D description of a surface. P. Bezier and P. de Casteljau independently developed the Bezier curves and surfaces in the late 1960s, which revolutionized the methods for describing surfaces. In general, surface modeling is the technique for describing a 3-D surface. There are three popular ways for specifying a surface, namely, implicit, parametric, and subdivision. They are described in the following sections.

IMPLICIT SURFACE

An implicit surface is a set of points $\mathbf{p} = (x, y, z)$ in space such that $f(\mathbf{p}) = k$, where k is constant. In general, an implicit surface is a function of the mapping $f : E^3 \rightarrow R$, where E^3 is the 3-D Euclidean space and R is the real axis. Popular implicit surfaces include the quadric surfaces and toruses. Implicit surfaces are unbounded. Extra constraints are required to specify a valid range for the surface. Direct display of an implicit surface can be performed with a ray tracing process. This process requires performing a ray/surface intersection, which is a time-consuming process. An alternative is to approximate the surface with a polygon mesh, which requires performing a polygonization process on $f(\mathbf{p})$. Adjusting the shape of an implicit surface requires modifying the function f, which is not intuitive for general users. However, implicit surfaces are useful for modeling objects that can be described with implicit or algebraic functions, e.g., blends between objects. The following discussion focuses on parametric surfaces that are more commonly used in existing geometric modeling systems.

PARAMETRIC SURFACES

A parametric surface is a mapping $f : E^2 \rightarrow E^3$ that maps a point (u, v) in the parametric space to the 3-D Euclidean space, (Fig. 1):

$$\mathbf{s}(u,v) = f(u,v) = \lfloor\, f_x(u,v) \quad f_y(u,v) \quad f_z(u,v)\,\rfloor \tag{1}$$

Keeping u (or v) constant, and varying v (or u), an isoparametric curve is obtained. The tangents along the u and v directions are defined as

$$\mathbf{s}_u(u,v) = \frac{\partial \mathbf{s}(u,v)}{\partial u} = \begin{bmatrix} \dfrac{\partial f_x(u,v)}{\partial u} & \dfrac{\partial f_y(u,v)}{\partial u} & \dfrac{\partial f_z(u,v)}{\partial u} \end{bmatrix} \tag{2}$$

$$\mathbf{s}_v(u,v) = \frac{\partial \mathbf{s}(u,v)}{\partial v} = \begin{bmatrix} \dfrac{\partial f_x(u,v)}{\partial v} & \dfrac{\partial f_y(u,v)}{\partial v} & \dfrac{\partial f_z(u,v)}{\partial v} \end{bmatrix} \tag{3}$$

These two tangent vectors define a tangent plane at $\mathbf{s}(u, v)$ and the normal to the parametric surface is the normal to the tangent plane and is expressed as

$$\mathbf{n}(u,v) = \frac{\mathbf{s}_u(u,v) \times \mathbf{s}_v(u,v)}{|\mathbf{s}_u(u,v) \times \mathbf{s}_v(u,v)|} \tag{4}$$

The twist vector of a surface $\frac{\partial^2 \mathbf{s}(u,v)}{\partial u \partial v}$ measures the rate of change of a u-tangent (v-tangent) in the v-direction (u-direction).

Commonly used parametric surfaces include the sweep surfaces, ruled surfaces, Coon's surfaces, Bezier surfaces, B-spline surfaces, and NURBS surfaces as described below.

SWEEP SURFACE

A sweep surface is a surface obtained by transforming a curve in space. Given a curve $\mathbf{p}(u)$ defined in its local coordinate frame, a 3×3 transformation matrix $\mathbf{M}(v)$, and a translation vector $\mathbf{T}(v)$, a sweep surface is defined as

$$\mathbf{s}(u,v) = \mathbf{p}(u)\mathbf{M}(v) + \mathbf{T}(v) \tag{5}$$

The curve $\mathbf{p}(u)$ is sometime referred to as the sweep contour. Surfaces such as the surfaces of revolution, tabulated cylinders, or extrusion surface are particular cases of sweep surfaces. In a surface of revolution, $\mathbf{M}(v)$ is a rotation. In an extrusion surface, $\mathbf{M}(v)$ is an identity or a scaling transformation if a tapered extrusion is performed. To allow the construction of more general sweep transformation, $\mathbf{M}(v)$ can be defined with a rail curve $\mathbf{c}(v)$, $0 \leq v \leq 1$, such that $\mathbf{M}(v)$ is a rotation about an axis $\dot{\mathbf{c}}(0) \times \dot{\mathbf{c}}(v)$ through an angle $\theta = \cos^{-1}\left(\frac{\dot{\mathbf{c}}(0) \bullet \dot{\mathbf{c}}(v)}{|\dot{\mathbf{c}}(0)||\dot{\mathbf{c}}(v)|}\right)$. An example is shown in Fig. 2. If the curve $\mathbf{p}$ is allowed to change in the sweep, or $\mathbf{p}$ is also a function of v, i.e., $\mathbf{p} = \mathbf{p}(u, v)$, a more complex surface form can be obtained. This is often specified with two sweep contours $\mathbf{p}_0(u)$ and $\mathbf{p}_1(u)$, where $\mathbf{p}_0(u)$ denotes the sweep contour at $v = 0$ and $\mathbf{p}_1(u)$ denotes the sweep contour at $v = 1$. The sweep contour along the sweep is determined by blending $\mathbf{p}_0(u)$ and $\mathbf{p}_1(u)$, i.e.,

$$\mathbf{p}(u,v) = \alpha(v)\mathbf{p}_0(u) + \beta(v)\mathbf{p}_1(u) \tag{6}$$

where $\alpha(v)$ and $\beta(v)$ are blending functions of $\mathbf{p}_0(u)$, and $\mathbf{p}_1(u)$, respectively, such that $\alpha(v) + \beta(v) = 1$[1]. A popular set

[1] $\alpha(v) + \beta(v) = 1$ confines $\mathbf{p}(u,v)$ to lie between $\mathbf{p}_0(u)$ and $\mathbf{p}_1(u)$.

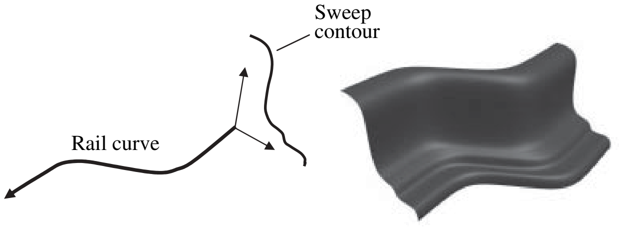

Figure 2. A sweep surface.

of blending functions are $\alpha(v) = 1 - v$, and $\beta(v) = v$. To provide a more flexible sweep operation, the sweep transformation can be defined with two rail curves $\mathbf{c}_1(v)$, $\mathbf{c}_2(v)$; $0 \le v \le 1$ as shown in Fig. 3. The vectors $\mathbf{d}(0) = \mathbf{c}_2(0) - \mathbf{c}_1(0)$ and $\mathbf{d}(v) = \mathbf{c}_2(v) - \mathbf{c}_1(v)$ define the orientation, location, and the size of $\mathbf{p}(u,v)$. The transformation $\mathbf{M}(v)$ is a rotation about an axis $\mathbf{d}(0) \times \mathbf{d}(v)$ through an angle $\theta = \cos^{-1}(\frac{\mathbf{d}(0) \bullet \mathbf{d}(v)}{|\mathbf{d}(0)||\mathbf{d}(v)|})$. Using the rail curves to define the sweep transform, the sweep contour is expressed as

$$\mathbf{p}(u,v) = k(v)[\alpha(v)(\mathbf{p}_0(u) - \mathbf{c}_1(0)) + \beta(v)(\mathbf{p}_1(u) - \mathbf{c}_1(0))] \quad (7)$$

where $k(v) = \frac{|\mathbf{c}_2(v) - \mathbf{c}_1(v)|}{|\mathbf{c}_2(0) - \mathbf{c}_1(0)|}$. The sweep surface is thus obtained with the expression

$$\mathbf{s}(u,v) = \mathbf{p}(u,v)\mathbf{M}(v) + \mathbf{T}(v) \quad (8)$$

where $\mathbf{T}(v) = \mathbf{c}_1(v)$.

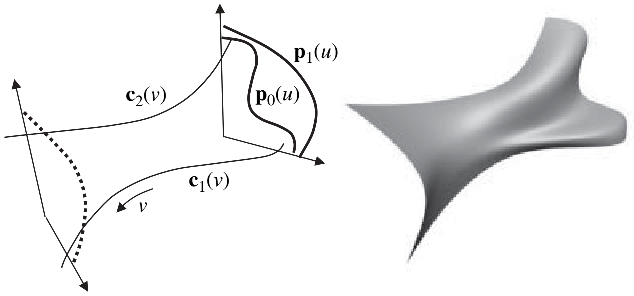

Figure 3. A sweep surface with two rail curves.

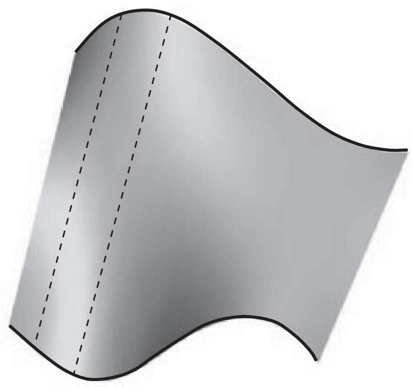

Figure 4. A ruled surface.

RULED SURFACE

A ruled surface is the surface obtained by linearly interpolating between two given curves. Assuming the curves are $\mathbf{p}(u)$ and $\mathbf{q}(u)$, where $0 \le u \le 1$, a linear interpolation between $\mathbf{p}(u)$ and $\mathbf{q}(u)$ gives

$$\mathbf{s}(u,v) = (1 - v)\mathbf{p}(u) + v\mathbf{q}(u) \quad (9)$$

An example of a ruled surface is shown in Fig. 4. If $\mathbf{p}(u)$, $\mathbf{q}(u)$ are straight lines, so that $\mathbf{p}(u) = (1 - u)\mathbf{p}_0 + u\mathbf{p}_1$ and $\mathbf{q}(u) = (1 - u)\mathbf{q}_0 + u\mathbf{q}_1$, then

$$\mathbf{s}(u,v) = (1 - u)(1 - v)\mathbf{p}_0 + u(1 - v)\mathbf{p}_1 + v(1 - u)\mathbf{q}_0 + uv\mathbf{q}_1 \quad (10)$$

The surface define with Equation (10) is specified with four points and is usually referred to as a bilinear surface (Fig. 5).

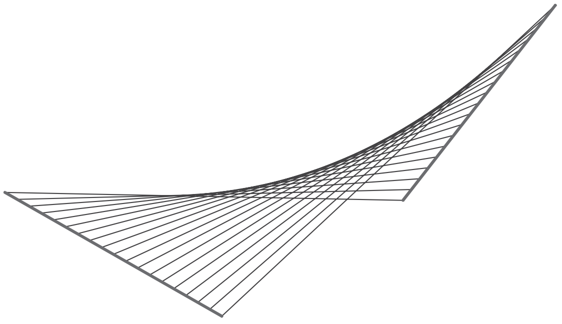

Figure 5. A bilinear surface.

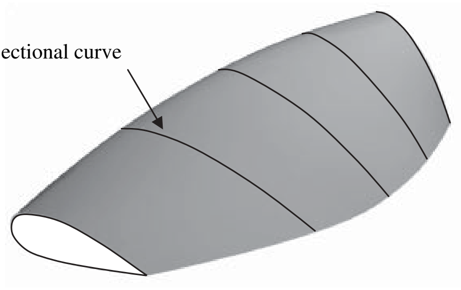

Figure 6. A lofted surface.

LOFTED SURFACE

A lofted surface is a surface interpolating a series of sectional curves as shown in Fig. 6. Given a set of curves $\mathbf{p}_i(u)$, $0 \le u \le 1$, a surface $\mathbf{s}_i(u, v)$ interpolating $\mathbf{p}_i(u)$ and $\mathbf{p}_{i+1}(u)$ can be expressed as

$$\mathbf{s}_i(u,v) = \alpha(v)\mathbf{p}_i(u) + \beta(v)\mathbf{p}_{i+1}(u) \tag{11}$$

where $0 \le u \le 1$ and $\alpha(v)$, $\beta(v)$ are blending functions of $\mathbf{p}_i(u)$ and $\mathbf{p}_{i+1}(u)$, respectively, such that $\alpha(v) + \beta(v) = 1$[2]. To maintain the continuity of the lofted surface, continuity across the boundaries of consecutive $\mathbf{s}_i(u, v)$ has to be maintained. This can be easily achieved by using a cubic blending functions (1), $\alpha(v) = 3v^2 - 2v^3$, and $\beta(v) = 1 - 3v^2 + 2v^3$.

COON'S BILINEAR SURFACE

A Coon's bilinear surface defines a surface with four contiguous boundary curves. Given four curves $\mathbf{p}_0(u)$, $\mathbf{p}_1(u)$, $\mathbf{q}_0(w)$, $\mathbf{q}_1(w)$, $0 \le u \le 1$, $0 \le v \le 1$, such that $\mathbf{p}_0(0) = \mathbf{q}_0(0)$, $\mathbf{q}_0(1) = \mathbf{p}_1(0)$, $\mathbf{p}_1(1) = \mathbf{q}_1(1)$, $\mathbf{q}_1(0) = \mathbf{p}_0(1)$ as shown in Fig. 7(a), a Coon's bilinear surface interpolates all boundary curves and corner points and is expressed as

$$\begin{aligned}\mathbf{s}(u,v) &= (1-v)\mathbf{p}_0(u) + v\mathbf{p}_1(u) + (1-u)\mathbf{q}_0(v) + u\mathbf{q}_1(v)\\ &-(1-u)(1-v)\mathbf{p}_0(0) - u(1-v)\mathbf{p}_0(1) - v(1-u)\mathbf{p}_1(0) - uv\mathbf{p}_1(1)\end{aligned} \tag{12}$$

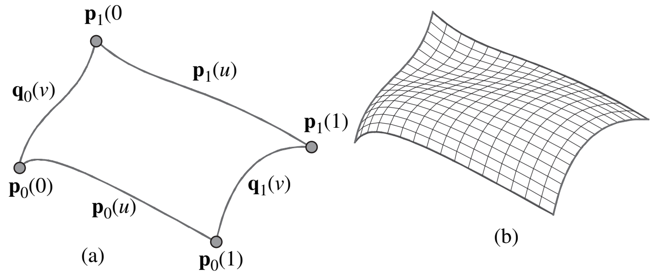

Figure 7. A Coon's bilinear surface: (a) corner vertices and boundary curves and (b) the Coon's bilinear surface.

Expressing Equation (12) in matrix form gives

$$\mathbf{s}(u,v) = \begin{bmatrix} 1-u & u & 1 \end{bmatrix} \begin{bmatrix} -\mathbf{p}_0(0) & -\mathbf{p}_1(0) & \mathbf{q}_0(v) \\ -\mathbf{p}_0(1) & -\mathbf{p}_1(1) & \mathbf{q}_1(v) \\ \mathbf{p}_0(u) & \mathbf{p}_1(u) & 0 \end{bmatrix} \begin{bmatrix} 1-v \\ v \\ 1 \end{bmatrix} \tag{13}$$

A Coon's bilinear surface is usually interpreted as the result of subtracting a bilinear surface defined by the corner points $\mathbf{p}_0(0)$, $\mathbf{p}_0(1)$, $\mathbf{p}_1(0)$, $\mathbf{p}_1(1)$ from the sum of two ruled surfaces defined by $\mathbf{p}_0(u)$, $\mathbf{p}_1(u)$ and $\mathbf{q}_0(v)$, $\mathbf{q}_1(v)$.

BICUBIC SURFACE

A bicubic surface is a surface in which the isoparametric curves are cubic curves and is given by the expression

$$\mathbf{s}(u,v) = \mathbf{F}(u)\mathbf{G}\mathbf{F}^{\mathrm{T}}(v), \tag{14}$$

where

$$\begin{aligned}\mathbf{F}(u) &= [F_1(u) \quad F_2(u) \quad F_3(u) \quad F_4(u)]\\ \mathbf{F}^{\mathrm{T}}(v) &= [F_1(v) \quad F_2(v) \quad F_3(v) \quad F_4(v)]^{\mathrm{T}}\end{aligned}$$

$$\mathbf{G} = \begin{bmatrix} \mathbf{s}(0,0) & \mathbf{s}(0,1) & \mathbf{s}_w(0,0) & \mathbf{s}_w(0,1) \\ \mathbf{s}(1,0) & \mathbf{s}(1,1) & \mathbf{s}_w(1,0) & \mathbf{s}_w(1,1) \\ \mathbf{s}_u(0,0) & \mathbf{s}_u(0,1) & \mathbf{s}_{uw}(0,0) & \mathbf{s}_{uw}(0,1) \\ \mathbf{s}_u(1,0) & \mathbf{s}_u(1,1) & \mathbf{s}_{uw}(1,0) & \mathbf{s}_{uw}(1,1) \end{bmatrix}$$

and

$$\begin{aligned}F_1(u) &= 1 - 3u^2 + 2u^3, F_2(u) = 3u^2 - 2u^3\\ F_3(u) &= u - 2u^2 + u^3, F_4(u) = -u^2 + u^3\\ F_1(v) &= 1 - 3v^2 + 2v^3, F_2(v) = 3v^2 - 2v^3\\ F_3(v) &= v - 2v^2 + v^3, F_4(v) = -v^2 + v^3\end{aligned}$$

Equation (14) can be rewritten as

$$\mathbf{s}^c(u,v) = \mathbf{U}\mathbf{N}_c\mathbf{G}\mathbf{N}_c{}^{\mathrm{T}}\mathbf{V} \tag{15}$$

where

$$\mathbf{U} = [u^3 \quad u^2 \quad u \quad 1], \mathbf{V} = [v^3 \quad v^2 \quad v \quad 1],$$

$$\mathbf{N}_c = \begin{bmatrix} 2 & -2 & 1 & 1 \\ -3 & 3 & -2 & -1 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix}$$

The matrix $\mathbf{G}$ can be partitioned into four 2 × 2 matrices

$$\mathbf{G} = \begin{bmatrix} \mathbf{G}_{1,1} & \mathbf{G}_{1,2} \\ \mathbf{G}_{2,1} & \mathbf{G}_{2,2} \end{bmatrix}$$

[2] $\alpha(v) + \beta(v) = 1$ confines $\mathbf{s}(u,v)$ to lie between $\mathbf{p}_i(u)$ and $\mathbf{p}_{i+1}(u)$.

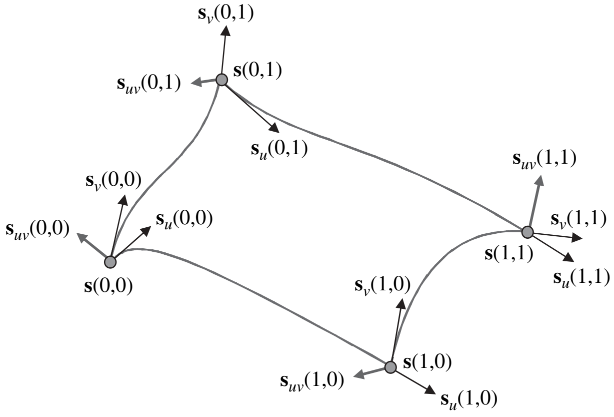

Figure 8. Parameters defining a Bi-cubic surface.

where

$$\mathbf{G}_{1,1} = \begin{bmatrix} \mathbf{s}(0,0) & \mathbf{s}(0,1) \\ \mathbf{s}(1,0) & \mathbf{s}(1,1) \end{bmatrix}, \qquad \mathbf{G}_{1,2} = \begin{bmatrix} \mathbf{s}_v(0,0) & \mathbf{s}_v(0,1) \\ \mathbf{s}_v(1,0) & \mathbf{s}_v(1,1) \end{bmatrix}$$

$$\mathbf{G}_{2,1} = \begin{bmatrix} \mathbf{s}_u(0,0) & \mathbf{s}_u(0,1) \\ \mathbf{s}_u(1,0) & \mathbf{s}_u(1,1) \end{bmatrix}, \quad \mathbf{G}_{2,2} = \begin{bmatrix} \mathbf{s}_{uv}(0,0) & \mathbf{s}_{uv}(0,1) \\ \mathbf{s}_{uv}(1,0) & \mathbf{s}_{uv}(1,1) \end{bmatrix}$$

These submatrices $\mathbf{G}_{1,1}$, $\mathbf{G}_{1,2}$, $\mathbf{G}_{2,1}$, and $\mathbf{G}_{2,2}$ specifies the positions, the v-tangents, the u-tangents, and the twist vectors at the corner vertices of the surface. These parameters at the corner vertices of the surface determine the shape of the bicubic surface (Fig. 8). A change in these parameters except the twist vectors will affect the boundary of the surface, whereas a change in the twist vector will only affect the interior of the surface as shown in Fig. 9.

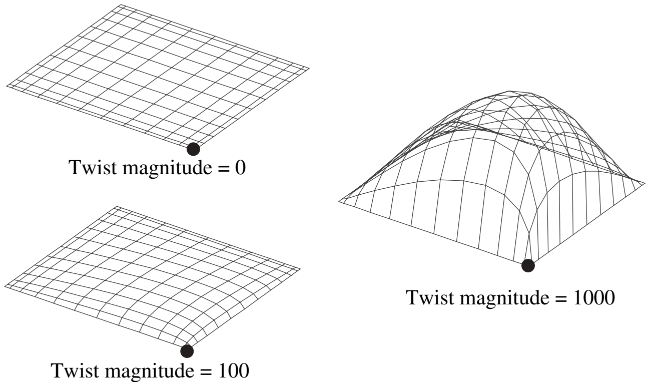

Figure 9. Effect of the twist vector at a vertex on a Bicubic surface.

GENERAL PROPERTIES OF TENSOR PRODUCT SURFACES

Bezier surfaces, B-spline surfaces, and NURBS surfaces are usually referred to as tensor product surfaces. These surfaces are in general represented as the weighted sum of a set of points $\mathbf{p}_{i,j}$ in E^3, i.e.,

$$\mathbf{s}(u,v) = \sum_{i=0}^{n}\sum_{j=0}^{m} \alpha_i(u)\beta_j(v)\mathbf{p}_{i,j} \tag{16}$$

where $\sum_{i=0}^{n}\alpha_i(u) = 1$, $\sum_{j=0}^{m}\beta_i(u) = 1$, and hence, $\sum_{i=0}^{n}\sum_{j=0}^{m}\alpha_i(u)\beta_j(v) = 1$. The surface $\mathbf{s}(u,v)$ is thus a barycentric combination of $\mathbf{p}_{i,j}$ and is invariant under affine transformation, i.e., applying an affine transformation to $\mathbf{s}(u,v)$ is the same as applying the transformation to $\mathbf{p}_{i,j}$. The surface $\mathbf{s}(u,v)$ is also a convex combination of $\mathbf{p}_{i,j}$, or $\mathbf{s}(u,v)$ always lies in the convex hull defined by the points $\mathbf{p}_{i,j}$. A detailed description of the mathematical properties of parametric surfaces can be found in Ref. 2.

BEZIER SURFACE

A Bezier surface is defined with a polygon mesh of control vertices $\mathbf{b}_{ij,}$ $i = 0,\ldots,n, j = 0,\ldots,m$ shown in Fig.10. Using the de Casteljau algorithm (2), a point on the surface defined by $\mathbf{b}_{i,j}$ is obtained by applying a series of linear interpolations on the control points iteratively. P. Bezier (3) adopted a different approach and expressed the surface explicitly as

$$\mathbf{s}(u,w) = \sum_{i=0}^{n}\sum_{j=0}^{m} \mathbf{b}_{i,j}J_{n,i}(u)K_{m,j}(v) \tag{17}$$

where $0 \le u \le 1, 0 \le v \le 1$, and $J_{n,i}(u)$, $K_{m,j}(v)$ are Bernstein basis functions

$$J_{n,i}(u) = \binom{n}{i}u^i(1-u)^{n-i}, \quad \binom{n}{i} = \frac{n!}{i!(n-i)!}$$

$$K_{m,j}(v) = \binom{m}{j}v^j(1-v)^{m-j}, \quad \binom{m}{j} = \frac{m!}{j!(n-j)!}$$

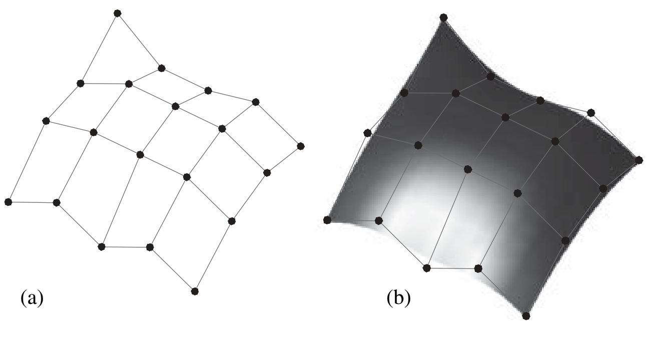

Figure 10. A Bezier surface and its control polygon mesh: (a) control polygon mesh and (b) the Bezier surface.

As $J_{n,i}(u)$, $K_{m,j}(v)$ are Bernstein basis functions $\sum_{i=0}^{n} J_{n,i}(u) \equiv 1$, and $\sum_{j=0}^{m} K_{m,j}(v) \equiv 1$; hence, $\sum_{i=0}^{n}\sum_{j=0}^{m} J_{n,i}(u) K_{m,j}(v) \equiv 1$. A Bezier surface is thus a barycentric combination of its control polygon vertices $\mathbf{b}_{i,j}$ and is determined by the basic properties of a tensor product surface as discussed in the previous section.

The degree of the surface in each parametric direction is determined by the number of control polygon vertices in that direction. The degree of the surface in the u direction is n, and the degree of the surface in the v direction is m. The continuity of the surface is thus C^{n-1} and C^{m-1} in the u and v directions, respectively. A Bezier surface passes through the corner points of the defining polygon mesh, and its shape generally follows the shape of the defining polygon mesh.

Consider a Bezier surface $\mathbf{s}_b(u, w)$ constructed with a 4×4 polygon mesh; i.e., $\mathbf{s}^b(u,v) = \sum_{i=0}^{4}\sum_{j=0}^{4} \mathbf{b}_{i,j} J_{4,i}(u) K_{4,j}(v)$. Expending and converting into matrix form gives

$$\mathbf{s}^b(u,w) = \mathbf{U}\mathbf{N}_b\mathbf{B}\mathbf{N}_b{}^{\mathrm{T}}\mathrm{V} \tag{18}$$

where

$$\mathbf{U} = \begin{bmatrix} u^3 & u^2 & u & 1 \end{bmatrix}, \quad \mathbf{V} = \begin{bmatrix} v^3 & v^2 & v & 1 \end{bmatrix}^{\mathrm{T}}$$

$$\mathbf{N}_b = \begin{bmatrix} -1 & 3 & -3 & 1 \\ 3 & -6 & 3 & 0 \\ -3 & 3 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} \mathbf{b}_{0,0} & \mathbf{b}_{0,1} & \mathbf{b}_{0,2} & \mathbf{b}_{0,3} \\ \mathbf{b}_{1,0} & \mathbf{b}_{1,1} & \mathbf{b}_{1,2} & \mathbf{b}_{1,3} \\ \mathbf{b}_{2,0} & \mathbf{b}_{2,1} & \mathbf{b}_{2,2} & \mathbf{b}_{2,3} \\ \mathbf{b}_{3,0} & \mathbf{b}_{3,1} & \mathbf{b}_{3,2} & \mathbf{b}_{3,3} \end{bmatrix}$$

If this 4×4 Bezier surface is the same as a bicubic surface, then from Equation (15)

$$\mathbf{U}\mathbf{N}_c\mathbf{G}\mathbf{N}_c{}^{\mathrm{T}}\mathbf{V} = \mathbf{U}\mathbf{N}_b\mathbf{B}\mathbf{N}_b{}^{\mathrm{T}}\mathbf{V}$$

and hence,

$$\mathbf{G} = \mathbf{N}_c^{-1}\mathbf{N}_b\mathbf{B}\mathbf{N}_b^{\mathrm{T}}[\mathbf{N}_c^{\mathrm{T}}]^{-1}$$

This gives

$$\mathbf{G} = \begin{bmatrix} \mathbf{b}_{0,0} & \mathbf{b}_{0,3} & 3(\mathbf{b}_{0,1} - \mathbf{b}_{0,0}) & 3(\mathbf{b}_{0,3} - \mathbf{b}_{0,2}) \\ \mathbf{b}_{3,0} & \mathbf{b}_{3,3} & 3(\mathbf{b}_{3,1} - \mathbf{b}_{3,0}) & 3(\mathbf{b}_{3,3} - \mathbf{b}_{3,2}) \\ 3(\mathbf{b}_{1,0} - \mathbf{b}_{0,0}) & 3(\mathbf{b}_{1,3} - \mathbf{b}_{0,3}) & 9(\mathbf{b}_{0,0} - \mathbf{b}_{1,0} - \mathbf{b}_{0,1} + \mathbf{b}_{1,1}) & 9(\mathbf{b}_{0,0} - \mathbf{b}_{1,0} - \mathbf{b}_{0,1} + \mathbf{b}_{1,1}) \\ 3(\mathbf{b}_{3,0} - \mathbf{b}_{2,0}) & 3(\mathbf{b}_{3,3} - \mathbf{b}_{2,3}) & 9(\mathbf{b}_{2,0} - \mathbf{b}_{3,0} - \mathbf{b}_{2,1} + \mathbf{b}_{3,1}) & 9(\mathbf{b}_{2,2} - \mathbf{b}_{3,2} - \mathbf{b}_{2,3} + \mathbf{b}_{3,3}) \end{bmatrix}$$

The control polygon vertices on the boundary thus specify the positions and tangent vectors at the corner of the surface, whereas the interior polygon vertices control the twist at the corner of the surface.

B-SPLINE SURFACE

A B-spline surface is defined with a mesh of control polygon vertices $\mathbf{b}_{i,j}$, $i = 0, \ldots, n$, $j = 0, \ldots, m$:

$$\mathbf{s}(u,v) = \sum_{i=0}^{n}\sum_{j=0}^{m} \mathbf{b}_{i,j} N_{i,k}(u) N_{j,l}(v) \tag{19}$$

where k and l are the orders of the surface in the u and v directions, respectively; u and v lie in the range defined by the knot sequences $\{u_0, u_1, \ldots, u_{n+k+1}\}$ and $\{v_0, v_1, \ldots, v_{m+l+1}\}$, respectively, such that $u_i \le u_{i+1}$, $v_j \le v_{j+1}$, and

$$\begin{aligned} N_{i,k}(u) &= \frac{(u - u_i)N_{i,k-1}(u)}{u_{i+k-1} - u_i} + \frac{(u_{i+k} - u)N_{i+1,k-1}(u)}{u_{i+k} - u_{i+1}}, \\ N_{i,k}(u) &= \begin{cases} 1 & \text{if } u_i \le u \le u_{i+1} \\ 0 & \text{otherwise} \end{cases} \\ N_{j,l}(v) &= \frac{(v - v_j)N_{j,l-1}(v)}{v_{j+l-1} - v_j} + \frac{(v_{j+l} - v)N_{j+1,l-1}(v)}{v_{j+l} - v_{j+1}}, \\ N_{j,l}(v) &= \begin{cases} 1 & \text{if } v_j \le v \le v_{j+1} \\ 0 & \text{otherwise} \end{cases} \end{aligned}$$

The basis functions are partition of unity; i.e.,$\sum_{i=0}^{n} N_{i,k}(u) \equiv 1$, $\sum_{j=0}^{l} N_{j,l}(u) \equiv 1$, and hence, $\sum_{i=0}^{n}\sum_{j=0}^{l} N_{i,k}(u) N_{j,l}(v) \equiv 1$. It follows that a B-spline surface is a barycentric combination of its control polygon vertices $\mathbf{b}_{i,j}$ and thus possesses the basic properties of a free-form surface.

In general, three types of knot sequences affect the shape of the surface. These knot sequences are the periodic, open uniform, and open nonuniform sequence. Consider the knot sequence in the u direction. The knot sequence is Periodic, if $\Delta u = u_{i+1} - u_i$ is a constant. In an open uniform knot sequence, assuming Δu is a constant,

$$\begin{aligned} u_i &= u_0, & 1 &\le i \le k \\ u_i &= u_{i-1} + \Delta u, & k + 1 &\le i \le n + 2 \\ u_i &= u_{n+2}, & n + 3 &\le i \le n + k + 1 \end{aligned}$$

For an open nonuniform knot sequence,

$$\begin{aligned} u_i &= u_0, & 1 &\le i \le k \\ u_i &\le u_{i+1}, & k + 1 &\le i \le n + 2 \\ u_i &= u_{n+2}, & n + 3 &\le i \le n + k + 1 \end{aligned}$$

The use of a periodic knot sequence results in a surface that does not pass through the corner vertices. Figure 11(b) shows an example in which a B-spline surface is constructed with a periodic knot sequence in both directions. Figure 11(a) shows the B-spline surface using a periodic knot sequence in one direction, and an open uniform knot sequence in the other direction. Figure 11(c) illustrates a

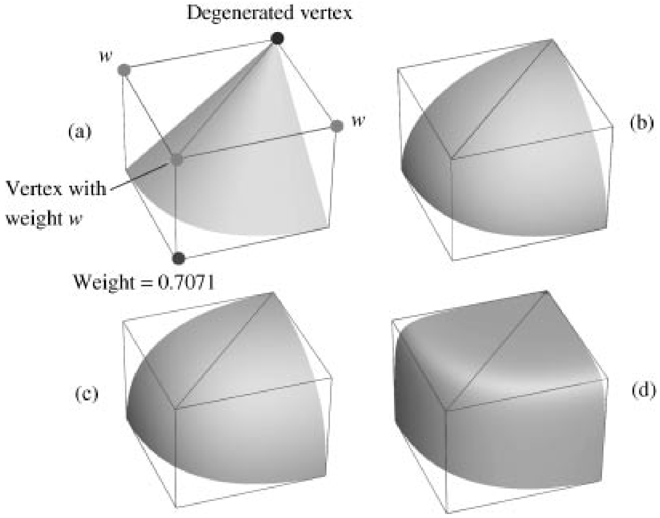

Figure 12. Constructing Quadric surfaces with NURBS: (a) sector of a cone, $w = 0$,(b) sector of a paraboloid, $w = 1$,(c) sector of a sphere, $w = 0.7071$, and (d) sector of hyperboloid, $w = 10$.

B-spline surface using an open uniform knot sequence in both directions.

The maximum order of a B-spline surface in each parametric direction is the number of control polygon vertices in that direction. Given a B-spline surface $\mathbf{s}(u, v)$ of order k in the u -direction and order l in the v direction, the maximum continuity of $\mathbf{s}(u, v)$ is C^{k-2} in the u direction, and C^{l-2} in the v direction. A B-spline surface constructed with open uniform knot sequences in both u and v directions reduces to a Bezier surface when the orders of the surface in the u and v directions are the same as the number of control polygon vertices in the corresponding directions.

RATIONAL B-SPLINE SURFACE

A rational B-spline surface (4) is an extension of a B-spline surface and is thus defined over a mesh of control polygon vertices. A rational B-spline surface constructed with non-uniform knot sequences is commonly referred to as a non-uniform rational B-spline surface (NURBS). Using the same notations as in the description of B-spline surface, a rational B-spline surface is expressed as

$$\mathbf{s}(u,v) = \frac{\sum\limits_{i=0}^{n}\sum\limits_{j=0}^{m} w_{i,j}N_{i,k}(u)N_{j,l}(v)\mathbf{b}_{i,j}}{\sum\limits_{i=0}^{n}\sum\limits_{j=0}^{m} w_{i,j}N_{i,k}(u)N_{j,l}(v)} \tag{20}$$

where $w_{i,j}$ is a weight associated with a control polygon vertex $\mathbf{b}_{i,j}$. By setting all $w_{i,j}$ the same, a rational B-spline surface reduces to a B-spline surface. The use of a weight for each polygon vertex provides extra control over the shape of the surface. With suitable weight adjustment and knot sequence, a rational quadric B-spline surface can be reduced to a quadric surface. Figure 12 shows a rational B-spline surface constructed with a 3×3 control polygon mesh. A third-order open uniform basis function is assumed for both parametric directions of the surface. The weights associated with all control vertices except those indicated in Fig. 12(a) are set to one. By adjusting the weights w associated with the vertices as indicated, various quadric surfaces can be obtained as shown in Fig. 12(b)–(d). In general, increasing the weight of a vertex pulls the surface toward the vertex.

The shape of a Bezier, B-spline, or rational B-spline surface can be easily adjusted by modifying the order of the basis function and the knot sequence and by relocating the control polygon vertices. Given a surface of order $k \times l$, a sharp edge exists on the surface if the multiplicity of the vertices on a row of the mesh is $k - 1$, or the multiplicity of the vertices on a column of the mesh is $l - 1$ (Fig.13).

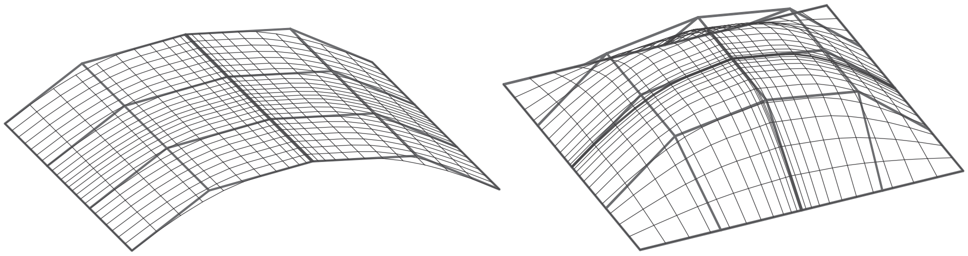

Figure 13. A fourth-order B-spline surface with multiple coincident net lines.

Multiplicity of a vertex refers to the number of repeated occurrence of the vertex at the same location.

COMPOSITE PATCHES AND CONTINUITY

Objects with a complex shape are usually constructed with a composite of surfaces. This process often requires maintaining the continuity between adjacent surface patches. There are two different types of continuity, namely, the parametric continuity and the geometric continuity. Parametric continuity refers to the continuity of derivatives across the common surface boundaries. Given two surfaces $\mathbf{g}(u,\ v)$, $0 \le u \le 1, 0 \le v \le 1$, and $\mathbf{h}(s,\ t)$, $0 \le s \le 1$, $0 \le t \le 1$, such that $\mathbf{g} = (1, v) = \mathbf{h}(0, t)$, and denotes $\mathbf{f}^n_u(u, v)$ as the n-th derivative of $\mathbf{f}(u, v)$ relative to u, then $\mathbf{s}$ and $\mathbf{r}$ are C^n continuous if $\mathbf{g}^n_u(1, v) = \mathbf{h}^n_s(0, t)$ and $\mathbf{g}^n_v(1, v) = \mathbf{h}^n_{\mathrm{t}}(0, t)$. That is, two surfaces are C^n continuous if the n-th derivates of their ccorresponding isoparametric lines are the same at the common boundary point.

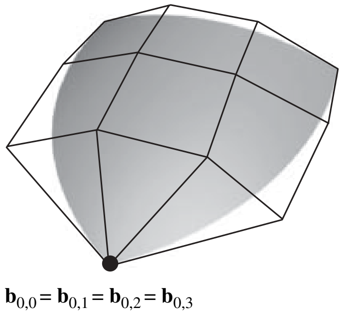
In general, C^1 or C^2 is sufficient for most applications. In cases in which only the visual or geomentic continuity is considered, only the directions of the derivatives are considered. For instance, G^1 continuity between $\mathbf{g}$ and $\mathbf{h}$ requires continuity of the surface normal along the common boundaries, which can be expressed as

$$\mathbf{g}_u(1, v) \times \mathbf{g}_v(1, v) = \lambda \mathbf{h}_s(0, t) \times \mathbf{h}_t(0, t) \tag{21}$$

where λ is an arbitrary constant. A singularity arises when degenerated vertices exist in a control polygon mesh. For instance, in Fig. 14, the surface normal is not well defined at the degenerated vertex. In this case, a unique surface normal can only be guaranteed if all polygons sharing the degenerated vertex are coplanar.

SUBDIVISION SURFACE

Tensor product surfaces are in general restricted to model surfaces with a rectangular topology. To model objects with irregular topology, control polygons with degenerated vertices are usually required. Because of the singularity of the surface at the degenerated vertices, this is often undesirable. The subdivision surface, which was introduced in the late 1970s, is capable of modeling surfaces with irregular topology.



$\mathbf{b}_{0,0} = \mathbf{b}_{0,1} = \mathbf{b}_{0,2} = \mathbf{b}_{0,3}$

Figure 14. A surface with a degenerated vertex.

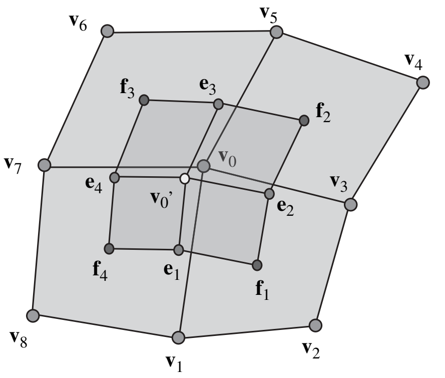


Figure 15. A Catmull–Clark subdivision surface.

Classic subdivision schemes include the Catmull–Clark scheme (5) that generates bicubic B-spline surfaces and the Doo–Sabin scheme (6) for producing quadric B-spline surfaces. Other popular subdivision schemes include the Loop scheme (7) that works on triangular meshes and the interpolative Butterfly scheme (8). A description of the Catmull–Clark scheme is given below. Details on the other schemes can be found in Ref. 9.

Consider the subdivision of a mesh as shown in Fig. 15 using the Catmull–Clark scheme. Assume there are four edges incident to a vertex $\mathbf{v}_0$. The mesh sharing $\mathbf{v}_0$ is subdivided by generating a set of face points, edge points, and vertex points. New face points are placed at the center of each face as expressed below:

$$\begin{aligned} \mathbf{f}_1 &= \frac{1}{4}(\mathbf{v}_0 + \mathbf{v}_1 + \mathbf{v}_2 + \mathbf{v}_3), \quad \mathbf{f}_2 = \frac{1}{4}(\mathbf{v}_0 + \mathbf{v}_3 + \mathbf{v}_4 + \mathbf{v}_5) \\ \mathbf{f}_3 &= \frac{1}{4}(\mathbf{v}_0 + \mathbf{v}_5 + \mathbf{v}_6 + \mathbf{v}_7), \quad \mathbf{f}_3 = \frac{1}{4}(\mathbf{v}_0 + \mathbf{v}_7 + \mathbf{v}_8 + \mathbf{v}_1) \end{aligned} \tag{22}$$

New edge points are inserted at

$$\begin{aligned} \mathbf{e}_1 &= \frac{1}{2}\left[\frac{(\mathbf{v}_0 + \mathbf{v}_1)}{2} + \frac{(\mathbf{f}_4 + \mathbf{f}_1)}{2}\right], \quad \mathbf{e}_2 = \frac{1}{2}\left[\frac{(\mathbf{v}_0 + \mathbf{v}_3)}{2} + \frac{(\mathbf{f}_1 + \mathbf{f}_2)}{2}\right] \\ \mathbf{e}_3 &= \frac{1}{2}\left[\frac{(\mathbf{v}_0 + \mathbf{v}_5)}{2} + \frac{(\mathbf{f}_2 + \mathbf{f}_3)}{2}\right], \quad \mathbf{e}_4 = \frac{1}{2}\left[\frac{(\mathbf{v}_0 + \mathbf{v}_7)}{2} + \frac{(\mathbf{f}_3 + \mathbf{f}_4)}{2}\right] \end{aligned} \tag{23}$$

and new vertex points are inserted at

$$\mathbf{v}_0' = \frac{\mathbf{Q}}{4} + \frac{\mathbf{R}}{2} + \frac{\mathbf{v}_0}{4} \tag{24}$$

where

$$\mathbf{Q} = \frac{1}{4}(\mathbf{f}_1 + \mathbf{f}_2 + \mathbf{f}_3 + \mathbf{f}_4)$$

and

$$\mathbf{R} = \frac{1}{4}\left(\frac{\mathbf{v}_0 + \mathbf{v}_1}{2} + \frac{\mathbf{v}_0 + \mathbf{v}_3}{2} + \frac{\mathbf{v}_0 + \mathbf{v}_5}{2} + \frac{\mathbf{v}_0 + \mathbf{v}_7}{2}\right)$$

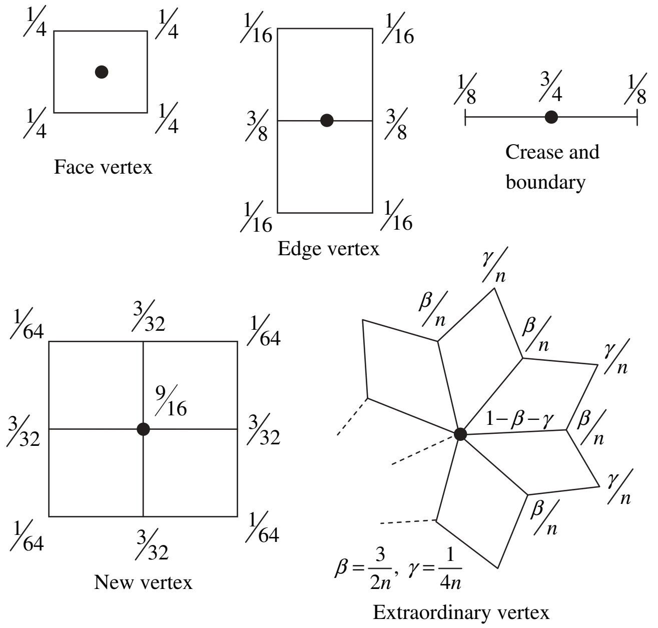

Figure 16. Masks for Catmull–Clark subdivision.

In general, for meshes with irregular mesh topology, a new face point is the average of all old points defining the face. A new edge points is the average of the midpoints of the old edge and the average of the two new face vertices of the faces sharing the edge. A new vertex point is obtained with the expression

$$\frac{\mathbf{Q}}{n}+\frac{2\mathbf{R}}{n}+\frac{\mathbf{S}(n-3)}{n} \tag{25}$$

where n is the number of edges sharing the vertex, $\mathbf{S}$ is the old vertex point, $\mathbf{Q}$ is the average of the new face points of all faces sharing the old vertex point, and $\mathbf{R}$ is the average of the midpoints of all old edges incident to the old vertex point.

An edge can be tagged as creased such that it is not smoothed in the subdivision process. In this case, a new face point remains the average of the vertices bounding the face. A new edge point is the midpoint of the edge. Assuming there are n creased edges incident to a vertex $\mathbf{v}_0$, the new vertex point of $\mathbf{v}_0$ is generated according to the following rules:

1. If $n \le 1$, the new vertex point is computed with Equation (25).
2. If $n = 2$, and the vertices of the creased edges are $(\mathbf{v}_0, \mathbf{v}_a), (\mathbf{v}_0, \mathbf{v}_b)$, the new vertex point is given by $\mathbf{v}_0' = \frac{1}{8}\mathbf{v}_a + \frac{3}{4}\mathbf{v}_0 + \frac{1}{8}\mathbf{v}_b$.
3. if $n{>}2$, then $\mathbf{v}_0' = \mathbf{v}_0$.

The subdivision rule for a subdivision scheme is often described using the mask notation.Figure 16 gives the mask notation for the Catmull–Clark subdivision rules. The new position of the highlighted vertex is given by the sum of the products of the mask weights and the corresponding vertices.

The number of edges incident to a vertex is usually referred to as the valency of a vertex. In a regular Catmull–Clark subdivision mesh, the valency is four. Vertices with valency other than four are called extraordinary vertices. By applying one subdivision to a base mesh, the mesh will be composed of all quadrilateral faces. The total number of extraordinary vertices is hence fixed after one subdivision. Figure 17 shows an example of a Catmull–Clark subdivision surface at different subdivision levels.

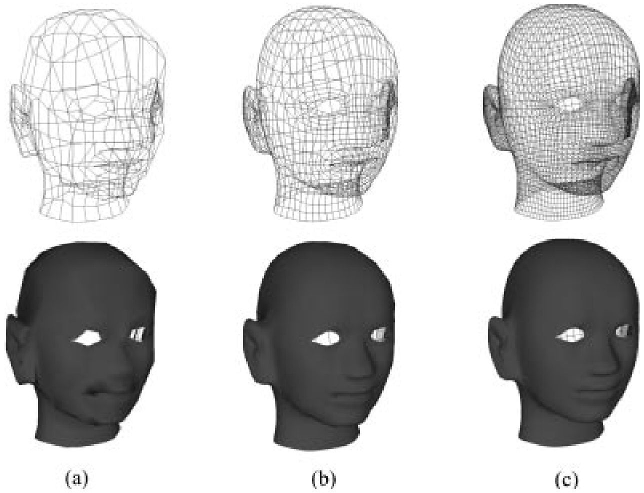

Figure 17. A head model constructed with the Catmull–Clark subdivision scheme: (a) base mesh, (b) subdivision level = 1, and (c) subdivision level = 2.

REMARKS

Surface modeling is an essential technique for the construction of 3-D objects. A wide variety of different surface construction techniques have been developed. The description given above in no way covers all different surfaces types. It only attempts to describe those popularly used surfaces and their characteristics. For other surfaces, e.g., Bezier triangles (2) and Gregory patch (10), details can be found in the corresponding references.

VIRTUAL CLOTHING

INTRODUCTION

Virtual garment simulation is the result of a large combination of techniques that have dramatically evolved during the last decade. Unlike the mechanical models used for existing mechanical engineering for simulating deformable structures, several new challenges are associated with the highly versatile nature of cloth. The central pillar of garment simulation is the development of efficient mechanical simulation models that can reproduce accurately the specific mechanical properties of cloth. However, cloth is by nature highly deformable and specific simulation problems exist from this fact. First, the mechanical representation should be accurate enough to deal with the nonlinearities and large deformations occurring at any place in the cloth, such as folds and wrinkles. Moreover, the garment cloth interacts strongly with the body that wears it, as well as with the other garments of the apparel. This strong interaction requires advanced methods to detect efficiently the geometrical contacts constraining the behavior of the cloth, and to integrate them in the mechanical model (collision detection and response). All of these methods require advanced and complex computational methods where the most important issues are computation speed and efficiency. For real-time applications, however, only specific approximation and simplification methods allow the computation of garment animation, giving up some of the mechanical accuracy toward a more realistic.

Garment simulation, which started in the late 1980s with very simple models such as Weil's approach (1), has benefited from the increase in performance of computer hardware and tools as well as from the development of specific simulation technologies that have led to impressive applications not only in the field of simulation of virtual worlds but also in the fashion garment industry. In Fig. 1, we can see complex clothes models done from sketches of famous designers of the sixties.

EARLY DEVELOPMENTS IN VIRTUAL GARMENT SIMULATION

In the field of computer graphics, the first applications for mechanical cloth simulation appeared in 1987 with the work of Terzopoulos et al. (2,3) in the form of a simulation system that relies on the Lagrange equations of motion and elastic surface energy. Solutions were obtained through finite difference schemes on regular grids, which allowed simple scenes involving cloth to be simulated, such as the accurate simulation of a flag or the draping of a rectangular cloth. However, the first applications that simulated garments realistically started in 1990 (Fig. 2) with the considerations of many other technologies complementing cloth simulation (4,5), such as body modeling, body animation, and collision detection and response (6). These applications innovated the fashion industry by providing the first virtual system allowing virtual garment patterns to be sewed together around a character.

Since then, most developments were aimed toward optimizing the accuracy and efficiency of the methods for simulating cloth accurately and efficiently, along with the developments of actual applications and commercial products.

MECHANICAL MODELS

Two major stages are to be considered in the design of an accurate mechanical simulation system:

1. The characterization and measurement of the mechanical properties of the material to be simulated, which includes the identification of the main factors that characterize the material and their quantitative measurement through a set of mechanical parameters, or behavior curves, possibly with their analytical modelization.
2. The reproduction of these mechanical properties in a numerical resolution system that uses state-of-the-art numerical methods and algorithms to reproduce accurately the resulting static or the dynamic behavior.

MECHANICAL CHARACTERIZATION OF CLOTH

The mechanical properties of deformable surfaces can be grouped into four main families:

1. Elasticity: the internal stress resulting from a given geometrical strain.
2. Viscosity: the internal stress resulting from a given strain rate.
3. Plasticity: how the properties evolve according to the deformation history.
4. Resilience: the limits at which the structure will break.

Elastic properties are the main contributor of mechanical effects in the usual contexts where cloth objects are used. Deformations are often small and slow enough to make the effects of viscosity, plasticity, and resilience insignificant. One major hypothesis is that quasistatic models in the domain of elastic deformations will suffice for models intended to simulate the rest position of the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

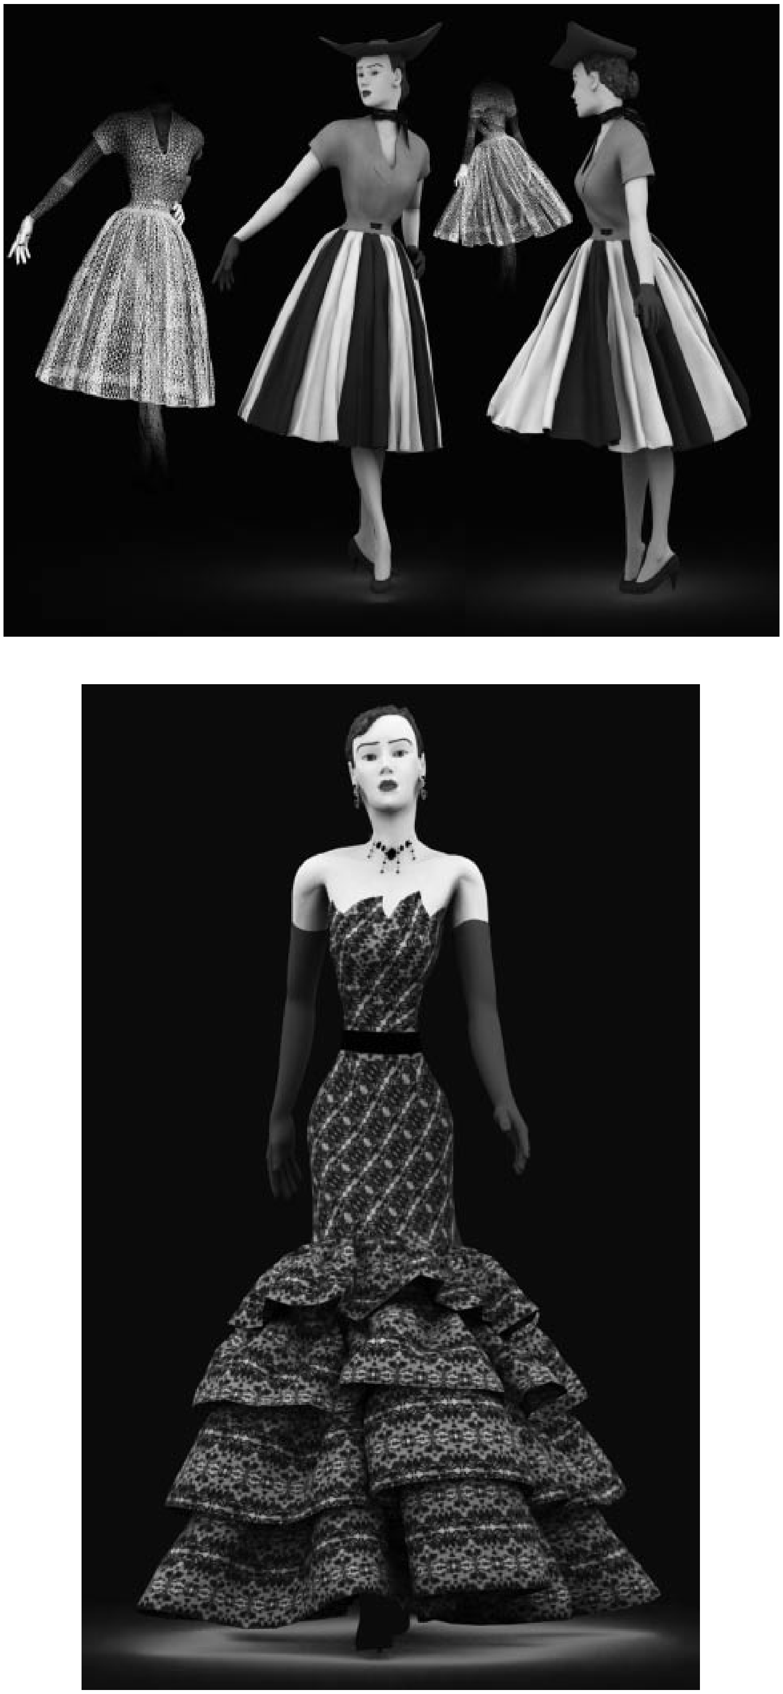

Figure 1. From the award-winning film "High Fashion in Equations," MIRALab–University of Geneva.

Figure 1. (*Continued*)

garment on an immobile mannequin (draping). However, when a realistic animation is needed, the parameters relating energy dissipation through the evolution of the deformation are also needed, and complete dynamic models, including viscosity and plasticity, should be used.

Depending on the amplitude of the mechanical phenomena under study, the curves expressing mechanical properties exhibit shapes of varying complexity. If the amplitude is small enough, these shapes may be approximated by straight lines. This linearity hypothesis is a common way to simplify the characterization and modeling of mechanical phenomena. However, in general, the nonlinear properties of cloth are captured through strain–stress curves. More complex models also consider more complex phenomena, such as the plasticity behavior, appearing as hysteresis in the strain–stress curves.

It is common in elasticity theory to consider that the orientation of the material has no effect on its mechanical properties (isotropy). This, however, is inappropriate for cloth, as its properties depend considerably on their orientation relative to the fabric thread.

Elastic effects can be divided into two main contributions:

1. Metric elasticity: deformations along the surface plane.
2. Bending elasticity: deformations orthogonally to the surface plane.

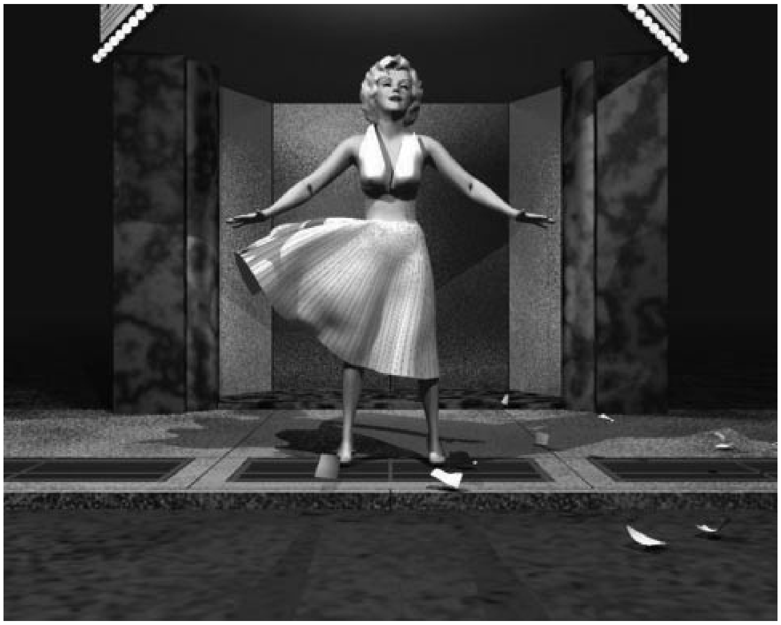

Figure 2. “FlashBack”: Early virtual garments used context-dependent simulation of simplified cloth models (image courtesy of MIRALab–University of Geneva).

The garment industry needs the measurement of major fabric mechanical properties through normalized procedures to guarantee consistent information exchange between garment industry and cloth manufacturers. The Kawabata evaluation system for fabric (KES) is a reference methodology for the experimental observation of the elastic properties of the fabric material. Using five experiments, 15 curves are obtained, which determine 21 parameters for the fabric.

Four standard tests are part of KES to determine the mechanical properties of cloth, using normalized measurement equipment (Fig. 3). The *tensile test* measures the force/deformation curve of extension for a piece of fabric of normalized size along weft and warp directions and allows the measurement of tensile elongation strain–stress behavior along with other parameters assessing nonlinearity and hysteresis. The *shearing test* is the same experiment using shear deformations, which allows the measurement of tensile shear strain–stress behavior. The *bending test* measures the curves for bending deformation in a similar way and measures the bending strain–stress behavior. Finally the *compression test* and the *friction test* measure parameters related to the compressibility and the friction coefficients. Allthough the KES measurements determine parameters assessing the nonlinearity of the behavior curves and some evaluation of the plasticity, other methodologies, such as the FAST method, use simpler procedures to determine the linear parameters only.

Whereas KES measurements and similar systems summarize the basic mechanical behaviors of fabric material, the visual deformations of cloth, such as buckling and wrinkling, are a complex combination of these parameters with other subtle behaviors that cannot be characterized and measured directly.

To take these effects into account, other tests focus on more complex deformations. Among them, the draping test considers a cloth disk of a given diameter draped onto a smaller horizontal disk surface. The edge of the cloth will fall around the support and produce wrinkling. The wrinkle pattern can be measured (number and depth of the wrinkles) and used as a validation test for simulation models.

Tests have also been devised to measure other complex deformation of fabric material, mostly related to bending, creasing, and wrinkling.

Methods for Mechanical Cloth Simulation

Continuum Mechanics Models. Well known in mechanical engineering, the finite element method measures the cloth surface as discretized in interpolation patches for a given order (bilinear, trilinear, quadrilinear) and measures an associated set of parameters (degrees of freedom) that give the actual shape to the interpolation surface over the element. From the mechanical properties of the material, the mechanical energy is computed from the deformation of the surface for given values of the interpolation parameters. An equation system based on the energy variation is then constructed with these degrees of freedom. Surface continuity between adjacent elements imposes additional constraint relationships. A large, sparse linear system is

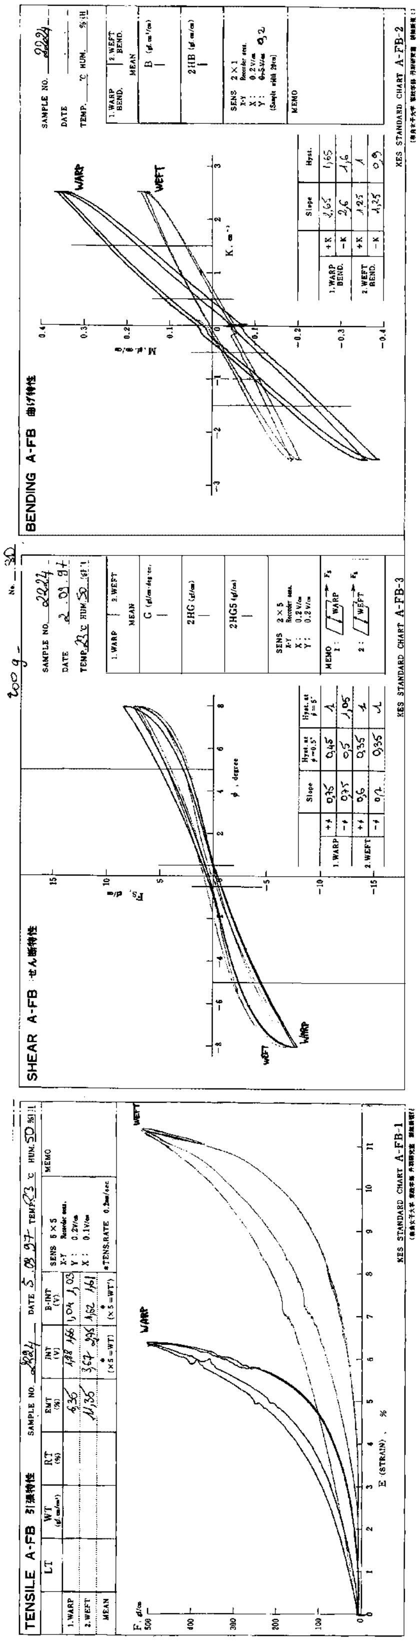

Figure 3. Examples of elongation, shear and bending strain–stress curves measured during KES evaluation of a fabric sample.

built by assembling successively the contributions of all elements of the surface and then it is solved using optimized iterative techniques, such as the conjugate gradient method.

In the beginning, finite elements had only a marginal role in cloth simulation. The main attempts are described in Refs. (7-9). Most implementations focus on the accurate reproduction of mechanical properties of fabrics, but they restrict the application field to the simulation of simple garment samples under elementary mechanical contexts, mostly because of the huge computational requirements of these models. Furthermore, accurate modeling of highly variable constraints (large nonlinear deformations, highly variable collisions) is difficult to integrate into the formalism of finite elements, and this sharply reduces the ability of the model to cope with the very complicated geometrical contexts that develop in real-world garment simulation on virtual characters.

Some recent developments have attempted to speed up the computation times required for finite elements. These developments have been used particularly in the context of interactive simulation for virtual surgery systems (10,11). For instance, preinverting the resolution matrix (as done in Ref. 12 for particle systems) may speed up the computation (13), but it restricts the application field to linear models and to very small mechanical systems (14). The “explicit finite elements” described in Ref. 15 come close to a good computational charge compromised by locally approximating the resolution of each element (16). These models also rely on simple linear formulations of the strain tensor that are inappropriate for the large deformations or displacements encountered in cloth simulation. Alleviating this problem through the use of a linearized form of the Green Lagrange strain tensor has led recently to more accurate models (10,17). A coordinate rotation is used to ensure accuracy of the linearized form in the context of large deformations (18-20). However, none of these methods has been implemented in the context of general nonlinear strain–stress mechanical behaviors.

Particle Systems. An easier and more pragmatic way to perform cloth simulation is to use of particle systems. Particle systems consider the cloth to be represented only by the set of vertices that constitute the polygonal mesh of the surface. These particles are moved through the action of forces that represent the mechanical behavior of the cloth, which are computed from the geometric relationships between the particles that measure the deformation of the virtual cloth. Among the different variations of particle systems, the spring-mass scheme is the simplest and most widely used. It considers the distance between neighboring particle pairs as the only deformation measurement and interaction source representing the internal elasticity of the cloth.

The simplest approach is to construct the springs along the edges of a triangular mesh describing the surface. This approach, however, leads to a model that cannot accurately display the anisotropic strain–stress behavior or the bending behavior of the cloth material. More accurate models are constructed on regular square particle grids describing the surface. Whereas elongation stiffness is modeled by springs along the edges of the grid, shear stiffness is modeled by diagonal springs, and bending stiffness is modeled by leapfrog springs along the edges. This model still is inaccurate because of the unavoidable cross-dependencies between the various deformation modes relative to the corresponding springs. Also, it is inappropriate for nonlinear elastic models and large deformations. More accurate variations of the model consider angular springs rather than straight springs to represent shear and bending stiffness, but the simplicity of the original spring-mass scheme is then lost (Fig. 4).

Particle systems are among the simplest and most efficient ways to define rough models that compute highly deformable mechanical systems, such as cloth, with computation times small enough to integrate them into systems to simulate complete garments on virtual bodies. Among the main contributions on particle system models, early works considered simple viscoelastic models on regular grids with applications for draping problems with simple

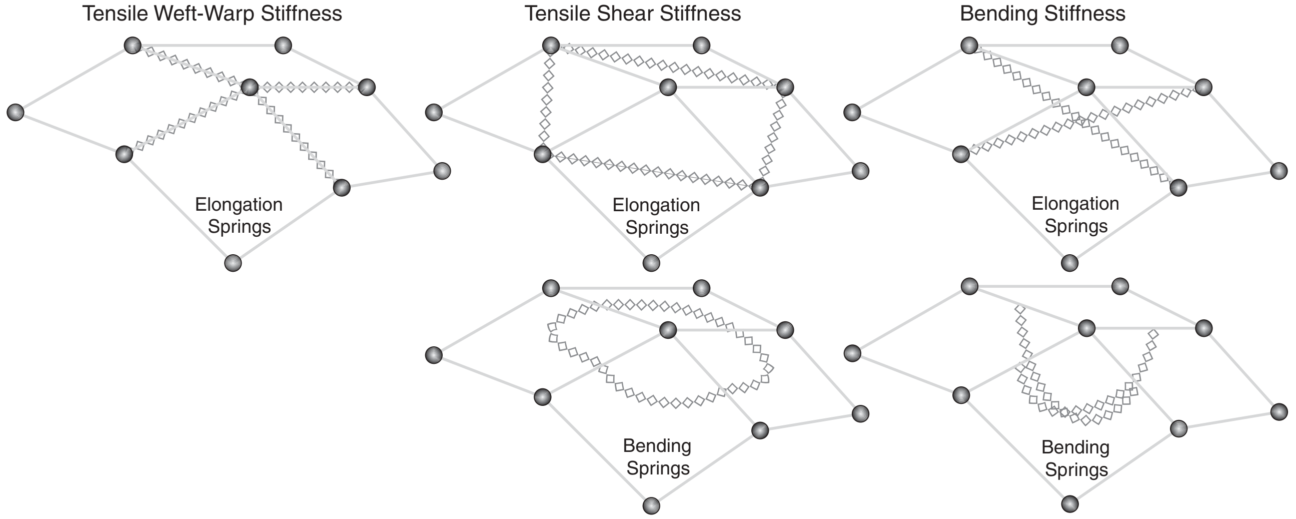

Figure 4. Various structures of spring-mass systems used in cloth simulation.

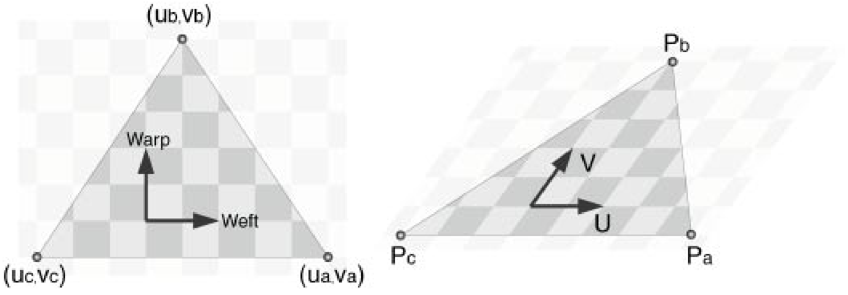

Figure 5. Accurate representation of tensile elasticity using particle systems: A triangle of cloth element defined on the 2-D cloth surface (left) is deformed in 3-D space (right), and its deformation state is computed from the deformation of its weft-warp coordinate system.

numerical integration schemes (21). Accurate models started with Breen et al. (22) modeling the microstructure of cloth using parameters derived from KES behavior curves and integration based on energy minimization. However, such accurate models required a lot of computation for solving problems that were restricted to draping. On the other hand, more recent models trade accuracy for speed, such as the grid model detailed by Provot (23), which includes geometric constraints for limiting large deformation of cloth. Additional contributions from Eberhardt et al. (24) include the simulation of KES parameters and the comparison of the efficiency between several integration methods. Advanced surface representations were used in Ref. 25, where the simulation model and collision detection takes advantage of the hierarchical structure of subdivision surfaces. Modeling animated garments on virtual characters is the specific aim of the work described by Volino et al. (26,27), which investigates improved spring-mass representations for better accuracy of surface elasticity modeling on irregular meshes. Finally, advanced particle systems that describe accurately the deformable behavior of elastic materials (17) also can describe accurately the anisotropic and nonlinear behavior of cloth materials (28). Such models can represent surface properties as accurately as first-order finite elements, offering a very good compromise between accuracy and computation speed (Fig. 5).

Simulating Bending Stiffness. Tensile stiffness only involves computing deformations and forces within mesh elements. On the other hand, the simulation of bending stiffness necessitates the action of out-of-plane forces between several adjacent mesh elements.

Several solutions have been proposed in the literature, representing two main approaches (Fig. 6). The first solution is to use crossover springs that extend the surface, opposing transversal bending (23,24). The second is to evaluate precisely the angle between adjacent mesh elements and to create between them normal forces that oppose this angle through opposite bending momentum (26,29–31). This approach can reach similar accuracy as grid continuum-mechanics (2) and grid particle system derivatives (32), which are complex to evaluate. Another solution proposed in Ref. (33) is to evaluate bending as a second-order discrete derivative vector computed linearly from the vertex positions, and to compute bending forces directly from it. It offers the advantage of a completely linear formulation that can efficiently be integrated by numerical algorithms.

Numerical Integration Methods. Although various models can be used to compute the force applied on each particle given their position and velocity, these forces must be integrated along time to obtain the position and velocity of the particle for the following time-steps using methods related to the integration of ordinary differential equation systems. Most recent contributions focus on improvements of the numerical integration methods in order to improve the efficiency of the simulation.

Explicit integration methods are the simplest methods available to solve first-order ordinary differential systems. They predict the future system state directly from the value of the derivatives. The best known techniques are the Runge–Kutta methods. Among them, the fast but unstable and inaccurate first-order Euler method, used in many

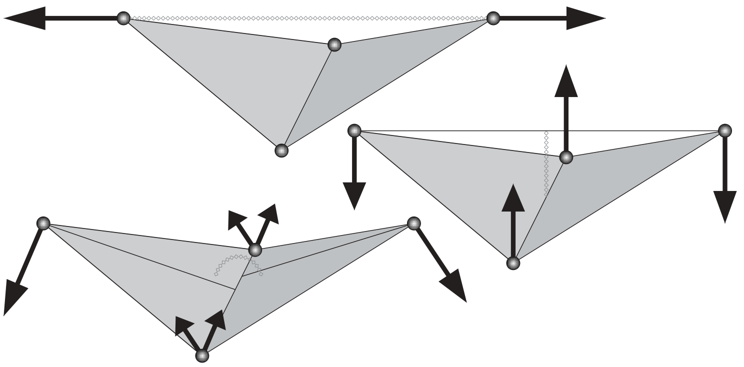

Figure 6. Three ways for creating bending stiffness in a triangle mesh: Using tensile crossover springs over mesh edges (top), using forces along triangle normals (bottom), and using forces linearly evaluated from a weighted sum of vertex positions (right).

early implementations, extrapolates directly the future state from the current state and from the derivative. Higher order and more accurate methods also exist, such as the second-order Midpoint method, used for instance in early models by Volino et al.(26), and the very accurate fourth-order Runge–Kutta method, used for instance by Eberhardt et al. (24).

In addition to considerations for accuracy, stability and robustness are other key factors to consider. For most situations encountered in cloth simulation, the numerical stiffness of the equations (stiff elastic forces, small surface elements) require the simulation time-steps to be small enough to ensure the stability of the system, and this limits the computation speed much more than accuracy considerations. Adequate time-step control is therefore essential for an optimal simulation. A common solution is to use the fifth-order Runge–Kutta algorithm detailed in Ref. (34) which embeds integration error evaluation used for tuning the time-step adaptively (29).

To circumvent the problem of instability, implicit numerical methods are used. For cloth simulation, this was outlined first by Baraff et al. (32). The most basic implementation of the implicit method is the Euler step, which finds the future state for which "backward" Euler computation would return the initial state. It performs the computation using not the derivative at the current time-step but the predicted derivative for the next time-step. Besides the inverse Euler method other, more accurate, higher order implicit methods exist, such as the inverse Midpoint method, which quite simple but exhibits some instability. A simple solution is to interpolate between the equations of the Euler and the Midpoint methods, as proposed by Volino et al. (40). Higher order methods, such as the Rosenbrook method, do not exhibit convincing efficiencies in the field of cloth simulation. Multistep methods, which perform a single-step iteration using a linear combination of several previous states, are good candidates for a accuracy–stability compromise. Among them, the second-order backward differential formula has shown some interesting performances, as used by Eberhardt,(35) Hauth et al. (36) and Choi et al. (37).

Whatever variation chosen, the major difficulty with implicit integration methods is that they involve the resolution of a large and sparse linear equation system for each iteration, constructed from the Jacobian matrix of the particle forces against their position and velocity. A commonly used simplification involves linearization of the mechanical model so as to obtain a linear approximation of the matrix that does not evolve along time, and on which initial construction and preprocessing allows an efficient resolution method to be used, as for example in Kang et al. (38), or even the matrix inverse to be precomputed as done by Desbrun et al. (12). Another simplification is to suppress completely the need for computing the matrix using an adapted approximation embedded directly in an explicit iteration. A big drawback of all these methods results from the approximation of the matrix that cannot take into account the nonlinearities of the model (mostly those resulting from the change in orientation of the surface elements during the simulation). Although this change is acceptable draping applications, animations usually behave poorly because of excessive numerical damping, which also increases as the time-step becomes large.

The best numerical method to resolve the linear system seems to be the conjugate gradient method, as suggested by Baraff et al. (32), with many variations and preconditioning schemes depending on how the mechanical model is formulated and on how the geometrical constraints of the cloth are integrated.

Most models that use implicit integration schemes restrict themselves to using spring-mass systems as their simple formulation to ease the process of defining the linear system to be resolved. However, implicit integration methods also can be used to integrate accurate surface-based particle systems as the one described above, from derivation of the particle force expressions relative to the particle positions and velocities (39). This approach is integrated simply into the implicit formulations described by Volino et al. (40) and is extended toward other advanced methods as by Hauth et al. (36). These formulations blur the line between particle systems and finite element methods, as the described particle system is indeed a first-order finite element method where the implicit resolution scheme corresponds to the energy minimization scheme of finite elements and the build of the linear system matrix corresponds to the assembly process of elements into the global system to be resolved. This key idea to design a new system combines the accuracy of finite elements with the efficiency of the techniques used for creating a particle system.

Collision Processing. Collision detection is one of the most time-consuming tasks when it comes to simulating virtual characters wearing complete garments (41). The usual complexity of collision detection processes result from the large number of primitives that describe these surfaces. Most of the collision detection applications need to compute which polygons of large meshes do actually collide. In most of the cases, these meshes are animated (through user interaction or simulation processes) and collision detection must be involved at each step of the animation process to ensure immediate and continuous feedback to the animation control.

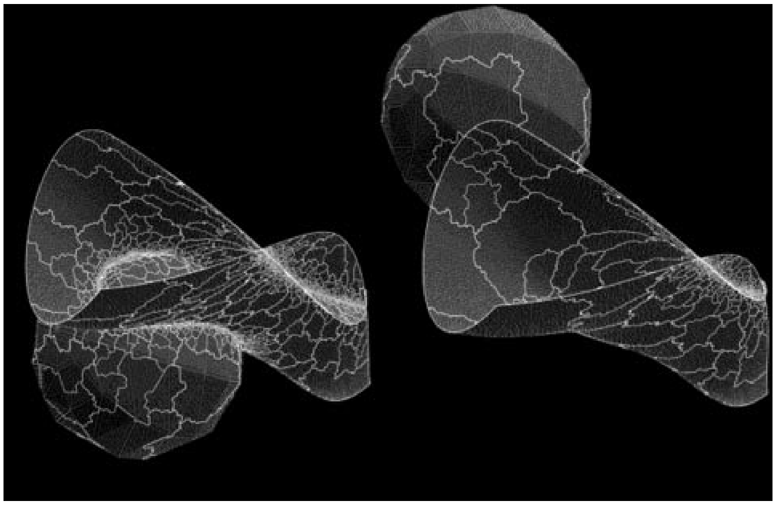
Most of the efficient collision detection algorithms take advantage of a hierarchical decomposition of the complex scheme, which allows for avoiding the quadratic time of testing extensively collisions between all possible couples of primitives. Two major ways of constructing such hierarchies are as follows:

1. Space subdivision schemes: the space is divided in to a hierarchical structure, typically octree methods. Using such structure, a reduced number of geographical neighbors of a given primitive are found in log(n) time (the depth of a hierarchy separating geographically n primitives) and tested for collisions against it.
2. Object subdivision schemes: the primitives of the object are grouped in to a hierarchical structure. These methods are based on bounding volume hierarchies. Using such structure, large bunches of primitives may

be discarded in log(n) time (the depth of a well-constructed hierarchy tree of n primitives) through simple techniques such as bounding-volume evaluations.

In the context of cloth simulation, object subdivision schemes are the most appropriate, as they take advantage of the constant topology of the mesh, which defines a near-constant, local geometric proximity relationship between mesh elements. This task is performed through an adapted bounding-volume hierarchy algorithm, which can use a constant discrete-orientation-polytope hierarchy constructed on the mesh and an optimization for self-collision detection using curvature evaluation on the surface hierarchy (29,42). This algorithm is fast enough to detect full collision and self-collision between all objects of the scene with acceptable impact on the processing time) (Fig. 7). Thus, body and cloth meshes are handled symmetrically by the collision detection process, ensuring perfect versatility of the collision handling between the body and the several layers of garments.

Collision response may either be force-based, using strong nonlinear penalty forces that simulate contact forces, or impulse-based, using a geometrical scheme based on correction of the mesh position, velocity, and acceleration. Allthough force-based models ensure good integration with the mechanical simulation process, the high nonlinearity of the forces degrades the performance of the numerical resolution. Impulse-based methods are more difficult to integrate into the mechanical model, but they offer a more controllable geometric constraint enforcement that does not affect the numerical resolution too much (27,40) (Fig. 8).



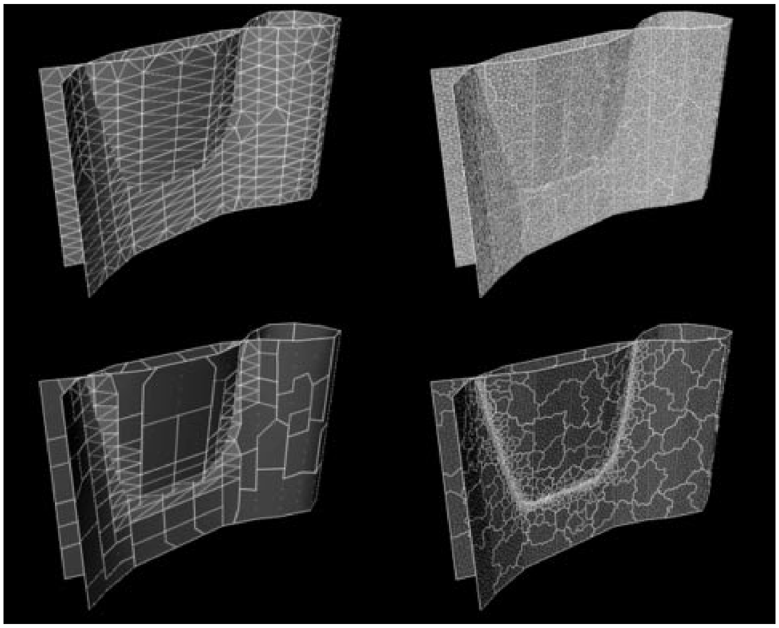


Figure 7. Collision detection using bounding-volume hierarchies: Only colliding regions are subdivided for detecting colliding mesh elements.

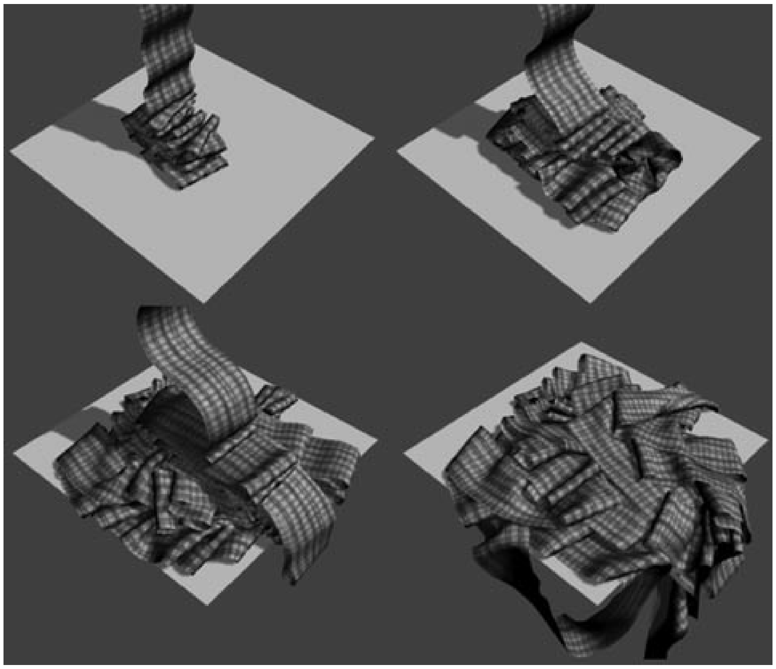

Figure 8. Advanced collision methods are required for solving such challenging situations in cloth simulation.

GARMENT DESIGN AND SIMULATION

Since the first developments of simulated garments on virtual characters (4,5), cloth simulation and garment animation has made its way not only into computer research (27), but also into commercial products aimed both for 3-D computer design and the garment industry.

A System for Pattern-Based Garment Design

Allthough essential, computational techniques alone are not sufficient to produce a powerful tool to allow accurate and convenient creation and prototyping of complex garments. All state-of-the-art techniques have to be integrated into a garment design and simulation tool aimed at prototyping and virtual visualization, to allow fashion designers to experiment virtually on new collections with high-quality preview animations, as well as to allow pattern makers to adjust precisely the shape and measurements of the patterns to fit the body optimally for best comfort (Fig. 9).

The most intuitive and natural approach for building garments takes its inspiration from the traditional garment industry, where garments are created from two-dimensional patterns and then seamed together (Fig. 10). Working with 2-D patterns is the simplest way to keep an accurate, precise, and measurable description and representation for a cloth surface. In the traditional

Figure 9. From the award-winning film “High Fashion in Equations,” MIRALab–University of Geneva.

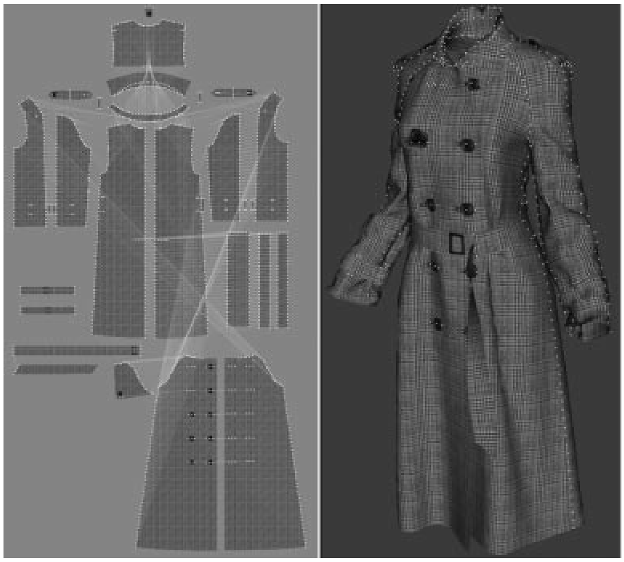

Figure 10. Between real and virtual: A garment design system should offer high-quality garment simulation, along with highly interactive pattern 2-D–3-D design and preview tools allowing complex garment models to be designed efficiently with many features such as seams, buttons, pockets, and belts.

garment and fashion design approach, garments usually are described as a collection of cloth surfaces, tailored in fabric material, along with the description of how these patterns should be seamed together to obtain the final garment. Many computer tools already are available in the garment industry for this purpose. A powerful virtual garment design system reproduces this approach by providing a framework to design the patterns accurately with the information necessary for their correct seaming and assembly. Subsequently, these patterns are placed on the 3-D virtual bodies and animated along with the virtual actor's motion.

Garment Prototyping

Combined with the accuracy and the speed of state-of-the-art mechanical simulation techniques, tasks such as comfortability evaluations are open to the garment designer, through the addition of several visualization tools, such as:

- Preview of fabric deformations and tensions along any weave orientation.
- Preview of pressure forces of the garment on the body skin.
- Immediate update of these evaluations according to pattern reshaping and sizing, fabric material change, and body measurements and posture change.

These tools allow the pattern designer to virtually test and adjust the measurements of complex garment patterns to the body size and postures of numerous different "virtual mannequins," assessing the strain and stress of the cloth, as well as the pressure exerted on the skin, assessing how the garment feels and slides on the body as it moves, and detecting eventual gesture limitations resulting from particular garment features (Fig. 11).

Commercial Products

Two kinds of virtual garment design products currently are available: those created for general cloth simulation and animation, and those specialized for draping and fitting garment models on virtual mannequins. The first category offers tools to simulate any kind of deformable surface

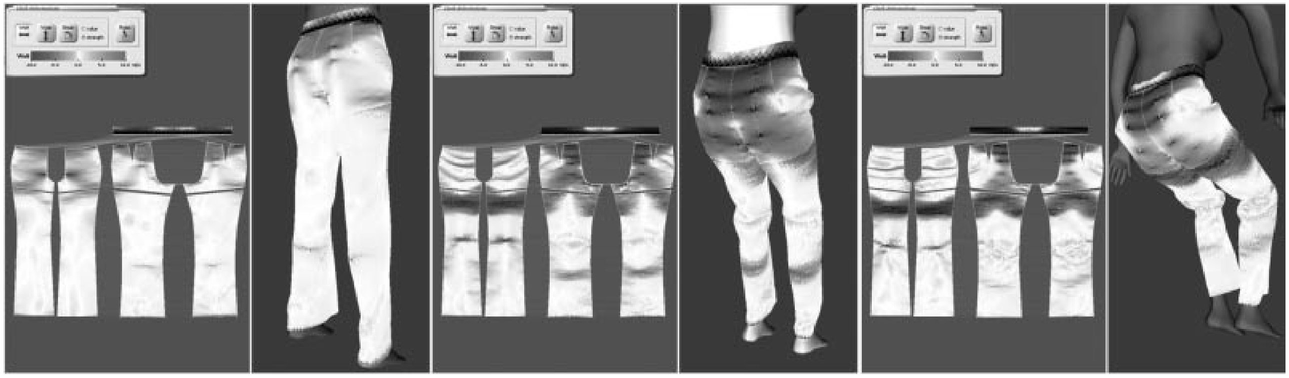

Figure 11. Virtual prototyping: Displaying weft constraints on an animated body (from standing to sitting).

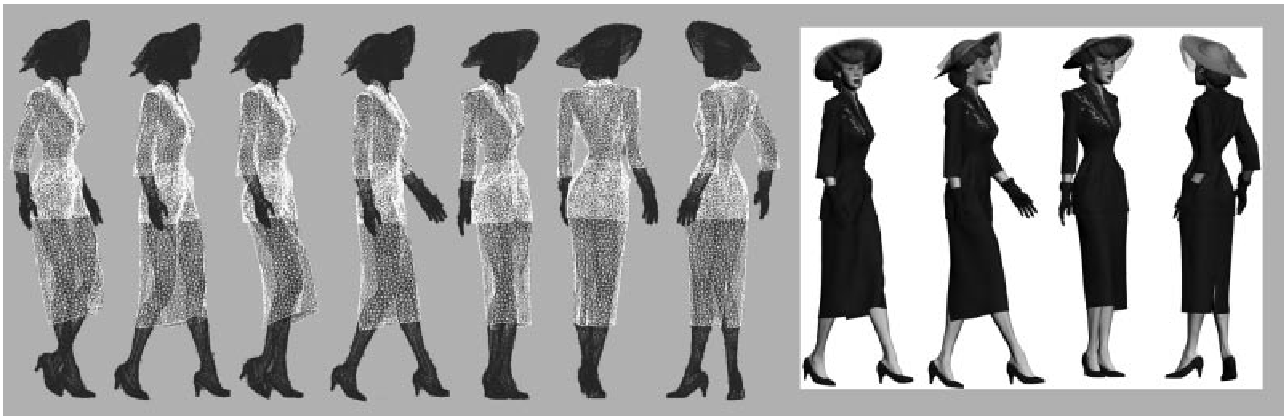

Figure 12. An animation sequence from the film “High Fashion in Equations.”

mechanically. These products usually offer a simple mechanical model containing only the basic mechanical parameters of cloth (stiffness, viscosity, bending, and gravity) modeled as a spring-mass particle system and simulated using state-of-the-art integration techniques. They allow the computation of realistic cloth animation, but they do not provide any tool for designing garments. Also these products offer general collision detection schemes for interaction with any other objects. These tools are usually integrated as plug-ins into 3-D design and animation frameworks.

The second category focuses on garment draping on virtual mannequins for visualization (virtual fashion, web applications) and prototyping purposes (garment design applications). The CAD applications specialize in the simulation of pattern assembly and of garment draping using accurate mechanical models of fabrics, whereas the visualization application takes advantage of geometric techniques for quickly generating realisticsally dressed mannequins out of design choices. Both applications use pattern models imported from professional pattern design tools. These tools also provide a stand-alone environment for setting up the simulation and for visualizing the results (Fig. 12).

VOLUME GRAPHICS AND VOLUME VISUALIZATION

Volume graphics is concerned with graphics scenes, where models are defined using volume representations instead of, or in addition to, traditional surface representations. It is a study of the input, storage, construction, manipulation, display, and animation of volume models in a true three-dimensional (3-D) form. Its primary aim is to create realistic and artistic computer-generated imagery from graphics scenes comprising volume objects (see Figs. 1 and 2), and to facilitate the interaction with these objects in graphical virtual environments. A generalized specification of a volume model is a set of scalar fields, $\boldsymbol{F}_1(p)$, $\boldsymbol{F}_2(p)$, ..., $\boldsymbol{F}_\mathrm{k}(p)$, which define the geometrical and physical attributes of every point p in 3-D space. Scalar fields related to a specific attribute are usually grouped together to form a vector or tensor field. Unlike a surface model or a surface-bounded solid model, a volume model does not normally have an explicit geometric boundary and its physical attributes are not defined homogeneously within its bounding volume. As true 3-D representations of graphical models, volume representations possess more descriptive power than surface representation. They provide an effective means for modeling objects with complex internal structures (such as human bodies) as well as objects without well-defined geometry (such as fires and smoke). Many modern data acquisition technologies are capable of capturing volumetric attributes of such objects in volume representations, facilitating physically faithful modeling of the real world.

Volume visualization is also concerned with volume data representations that are used to store measured physical attributes of real-world objects and phenomena, or to represent computer-generated models and their attributes in volumetric forms. Although it is typical and conventional for volume datasets (such as in computed tomography) to correspond spatially to the 3-D physical world, it is also common in many visualization applications to use volume datasets to store nonspatial physical data as well as abstract information. As a volume representation gives a full 3-D description of everywhere in a 3-D volume, it is usually difficult to comprehend a volume dataset visually when it is projected directly onto a two-dimensional (2-D) display. We can appreciate such difficulties by imagining viewing a photograph (i.e., a 2-D dataset) horizontally at the eye level (i.e., a one-dimensional (1-D) projection). Therefore, the primary aim of volume visualization is to extract important information from volume data and convey such information visually to reviewers. This aim justifies deflection from creation of realistic imagery, which is the primary aim of volume graphics, and allows simplifications and embellishments, if they improve the desired understanding. Otherwise, in many ways, the subject of volume visualization encompasses most aspects of volume graphics. Nevertheless, the development of the subject has been heavily influenced by many applications, including medical imaging and scientific computation.

Since the emergence of computer graphics in the 1960s, visual realism and real-time interaction have been the two main driving forces behind its development. As for many objects in the real world we observe normally only their surfaces, in general, it is computationally more economic to deal with geometric specifications in surface representations by assuming empty or homogeneous object interiors. Hence, in traditional computer graphics, most existing modeling and rendering methods deal with graphics models specified as surfaces or surface-bounded solids, and this focus has led to the dominance of triangular meshes in the state-of-the-art graphics hardware and software. This collection of methods is often referred to as *surface graphics* techniques. The primary deficiencies of surface graphics include its inability to encapsulate the internal description of a model and the difficulties in modeling and rendering amorphous phenomena.

Various volumetric techniques, including hypertextures and clouds modeling, have been proposed to address the shortcomings of surface graphics. Driven by several applications, there have also been significant advances in volume visualization, yielding numerous methods for processing and rendering volume datasets, many of which can be performed interactively. Coupled with the rapid increase in the processing power and storage capacity of computers over the past few decades, volume visualization now provides an indispensable means in science, engineering, and medicine, assisting in the observation, measurement, modeling, experimentation, abstraction, and analysis of the physical world. In the meantime, volume graphics is offering some striking visual realism in commercial animation production, for instance, in the modeling and rendering of animal fur. These developments have led to beliefs that volume-based techniques have the potential to match and overtake surface-based techniques in computer graphics. In 1993, Kaufman, et al. (1) first outlined the framework of volume graphics as a subfield of computer graphics. Since then, considerable progress has been made in the field.

VOLUME MODELS AND DATA REPRESENTATIONS

A volume model represents a graphical object by defining its geometrical and physical attributes at every point p in 3-D Euclidean space $\mathbb{E}$ or a volumetric subdomain $\mathbb{D}(\mathbb{D} \subseteq \mathbb{E})$. With scalar fields as its underlying concept, it provides a consistent means for specifying the geometry and physical properties of a spatial entity intrinsically in a true 3-D manner. In particular, volume modeling represents conceptually an important extension to surface-based modeling by allowing the specification of the internal structures of objects and amorphous phenomena. All volume rendering integrals assume that optical properties of a volume model are not homogeneously defined in $\mathbb{D}$. Most volume

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

rendering algorithms are designed to handle volume models only.

Similar to surface representations, a volume model can be specified procedurally or using sampled datasets. Procedurally defined models typically allow more accurate computation of various geometric properties of the models, but they may not be suitable for representing complex real-world objects. Volume models that are defined upon sampled data have been the main focus of volume graphics and visualization, largely because several digitization technologies (see **ADVANCED TOPICS**) exist for acquiring various physical attributes in volume data representations. A collection of such data for representing a volume model is referred as a *volume dataset*. A scheme that defines the data types of data primitives and governs the inter-relationship between different types of data primitives is referred to as a *data representation*.

Spatially Sampled Data Representations

The basic notion of a *spatially sampled volume dataset* is a set of samples $\mathbf{V} = \{(p_i, v_i) | i = 1, 2, \ldots, n\}$, where v_i is a scalar value that represents some property (such as luminance intensity) at each sampling location p_i in 3-D Euclidean space $\mathbb{E}$. In most applications, we are only interested in a subdomain of $\mathbb{E}$ that encloses the set of sample points $p_i (i = 1, 2, \ldots, n)$ specified in $\mathbf{V}$. We denote such a subdomain as $\mathbb{D}(\mathbb{D} \subseteq \mathbb{E})$, and $\mathbb{D}$ in effect defines an *object domain*, that is, the valid spatial domain of a volume object. As the underlying model of the dataset $\mathbf{V}$ is a continuous scalar field $\boldsymbol{F}(p)$ defined in $\mathbb{D}$, it is necessary to define a scalar value for every point in $\mathbb{D}$, especially for those points that are not specified in $\mathbf{V}$. Here we consider only a single scalar field, and the concept can easily be generalized to multiple scalar fields. The typical methods for obtaining a specification of $\boldsymbol{F}(p)$ from a volume dataset depend mainly on the following three aspects:

1. The *interpolation function* that derives a value v at an arbitrary point p in $\mathbb{D}$ from several known point-value pairs. Hence it is necessary for such an interpolation function to have the knowledge of a subset of point-value pairs in $\mathbf{V}$, which should have influence on the value of any given point p in $\mathbb{D}$. A large number of interpolation functions require the subdomain $\mathbb{D}$ to be further divided into elementary volumes such that all sample points $p_i (i = 1, 2, \ldots, n)$ are only located at the boundary of these elementary volumes. This restricts the influence of each known point-value pair (p_i, v_i) to those elementary volumes, to which p_i is connected. Normally elementary volumes do not overlap with each other except along the shared boundaries. For some interpolation functions that do not require a nonoverlapping partition of $\mathbb{D}$, it is common to determine a subset of known point-value pairs in $\mathbf{V}$ for a given p in $\mathbb{D}$ based on proximity, or by simply including all point-value pairs in $\mathbf{V}$. Usually, a volume dataset is not fixed with a specific interpolation function, and an appropriate interpolation is normally selected at the rendering or resampling stage according to various application needs such as accuracy and performance.
2. The *geometrical positioning* of the set of sample points $p_i (i = 1, 2, \ldots, n)$ in $\mathbf{V}$. Such information may be defined *explicitly* or *implicitly* in a volume dataset. In those data representations with an implicit geometry specification, all sampling points are organized with regular and recurring elementary structures, such as a 3-D regular grid with cubic cells; and sampling locations can thereby be derived from some mathematical formulas.
3. The *topological relationship* or *connectivity* between the known sample points in $\mathbf{V}$. Such information may be defined *explicitly* or *implicitly* in a volume dataset. As mentioned, it is common to use an interpolation function in conjunction with a nonoverlapping spatial partition of $\mathbb{D}$. In an explicit connectivity specification, additional elementary structures, such as edges and cells, are included in a dataset, and they are normally defined by connecting known sample points in $\mathbf{V}$ to form an elementary structure. In an implicit specification, the elementary volumes are presupposed to have a regular and recurring structure in relation to the geometrical locations of the sample points in $\mathbf{V}$. In some cases, the connectivity information is neither explicitly nor implicitly defined for a dataset but requires to be derived *dynamically* from the geometrical information in $\mathbf{V}$.

Many volume data representations feature different types of specifications for geometrical positioning, topological connectivity, and interpolation function. Some of the most commonly used volume data representations are listed below.

3-D Regular Grid. This data representation is the most popular, where samples are taken at regularly spaced intervals along three orthogonal axes (e.g., the clouds in Fig. 1, the chess pieces in Fig. 2, the CT head in Fig. 3, and the four objects in Fig. 4). The sample points are commonly referred to as *voxels* (volume elements), as the 3-D analog of pixels. The straight lines, which link consecutive voxels in the three axial directions, collectively form a *regular grid*. Such a grid with a constant spacing in all three directions is said to be *isotropic* and, otherwise, *anisotropic*. The grid inherently subdivides its rectangular object domain $\mathbb{D}$ into many elementary cells in the form of cubes (in an isotropic grid) or cuboids (in an anisotropic grid). The value at any point inside such a cell is typically obtained using tri-linear interpolation of the values of the eight neighboring voxels. As the values at sample points can be stored by using a 3-D array (commonly called a *3-D raster* or a *volume buffer*) with implicit geometrical and topological specifications, this data representation is economic to store and efficient to process.

Note that the original definition of voxels, for instance, in *spatial occupancy enumeration* (see **VOLUME AND SURFACE**), implies that each voxel occupies a small cubic domain. Nevertheless, it is common nowadays to consider that a voxel is simply a discrete sample in a continuous volumetric domain.

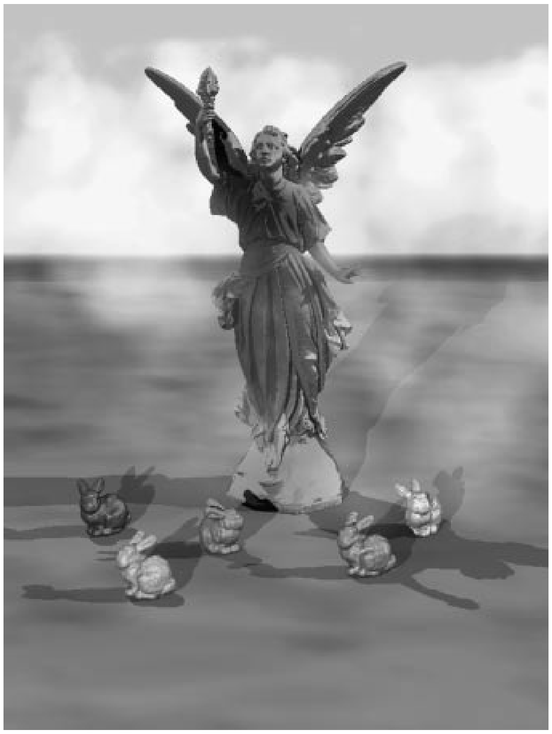

Figure 1. This is a volumetric scene, where the clouds (from the Universität Erlangen-Nürnberg) are represented by a 3D regular grid, and the Lucy and Bunny models (both from Stanford University) are point-based volume objects specified with radial basis functions. The image was produced by M. Chen (for details, see D. Chisnall, M. Chen and C. Hansen, "Ray-driven dynamic working set Rendering," *The Visual Computer*, **23**(3):167–179, 2007).

Tetrahedral Mesh. Data representations that require explicit geometrical and topological information are collectively referred to as *irregular grids*. One such data representations is a *tetrahedral mesh* that typically comprises a list of point-value pairs (as in the general notion) and a list of elementary cells in the form of tetrahedra. The convex hull of all sample points defines the valid spatial domain $\mathbb{D}$ of the dataset. Each tetrahedral cell is specified by four sampling points as its vertices, and the value of any point p inside the cell is typically determined by using the barycentric coordinates of p with respect to the four vertices.

Sometimes a volume dataset contains only a list of scattered samples without an explicit specification of topological connectivity. We can construct a tetrahedral mesh using a *tetrahedralization* algorithm that subdivides the convex hall of the given sample points into a set of tetrahedral cells with sample points as vertices. One such algorithm is the *3-D Delaunary triangulation* that ensures that no sample point falls inside the circumsphere of any tetrahedral cell.

Radial Basis Functions. Some volume data representations do not demand the partitioning of the object domain $\mathbb{D}$. One approach is to associate each point-value pair $(p_{i,} v_i)$ with a spherical *radial basis function* (RBF) that defines the influence of (p_i, v_i) upon any arbitrary point p in $\mathbb{E}$, which is normally in inverse proportion to the distance between p and p_i. Let $\boldsymbol{\omega}(p,\ p_i,\ r_i)$ be a radial basis function, where $r_i \in [0,\ \infty]$ is called the *radius of influence* that defines a sphere such that for any point p that falls outside of the sphere, $\boldsymbol{\omega}(p,\ p_i,\ r_i) = 0$. In many cases, a constant radius of influence is applied to all sample points; whereas in the others, each sample point is associated with an individual r_i that typically reflects the confidence or accuracy of the sampling process. A scalar field $\boldsymbol{F}(p)$ can therefore be - obtained as the sum of all $\boldsymbol{\omega}(p,\ p_i,\ r_i) \cdot v_i\ (i = 1,\ 2,\ \ldots,\ n)$ (e.g., the Lucy and Bunny models in Fig. 2). Many proposed radial basis functions can be used in conjunction with a volume data representation, including the Gaussian function that assumes an infinite radius of influence for every sample point, and several polynomial functions that approximate the Gaussian while facilitating the control of the radius of influence.

In general, it is not essential for a radial basis function to define the influence of p_i solely based on distance. Other considerations can be featured in $\omega(p,\ p_i,\ r_i)$. For example, when the set of voxels $\mathbf{V}$ is known to represent samples on a surface, one may use an ellipsoidal function to reduce the influence along the normal at p_i. We call a $\omega(p,\ p_i,\ r_i)$, with which the influence of p_i falls away from p_i at different rates in different directions, as an *anisotropic* or *nonuniform radial basis function*.

Nonspatial Data Representations

The 3-D Fourier transformation has been used to represent volume data in the frequency domain, which offers sensitive detection of spatial frequency components of the intensity variations along each axis. In the Fourier domain, an object with a given intensity texture will contribute the same Fourier frequency components independent of its position in the volume, thus enabling a unique shape description. It is also useful in constructing high-pass filters for boundary enhancement and low-pass filters for noise reduction. In addition to the qualities of Fourier transformation, 3-D wavelet transformation also facilitates a multiresolution decomposition and scale-invariant interpretation of volume data in the wavelet domain. The 3-D wavelets have successfully been used in several applications of volume visualization.

As a 3-D representation of spatial information, volume datasets may demand substantial storage space and are slow to navigate. Several compressed data representations have been proposed to overcome these difficulties.

VOLUME AND SURFACE

The most intrinsic representation of a volume model is a scalar field $\boldsymbol{F}(p)$ in 3-D Euclidean space $\mathbb{E}$. Conceptually we can consider $\mathbb{E}$ being the valid spatial domain of the volume model. The most intrinsic representation of a surface model, in a form related to the scalar field, is $\boldsymbol{F}(p) = \tau$ such that its valid spatial domain $\mathbb{D}$ contains only those points where $\boldsymbol{F}(p)$ is equal to a specific scalar value τ, that is, $\mathbb{D} = \{p | p \in \mathbb{E},\ \boldsymbol{F}(p) = \tau\}$. At least notionally, $\boldsymbol{F}(p)$ contains more information than $\boldsymbol{F}(p) = \tau$, whereas $\boldsymbol{F}(p) = \tau$ is an abstraction of $\boldsymbol{F}(p)$, hence potentially a more compact representation.

In traditional computer graphics, most existing modeling and rendering methods deal with graphics models specified as surfaces. Most graphics rendering pipelines are designed to support the display of surfaces. Surface representations, especially triangular meshes, are often the only acceptable form of input to many traditional graphics pipelines. Against this background, much of the early effort in volume visualization has been made to approximate a volume model by a surface model that can then be rendered using a surface-based graphics system. Such a rendering process is usually referred to as *indirect volume rendering*. There has also been effort for converting surface models to volume models in order to take advantage of the extensive collections of surface models available in the public domain, and to render such surface models using *direct volume rendering* (see **VOLUME RENDERING**).

Surface Extraction

Surface extraction is a process of generating a surface representation **S** from a volume representation **V**, where the underlying specification of **V** is a scalar field $\boldsymbol{F}(p)$, and that of **S** is $\boldsymbol{F}(p) = \tau$, which defines the set of all points in a scalar field with a specific scalar value τ. The scalar value τ is referred to as an *iso-value*, and $\boldsymbol{F}(p) = \tau$ an *iso-surface* (also called a *level surface* or a *a level-set*). Often the extraction process is also referred to as *iso-surfacing, surface reconstruction, surface tiling*, and *surface tracking*, some of which were used only in the context of a specific group of algorithms.

Notionally, deriving $\boldsymbol{F}(p) = \tau$ from $\boldsymbol{F}(p)$ seems to be a trivial process. In fact, both volume and surface representations, **V** and **S**, are normally defined in different forms of discrete data representations, and not all points on the iso-surface can easily be identified in **V** or stored in **S**. This gives rise to several groups of surface extraction algorithms.

Marching Cubes. Consider a common requirement for extracting an iso-surface in the form of a triangular mesh from a volume model in the form of a 3-D regular grid, where the tri-linear interpolation function is used to define the underlying scalar field. The most popular method for addressing this requirement is the *marching cubes algorithm* (2). Given a regular grid of $n_x \times n_y \times n_z$ voxels, and an iso-value τ, there are $(n_x - 1) \times (n_y - 1) \times (n_z - 1)$ cubic cells, each bounded by eight neighboring voxels. The algorithm examines these cubic cells one by one. For each cell, it first determines whether the iso-surface intersects with the cell. If there is an intersection, it creates a triangle or a few triangles to represent the part of the iso-surface within the cell. These triangles can then be organized into a triangular mesh (or a few disjoint meshes) to be displayed by a surface-based graphics system. As the iso-surface within such a cell is usually a curved surface because of the tri-linear interpolation, the triangular representation is mostly only an approximation.

The core of the marching cubes algorithm is to determine the number of triangles in each cell and their topological arrangement in relation to the cell boundary and to each other. There are 256 possible cases (including two cases of non-intersection), if we classify each cell by considering each of its eight voxels as either "$\geq \tau$" or "$< \tau$". Through three types of symmetrical transformations (i.e., complementary, rotational, and reflectional transformations), or a combination of a series of them, the 256 cases can be reduced to 14 basic topological cases, only 1 of which indicates that there is no intersection between the cell and the iso-surface.

However, what complicates the marching cubes algorithm is the fact that many basic cases are ambiguous; that is, the binary classification of the eight voxels alone does not always uniquely determine a topological structure for the triangular representation within the cell. Some ambiguous cases may have up to 7 possible variants and some may involve a less desirable structure called tunnels. In fact a similar but much simpler ambiguity problem exists in a class of 2-D contouring algorithms that extract contour lines from 2-D regular grids. The 2-D ambiguity can be resolved by a method called *asymptotic decider*, which analyzes the asymptotes of the hyperbola representing the bilinear interpolation of a square cell. One observation is that all ambiguous cubic cells involve one or more faces that are considered to be ambiguous in 2-D contouring. By applying the asymptotic decider to all ambiguous faces on a cube, one can determine the external edges of the triangles to be constructed. In some cases, these edges can adequately define the topology of these triangles, whereas in others, additional computation of some internal properties of the cell is necessary for further discriminatory analysis.

Extracting other Geometry Descriptions. In addition to surfaces, several algorithms have been developed for extracting a set of points on a medial surface and on a line-like skeleton representing the central axis of a volume model. Algorithms have also been proposed for extracting multiple iso-surfaces from volumetric datasets and, in particular, for constructing a tetrahedral mesh representing an *interval volume*, $\tau_1 \leq F(p) \leq \tau_2$, which is a collection of all iso-surfaces defined by iso-values in the range $[\tau_1, \tau_2]$. Such a representation is particularly useful in describing real-life surface structures that do not have the properties of perfect mathematical surfaces (e.g., zero or uniform thickness). It is also a fundamental data type used in rapid prototyping and, in particular, the layered manufacturing process.

Voxelization

Voxelization is a process for converting from a surface model (or a surface-bounded solid model) to a discrete volume data representation. The target volume data representation is usually in the form of a 3-D regular grid, and thus, the process is also sometimes referred to as *3-D rasterization* and *3-D scan-conversion*. If we draw an analogy between a surface specification $\boldsymbol{F}(p)$=0 and a continuous 3-D signal, voxelization is essentially a process of digitization, which takes samples in a spatial domain, measures the relationship between each sampling position and the surface specification concerned, and records the measurement in a volume data representation.

Spatial-Occupancy Enumeration. This is one of the early schemes for object decomposition in computer graphics, and it is nowadays referred to as *binary voxelization* in volume graphics and visualization. Given a surface or a surface-bounded solid model, a binary voxelization algorithm generates a cellular representation that best approximates the spatial occupancy. The cellular primitives are normally organized as an array of cubes in a 3-D regular grid, resulting in the most basic discrete representation of a volume model. The term "voxel" (volume element) is believed to be coined in association with *spatial-occupancy enumeration,* where it refers to such a cellular primitive. Algorithms have been developed for obtaining binary voxel representations for a range of objects, including lines, circles, curves, polygons, polyhedra, quadric objects, implicit solids, and constructive solid geometry.

A critical consideration in binary voxelization is to ensure that the geometrical connectivity between voxels in the voxelized model reflects with the continuity of the original surface model, and the two models feature the same topology. The geometrical and topological properties of such voxelized models are part of the studies of *discrete geometry and topology*, which are often referred to as *digital geometry and topology* in the context of computer graphics and image processing.

Multivalued Voxelization. With the limited resolution of a volume buffer, binary voxelization often results in discrete volume objects that exhibit noticeable object space aliasing. Similar to anti-aliasing in image processing, one effective approach for combating the object space aliasing is to increase the depth of voxel values from the binary domain to the integer or real domain. However, unlike anti-aliasing in the image space that focuses largely on an optical illusion of a smooth object boundary, the main objective of anti-aliasing in the object space is to obtain a better approximation of a continuous object, and to facilitate more accurate sampling during volume rendering. One approach is to use the value at each voxel to encode the intersected area (or volume) between the corresponding cellular primitive and the original surface model (or surface-bounded solid model). Another approach is to apply smoothing convolution filters to a binary volume representation by treating the value at each voxel represents the signal level at a point in space. The most popular multivalued volume representation for approximating a surface model is the *distance field* model.

Distance Field. A *distance field*(3) $\boldsymbol{D}_{\mathrm{X}}(p)$ is a scalar field that defines the closest distance from every point p in 3-D Euclidean space $\mathbb{E}$ to a given point set $\mathbf{X}$. Typically $\mathbf{X}$ is specified as a set of all points on a continuous surface, or inside a surface-bounded solid, although conceptually $\mathbf{X}$ can also be a discontinuous point set. For a closed surface $\mathbf{S}$ that separates $\mathbb{E}$ to two disjoint subdomains, $\mathbb{X}$ and $\mathbb{E}$–$\mathbb{X}$, where $\mathbb{X}$ contains all points inside or on $\mathbf{S}$, a *signed distance field* $\boldsymbol{D}_{\mathrm{S}}(p)$ for $\mathbf{S}$ associates a sign to the distance at each point p to indicate whether p belongs to $\mathbb{X}$, conventionally positive for $p \notin \mathbb{X}$, and negative for $p \in \mathbb{X}$. Hence, the process of rendering $\mathbf{S}$ in surface graphics is transformed to that of rendering the iso-surface $\boldsymbol{D}_{\mathrm{S}}(p)= 0$ in volume graphics.

Like other volume models, a distance field can be represented by a spatially sampled volume dataset, mostly in the form of an isotropic regular grid. Such a dataset is customarily referred to as a *distance volume* (e.g., the chess pieces in Fig. 2) . Although a distance volume dataset may be obtained by sampling every voxel p_i within a bounding volume $\mathbb{D}(\mathbb{X} \subseteq \mathbb{D} \subset \mathbb{E})$ against the specification of $\mathbf{S}$, this approach can often be computationally costly, when it is not straightforward to identify the closest point $x \in \mathbb{X}$ for an arbitrarily given voxel $p_i \in \mathbb{D}$. A number of methods have been proposed for accelerating the identification of the closest point or a small region that contain the closest point, typically by spatially partitioning $\mathbb{D}$ based on the primitives of $\mathbf{S}$ (e.g., triangles in a triangular mesh) or in relation to the parameter space of $\mathbf{S}$ (e.g., in the case of many parametric surfaces). These methods facilitate an efficient search for the closest point by exploiting the precomputed correlation between the subdivisions of $\mathbb{D}$ and the components or parameters of $\mathbf{S}$, as well as the spatial coherence within the subdivisions of $\mathbb{D}$.

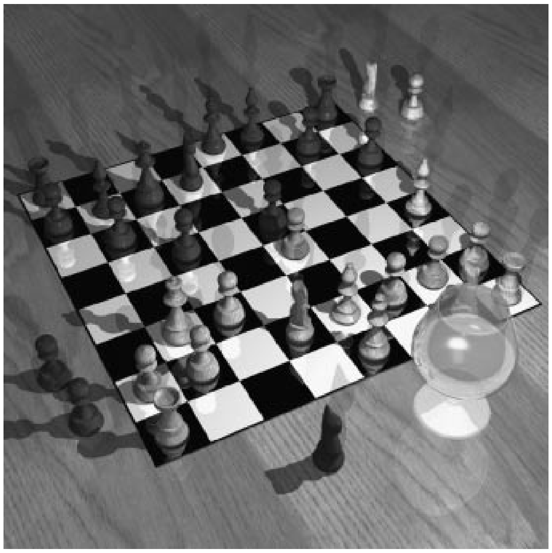

Figure 2. This scene contains over 30 volume objects. The wine glass is a volume object constructed by applying a rotational sweeping to an image (for details, see A. S. Winter and M. Chen, "Image-swept volumes," *Computer Graphics Forum*, **21**(3):441–456, 460, 2002). The chess pieces are distance field models voxelized by M. W. Jones (for details, see M. W. Jones, "The production of volume data from triangular meshes using voxelisation," *Computer Graphics Forum*, **15**(5), 311–318, 1996). The scene was constructed and rendered by A. S. Winter.

An alternative approach to the direct sampling of every voxel in $\mathbb{D}$ is to approximate the distance computation for most voxels using *distance transform*. For many types of surface models, it is relatively easy to determine their spatial occupancy in $\mathbb{D}$, for instance, using a binary voxelization method. Hence a distance volume can be initialized as 0 for occupied voxels and ∞ for unoccupied voxels. It is often desirable to improve this initial distance volume to further classify the occupied voxels, and sometimes additional voxels in their close neighborhood, with more accurate distance calculation. The finite distances calculated are then propagated to the entire volume by systematically evaluating all voxels with an initial distance of ∞. For each of such voxels, p_i, its distance to $\mathbf{S}$ is estimated based on the known distances of the neighboring voxels. Distance transform is normally an iterative process, where a voxel may be evaluated more than once, and the distance volume records only the smallest distance estimated at each voxel.

VOLUME RENDERING

Volume rendering is a computational process for synthesizing 2-D images from volume models. Nowadays the term "volume rendering" usually implies *direct volume rendering,* in which the rendering algorithm processes a volume model directly without the need for extracting an intermediate surface model. As mentioned, a generalized specification of a volume model is a set of scalar fields, $\boldsymbol{F}_1(p), \boldsymbol{F}_2(p), \ldots, \boldsymbol{F}_k(p)$, which define the geometrical and physical attributes of every point p in 3-D space. An ideal volume model would assemble all such attributes for specifying how the model, at each point p in its spatial domain $\mathbb{D}$, would interact with lights coming from all directions. An ultimate volume rendering process would combine all lights that arrive at each pixel to be rendered, taking into account their traversal paths through, and interaction with, the volume model. However, this is computationally intractable, and often, for example in volume visualization, not necessary. In practice, a volume rendering algorithm is confined to evaluating only a specific set of attributes of a volume model, a limited number of light paths, and certain types of interaction between the lights and the volume model.

In volume visualization, a volume data representation often does not contain the geometrical and physical attributes required by a volume rendering algorithm. It is therefore necessary to map the values of the known scalar fields in the data representations to the required attributes. Such a mapping function is referred to as a *transfer function*. Here we assume that all necessary attributes are available to a volume rendering algorithm. Algorithms for direct volume rendering fall into two main categories, namely *image-order* methods and *object-order* (or *volume-order*) methods, which indicate whether a rendering process is executed according to the order of elements of an image or those of a volume representation.

Volume Rendering Integrals

Given a path U along which a light ray passes through a volumetric medium, the light transport between the two endpoints of this path involves a Riemann integral of a function Ξ over the position variable $u \in [\mathrm{a}, \mathrm{b}]$ on the path. This function Ξ defines the interaction between light and material. Such an integral is called *a volume rendering integral* (4,5). For computationally efficiency, many commonly used volume rendering algorithms are confined to evaluate only those paths in a straight line, although it is not necessary for a light ray to follow a straight line. Some of the most commonly used volume rendering integrals are given below.

Emission-Only Integral. This is perhaps the simplest volume rendering integral, which presupposes that the volume model concerned is fully transparent and every point in the object domain $\mathbb{D}$ may potentially emit some light uniformly in all directions. Hence the volume model can be represented by a scalar field $\boldsymbol{E}(p, \lambda)$, which specifies the radiative power emitted at every point $p \in \mathbb{D}$ in the form of a *spectral power distribution* (SPD), where λ is the wavelength within the radiation band concerned. It is common to limit this range to the visible spectrum $\lambda \in [380\,\mathrm{nm}, 770\,\mathrm{nm}]$, or often a narrower range, $\lambda \in [400\,\mathrm{nm}; 700\,\mathrm{nm}]$, to which human eyes are more sensitive. We can also approximate the light using other color representations, such as the RGB color representation, yielding a volume model with three scalar fields, $\boldsymbol{R}(p)$, $\boldsymbol{G}(p)$, and $\boldsymbol{B}(p)$. To maintain the generality, we do not draw explicit distinction between different color representations in the following discussions. For example, we use $\boldsymbol{E}(p)$ as an abstraction for both the spectral and the RGB representations of emitted light.

Because of the assumption of a fully transparent volumetric medium, the light emitted by every point along the light ray will reach the end of the ray. This results in an accumulated light intensity I, which can be expressed by a simple volume rendering integral as shown in Table 1. This integral offers a reasonably accurate approximation of a class of volumetric display hardware, namely *emissive displays*, although the absence of absorption specification restricts its deployment in volume graphics and visualization.

Absorption-Only Integral. This integral is concerned with a translucent volumetric medium with no internal light emitting source. The volume model features essentially only an absorptivity field $\boldsymbol{A}(p)$. In physics, the absorptivity of a homogeneous or infinitesimal volume is normally specified in a spectral representation. However, in volume graphics and visualization, it is commonly approximated by a single scalar value that defines a uniform absorptivity across the visible color spectrum. For a light ray passing through a homogeneous volume with a constant absorptivity α, the light intensity of the ray decreases exponentially with the path length Δu. Let L and I be the intensity of the light entering and leaving the volume, respectively. We have $I = L \cdot e^{-\alpha \cdot \Delta u}$, where $\alpha \cdot \Delta u$ is also referred to as *internal optical density*. This is known as *Lambert's* or *Bouguer's law*. For a volume model with inhomogeneous absorptivity

Table 1. Summary of Commonly Used Volume Rendering Integrals

Name	Attribute Field	Volume Rendering Integral
Emission-only	Emissive Intensity $\boldsymbol{E}(p)$	$I = \int_a^b \boldsymbol{E}(u)du$
Absorption-only	Absorptivity $\boldsymbol{A}(p)$	$I = L \cdot e^{-\int_a^b A(u)du}$ or $\ln L - \ln I = \int_a^b \boldsymbol{A}(u)du$
Absorption and emission	Emissive Intensity $\boldsymbol{E}(p)$, Absorptivity $\boldsymbol{A}(p)$	$I = \int_a^b \boldsymbol{E}(u) \cdot e^{-\int_u^b A(t)dt} du$

defined by a scalar field $\boldsymbol{A}(p)$, the relationship between L and I involves the second volume rendering integral in Table 1. The approximation results from the assumption that the volume model has a constant refractive index, allowing the omission of the partial backreflection in the integral.

In volume visualization, this particular integral is usually used in conjunction with a directional light source placed at the back of a volume model. The light, of an initial intensity L, transmits through the volume model, registering the remaining intensity on the synthesized image, which usually bears a strong resemblance to an inversed x-ray image.

Absorption and Emission Integral. This inevitably leads to the consideration of a volume model with both emission and absorption attributes. Considering an infinitesimal path length du, the emission at each point u along the path of the light is attenuated by the absorption taken place between u and the end of the path. This results in the third volume integral in Table 1. This integral can be used to simulate some imaging devices, such as in nuclear medicine imaging. However, most objects in the real world do not emit light, and uniform emission in all directions cannot convey the shape of an object effectively. This leads to the introduction of the following popular volume rendering integral.

Approximating Volume Rendering Integrals

The above-mentioned volume rendering integrals are usually approximated by a Riemann sum for the corresponding function Ξ and a partition defined by a series of samples $\{u_1, u_2, \ldots, u_n\}$ along a path U. In volume visualization, it is also common to introduce simplifications (e.g., in maximum intensity evaluation) and embellishments (e.g., replacing emissive intensity with rendered color), in order to facilitate the desired system performance and user understanding.

Opacity and Color Integral. This volume rendering integral is based on the absorption and emission integral, but it replaces the emission specification $\boldsymbol{E}(p)$ with a computed reflection specification $\boldsymbol{C}(p)$. The computation of $\boldsymbol{C}(p)$ usually involves one or more external point light sources and considers both the light reflection from and transmission through a volume medium. It makes a number of computationally useful, but conceptually crude, assumptions. For instance, it normally assumes that an external light can reach any point inside the object domain $\mathbb{D}$ without considering the absorption along the light path (i.e., the soft shadow effect). It does not take any secondary lighting into account. It can accommodate refractive transmission, but it usually confines to only specular transmission. Despite its relatively crude assumptions, the introduction of reflection enables more effective depiction of the shape of level-surfaces within a volume model, especially through some familiar visual effects such as the combination of diffuse and specular reflection.

The absorption calculation within the light ray toward the viewer is also simplified by first approximating the inner integral with a corresponding Riemann sum and by sampling discretely between u and b with an interval Δt, resulting in $\prod_{t_1=u+\Delta t}^{t_m=b} e^{-A(t_j)\Delta t}$. We then substitute each exponential function in the product with the first two terms of its Maclaurin's expansion, resulting in $\prod_{t_1=u+\Delta t}^{t_m=b}(1-\boldsymbol{A}(t_j)\Delta t)$, where $\boldsymbol{A}(t_j)\Delta t$ and $1-\boldsymbol{A}(t_j)\Delta t$ are commonly referred to as the *opacity* and *transparency*. Finally, we approximate the whole integral with a Riemann sum of a partition with a series of samples $\{u_1, u_2, \ldots, u_n\}$ along U. This gives an approximated piecewise integral as

$$I \approx \sum\nolimits_{i=1}^{n} \boldsymbol{C}(u_i) \cdot \prod\nolimits_{j=i+1}^{n} (1-\boldsymbol{A}(u_j)\cdot \Delta u)\cdot \Delta u$$

Here we consider an uncomplicated case, where U is a straight line and $\Delta t = \Delta u = u_i - u_{i-1}$ is a constant. We also explicitly make $\prod_k^k (1 - A(u_k)\Delta u) = 1$ because Δu is 0 in this case.

This volume rendering integral is normally used in conjunction with a volume model that features an opacity field $\boldsymbol{\alpha}(p)$ and an object color field $\boldsymbol{c}(p)$. The former is a colloquial reference to the specification of absorptivity and is usually used to attenuate $\boldsymbol{c}(p)$ by assuming that all absorbed energy is transformed to out-scattering energy without change in wavelength. Thus, $\boldsymbol{\alpha}(p)\cdot\boldsymbol{c}(p)$ corresponds to the reflectance of a material independent of any light source, and the result of the product is colloquially referred to as an *opacity-weighted color*. At an arbitrary point $p \in \mathbb{D}$, we determines the reflection of a level-surface at p in relation to the external light sources using an illumination model, such as the Phong and Blinn–Phong models. The computed reflection intensity gives the specification of $\boldsymbol{C}(p)$, which is colloquially referred to as the *rendered color* at p.

Maximum Intensity Evaluation. Given a scalar field $\boldsymbol{B}(p)$ specifying the brightness at every point $p \in \mathbb{D}$, often a volume rendering algorithm is only interested in the maximum brightness value along a light path U. $\boldsymbol{B}(p)$ can be computed from other color specifications, such as emission $\boldsymbol{E}(p)$ and reflected color $\boldsymbol{C}(p)$. More often it relates directly to the grayscale intensity specification of a captured volume dataset, for instance, in medical imaging. To obtain this maximum value, one has to invoke a search, instead of an integration, along U. Although strictly this is not an integral and has little basis in physics, it offers a simpler and faster alternative to the above-mentioned volume rendering integrals. We thereby include this concept here as a "pseudo-integral" because it is applicable to all volume rendering algorithms discussed hereinafter. A volume rendering algorithm based on maximum intensity evaluation is customarily referred to as *maximum intensity projection* (MIP), although it does not necessarily imply the use of an object-order algorithm based on voxel projection.

Transfer Functions

In volume visualization, the physical attributes required by a volume rendering integral, such as absorption and emission, are often not present in a volume model, where the given scalar fields, $\boldsymbol{F}_1(p), \boldsymbol{F}_2(p), \ldots, \boldsymbol{F}_k(p)$, usually represent some captured properties (e.g., sonic reflection,

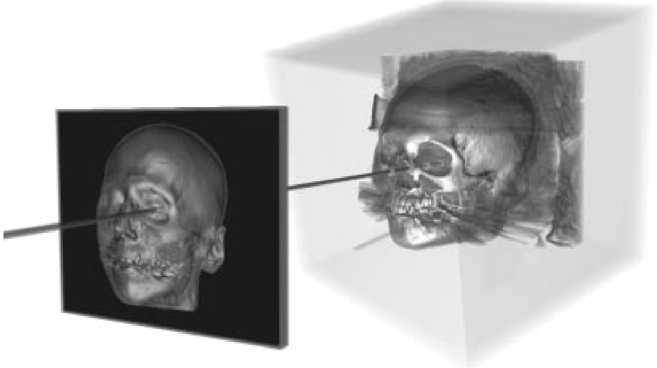

Figure 3. This is an illustration of the ray casting method for direct volume rendering. The scene is comprised of several volume objects, including a CT head dataset (University of North Carolina, Chapel Hill), and a pre-rendered image (a 2D regular grid) containing a visualization of the CT head. Both the scene and the visualization image were themselves rendered using ray casting with different transfer functions. The scene was constructed and rendered by M. Chen.

temperature) that are not relevant to the integral. Hence it is necessary to create the required scalar fields, such as $\boldsymbol{A}(p)$ and $\boldsymbol{E}(p)$ in the case of the absorption and emission integral, by mapping from the given scalar fields, $\boldsymbol{F}_1(p)$, $\boldsymbol{F}_2(p)$, $\ldots$, $\boldsymbol{F}_k(p)$. Such a mapping function is referred to as a *transfer function*. Simple transfer functions typically define a mapping from every possible value in an input scalar field to an appropriate value that is meaningful to the output scalar field. For example, for visualizing a computed tomography dataset, one can create scalar fields for color and opacity from a given scalar field for x-ray attenuation, where different attenuation levels encode different materials (e.g., bones and soft tissues). It is also common to implement such a transfer function using a look-up table.

However, designing an effective transfer function is usually not a trivial task. In some more sophisticated methods, regional properties (e.g., gradient vectors) are used in the design of a transfer function to highlight specific visual features (e.g., material boundary) in the synthesized imagery. Many recent developments in this area have been focused on automatic and semi-automatic construction of transfer functions guided by high-level information, such as a histogram or a contour tree, about a given dataset.

Ray Casting

Ray casting is the principal algorithm for direct volume rendering (6), and it realizes a volume rendering integral by approximating it with a corresponding Riemann sum. It is a nonrecursive variant of the ray tracing method commonly used in computer graphics and is a typical example of image-order methods. The algorithm can be used in conjunction with continuous volume models and sampled volume representations as well as some high-level representations such as volume scene graphs. In principle, it can easily be extended to realize recursive ray tracing and photon ray tracing. Here we consider only a simple case of casting a single eye-ray to realize a volume rendering integral (as illustrated in Fig. 3).

To synthesize an image, the algorithm casts an imaginary ray from a viewing position (i.e., center of projection), through each pixel in the image (i.e., image plane), into the scene containing volume models. Let U be a section of a light path passing through a volume model. The algorithm takes samples of the relevant scalar fields at a series of discrete locations, $\{u_1, u_2, \ldots, u_n\}$, along U. As an example, we use the popular *opacity and color integral* in the form of $\boldsymbol{I} \approx \sum_{i=1}^{n} \boldsymbol{C}(u_i) \cdot \prod_{1}^{j=i}(1 - \boldsymbol{\alpha}(u_j) \cdot \Delta u) \cdot \Delta u$ for computing the light intensity at u_1. Note the changes of upper and lower limits of both the summation and the product. This is because we take samples in the reverse direction of the light from a viewing position. One implementation of this algorithm for a single ray is described by the iterative pseudocode in Table 2. This is normally referred to *as front-to-back ray casting*. It facilitates so-called *early ray termination*, allowing the ray casting to complete whenever the ray has accumulated a sufficient amount of opacity.

An alternative implementation, referred to as *back-to-front ray casting*, is to accumulate the intensity from u_n to u_1, in the same way as the light travels. As shown in Table 2, this provides relatively simpler operations in the iteration without the need for accumulating the opacity, but it loses the advantage of early ray termination. When $\boldsymbol{C}(u_i)$ is derived from $\alpha(u_i) \cdot c(u_i)$, the main operation for computing the compositing color in each iteration is essentially the so-called *alpha blending* operation frequently used for combining multiple layers of images. As the alpha blending operation is widely supported by graphics hardware primarily for texture mapping, the back-to-front approach provides the basis for a particular class of accelerated volume rendering algorithms, namely *texture-based volume rendering*.

Voxel Projection

This class of algorithms is designed to render volume models in spatially sampled data representations. In contrast with the image-order methods that synthesize an

image pixel by pixel, object-order methods process a volumetric dataset voxel by voxel and project those displayable voxels onto one or more pixels in the image plane. The voxels in a volume are normally traversed in either a back-to-front or a front-to-back manner in relation to the distances from voxels to the image plane.

Primitive Projection. Most of the early work in this category involves the projection of an opaque 2-D primitive approximating the projected image of a voxel or parts of its cellular representation, such as a point or a quadrilateral, onto the image plane. Coloring or shading can be applied to each primitive. When several voxels are projected onto the same pixel, the back-to-front approach enables the pixel value of a later voxel (i.e., a voxel in the front) to overwrite that of an earlier voxel (i.e., a voxel at the back). The front-to-back approach often facilitates less drawing operations but requires the support of a z-buffer.

Splatting. As each displayable voxel does not contribute equally to all pixels within its projection on the image plane, visualization generated by projecting opaque primitives often lacks in accuracy and realism. The most effective solution to this problem is the *splatting* algorithm (7). For each voxel, the algorithm evaluates a 3-D function that defines the potential contribution of the voxel to every point in $\mathbb{E}$. Hence, if represents a reconstruction of the original signal available to the data acquisition process. Given a voxel at p_i, the general form of this 3-D function is a radial basis function $\boldsymbol{\omega}$, which is referred to as a *volume reconstruction kernel* or *interpolation kernel*. Note that the influence of p_i often does not have a uniform distribution solely based on the distance to p_i. Several factors that commonly affect the specification of $\boldsymbol{\omega}$.

In perspective projection, for example, we may moderate the influence of p_i in the directions perpendicular to the viewing direction according to the distance from p_i to the view plane, facilitating sharp definition for close-by voxels, and anti-aliasing for distant voxels. With some data representations, such as an anisotropic 3-D grid, the voxel positions that are fed into a volume rendering pipeline are usually specified in the grid coordinates, representing a deformed 3-D Euclidean space. It is thereby necessary to use a nonuniform radial basis function to correct the distortion (see **also VOLUME MODELS AND DATA REPRESENTATIONS**).

Given a voxel p_i and its reconstruction kernel $\boldsymbol{\omega}$, we can synthesize an image of $\boldsymbol{\omega}$ that represents the total amount of contribution, which will be projected from p_i onto the image plane. For each pixel η in this image, the light ray U_η, which passes through $\boldsymbol{\omega}$ and arrives at η, records the contribution of p_i as $\boldsymbol{\Omega}(\eta) = \int_{u_a}^{u_b} \boldsymbol{\omega}(u,\ p_i)du$, where u_a and u_b are the two endpoints of the intersection between U_η and the bounding volume of $\boldsymbol{\omega}$. This image of $\boldsymbol{\omega}$ is called *a footprint*, and a reconstruction kernel with a finite radius of influence has a finite footprint. Let p_i be associated with an intensity value v_i. The projection of this voxel on the image plane is thereby a "splat" that can be computed from the footprint as $v_i \cdot \boldsymbol{\Omega}(\eta)$, for all η in the footprint. One of the central technical issues of the splatting algorithm is the pre-computation of a footprint table, independent from any particular voxels, in order to reduce the cost of computing integration during the rendering. Another is the combination of different splats in the image plane. For an *order-independent* integral, such as the emission-only or absorption-only integral, it is not necessary to process the voxels in any particular order. However, for an *order-dependent* integral, such as the combined absorption and emission integral or the opacity and color integral, we need to process the projected splats in an order that is consistent within the ordering of the corresponding voxels. The compositing of consecutive splats in relation to a particular pixel is similar to the compositing of consecutive samples along a ray in ray casting.

Illumination

For the opacity and color integral, a commonly adopted approach is to involve one or more light sources in the computation of $\boldsymbol{C}(p)$. In theory, the illumination at p depends on not only the optical properties sampled at p and the intensity of each light source, but also indirect light reflected toward p from another part of the medium (i.e., scattering) as well as the absorptivity of the medium that determines how much light can eventually arrive at p (i.e., shadows). Such an illumination model is referred to as *global illumination*. To avoid costly computation with a global illumination model, it is common to adopt a *local illumination* model where $\boldsymbol{C}(p)$ is estimated based only on the optical properties sampled at p and the intensity of each light source. In many applications, a local illumination model is normally adequate for rendering a single iso-surface within a volume. When handling multiple iso-surfaces, or amorphous regions, one needs to be aware of the limitation of such a model and the potential perceptual discrepancy due to the omission of shadows and indirect lighting.

Note that in traditional computer graphics, the terms "global" and "local" can sometimes lead to ambiguous interpretation in volume graphics. Some commonly used volume rendering integrals can produce some typical effects usually associated with global illumination only. For example, the absorption-only integral is in effect a shadow algorithm for back-lit objects. The opacity and color integral, in conjunction with back-to-front ray casting, takes into account indirect light reflected toward a sample from all previously sampled points on the ray. Frequently, the two terms are considered to be the two extremes of a scale, and all illumination models fall somewhere on the scale in a subjective manner. For consistency, in volume graphics, we use the term "global illumination" to imply an illumination model that requires the rendering algorithm to gather indirect light dynamically during rendering at each point to be illuminated, and "local illumination" for one that does not require the gathering of indirect light dynamically, but can use pre-stored luminance at each point due to indirect light. Hence, a model that involves a precomputed shadow volume is a local illumination model (or more precisely with precomputed global illumination data), whereas a model that computes soft shadows by tracing a ray through volumetric medium toward a light source during rendering is a global illumination model. Hence, the challenge is to use a local illumination model to produce as much global illumination effects as possible, with a practicable space requirement and sufficient scene dynamics.

Classic Illumination Models. Given a light source L, one can estimate the reflection at a sampling point locally by using one of the empirical or physically based illumination models designed for surface geometry, such as the Phong, Phong–Blinn, and Cook–Torrance models. When such a model is used in volume rendering, it is assumed that each sampling position, p, is associated with a level-surface or microfacet. This assumption allows us to compute the surface normal at p, which is required by almost all surface-based illumination models. In volume models, surface geometry is normally not explicitly defined, and in many situations, models do not even assume the existence of a surface. Hence, the computation of surface normals is usually substituted by that of gradient vectors. Although for some parametric or procedurally defined volume models, it is possible to derive gradient vectors analytically, in most applications, especially where discrete volumetric models are used, gradient vectors are estimated, for example, using the *finite differences* method for rectangular grids, and *4-D linear regression* for both regular and irregular grids. The commonly used *central differences* method is a reduced form of finite differences based on the first two terms of the Taylor series. For a given point $p = (x, y, z)$, and a small volume domain defined by $[-\delta_x, \delta_x] \times [-\delta_y, \delta_y] \times [-\delta_z, \delta_z]$, the gradient at p can be obtained from a scalar field $\boldsymbol{F}$ as

$$\left(\frac{F(x+\delta_x, y, z) - F(x-\delta_x, y, z)}{2\delta_x},\right.$$
$$\frac{F(x, y+\delta_y, z) - F(x, y-\delta_y, z)}{2\delta_y},$$
$$\left.\frac{F(x, y, z+\delta_z) - F(x, y, z-\delta_z)}{2\delta_z}\right)$$

Many other gradient estimation methods exist, including schemes that involve more or less neighboring samples and schemes where the discrete volume models are first convolved using a high-order interpolation function. Gradients are computed as the first derivative of the interpolation function.

Measured and Precomputed BRDFs. The light reflected from a point on a surface can be described by a *bidirectional reflection distribution function* (BRDF). Hence, it is feasible to obtain a BRDF in sampled form by either measurement or computer simulation(8). The measurements of a BRDF are usually made using a goniophotometer in a large number of directions, in terms of polar and azimuth angles, uniformly distributed on a hemisphere about a source. In computer graphics, it is also common to precompute discrete samples of a BRDF on a hemisphere surrounding a surface element. Given n sampling points on a hemisphere, and n possible incident directions of light, a BRDF can be represented by an $n \times n$ matrix. Given an arbitrary incident light vector, and an arbitrary viewing vector, one can determine the local luminance along the viewing vector by performing two look-up operations and interpolating up to 16 samples.

One major advantage of using measured or precomputed BRDFs is that the rendering algorithm does not require a complex illumination model. One can use measured data to compensate for the lack of an appropriate illumination model that accounts for a range of physical attributes or use precomputed data for a complicated and computationally intensive illumination model. Similar to a BRDF, the light transmitted at a point on a surface can be described by a *bidirectional transmittance distribution function* (BTDF). The combination of BRDF and BTDF provides a discrete specification of a *phase function*.

Phase Functions. A *phase function*, $\boldsymbol{P}(p, \psi, \phi)$, defines a probability distribution of scattering at point p in direction ψ with respect to the direction ϕ of the incident light. The fundamental difference between such an illumination model and those mentioned above is that it is entirely volumetric and does not assume the existence of a surface or microfacet at every visible point in space. Although phase functions are largely used in the context of global illumination, they can be used for local illumination in a perhaps rather simplified manner. Despite the omission of the multiple scattering in local illumination, phase functions allow a volumetric point to be lit by light from any direction. On the contrary, classic illumination models and BRDFs consider only light in front of the assumed surface or microfacet defined at the point concerned.

Multiple Scattering. The most referenced global illumination model is Kajiya's rendering equation, which defines the light transport from point p to point q as $\boldsymbol{I}(q, p) = v(q, p) \cdot (\boldsymbol{E}(q, p) + \int_{x \in \Sigma_S} \boldsymbol{R}(q, p, x)\boldsymbol{I}(p, x)dx)$, where $\boldsymbol{v}$ defines the visibility between p and q, $\boldsymbol{E}$ specifies the light emitted from p in the direction toward q, and $\boldsymbol{R}$ is a bidirectional reflectivity function defining a probability distribution of scattering in the direction from p to q for energy arriving at p from x. The integral is over $\boldsymbol{\Sigma}_S$, which is the set of all points on all surfaces in the scene, which specifies the indirect light reflected from p toward q.

We can modify this rendering equation for global illumination in volume graphics. Since any volume rendering integral featuring absorption would intrinsically take care of the visibility calculation betweenp p and q, we can remove v. We also need to replace Σ_S with a set of all volumetric points in the scene. Since we can cast a ray from p in every direction ϕ and use an appropriate volume rendering integral to gather all indirect light from direction ψ, we can in fact substitute Σ_S with the set of all directions $\boldsymbol{\Phi}$ from a unit sphere towards its center p. This results in Max's rendering equation (5) as

$$\boldsymbol{C}(p, \Psi) = \boldsymbol{E}(p, \Psi) + \int_{\phi \in \boldsymbol{\Phi}} \boldsymbol{\beta}(p)\boldsymbol{P}(p, \Psi, \phi)\boldsymbol{I}(p, \phi)d\phi$$

where $\boldsymbol{C}$ is the light transport from p toward direction Ψ, $\boldsymbol{E}$ is a volumetric emission function that specifies the light emitted from p in direction Ψ, $\boldsymbol{\beta}$ defines the probability light being scattered instead of being absorbed (which is called *albedo)* at p, $\boldsymbol{P}$ is a phase function as mentioned above, and $\boldsymbol{I}$ is the light transport arriving at p from direction ϕ. As we consider every point in space can potentially emit light, we can use the absorption and emission integral to compute $\boldsymbol{I}$. For each ray from p in direction $-\phi$, we have $I(p, \phi) = \int_0^\infty \boldsymbol{C}(p - u\phi) \cdot e^{-\int_I^0 A(p-t\phi)dt} du$. Let q be a pixel on the image plane. We can thus compute its intensity as $I = \int_{\psi \in \Psi} \boldsymbol{I}(q, \psi) d\psi$, where $\boldsymbol{\Psi}$ is the set of all directions from a unit hemisphere in front of the image plane toward its center q.

Max's rendering equation represents a complete solution for global illumination in volume graphics and visualization. However, solving this equation is not a trivial task. Much effort has been made to approximate the equation with various assumptions and simplifications.

One-Dimensional Rediosity

An optical model proposed by Kubelka and Munk considers both absorption and scattering but only in the directions of an incident flux and a reflected flux. It assumes that a volumetric colorant layer can be divided into a large number of homogeneous elementary layers. The optical properties of the volume thus depend on one direction. The two fluxes I_i and I_r flow in opposite directions. Given a volume model with two scalar fields, $\boldsymbol{K}(p)$ and $\boldsymbol{S}(p)$, representing the absorptivity and scattering coefficients, respectively, we can derive the reflectance R and transmittance T of a thin layer around p as

$$R = \frac{\sinh(b \cdot \boldsymbol{S}(p) \cdot \Delta u)}{a \cdot \sinh(b \cdot \boldsymbol{S}(p) \cdot \Delta u) + b \cdot \cosh(b \cdot \boldsymbol{S}(p) \cdot \Delta u)},$$

$$T = \frac{b}{a \cdot \sinh(b \cdot \boldsymbol{S}(p) \cdot \Delta u) + b \cdot \cosh(b \cdot \boldsymbol{S}(p) \cdot \Delta u)}$$

where Δu is the thickness of the layer, $a = 1 + \boldsymbol{K}(p)/\boldsymbol{S}(p)$, and $b = \sqrt{a^2 - 1}$. Given the reflectance and transmittance of a series of consecutive layers, (R_1, T_1), (R_2, T_2), ..., the infinite process of interaction among these layers can be realized using a front-to-back ray casting algorithm (9), as shown in Table 3. Such as infinite process of interaction can be considered as one-dimensional radiosity within the two fluxes, which is a typical effect of global illumination. As the rendering algorithm shown in Table 3 does not require gathering indirect light in addition to the computation of the volume rendering integral for reflectance and transmittance accumulation, it can be classified as a local illumination model based on the previous definition.

ADVANCED TOPICS

Research in volume visualization and volume graphics started in the late 1970s and early 1980s. Since then, significant advances have been made in the following areas.

Volume Modeling

Volume modeling is a process for constructing models of 3-D objects and phenomena using volume data representations, which can be specified procedurally or using sampled datasets. The ultimate aim is to provide users with efficient and effective tools for building complex scenes with such volumetric models. Technical advances in this area include constructive modeling of complex objects and scenes; interactive software systems for sculpting volume objects (see Figs. 1 and 2); data structures for space partitioning, multiresolution representation and data compression; and algorithms for antialiasing in object space.

Volumetric techniques are essential to the modeling and synthesizing of atmospheric and gaseous effects, such as clouds, smoke, and fire. *Volumetric textures*, including solid textures and hyper-textures, have provided vital support to achieve photo-realism in traditional surface graphics. In recent years, volumetric textures also played a central role in modeling and animating realistic hair.

High Performance Hardware and Software Systems

Parallel and distributed computation provided volume graphics and visualization with an indispensable means to achieve real-time performance until recently. Nowadays most volume rendering algorithms can be implemented on consumer PC hardware (10). However, with the increasing size of volume datasets, infrastructure-based computation will continue to play an important role in many applications of volume graphics and visualization. The technical issues to be considered in infrastructure-based volume rendering include *data partitioning and distribution, external memory management, task assignment and load balancing, image composition, collaborative visualization*, and *autonomic infrastructure management*.

Volume Manipulation, Deformation and Animation

Volume manipulation refers to the application of elementary processing operations to volume models usually in the form of sampled datasets. Any manipulation of a volume model will likely lead to changes of sampled values in the

Table 3. The Implementation of Ray Casting Based on the Kubelka and Munk Theory.

4. Add opaque background or no background	$\mathbf{R}_{with-bg} = \mathbf{R} + \dfrac{\mathbf{T}^2 \cdot R_{background}}{1 - \mathbf{R} \cdot R_{background}}$	*No background*
5. Post-illumination	$I = L_{front-light} \cdot \mathbf{R}_{with-bg}$	$I = L_{front-light} \cdot \mathbf{R} + L_{back-light} \cdot \mathbf{T}$

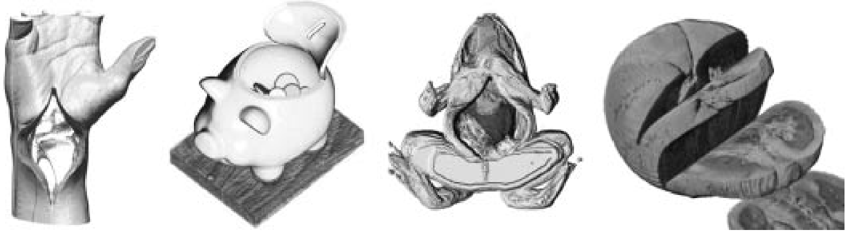

Figure 4. Different deformation operations, such as opening, peeling, and slicing, can be performed on volume models in real time using GPU-assisted techniques. These images were produced by C. Correa (for details, see C. Correa, D. Silver and M. Chen, "Feature aligned volume manipulation for illustration and visualization," *IEEE Transactions on Visualization and Computer Graphics*, **12**(5):1069–1076, 2006). The volume objects are from Lawrence Berkeley Laboratory and University of Erlangen.

datasets and may thereby result in alterations to geometrical, topological, and semantic attributes of the object(s) defined by the model. In general, techniques for manipulating volume models have reached a relatively mature status, with many well-studied technical problems and solutions, including *surface extraction, skeletonization, filtering, volume morphing, segmentation*, and *registration* (11).

Volume deformation refers to the intended change of geometric shape of a volume object under the control of some external influence such as a force. Applications of deformation techniques include computer animation, object modeling, computer-aided illustration (see Fig. 4), and surgical simulation. Techniques for volume deformation fall into two main categories, *empirical deformable models* and *physically based deformation models*. Recent advances in this area include hardware-assisted real-time deformation and mesh-free deformation techniques.

Volume animation refers to the simulation of motion and deformation of digital characters represented by volume models. Although the overall effort made in this area is so far limited, there are several major breakthroughs. Two types of control techniques, namely *block-based* and *skeleton-based*, have been used in volume animation.

Volume Data Capture and Reconstruction

Digitization is a family of technologies for acquiring volumetric models of real-life objects or phenomena. These technologies are based on measuring various physical properties, resulting in a wide range of modalities, including *computed tomography, magnetic resonance imaging*, *3-D ultrasonography, and positron emission tomography* in medical imaging; *seismic measurements* in geosciences; *confocal microscopy* in biology; and *electron microscopy* in chemistry.

Although some modalities involve a volumetric sampling process, which takes a collection of samples at discrete 3-D positions within an object domain, many can only take samples outside the object domain, hence require a *reconstruction* process to build volumetric models from the captured external samples. For example, in computed tomography, techniques have been developed for reconstructing an "intensity" volume from a set of x-ray images. These include *filtered back-projection* for transmission tomography and *algebraic reconstruction technique* and *maximum-likelihood expectation maximization* for emission tomography.

WARPING AND MORPHING

OVERVIEW

Warping and morphing are the techniques of synthesizing a novel graphical object by deforming given objects. Whereas warping is a purely geometric transformation, morphing (or metamorphosis) interpolates two or more graphical objects. Given two images of different persons as shown on the left and right in Fig. 1, an image morphing technique generates the intermediate images between them, so that the shape and appearance of the faces are transformed as if one person *evolves* into the other. In this article, the state-of-the-art techniques of morphing are introduced, and warping techniques are discussed in the context of the morphing techniques.

Consider the situation where an animator is given two images I_{src} and I_{dst}, and must make the morphing animation between them. The first step of generating a morphing sequence is determines feature correspondences between the images. The correspondences are specified by geometric primitives such as points, line segments, and/or mesh nodes.

The sparse correspondences between images are then converted into a mapping, which is referred to as a *warping function*, that spatially relates all pixels in the images. The warping function defines the smooth deformation of given images in a common coordinate system. The warped images are finally interpolated by a *blending function* into in-between images. The feature specification typically involves user interaction, but the rest of the process can be automated.

Techniques of warping and morphing have been used in both industry and academia. The application includes visual effects in television and film production, fluid and nonrigid body simulation, and visualization of time-series data. The range of application has been extended into various types of media formats used in computer graphics. In the next section, the morphing techniques for two-dimensional (2-D) images are first reviewed. The applications to volumes, three-dimensional (3-D) surface models, and light fields are introduced in the final section.

WARPING AND MORPHING OF IMAGES

Smooth transition between given images can be achieved through simple cross dissolving. The result is, visually poor, however, due to double-imaging effects apparent in misaligned regions. Morphing techniques generate a smooth transformation from one image to another by using a warping process followed by a cross-dissolving process. In this section, we explain several morphing algorithms, including those based on mesh warping, field morphing, scattered data interpolation, energy minimization, and free-form deformations. Some techniques toward automatic morphing are also reviewed. Readers should refer to the survey by Wolberg (1) for the comprehensive review of morphing techniques.

Mesh Warping

The technique of image warping was first developed by the film industry (2). Figure 2 illustrates the two-pass mesh warping algorithm. The top and bottom row are the warping processes of two different images, I_{src} and I_{dst}. In mesh warping, we define a 2-D mesh structure in each of the image coordinate systems. The mesh has the same topology and defines the warping function between the images. Image warping is then performed by deforming the grids between the two. The degree of warping can be controlled by a warping parameter $t \in [0,1]$ shown on a horizontal axis in Fig. 2. A sequence of morphing images is generated by using a linear blending function of two warped images with t as a blending parameter.

The algorithm of mesh warping can be summarized into three-step image processing in Algorithm 1. Some attempts to extend this algorithm to nonlinear interpolation exist. For instance, the Catmull–Rom spline interpolation for mesh warping is demonstrated by Wolberg (1).

Field Morphing

One drawback to mesh warping is that a user has to specify the feature points between images by a grid. Defining a grid structure for given images is not a trivial task, and the result of warping is affected by the mesh structure. Beier and Neely (3) propose a field morphing technique that allows a user to specify the correspondence between images by a sparse set of line segments. A globally smooth warping function is generated according to the distance to each segment. Points and curved lines can also be used for the primitives to define the correspondence. The final warping function is a weighted sum of the warping generated by all primitives. Figure 3 shows an example of field morphing.

Algorithm 1. Mesh Warping

```
for all $t \in [0, 1]$ do
  Warp $I_{src}$ into $W_{src}$ using $t$ as a warping parameter
  Warp $I_{dst}$ into $W_{dst}$ using $1 - t$ as a warping parameter
  Blend $W_{src}$ and $W_{dst}$ into $I_{morph}$ using $t$ as a blending parameter
end for
```

Scattered Data Interpolation

The most generic primitive for feature correspondence is a point, because lines and curves can be point sampled. The generic algorithm of image blending is then considered as the interpolation between two 3-D points, $(x_{src}, y_{src}, t_{src})$ and $(x_{dst}, y_{dst}, t_{dst})$, where a point (x_{src}, y_{src}) in an image I_{src} is warped with a warping parameter t_{src} and a point (x_{dst}, y_{dst}) in another image I_{dst} is warped with t_{dst}.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

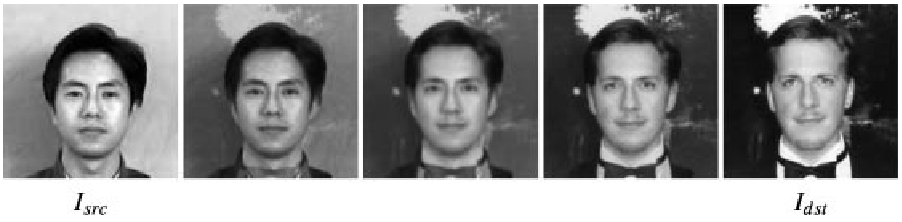

Figure 1. Image morphing: Given two images of objects, I_{src} and I_{dst}, an animation sequence between them is generated in the way that I_{src} deforms gradually into I_{dst}.

This formulation is investigated by Ruprecht and Miller (4). A framework using thin plate splines is developed by Lee et al. (5). Hassanien and Nakajima (6) propose a method of facial image metamorphosis that uses Navier splines. Arad et al. (7) use radial basis functions for the same application. Figure 4 shows the warping by radial basis functions. The techniques based on scattered data interpolation can generate a globally smooth warping from a coarse set of point correspondences. The computational cost is low, and the algorithm is generally more stable than field morphing.

Bijective Warping

Field morphing and scattered data interpolation do not guarantee one-to-one correspondences between two images and, therefore, do not have any physical meaning in the deformation. Lee et al. (8) proposed an energy minimization method for deriving one-to-one warp functions. They further extended their method and developed a more effective method (9) by combining an energy minimization approach with a free-form deformation (FFD) method proposed by Sederberg and Parry (10) in a multiresolution structure (see Fig. 5). This method is inspired by the nonrigid deformation in physics simulation, which enables natural-looking deformation in a morphing sequence.

Automated Morphing

The most time-consuming part in a morphing process is specifying correspondence between images. Suppose two images are sufficiently similar; then the techniques of image registration methods (11) can be used to generate the correspondences. When the images are different views of an object, the reconstruction of camera geometry gives us geometrically valid correspondences (12). For nonrigid objects, optical flow methods (13) and feature trackers (14) can be used.

The methods mentioned above assume that two images are captured under similar conditions and, therefore, that only small displacements must be recovered. This assumption, however, does not hold in general morphing applications where two images can be vastly different. Shinagawa and Kunii (15) propose a method of finding correspondences between images without using any constraints except image intensity. Yamazaki et al. (16) propose a linear filter bank to exploit the multilevel image structure.

Although automatic morphing can drastically reduce the work for a user, user interaction is essential for defining semantic correspondence or for remedying artifacts caused by erroneous correspondences. Gao and Sederberg (17) propose a hybrid system that allows a user to improve the correspondences generated by image-matching algorithms.

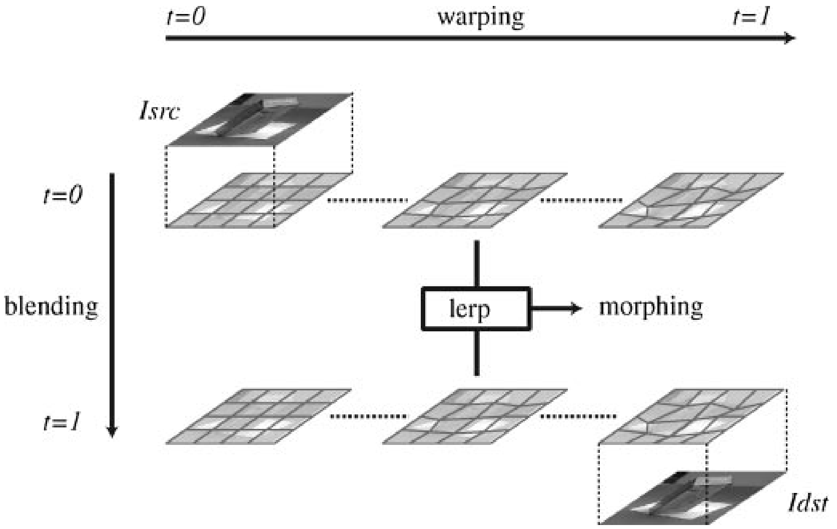

Figure 2. Mesh warping.

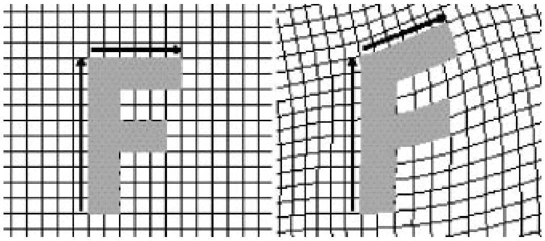

Figure 3. Field morphing: Two sides of an "F" character are specified by line segments. The weighted sum of linear transformation defined by each line segment gives us a globally smooth warping function [images by Beier and Neely (3)].

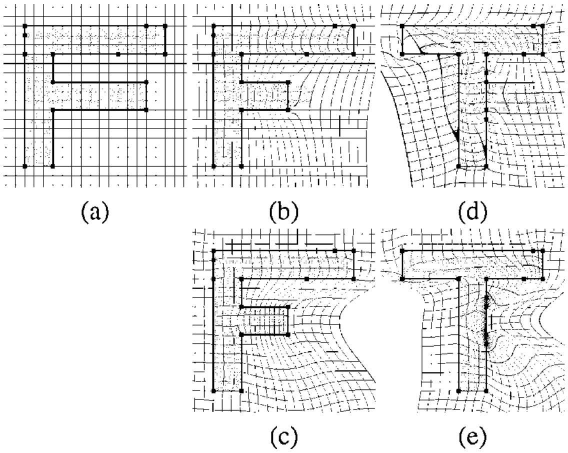

Figure 5. Free-form deformation from "F" to "T" characters. The top row shows results obtained by field morphing. The bottom row is the results by multilevel free-form deformation [images by Lee et al. (9)].

The user can specify some feature points as constraints on the warping between images, and the system then can determine the best image matching by solving a constrained optimization.

APPLICATIONS TO OTHER GRAPHICAL OBJECTS

Following the success of image morphing techniques shown in the previous section, many researchers have developed the techniques of morphing 3-D objects (18). Generally, a morphing of 3-D models includes the interpolation of their shapes as well as an interpolation of their attributes such as color, texture, or appearance of the surface. The challenge in these techniques is how to define an intrinsic morphing sequence between any two objects in arbitrary structure.

Volumetric Representation of 3-D Shape

Implicit surface (19), level set (20), and voxelized objects are commonly used representations of 3-D solids and 2-D closed surfaces. The shape of an object is defined by a set of points p such that $f(p) = c$ for some function f and shape attribute c. It is then a straightforward task to extend and generalize the techniques of 2-D image morphing to 3-D shapes or higher dimension.

Pasko and Savchenko (21) developed a warping algorithm for 3-D shapes represented in the scalar functions. This method, however, often suffers from unnecessary distortion or change in topology such as creation of many connected components. Cohen-Or et al. (22) solve this problem by combining a straightforward interpolation with a signed distance transformation that allows the algorithm to deform the whole space continuously. Figure 6 shows the morphing of 3-D shapes that have different topology. The signed distance representation of 3-D shapes is a mathematical abstraction of geometric properties, such as continuity or genus, and therefore, it allows continuous transition between different geometry without concerning the explicit properties in the sequence of morphing animation.

A specific user interface for designing a morphing sequence of two volumes is proposed by Lerios et al. (23) Their system provides users a graphical interface to specify feature correspondences by using simple geometric primitives such as points, lines, and boxes in the volumes in the same spirit as the Beier and Neely method (3). Figure 7 shows an example of the graphics user interface where 37 geometric primitives are used for feature correspondences.

Boundary Representation of 3-D Shape

Boundary representations of 3-D shape are very popular in the computer graphics community. A large number of models and data structures have been proposed to represent objects by their boundaries. The polygonal surfaces and the parameterized surfaces are the two main models.

The use of boundary representations has several advantages: efficient data structure, capability of texture mapping, and intuitive representation. As a counterpart, this representation is implicitly constrained both geometrically and topologically. The algorithm of morphing of 3-D shapes in boundary representation has to consider these constraints during the entire process of morphing.

Specifying corresponding points between two surface models is essential to constructing a single mesh with two geometric instantiations: one for each source and destination object. This single mesh can be obtained by merging the meshes (24) or by creating a new common mesh (25). The existence of a common mesh for two different models implies that they have the same topology.

DeCarlo and Gallier (26) propose a method of dealing with degenerated geometric instantiations of the common mesh where an edge or a face can be embedded onto a single point or edge (see Fig. 8). They use a sparse control mesh on each surface in order to define a mapping between the input objects. This method applies to general (triangulated) polyhedral surfaces.

Light Field

The light field (27, 28) is the representation of the appearance of 3-D objects without explicit geometry. The dataset is typically composed of a large number of images captured from various viewpoints. Each pixel in the images is regarded as a sample of rays passing in the 3-D space. Given a viewpoint at rendering, a corresponding view is synthesized by interpolating the sampled rays.

Zhang et al. (29) applied a feature-based morphing approach to the light field that is similar to the Beier and Neely system (3). Given two light field data, a user selects representative viewpoints for each light field and then specifies the correspondence that defines a common mesh structure on 2-D images of rendered light fields. The system then propagates the correspondence to other viewpoints that are not selected by the user, taking into account the occlusion.

In addition to the change of viewpoints, the variable light source is also modeled in surface light field rendering (30). This method assumes that the 3-D shape of an object of interest is given and that the variation of the appearance of all points of the surface is represented efficiently. Jeong et al. (31) applied the feature-based morphing technique to the surface light field. Because the surface appearance changes drastically, they propose a dynamic change of mesh structure defined by a user so that the highlights are not blurred by interpolation.

SUMMARY

In this article, some representative work for warping and morphing of images and 3-D object models are presented. The warping is an underlying process of morphing algorithms, although the warping techniques themselves have a wide range of applications in the context of image registration (11). The morphing can be used not only for visualization purposes but also for data compression (32). The biggest issue in warping and morphing processes is how to efficiently build correspondences between data. Several intuitive user interfaces that enable a user to specify complicated feature correspondences have been proposed, as well as a few algorithms that attempt to find correspondences automatically. Designing easy-to-use and powerful systems for general morphing purposes is still an open problem.

ARTIFICIAL INTELLIGENCE LANGUAGES

The process of programming a solution to a problem is inherently difficult. This has been recognized by conventional programmers for many years and has been one of the motivating forces behind both structured and object-oriented programming techniques. The problem seems to be that the human brain does not have the capacity to handle the complexity of the programming task for nontrivial problems. The solution has been to first use structured and then object-oriented techniques that break the problem into manageable "chunks." However, this "*divide et impera*" technique did not solve the problem of the imperative (procedural, commanding) description of the solution, i.e., of the explicit ordering of the actions leading to the solution. Moreover, the sequence of statements in imperative language also implies the need to have explicit commands to alter the sequence, for example, control structures such as "while…do," "repeat…until," or even "goto." Many errors in imperative languages are introduced because the specified sequencing is not correct. On the other hand, in declarative languages used mainly for AI programming, we describe the problem rather than the explicit way to solve it, or the order in which things must be done. The explicit ordering has been replaced by the implicit ordering, conditioned by the relationships between the objects. The lack of explicit sequence of control relieves the user of the burden of specifying the control flow in the program.

Declarative programming is the umbrella term that covers both functional programming and relational programming. Although the two approaches do have many superficial similarities—both classes of languages are nonprocedural and, in their pure forms, involve programming without side-effects—they do have different mathematical foundations. In writing functional programs, the programmer is concerned with specifying the solution to a problem as a collection of many-to-one transformations, which corresponds closely to the mathematical definition of a function. On the other hand, a relational program specifies a collection of many-to-many transformations. Thus, in relational programming languages, there is a set of solutions to a particular application rather than the single solution that is produced from a function application. Although the execution mechanisms that have been proposed for relational programming languages are radically different from the approaches for a functional programming language, both approaches have been widely used in artificial intelligence programming.

To provide AI-related comparison, we have included two equally popular AI-language alternatives, a functional language Lisp and relational language Prolog. From the beginning, Lisp was the language of choice for American AI researchers. The reasons are many, but primarily they result from the strong mathematical roots of the language, symbolic rather than numeric processing, and its ability to treat its own code as data. Researchers have exploited this capability of the Lisp program to modify themselves at runtime for research in machine learning, natural-language understanding, and other aspects of AI. Moreover, artificial intelligence programming requires the flexibility, extensibility, modularity, and underlying data structures and data abstraction facilities that Lisp provides. Although Lisp is one of the older programming languages in use, it has remained the most widely used language in AI programming.

The logic programming language Prolog has been growing in popularity since it was originally introduced in Europe in the early 1970s. Prolog is most easily matched to tasks involving logic and proof-like activities. A Prolog program is essentially a description of objects and relations between them. A subset of formal logic (called Horn clause logic) is used to specify the desired conditions. Prolog's adherent believes that it is easier to learn and use than Lisp. They say that it uses less memory and is more easily moved from one computer to another.

Although both Lisp and Prolog have been supported with almost religious intensity by passionate advocates, the dilemma of Prolog versus Lisp has softened over the years, and many now believe in a combination of ideas from both worlds. New AI languages can be roughly divided into Lisp-like languages, Prolog-like languages, hybrid languages, object-oriented languages, agent-oriented languages, semantic Web languages, and specialized AI programming languages.

Before we discuss specific AI programming paradigms and languages, it would be useful to underline the specific features that facilitate the production of AI programs as distinct from a language for writing other types of applications. Apart from the features that are now needed for building almost any kind of complex systems, like possessing a variety of data types, a flexible control structure, and the ability to produce efficient code, the features that are particularly important in building AI systems are as follows (1–4):

- Good symbol manipulation facilities, because AI is concerned with symbolic rather than numeric processing.
- Good list manipulating facilities, because lists are the most frequently used data structures in AI programs.
- Late binding times for the object type or the data structure size, because in many AI systems, it is not possible to define such things in advance.
- Pattern matching facilities, both to identify data in the large knowledge base and to determine control for the execution of production systems.
- Facilities for performing some kind of automatic deduction and for storing a database of assertions that provide the basis for deduction.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

- Facilities for building complex knowledge structures, such as frames, so that related pieces of information can be grouped together and assessed as a unit.
- Mechanisms by which the programmer can provide additional knowledge (meta-knowledge) that can be used to focus the attention of the system where it is likely to be the most profitable.
- Control structures that facilitate both goal-directed behavior (top-down processing or backward-chaining) and data-directed (or bottom-up processing or forward chaining).
- The ability to intermix procedural and declarative knowledge in whatever way best suits a particular task.
- Good programming environment, because AI programs are among the largest and most complex computer systems ever developed and present formidable design and implementation problems.

No existing language provides all of these features. Some languages do well at one at the expense of others, and some hybrid languages combine multiple programming paradigms trying to satisfy as many of these needs as possible. However, the main differentiator between various AI programming languages is their ability to represent knowledge clearly and concisely.

LOGIC PROGRAMMING

Logic programming began in the early 1970s as a direct outgrowth of earlier work in automatic theorem proving and artificial intelligence. It can be defined as the use of symbolic logic for the explicit representation of problems, together with the use of controlled logical inference for the effective solution of those problems.

The credit for the introduction of logic programming goes mainly to Kowalski (5), (6) and Colmerauer et al. (7), although Green (8) and Hayes (9) should also be mentioned in this regard. In 1972, Kowalski and Colmerauer were led to the fundamental idea that logic can be used as a programming language. The acronym PROLOG [PROgramming in LOGic) was conceived, and the first PROLOG interpreter was implemented in the language ALGOL-W by Roussel in 1972.

The idea that first-order logic, or at least substantial subsets of it, can be used as a programming language was revolutionary, because until 1972, logic had only ever been used as a specification language in computer science. However, it has been shown that logic has a procedural interpretation, which makes it very effective as a programming language. Briefly, a program clause $A < = B_1, \ldots, B_n$ is regarded as a procedure definition. If $< = C_1, \ldots, C_k$ is a goal clause, then each C_j is regarded as a procedure call. A program is run by giving it an initial goal. If the current goal is $< = C_1, \ldots, C_k$, a step in the computation involves unifying some C_j with the head A of a program clause $A < = B_1, \ldots, B_n$ and thus reducing the current goal to the goal $< = (C_1, \ldots, C_{j-1} B_1, \ldots, B_n, C_{j+1}, \ldots, C_k)\theta$, where θ is the unifying substitution. Unification thus becomes a uniform mechanism for parameter passing, data selection, and data construction. The computation terminates when the empty goal is produced.

One of the main ideas of logic programming, which is due to Kowalski, is that an algorithm consists of two disjoint components, the logic and the control. The logic is the statement of *what* the problem is that has to be solved. The control is the statement of *how* it is to be solved. The ideal of logic programming is that the programmer should only have to specify the logic component of an algorithm. The logic should be exercised solely by the logic programming system. Unfortunately, this ideal has not yet been achieved with current logic programming system because of two broad problems. The first of these is a control problem. Currently, programmers need to provide a lot of control information, partly by the ordering of clauses and atoms in clauses and partly by extra-logical control features, such as *cut*. The second problem is the negation problem. The Horn clause subset of logic does not have sufficient expressive power, and hence the Prolog system allows negative literals in the bodies of clauses.

Logic has two other interpretations. The first of these is the database interpretation. Here a logic program is regarded as a database. We thus obtain a very natural and powerful generalization of relational databases, which correspond to logic programs consisting solely of ground unit clauses. The concept of logic as a uniform language for data, programs, queries, views, and integrity constraints has great theoretical and practical potential.

The third interpretation of logic is the process interpretation. In this interpretation, a goal $< = B_{-1}, \ldots B_n$ is regarded as a system of concurrent processes. A step in the computation is the reduction of a process to a system of processes. Shared variables act as communication channels between processes. Now several Prologs are based on the process interpretation. This interpretation allows logic to be used for operating system applications and object-oriented programming.

It is clear that logic provides a single formalism for apparently diverse parts of computer science. Logic provides us with a general-purpose, problem-solving language, a concurrent language suitable for operating systems and a foundation for database systems. This range of applications together with the simplicity, elegance, and unifying effect of logic programming assures it of an important and influential future.

One of the most important practical outcomes of the research in logic programming has been the language Prolog, based on a *Horn clause* subset of logic. Most of logic programming systems available today are either Prolog interpreters or compilers. Most use the simple computation rule, which always selects the leftmost atom in a goal. However, logic programming is by no means limited to a Prolog. It is essential not only to find more appropriate computation rules, but also to find ways to program in a larger subset of logic, not just in a clausal subset. In this entry we will also briefly cover a database query language based on logic programming, Datalog, and several hybrid languages supporting the logic programming paradigm (together with some other paradigms, functional, for instance).

Prolog

Prolog stands for programming in logic—an idea that emerged in the early 1970s to use logic as a programming language. The early developers of this idea included Robert Kowalski at Edinburgh (on the theoretical side), Maarten van Emden at Edinburgh (experimental demonstration), and Alain Colmerauer at Marseilles (implementation). The curent popularity of Prolog is largely due to David Warren's efficient implementation at Edinburgh in the mid-1970s.

Prolog has rapidly gained popularity in Europe as a practical programming tool. The language received impetus from its selection in 1981 as the basis for the Japanese Fifth Generation Computers project. On the other hand, in the United States its acceptance began with some delay, due to several factors. One was the reaction of the "orthodox school" of logic programming, which insisted on the use of pure logic that should not be marred by adding practical facilities not related to logic. Another factor was a previous American experience with the Microplanner language, also akin to the idea of logic programming, but inefficiently implemented. And the third factor that delayed the acceptance of Prolog was that for a long time Lisp had no serious competition among languages for AI. In research centers with strong Lisp tradition, there was therefore a natural resistance to Prolog.

The language's smooth handling of extremely complex AI problems and ability to effect rapid prototyping has been a big factor in its success, even in the United States. Whereas conventional languages are procedurally oriented, Prolog introduces the descriptive or declarative view, although it also supports the procedural view. The declarative meaning is concerned only with the *relations* defined by the program. This greatly alters the way of thinking about problem and makes learning to program in Prolog an exciting intellectual challenge. The declarative view is advantageous from the programming point of view. Nevertheless, the procedural details often have to be considered by the programmer as well.

Apart from this dual procedural/declarative semantics, the key features of Prolog are as follows (10–12):

- Prolog programming consists of defining *relations* and querying about relations.
- A program consists of *clauses*. These are of three types: *facts*, *rules*, and *questions*.
- A relation can be specified by *facts*, simply stating the n-tuples of objects that satisfy the relation, or by stating *rules* about the relation.
- A *procedure* is a set of clauses about the same relation.
- Querying about relations, by means of *questions*, resembles querying a database. Prolog's answer to a question consists of a set of objects that satisfy the question.
- In Prolog, to establish whether an object satisfies a query is often a complicated process that involves logical inference, exploring among alternatives and possibly *backtracking*. All this is done automatically by the Prolog system and is, in principle, hidden from the user.

Different programming languages use different ways of representing knowledge. They are designed so that the kind of information you can represent, the kinds of statements you can make, and the kinds of operations the language can handle easily all reflect the requirements of the classes of problems for which the language is particularly suitable. The key features of Prolog that give it its individuality as a programming language are as follows:

- Representation of knowledge as *relationships* between objects; the core representation method consists of relationships expressed in terms of a predicate that signifies a relationship and arguments or objects that are related by this predicate.
- The use of *logical rules* for deriving implicit knowledge from the information explicitly represented, where both the logical rules and the explicit knowledge are put in the *knowledge base* of information available to the Prolog.
- The use of *lists* as a versatile form of structuring data, although not the only form of structuring data that is used in Prolog.
- The use of *recursion* as a powerful programming technique.
- Variables acquire values by a process of *pattern matching* in which they are instantiated or bound to various values.

The simplest use of Prolog is to use it as a convenient system for retrieving the knowledge explicitly represented, i.e., for interrogating or queering the knowledge base. The process of asking a question is also referred to as "setting a GOAL for the system to satisfy." You type the question, and the system searches the knowledge base to determine whether the information you are looking for is there.

The next use of Prolog is to supply the system with part of the information you are looking for and to ask the system to find a missing part.

In both cases above Prolog works fundamentally by pattern matching. It tries to match the pattern of our question to the various pieces of information in the knowledge base.

The third case has a distinguishing feature. If your question contains variables (a word beginning with an uppercase letter), Prolog also has to find what are the particular objects (in place of variables) for which the goal are satisfied. The particular instantiation of variables to these objects are shown to the user.

One advantage of using Prolog is that Prolog interpreter is in essence a built-in inference engine that draws logical conclusions using the knowledge supplied by the facts and rules.

To program in Prolog, one specifies some facts and rules about objects and relationships and then asks questions about objects and relationships. For instance, if one entered the following facts:

```
likes(peter, mary)
likes (paul, mary)
likes (mary, john)
```

and then asked

```
?-likes (peter, mary)
```

Prolog would respond by printing

```
yes.
```

In this trivial example, the word `likes` is the *predicate* that indicates that such a relationship exists between one object, `peter`, and a second object, `mary`. In this case Prolog says that it can establish the truth of the assertion that “Peter likes Mary” based on the three facts it has been given. In a sense, computation in Prolog is simply controlled logical deduction. One simply states the facts that one knows, and Prolog can tell whether any specific conclusion could be deduced from those facts. In knowledge engineering terms, Prolog’s control structure is logical inference.

Prolog is the best current implementation of logic programming, although a programming language cannot be strictly logical, because input and output operations necessarily entail some extralogical procedures. Thus, Prolog incorporates some basic code that controls the procedural aspects of its operations. However, this aspect is kept at a minimum, and it is possible to conceptualize Prolog strictly as a logical system.

Indeed, there are two Prolog programming styles: a *declarative* style and a *procedural* style. In declarative programming, one focuses on telling the system what it should know and relies on the system to handle the procedures. In procedural programming, one considers the specific problem-solving behavior the computer will exhibit. For instance, knowledge engineers who are building new expert system concerns themselves with procedural aspects of Prolog. Users, however, need not to worry about procedural details and are free simply to assert facts and ask questions.

One of the basic demands that AI language should satisfy is a good list processing. A *list* is virtually the only complex data structure that Prolog has to offer. Lists is said to have a head and a tail. The head is the first list item. The tail is the list composed of all remaining lists. The atom on the left of vertical bar is the list head, and the part to the right is the list tail.

The following example illustrates the way the list appending operation is performed in Prolog:

```
  append ([ ] , L,L).
  append ([ X|L1] ,L2, [ X|L3] )
      :- append (L1,L2,L3).
```

This simple Prolog program consists of two relations. The first says that the result of appending the empty list ([ ]) to any list L is simply L. The second relation describes an inference rule that can be used to reduce the problem of computing the result of an append operation involving a shorter list. Using this rule, eventually the problem will be reduced to appending the empty list, and the value is given directly in the first relation. The notation [X | L1] means the list whose first element is X, and the rest of which is L1. So the second relation says that the result of appending [X|L1] to L2 is [X|L3] provided that it can be shown that the result of appending L1 to L2 is L3.

FUNCTIONAL PROGRAMMING

Historically, the most popular AI language, Lisp (13–15), has been classified as a functional programming language in which simple functions are defined and then combined to form more complex functions. A function takes some number of arguments, binds those arguments to some variables, and then evaluates some forms in the context of those bindings.

Functional languages became popular within the AI community because they are much more problem-oriented than conventional languages. Moreover, the jump from formal specification to a functional program is much shorter and easier, so the research in the AI field was much more comfortable.

Functional programming is a style of programming that emphasizes the evaluation of expressions, rather than the execution of commands. The expressions in this language are formed by using functions to combine basic values. A functional language is a language that supports and encourages programming in a functional style.

For example, consider the task of calculating the sum of the integers from 1 to 10. In an imperative language such as C, this might be expressed using a simple loop, repeatedly updating the values held in an accumulator variable `total` and a counter variable `i`:

```
total = 0;
for (i=1; i<=10; ++i)
  total += i;
```

In a functional language, the same program would be expressed without any variable updates. For example, in Haskell, a non-strict functional programming language, the result can be calculated by evaluating the expression:

```
    sum[ 1..10]
```

Here `[ 1..10]` is an expression that represents the list of integers from 1 to 10, whereas `sum` is a function that can be used to calculate the sum of an arbitrary list of values.

The same idea could be used in strict functional languages such as SML or Scheme, but it is more common to find such programs with an explicit loop, often expressed recursively. Nevertheless, there is still no need to update the values of the variables involved as follows.

SML:

```
let fun sum i tot = if i=0 then tot else sum (i-1)
  (tot+i)
in sum 10 0
  end
```

Scheme:

```
  (define sum
    (lambda (from total)
      (if (= 0 from)
        total
        (sum (- from 1) (+ total from)))))
(sum 10 0)
```

It is often possible to write functional-style programs in an imperative language, and vice-versa. It is then a matter of opinion whether a particular language can be described as functional. It is widely agreed that languages like Haskell and Miranda are "purely functional," whereas SML and Scheme are not. However, there are some small differences of opinion about the precise technical motivation for this distinction. One definition that has been suggested says that "purely functional" languages perform all their computations via function application. This is in contrast to languages, such as Scheme and SML, that are predominantly functional but also allow computational effects caused by expression evaluation that persist after the evaluation is completed. Sometimes, the term "purely functional" is also used in a broader sense to mean languages that might incorporate computational effects, but without altering the notion of "function" (as evidenced by the fact that the essential properties of functions are preserved). Typically, the evaluation of an expression can yield a "task," which is then executed separately to cause computational effects. The evaluation and execution phases are separated in such a way that the evaluation phase does not compromise the standard properties of expressions and functions. The input/output mechanism of Haskell, for example, is of this kind.

There is also much debate in the functional programming community about the distinction and the relative merits of strict and non-strict functional programming languages. In a strict language, the arguments to a function are always evaluated before it is invoked, whereas in a non-strict language, the arguments to a function are not evaluated until their values are actually required. It is possible, however, to support a mixture of these two approaches like in some versions of the functional language Hope.

It is not possible to discuss the mathematical foundation of functional programming without a formal notation for function definition and application. The usual notation that is used in applicative functional languages is so-called λ–(lambda) calculus. It is a simple notation and yet powerful enough to model all of the more esoteric features of functional languages. The basic symbols in the λ–calculus are the variable names, λ, dot (·), and open and closed brackets. The general form for a function definition is

$$\lambda x.M$$

which denotes the function F such that for any value of x, $F(x) = M$, and the value of F can be computed on an argument N by substituting N into defining equation. A valid -expression, described in BNF notation, is as follows:

```
Expression : : = Variablename |
           Expression Expression |
           λ Variable_name_list. Expression |
           ( Expression )
```

The primary relevance of the λ–calculus to artificial intelligence is through the medium of Lisp. Lisp's creator McCarthy used λ–calculus as the bases of Lisp's notation for procedures. Since that time, other programming languages used the λ–calculus in a more pervasive way. However, from the point of view of artificial intelligence, the most important among functional languages is definitely Lisp, which will be given more attention in the following paragraphs.

Lisp

Lisp (*List* processing) is a family of languages with a long history. Early key ideas in Lisp were developed by John McCarthy during the Darthmouth Summer Research Project on Artificial Intelligence in 1956. Of the major programming languages still in use, only FORTRAN is older then Lisp. Since then it has grown to be the most commonly used language for Artificial Intelligence and Expert Systems programming, McCarthy's motivation was to develop an algebraic list processing language for artificial intelligence work.

John McCarthy, the language creator, describes the key ideas in Lisp as follows (13):

- Computing with symbolic expressions rather than numbers; that is, bit patterns in a computer's memory and registers can stand for arbitrary symbols, not just those of arithmetic.
- List processing, that is, representing data as linked-list structures in the machine and as multilevel lists on paper.
- Control structure based on the composition of functions to form more complex functions.
- Recursion as a way to describe processes and problems.
- Representation of LISP programs internally as linked lists and externally as multilevel lists, that is, in the same form as all data are represented.
- The function EVAL, written in LISP itself, serves as an interpreter for LISP and as a formal definition of language.

One major differences between Lisp and conventional programming languages (such as FORTRAN, Pascal, Ada, and C) is that Lisp is a language for symbolic rather than for numeric processing. Although it can manipulate numbers as well, its strength lies in being able to manipulate *symbols* that represent arbitrary objects from the domain of interest. Processing pointers to objects and altering data structures comprising other such pointers is the essence of symbolic processing. *Symbols*, also called *atoms* because of the analogy to the smallest indivisible units, are the most important data types in Lisp. Their main use is as a way of describing programs and data for programs. Symbol is a Lisp object. It has a name associated with them and several aspects or uses. First, it has a value, which can be accessed or altered using exactly the same forms that access or alter the value of a lexical variable. In fact, the methods of naming symbols are the same as those used for naming a lexical variable. In addition to a value, a symbol can have a property list, a package, a print name, and possibly a function definition associated with it. A property list is simply a list of indicators and values used to store properties associated with some objects that the symbol is defined by the programmer to represent. A print name is usually the string of characters that constitutes the identifier. A package is a structure that establishes a mapping between an identifier and a symbol. It is usually a hash table containing symbols. A function is normally associated with a lexical variable or a symbol. The symbol printed representation is as a sequence of alphabetic, numeric, pseudo-alphabetic, and special characters.

Other typical data types are lists, trees, vectors, arrays, streams, structures, and so on. Out of these data structures can be built representations for formulas, real-world objects, natural-language sentences, visual scenes, medical concepts, geographical concepts, and other symbolic data (even other Lisp programs). It is important to note that in Lisp it is data objects that are typed, not variables. Any variable can have any Lisp object as its value.

Historically, list processing was the conceptual core of Lisp (the name was taken from **Lis**t **p**rocessing). Lists in Lisp are reprinted in two basic forms. The external, visible, form of list is composed of an opening parenthesis followed by any number of symbolic expressions followed by a closing parenthesis. A symbolic expression can be a symbol or another list. Internally, a list is represented as a chain of CONS cells. The CONS cell is the original basic building block for Lisp data structures. Each CONS cell is composed of a CAR (the upper half, the “data” part) and CDR (the lower half, the “link” part). Lists are represented internally by linking CONS cells into chains by using the CDR of each cell to point to the CAR of the next cell. *CONS cells* can be linked together to form data structures of any desired size or complexity. NILL is the Lisp symbol for an “empty list,” and it is used to represent the Boolean value “false.”

The list appending function in Lisp would be as follows:

```
(DE APPEND (L1 L2)
    (COND (( NULL L1) L2)
    (( ATOM L1) (CONS L1 L2)
    ( TRUE (CONS (CAR L1) (APPEND (CDR L1) L2)0000
```

The Lisp function returns a list that is the result of appending L1 to L2. It uses the Lisp function CONS to attach one element to the front of a list. It calls itself recursively until all elements of L1 have been attached. The Lisp function CAR returns the first element of the list it is given and the function CDR returns the list it is given minus the first element. ATOM is true if its argument is a single object rather than a list.

Lisp relies on dynamic allocation of space for data storage. Memory management in Lisp is completely automatic, and the application programmer does not need to worry about assigning storage space. It manages storage space very efficiently and frees the programmer to create complex and flexible programs.

Lisp is a very good choice for an artificial intelligence project programming for several reasons. Most AI projects involve manipulation of symbolic rather than of numeric data, and Lisp provides primitives for manipulating symbols and collections of symbols. Lisp also provides automatic memory-management facilities so you do not need to write and debug routines to allocate and reclaim data structures. Lisp is extensible and contains a powerful macro facility that allows layers of abstraction.

Lisp’s lists can be of any size and contain objects of any data types (including other lists), so that programmers can create very complex data structures for representing abstract concepts such as object hierarchies, natural-language parse trees, and expert-systems rules. A collection of facts about an individual object can easily be represented in the property list that is associated with the symbol representing the concept. The property list is simply a list of attribute-value pairs. The fact that both data and procedures are represented as lists makes it possible to integrate declarative and procedural knowledge into a single data structure such as a property list.

Although symbols and lists are central to many artificial intelligence programs, other data structures such as arrays and strings are also often necessary.

The most natural Lisp control structure is recursion, which often represents the most appropriate control strategy for many problem-solving tasks.

Moreover, Lisp has the ability to treat its code as data. Researchers have exploited this capability of the Lisp program to modify themselves at runtime for research in machine learning, natural-language understanding, and other aspects of AI. Lisp implementation also encourages an interactive style of development ideally suited to exploring solutions for difficult or poorly specified problems. This is of crucial importance in an AI application area where the problems are too hard to be solved without human intervention.

Perhaps the most successful artificial intelligence application in the business world is expert system technology. Lisp is tailored to expert system creation because the language is rich, with its flexible list data type and excellent support for recursion, because it is extensible, and has facilities for rapid prototyping, which lets the implementer experiment with design and customize the expert system. Programmers can use the built-in list data type for easy creation of the data structures necessary to represent parameters, rules, premise clauses, conclusion actions, and other objects that constitute the knowledge base. Even the expert systems that could process a wealth of expertise about such esoteric disciplines as chemistry, biology, and avionics and handle a complex and rapidly changing process in real time have been built into Lisp. A Lisp-based expert system shell G2, manufactured by Gensym of Cambridge, MA, has been used all around the world for building real-time expert systems. Even the most complex applications like space-shuttle fault-diagnosis or launch-operation support have been Lisp-based (15).

It is important to remember that Lisp can be an explorative language rather than a product producing one. Lisp is a marvelous research language that gives a programmer the ability to create and experiment without paying attention to the data types of variables or the way memory is allocated.

Lisp has strengths and weaknesses. It has had some real successes but also some real problems that still have to be solved (14). Nevertheless, it should be part of the toolkit of any professional AI programmer, particularly of those who routinely construct a very large and complex expert system.

NEW AI LANGUAGES

AI languages that emerged after Lisp and Prolog can be roughly classified into several categories, with no strict boundaries between them (i.e., the same language can belong to more than one group):

- Lisp-like languages
- Prolog-like languages
- Hybrid languages
- Object-oriented languages
- Agent-oriented languages
- Semantic Web languages
- Specialized programming languages

Being the first AI programming language and one of the first programming languages at all, Lisp became an ancestor of numerous incarnations of this popular language [Allegro CL (16), ECoLisp (17), Kali Scheme (18), RScheme (19), Screamer (20), etc.]. Allegro CL powered by Common Lisp is an object-oriented development system used for dynamic servers, Web services, knowledge management, data mining, smart data integration, and manufacture control. ECoLisp (Embeddable Common Lisp) is an implementation of Common Lisp designed for embedding into C-based applications. Kali Scheme is a distributed implementation of Scheme dialect of Lisp that permits efficient transmission of higher order objects such as closures and continuations. The integration of distributed communication facilities within a higher order programming language engenders several new abstractions and paradigms for distributed computing. RScheme is another object-oriented, extended version of the Scheme language that can be translated to C easily, and then compiled with a standard C compiler to generate machine code. Screamer is an extension of Common Lisp augmented with practically all of the functionality of both Prolog and constraint logic programming languages.

Prolog has also been extended and augmented numerous times [Ciao Prolog (21), GNU Prolog (22), Amzi! Prolog (23), etc.]. Ciao Prolog is a complete Prolog system with a novel modular design that allows both restricting and extending of the language. Ciao Prolog extensions currently include feature terms (records), higher order functions, constraints, objects, persistent predicates, a good base for distributed execution (agents), and concurrency. Libraries support Web programming, sockets, and external interfaces (C, Java, TCL/Tk, relational databases, etc.). GNU Prolog offers various extensions useful in practice (global variables, OS interface, sockets, etc.). In particular, it contains an efficient constraint solver over finite domains (FDs). This facilitates constraint logic programming, combining the power of constraint programming with the declarative nature of logic programming. The key feature of the GNU Prolog solver is the use of a single (low-level) primitive to define all (high-level) FD constraints. Amzi! Prolog offers a variety of rule-based components (configuration and pricing rules for products and services, government regulations for industry, legal and tax rules for forms filing, workflow rules for optimal customer service, diagnostic rules for problem-solving, integrity-checking rules with databases, parsing rules for documents, tuning rules with performance-sensitive applications, advisory rules with help systems, business rules with any commercial application) that can be easily embedded into Web applications.

Although Prolog is the first and most popular logic programming language, some other languages also fall into this category [e.g. Gödel (24), Mercury (25), etc.]. Gödel is a declarative, general-purpose programming language belonging to the family of logic programming languages. It is a strongly typed language, where the type system is based on many-sorted logic with parametric polymorphism. Gödel supports infinite precision integers, infinite precision rational numbers, and floating-point numbers. It can solve constraints over finite domains of integers and linear rational constraints, and it supports processing of finite sets. It also has a flexible computation rule and a pruning operator that generalizes the commit of the concurrent logic programming languages. Mercury is a new logic programming language, which is purely declarative. Like Prolog and many other logic programming languages, it is a high-level language that allows programmers to concentrate on the problem rather than on the low-level details such as memory management. Unlike Prolog, which is oriented toward exploratory programming, Mercury is designed for the construction of large, reliable, efficient software systems by teams of programmers.

A few hybrid AI programming languages combine different programming paradigms, such as JEOPS (26), Kiev (37), CLIPS (28), and Jess (29). JEOPS, The Java Embedded Object Production System, is a programming language intended to give Java the power of production systems. JEOPS extends Java by adding forward chaining, first-order production rules through a set of classes designed to provide this language with some kind of declarative programming. These features enable the development of intelligent applications, such as software agents or expert systems. The Kiev programming language is a backward-compatible extension of Java that includes support for lambda-calculus closures (i.e., functional programming) and Prolog-like logic programming. CLIPS is an expert system tool that provides a complete environment for the construction of rule-and/or object-based expert systems. It provides a cohesive tool for handling a wide variety of knowledge with support for three different programming paradigms: rule-based, object-oriented, and procedural. Jess is a rule engine and scripting environment written entirely in Java, originally inspired by CLIPS. It extends CLIPS by including backward chaining, working memory queries, and the ability to manipulate and reason upon Java objects.

Object-oriented programming languages [Eiffel, C++, Java, Python (30), Jython (31), etc.] are based on abstract data structures called classes. A class is used to represent data but also a behavior of that class, defined by its main operations often called methods. One of the most important characteristics of object-oriented programming languages is the ability to build hierarchies of classes and subclasses, where subclasses can inherit properties of their superclasses, which supports modularity and reusability. Among object-oriented languages, Java has recently become very popular in some areas of AI, especially for agent-based application, Internet search engines (and Internet applications in general), and data mining. Java supports automatic garbage collection and a multithreading mechanism, which makes it interesting from an AI perspective. Other popular object-oriented languages are Python and its Java version, Jython. These languages have been used in natural language processing, machine learning, constraint satisfaction, genetic algorithms, and expert systems. They are portable, interpretable, object-oriented languages. They use modules, classes, exceptions, very high-level dynamic data types, and dynamic typing. New built-in modules written in C, C++, or Java can be easily added.

During the last decade, Web applications and Web programming have been constantly gaining in popularity, and the AI community did not stay away from this trend. New fields such as intelligent agents and semantic Web emerged with the corresponding supporting programming languages. In the field of intelligent agents there are several programming languages such as APRIL (32) and Mozart (33). APRIL is a symbolic programming language, which is designed for writing mobile, distributed, and agent-based systems especially in a Web environment. It has the following advanced features such as a macro sublanguage, asynchronous message sending and receiving, code mobility, pattern matching, higher order functions, and strong typing. The Mozart Programming System is an advanced development platform for intelligent, distributed applications, which provides support in two areas: open distributed computing and constraint-based inference. Mozart is based on Oz language, which supports declarative programming, object-oriented programming, constraint programming, and concurrency as a part of a coherent whole, suitable for developing multiagent systems. Mozart is used for both general-purpose distributed applications as well as for hard problems requiring sophisticated optimization and inference abilities. It can be used to develop applications in different domains such as scheduling and time-tabling, placement and configuration, natural language and knowledge representation, multiagent systems, and sophisticated collaborative tools.

In the area of semantic Web several new ontology and schema languages such as XOL (34), SHOE (35), OML (36), RDFS (37), DAML+OIL (38), and OWL (39) have appeared. XOL is an XML-based ontology-exchange language, which was initially designed for exchange of bioinformatics ontologies, but it can also be used for ontologies in any domain. XOL is a language with the semantics of object-oriented knowledge representation systems but with XML syntax. SHOE (Simple HTML Ontology Extensions) is a small extension to HTML, which allows Web page authors to annotate their Web documents with machine-readable knowledge. OML (Ontology Markup Language) is based on description logics and conceptual graphs and allows representing concepts, organized in taxonomies, relations, and axioms in first-order logic. RDFS (RDF Schemas) is an extension of the RDF (Resource Description Framework). It is a declarative representation language influenced by ideas from knowledge representation (e.g., semantic nets, frames, and predicate logic) as well as database schema specification languages and graph data models. DAML+OIL is a semantic markup language for Web resources. It was built on earlier W3C standards such as RDF and RDF Schema, and it extends these languages with richer modeling primitives. DAML+OIL provides modeling primitives commonly found in frame-based languages. The Web Ontology Language (OWL) is a semantic markup language for publishing and sharing ontologies on the Web. OWL is developed as a vocabulary extension of RDF and is derived from the DAML+OIL.

The OWL, Web Ontology Language, is intended to be used when the information contained in documents needs to be processed by applications, as opposed to situations where the content only needs to be presented to humans. OWL can be used to explicitly represent the meaning of terms in vocabularies and the relationships between those terms. This representation of terms and their interrelationships is called an ontology. OWL has more facilities for expressing semantics than XML, RDF, and RDF Schema (RDF-S), and thus OWL goes beyond these languages in its ability to represent machine-interpretable content on the Web. OWL is a revision of the DAML+OIL Web ontology language incorporating lessons learned from the design and application of DAML+OIL.

OWL is part of the growing stack of W3C recommendations related to the semantic Web:

- XML provides a surface syntax for structured documents but imposes no semantic constraints on the meaning of these documents.
- XML Schema is a language for restricting the structure of XML documents and also extends XML with data types.
- RDF is a data model for objects ("resources") and relations between them, provides a simple semantics for this data model, and these data models can be represented in an XML syntax.
- RDF Schema is a vocabulary for describing properties and classes of RDF resources, with a semantics for generalization-hierarchies of such properties and classes.
- OWL adds more vocabulary for describing properties and classes: among others, relations amang classes (e.g., disjointedness), cardinality (e.g., "exactly one"), equality, richer typing of properties, characteristics of properties (e.g., symmetry), and enumerated classes.

OWL provides three increasingly expressive sublanguages designed for use by specific communities of implementers and users.

- *OWL Lite* supports those users primarily needing a classification hierarchy and simple constraints.

- *OWL DL* supports those users who want the maximum expressiveness while retaining computational completeness (all conclusions are guaranteed to be computable) and decidability (all computations will finish in finite time).
- *OWL Full* is meant for users who want maximum expressiveness and the syntactic freedom of RDF with no computational guarantees.

Each of these sublanguages is an extension of its simpler predecessor, both in what can be legally expressed and in what can be validly concluded. Ontology developers adopting OWL should consider which sublanguage best suits their needs. The choice between OWL Lite and OWL DL depends on the extent to which users require the more expressive constructs provided by OWL DL. The choice between OWL DL and OWL Full mainly depends on the extent to which users require the meta-modeling facilities of RDF Schema (e.g., defining classes of classes or attaching properties to classes). When using OWL Full as compared with OWL DL, reasoning support is less predictable because complete OWL Full implementations do not currently exist. OWL Full can be viewed as an extension of RDF, whereas OWL Lite and OWL DL can be viewed as extensions of a restricted view of RDF. Every OWL (Lite, DL, Full) document is an RDF document, and every RDF document is an OWL Full document, but only some RDF documents will be a legal OWL Lite or OWL DL document.

Specialized programming languages, such as DHARMI (40), ECLiPSe (41), Esterel (42), and Shift (43), are used to solve specific problems in different AI domains. DHARMI is a high-level spatial language whose components are transparently administered by a background process called the Habitat. The language was designed to make modeling prototypes and handle living data. Programs can be modified while running, which is accomplished by blurring the distinction among source code, program, and data. ECLiPSe is a programming language for the cost-effective development and deployment of constraint programming applications, e.g., in the areas of planning, scheduling, resource allocation, timetabling, and transport. It contains several constraint problem-solver-libraries, a high-level modeling and control language, interfaces to third-party solvers, an integrated development environment, and interfaces for embedding into host environments. Esterel is a synchronous programming language dedicated to control-dominated reactive systems, such as control circuits, embedded systems, human–machine interface, or communication protocols. Shift is a programming language aimed at describing dynamic networks of hybrid automata. Such systems consist of components that can be created, interconnected, and destroyed as the system evolves. Components exhibit hybrid behavior, consisting of continuous-time phases separated by discrete-event transitions. Components may evolve independently, or they may interact through their inputs outputs, and exported events. The interaction network may also evolve.

Many of the recently emerged AI languages could not be covered here because of the imposed constraints on the length of the contribution.

AUTONOMY-ORIENTED COMPUTING (AOC)

INTRODUCTION

Programming Paradigms

In computer science, several major programming paradigms exist, including *imperative, functional, logic*, and *object-oriented* paradigms. The imperative paradigm embodies computation in terms of a program state and statements for updating the program state. An imperative program specifies a sequence of commands for a computer to perform. In contrast to the imperative paradigm, the functional paradigm handles computation by means of evaluating a series of functional expressions rather than the execution of commands. Both the imperative and the functional paradigms emphasize the mapping between inputs and outputs. On the other hand, the logic paradigm represents a set of rules and facts and then finds a solution based on automated theorem proving. The object-oriented paradigm may be regarded as an extension of the imperative paradigm by encapsulating variables and their operations into classes. In the field of multiagent systems. Shoham proposed an *agent-oriented programming paradigm*(1) where the basic unit is an agent characterized by a set of mental attributes, such as beliefs, commitments, and choices.

Autonomy-Oriented Computing (AOC): A New Paradigm

This article describes a new programming paradigm called *autonomy-oriented computing* (AOC), which focuses on the construct of synthetic autonomy in locally interacting entities, and uses the aggregated effects of entity interactions to generate desired global solutions or systems dynamics. The fundamental working mechanism of *self-organization* that underlies the AOC paradigm offers the advantages of natural formulation as well as scalable performance to characterize complex systems or to handle computationally hard problems that are distributed and large scale in nature.

AOC versus OOP and AOP. Table 1 presents a brief comparison among object-oriented programming (OOP), agent-oriented programming (AOP), and AOC. We elaborate their essential differences as follows.

1. *Components:* Unlike OOP and AOP, AOC builds on the basic units of autonomous entities and the environment in which they reside. Autonomous entities are characterized by their internal state and goals, and are equipped with an evaluation function, self-organizing behavior, and behavioral rules. Here, *autonomous* means that an entity behaves and makes decisions to change its internal state without control from other entities or an external *commander*. The autonomous entities in AOC are not as complex, i.e., having mental attributes, as agents in AOP.
2. *Computation Philosophy:* In both OOP and AOP, the computation is embodied as a process of message passing and responses among objects or agents. Particularly, in AOP, the computation involves some techniques of artificial intelligence, such as knowledge representation, inference, and reasoning mechanisms. AOP is suitable for modeling distributed systems (e.g., workflow management) and for solving distributed problems (e.g., transport scheduling) (2).

The computation in AOC, on the other hand, relies on the self-organization of autonomous entities. Entities directly or indirectly interact with each other or with their environment to achieve their respective goals. As entities simultaneously behave and interact, the results of entity interactions will be aggregated nonlinearly. The aim of an AOC system is to find a solution through the nonlinear aggregation of local interactions. For instance, in the case of computational problem solving, the emergent AOC system states may correspond to the solutions of a problem at hand. Generally speaking, AOC works in a bottom-up manner, somewhat like the working mechanism of nature. It is one of the reasons why AOC is well suited to characterize the behavior of complex systems and to solve computationally difficult problems.

MOTIVATIONS AND GOALS OF AUTONOMY-ORIENTED COMPUTING

Nature is full of complex systems that exhibit interesting behavior (3,4). Scientists and researchers are interested in modeling complex systems primarily for two reasons: (*1*) to discover and to understand the underlying working mechanism of a complex system concerned, and (*2*) to simulate and to use the observed complex behavior to formulate problem-solving strategies such as global optimization. In general, one wants to be able to *explain, predict, reconstruct*, and *deploy* a complex system. Computer scientists and mathematicians have, in the past, developed various nature-inspired algorithms to solve their problems at hand.

Common techniques for complex systems modeling can be divided broadly into top-down and bottom-up approaches. Top-down approaches start from the high-level system and use various techniques such as ordinary and partial differential equations (5–7). These approaches generally simplify the behavior of individuals in a complex system and tend to model the average case well, where local variations in the behavior are minimal and can be ignored (8). However, such approaches are not always applicable. For instance, the distribution of antibodies in the human

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Table 1. A Comparison Among OOP, AOP [Shoham (1)], and AOC

	OOP	AOP	AOC
Basic unit	object	agent	autonomous entity and environment
Attributes of basic unit	member variables and member functions	beliefs, decisions, capabilities, and obligations	states, evaluation function, goals, self-organizing behavior, and behavioral rules
Computation	message passing and response methods	message passing and response methods	(i) self-organization of autonomous entities and (ii) self-aggregation of entities behavior and interaction
Interaction	inheritance and messages among objects	messages among agents, including inform, request, offer, promise, decline, etc.	(i) interaction between entities and their environment and (ii) direct/indirect interaction among entities
Constraints on methods	none	honesty, consistency, etc.	behavioral rules
Suitability	modeling and decomposition	(i) modeling distributed systems and (ii) solving distributed problems (2)	(i) characterizing the behavior of complex systems and (ii) solving computationally difficult problems

immune system tends to be heterogeneous. Therefore, the use of differential equations cannot accurately describe the emergent behavior and dynamics in such a biologic system (9). On the other hand, bottom-up approaches (10–13) start from the smallest element of a complex system and take into consideration the following characteristics of entities in the system:

- *Autonomous:* Entities are individuals with bounded rationality that will act independently. No central controller exists to direct and coordinate individual entities.
- *Distributed:* Autonomous entities with localized reactive or decision-making capabilities are distributed in a heterogeneous environment, and interact locally among themselves to exchange their state information or to affect the states of others.
- *Emergent:* Distributed autonomous entities collectively exhibit complex (purposeful) behavior that is not present nor predefined in the behavior of entities in a system.
- *Adaptive:* Entities often change their behavior in response to changes in the environment in which they are situated.
- *Self-organized:* Through entity interactions, the system self-aggregates and amplifies certain outcomes of entity behavior. In other words, autonomous entities can self-organize to evolve some system-level emergent behavior.

AOC is a bottom-up approach to characterize the behavior of complex systems and to solve computationally difficult problems. Specifically, AOC has three goals: The first goal is *to reproduce life-like behavior in computation.* With detailed knowledge of the underlying mechanism, simplified life-like behavior can be used as the model for general-purpose problem-solving techniques. The second goal is *to study the underlying mecnanism of a real-world complex system* by hypothesizing and repeated experimentation. The end product of these simulations is a better understanding of, or explanations to, the real working mechanism of the modeled system. The third goal concerns *the emergence of a problem solver in the absence of human intervention*. In other words, self-adaptive, self-discovery algorithms are desired.

THREE GENERAL APPROACHES TO AUTONOMY-ORIENTED COMPUTING

To build an AOC-based model, we need to carry out the following steps:

1. Observe the macroscopic behavior of a natural system.
2. Design entities with desired synthetic behavior as well as an environment where entities reside.
3. Observe the macroscopic behavior of the artificial system.
4. Validate the behavior of the artificial system against the natural counterpart.
5. Modify (*2*) in view of (*4*).
6. Repeat (*3*)–(*5*) until the result is satisfactory.
7. Find out a model/origin of (*1*) in terms of (*2*) or apply the derived model to solve problems.

AOC is intended to reconstruct, to explain, and to predict the behavior of complex systems, which is hard to model or compute using top-down approaches. Local interactions between autonomous entities are the primary driving force of AOC. Formulation of an autonomy-oriented computational system involves an appropriate analogy, which normally comes from nature. Employing such an analogy, therefore, requires identification, abstraction, and reproduction of a certain natural phenomenon. The process of abstraction inevitably involves certain simplification of the natural counterpart. An abstracted version of some natural phenomena is the starting point of AOC, such that the problem at hand can be recasted. In the following subsections, we present three main approaches of AOC in detail.

AOC-By-Fabrication

AOC-by-fabrication is intended to replicate certain self-organizing behavior observable in the real world to form a general-purpose problem solver. The operating mechanism is more or less known and may be simplified during the modeling process. Research in artificial life (Alife) (10) is related to this AOC approach up to the behavior replication stage. Nature-inspired techniques such as ant systems (14) and evolutionary algorithms (15,16) are typical examples of such an extension.

Building on the experience of complex systems modeling, AOC algorithms are used to solve computationally hard problems. For example, in the commonly used version of genetic algorithms (16) that belong to the family of evolutionary algorithms, the process of sexual evolution is simplified to selection, recombination, and mutation, without the explicit identification, of male and female in the gene pool. Evolutionary programming (15) and evolution strategy (17), on the other hand, are closer to asexual reproduction with the addition of constraints on mutation and the introduction of mutation operator evolution, respectively. Despite these simplifications and modifications, evolutionary algorithms still capture the essence of natural evolution and are proven global optimization techniques.

As a demonstration of the AOC-by-fabrication approach, Liu et al. have developed an autonomy-oriented algorithm for image segmentation which identifies homogeneous regions within an image (18,19). Autonomous entities are deployed to a 2-D grid representation of an image. Each entity is equipped with the ability to assess the homogeneity of the region within a predefined locality. When a nonhomogeneous region is found, the autonomous entity will diffuse to another pixel in a certain direction within the local region. In contrast, when an entity locates a homogeneous region within the range of the pixel it currently resides, it replicates (breeds) itself to give rise to a certain number of offspring entities, and delivers them to its local region in a certain direction. The breeding behavior enables the newly created offspring to be distributed near the pixels where the region is found to be homogeneous, so that it is more likely to find the extension to the current homogeneous region. Apart from breeding, the entity will also label the pixel found to be homogeneous. If an autonomous entity fails to find a homogeneous region during its lifespan (a predefined number of steps) or wanders off the search space during diffusion, it will be marked inactive. In essence, the stimuli from the pixels will direct the autonomous entities to two different behavioral tracts: breeding and pixel labeling, or diffusion and decay. The directions of breeding and diffusion are determined by their respective behavioral vectors, which contain weights (between 0 and 1) of all possible directions. The weights are updated by considering the number of successful siblings in the respective directions. An entity is considered to be successful if it has found one or more pixels that are within a homogeneous region during its lifetime. A similar technique also has been applied to a feature extraction task such as border tracing and edge detection (20).

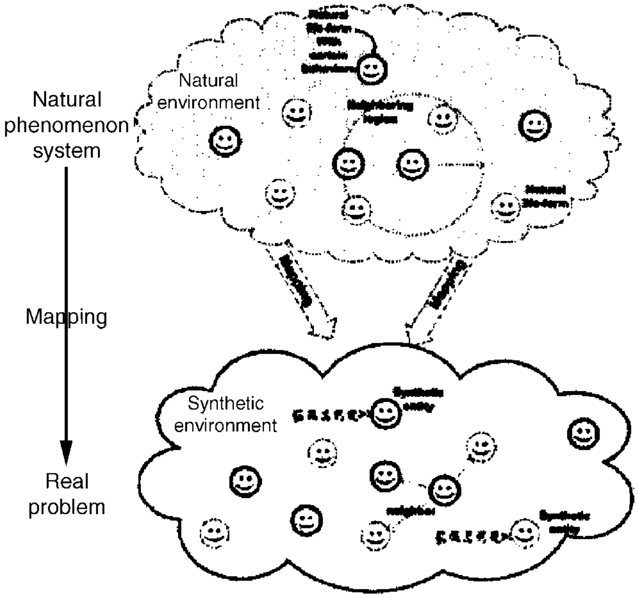

Figure 1. A schematic diagram of the AOC-by-fabrication approach, which is intended to build a mapping between a real problem and a natural phenomenon/system (21). In the figure, entities are characterized by a set of attributes (e.g., G, B, S, F, and R).

In general, the AOC-by-fabrication approach focuses on building a mapping between a real problem and a natural phenomenon/system, the working mechanism behind which is usually more or less known (see Fig. 1). In the mapping, the synthetic entities and their parameters (e.g., states or behavior) correspond, respectively, to the natural life-forms and their properties. Ideally, some special states of the natural phenomenon/system correspond to the solutions of the real problem. In particular, the AOC-by-fabrication approach has the following common characteristics:

1. There is a population of individuals, each of which is mainly characterized by its state, goals, self-organizing behavior, and behavioral rules. Individuals may be homogeneous or heterogeneous. Even in the homogeneous case, individuals may differ in certain detailed parameters.
2. The composition of the population may change over time, by the process analogous to birth (amplification of the desired behavior) and death (elimination of the undesired behavior). But, in some applications, the population has the fixed number of entities.
3. Tne interactions between individuals are local; neither global information nor central executive to control behavior or interactions is needed.

4. The environment acts as the center of information relating to the current status of the problem and as a place holder for information sharing between individuals.
5. The local goals of individuals drive the selection of local behavior at each step.
6. The global goal of the whole system is implicitly represented by the combination of all individuals' local goals or a universal fitness function, which measures the progress of the computation.

AOC-by-Prototyping

AOC-by-prototyping is a common AOC approach to understand the operating mechanism underlying a complex system. It models the system by simulating certain observed behavior, through characterizing the construct of synthetic autonomy in entities. Usually, AOC-by-prototyping involves a trial-and-error process to eliminate the difference between a prototype and its natural counterpart. Examples of this approach include the study of Internet ecology, traffic jams, and web log analysis. This AOC approach relates to multiagent approaches to complex systems in the field of distributed artificial intelligence.

With the help of a blueprint, we can build a model of a system in an orderly fashion. With insufficient knowledge about the mechanism of how the system works, it is difficult, if not impossible, to build such a model. Assumptions about the unknown workings have to be made to get the process started. We can verify the model by comparing its behavior with some observed behavior of the desired system. This process will have to be repeated several times before a good, probably not perfect, prototype is found. Apart from obtaining a working model of the desired system, an important by-product of the process is the discovery of the mechanisms that are unknown when the design process first started. This view is shared by researchers developing and testing theories about human cognition and social phenomena.

Liu et al. (22) and (23) have illustrated the AOC-by-prototyping approach to characterize the regularities of web surfing. They propose a web surfing model, which takes into account the characteristics of users, such as interest profiles, motivations, and navigation strategies. They view users as *information foraging entities* inhabiting the web space. The web space is a collection of websites connected by hyperlinks. Each website contains certain information contents, and each hyperlink between two websites signifies certain content similarity between them. The contents contained in a website are characterized by using a multidimensional *consent vector* where each component corresponds to the relative information weight on a certain topic. The web space is generated by assigning topics to each web page according to a certain statistical distribution. The variance of the distribution controls the similarity of the pages.

Liu and Zhang (23) have simulated users in the system by associating with them an *interest vector*, again generated randomly based on a statistical distribution with certain variance. Therefore, a parameter controls the degree of overlap in interest between users. When an information foraging entity finds certain websites in which the content is close to its interested topic(s), it will get more *motivated* to *surf* deeper. On the other hand, when the entity does not find any interesting information after some foraging steps or it has found enough contents to satisfy its interests, it will stop foraging and leave the web space. To model such a motivation-driven foraging behavior, they introduce a support function, which serves as the driving force for an entity to forage further. When the entity has found some useful information, it will get rewarded, and thus the support value will be increased. As the support value exceeds a certain threshold, which implies that the entity has obtained a sufficient amount of useful information, the entity will stop foraging. On the contrary, if the support value is too low, the entity will lose its motivation to forage further and thus leave the web space.

In summary, AOC-by-prototyping is used to uncover the working mechanism behind a natural phenomenon/system. In doing so, at the beginning, a preliminary prototype will be built to characterize or to simulate the natural counterpart. Then, by observing the difference between the natural phenomenon/system and the synthetic prototype, a trial-and-error process will be involved to fine-tune the prototype, especially the related parameters, to adjust the behavior of the synthetic entities. Figure 2 presents a schematic diagram of the process of AOC-by-prototyping.

In a sense, AOC-by-prototyping can be observed as an iterated application of AOC-by-fabrication with the addition of parameter tuning at each iteration. The difference between the desired behavior and the actual behavior of a prototype is the guideline to parameter adjustment. The process can be summarized, with reference to the summary of AOC-by-fabrication, as follows:

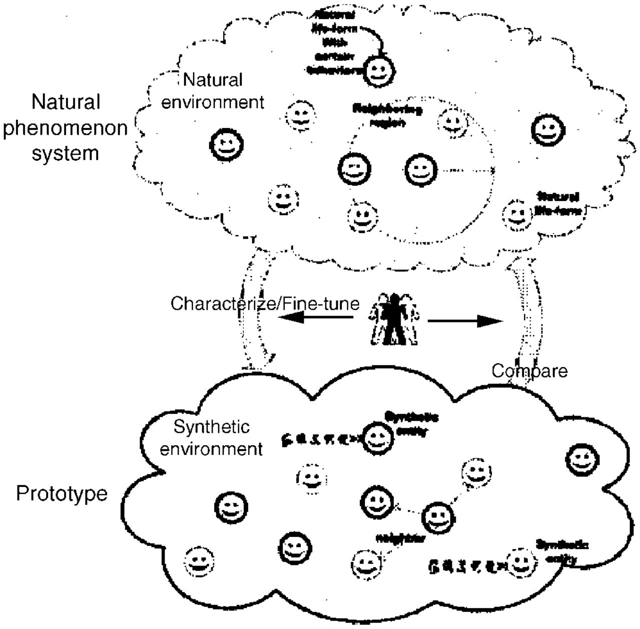

Figure 2. A schematic diagram of the process of AOC-by-prototyping, where the trial-and-error process, i.e., repeated *fine-tune* and *compare* steps, will be manually operated (as symbolized in the figure) (21).

1. The state, evaluation function, goals, self-organizing behavior, and behavioral rules of an entity can be changed from one prototype to the next.
2. The definition of the environment can also be changed from one version to the next.
3. There is an additional step to compare the synthetic model with the natural counterpart.
4. A new prototype is built by adopting (*1*) and (*2*) above, and by repeating the whole process.

AOC-by-Self-Discovery

AOC-by-self-discovery emphasizes the ability of an AOC-based computational system to find its own way to achieve what AOC-by-prototyping can do. The ultimate goal is to have a fully automated algorithm that can adjust its own parameters for different application domains. In other words, the AOC becomes autonomous. Some evolutionary algorithms that exhibit a self-adaptive capability are examples of this approach.

As inspired by diffusion in nature, Tsui and Liu (24,25) have developed an AOC-based method, called *evolutionary diffusion optimization* (EDO), to tackle a global optimization task. A population of entities is used to represent candidate solutions to the optimization problem at hand. The goal is to build a collective view of the landscape of the search space by sharing information among entities. Specifically, each entity performs a search in its local proximity, and captures the "direction" information of the landscape in a *probability matrix*—the likelihood estimate of success with respect to the direction of search in each object variable.

EDO defines three types of local behavior for each entity, namely *diffuse*, *reproduce*, and *aging*. Free-ranging entities that are searching for a position better than their birthplaces are called *active* entities. Those entities that already have become parents are called *inactive* entities.

Entities in EDO explore uncharted locations in the solution space by *diffusion*. *Rational move* refers to the kind of diffusion where an entity modifies its object vector by drawing a random number for each dimension of the object vector. Each random number is then used to choose between the set of fixed steps according to the probability matrix. An adjustment is then made by adding the product of the number of steps and the size of a step to the entry in question in the object vector. This process is repeated until all dimensions of the object vector are covered. The updated object vector then becomes the new position of the entity in the solution space. As an entity becomes older, it becomes more eager to find a better position. Therefore, it will decide probabilistically to act wild and to take a *random walk*. An entity will first choose randomly a direction of diffusion for each dimension, i.e., either no change, toward the upper bound, or toward the lower bound. In case a move is to be made, a new value between the chosen bound and the current value is then picked randomly. The process ends when all dimensions of the object vector are updated.

At the end of an iteration, the fitness of all active entities are compared with that of their parents, which have (temporarily) become inactive. All entities with higher fitness will *reproduce* via asexual reproduction—a reproducing entity replicates itself a number of times and sends the new entities off to new locations by rational moves. Parents and their offspring share the same probability matrix. Only when an entity becomes a parent then a new probability matrix will be created for it, which is an exact copy of the parent's updated one. Sharing the probability matrix between parents and siblings enables entities from the same family to learn from each other's successes as well as failures.

Aging is the process by which consistently unsuccessful entities are eliminated from the system. It is controlled by a *lifespan* parameter. Exceptions are granted to those entities whose ages have reached the set limit but that have the above-average fitness. On the other hand, entities whose fitness is at the lower 25% of the population will be eliminated before their lifespan expires.

Search algorithms need a scheme to implement the strategy that says "good" moves need to be rewarded while "bad" moves should be discouraged. All entities in EDO maintain a close link between parents and offspring via sharing the probability matrix. Therefore, it is very easy for EDO to implement the above strategy, and EDO has two feedback mechanisms for updating the probability matrix of the parent. *Positive feedback* increases the value of the entry in the probability matrix that corresponds to the "good" move. In contrast, *negative feedback* reduces the relevant probabilities that relate to the "bad" move. Although negative feedback is exercised after each diffusion, positive feedback can take place only after an entity has become a parent. Note also that all probabilities are normalized using their respective sum after updating.

EDO also adapts the *step-size* parameter, which determines the amount of change during *diffusion*, over time based on the performance measurement of the population. *Step-size* is reduced if the population has not improved over a period of time. Conversely, if the population has been improving continuously for some time, *step-size* is increased. The rationale is that the entities in the neighborhood of a minimum value need to make finer steps for careful exploitation, whereas using a large *step-size* during a period of continuous improvement attempts to speed up the search.

AOC-by-self-discovery can be used not only to build a mapping between a real problem and a certain natural phenomenon/system, but also to reveal the operating mechanism behind a natural phenomenon/system. In general, it combines the uses of AOC-by-fabrication and AOC-by-prototyping. In its implementation, AOC-by-self-discovery is the same as AOC-by-prototyping except that the process of trial-and-error in AOC-by-self-discovery is automated (see Fig. 3). The full automation of the prototyping process is achieved by having an autonomous entity to control another level of autonomous entities. The example described above shows that AOC-by-self-discovery is indeed a viable proposition. The steps for engineering this kind of AOC algorithm is the same as those stated, with the addition of one rule:

- System parameters are self-adapted according to some performance measurements.

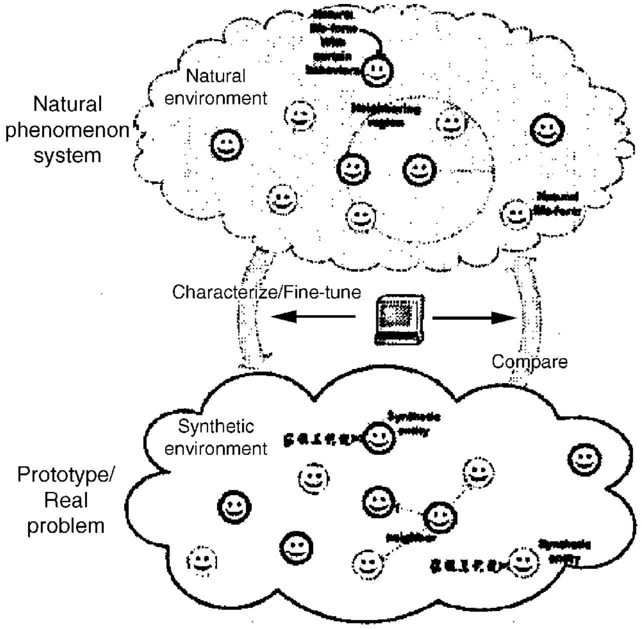

Figure 3. A schematic diagram of the process of AOC-by-self-discovery (21). As compared with AOC-by-prototyping (see Fig. 2), here the trial-and-error process, i.e., repeated *fine-tune* and *compare* steps, is automatically implemented by the system (as symbolized in the figure).

IMPORTANT CONCEPTS REVISITED

In this section, we will summarize the article by highlighting some of the key modeling concepts that we have introduced in the preceding descriptions of AOC approaches.

The Environment

As one of the main components in an AOC system, the environment usually plays three roles. First, the *environment* serves as the domain in which autonomous entities roam. This is a static view of the environment. Second, the environment acts as the *noticeboard* where the autonomous entities can read and/or post local information. In this sense, the environment can also be regarded as an indirect communication medium among entities. This is the dynamic view of the environment. Third, the environment also keeps the central clock that helps synchronize the behavior of all autonomous entities, if necessary.

Autonomous Entities

An autonomous entity possesses a way to find out what is going on with other entities as well as with the environment. As a result, it will modify its own state, exert changes to the environment, and/or affect other entities. Central to an autonomous entity is its *local behavior* and *behavioral rules* that govern how it should act or react to the information collected from the environment and its neighbors. The local behavior and behavioral rules determine to which state the entity will transit.

In different AOC systems, the neighbors of an entity can be fixed or dynamically changed.

At each moment, an entity is in a certain state. It, according to its behavioral rules, selects and performs its behavior to achieve certain goals with respect to its state. In doing so, it needs to interact with its neighbors and/or its environment to get the necessary information.

Interactions in an AOC System

The emergent behavior of an AOC system originates from its internal interactions. Generally speaking, there are two types of interactions, namely, *interactions between entities and their environment* and *interactions among entities*.

The interactions between an entity and its environment are implemented through state transitions as caused by the entity's self-organizing behavior.

Different AOC systems may have different ways of interactions among their entities. Those interactions can be categorized further into two categories: direct and *indirect* interactions. Direct interactions are implemented through direct state information exchanges among entities. In an AOC system with direct interactions, each entity can interact with its *neighbors*. Indirect interactions are implemented through the communication medium role of the environment. They can be carried out in two stages: (*1*) through the interactions between an entity and its environment, the entity will "transfer" its information to the environment, and (*2*) other entities will consider the information that has been "transfered" to the environment by the previous entity.

For further readings on AOC, e.g., more comprehensive surveys of related work, formal descriptions of the AOC approaches and formulations, and detailed discussions of examples as mentioned in this article, please refer to Refs. (21) and (26).

BIOINFORMATICS

INTRODUCTION

Almost all genetic information is stored in genome sequences. Genome sequences have been determined for many species, including humans, and thus huge amounts of sequence data have been obtained. Furthermore, a large amount of related data such as three-dimensional protein structures and gene expression patterns have also been produced. To analyze these data, we need new computational methods and tools. One major goal of *bioinformatics* is to develop such methods and tools, whereas another major goal of bioinformatics is to discover new biological knowledge using such kinds of tools. *Computational biology* is regarded as almost synonymous with bioinformatics. Although the difference between these two terms is very unclear, it seems that computational biology focuses on computational methods and on the actual process of analyzing and interpreting data.

Here, we overview important topics in bioinformatics: comparison of sequences, motif discovery, hidden Markov models (HMMs), protein structure prediction, kernel methods for bioinformatics, and analysis of gene expression patterns. Readers interested in more details may refer to the following textbooks (1–3) and handbook (4).

COMPARISON OF SEQUENCES

Comparison of two or multiple sequences is a fundamental and important problem in bioinformatics (1–3) because if two sequences of DNA or protein are similar to each other, it is expected that these DNAs or proteins have similar functions. Although there are many variants, we define here a basic version (global multiple alignment under the Sum-of-Pairs scoring scheme with linear gap costs) of the problem formally. Let $s_1, s_2, \ldots, s_k$ be sequences (i.e., strings) over a fixed alphabet Σ, where $k > 1$. Σ is usually either the set of bases {A, C, G, T} or the set of amino acids (i.e., $|\Sigma| = 20$). An *alignment* for $s_1, s_2, \ldots, s_k$ is obtained by inserting *gap symbols* (denoted by "– ") into or at either end of s_i such that the resulting sequences $s'_1, s'_2, \ldots, s'_k$ are of the same length l. Introduction of gaps is important because gaps correspond to insertions and deletions of bases (in DNA) or residues (in protein) that occur in the process of evolution. For example, consider three sequences CGCCAGTG, CGAGAGG, and GCCGTGG. Then examples of alignments are as follows:

M1	M2	M3
CGCCAGTG-	CGCCAGT-G	CGCCAGT-G-
CG--AGAGG	CG--AGAGG	-CGA-G-AGG
-GCC-GTGG	-GCC-GTGG	-GCC-GT-GG

In an alignment, letters in the same column correspond to each other: Bases or residues in the same column are regarded to have the same origin.

Let $f(x,y)$ be a function from $\Sigma' \times \Sigma'$ to $\mathcal{R}$ that satisfies $f(x,y) = f(y,x)$ and $f(x,-) = f(-,y) = -d$ for all $x, y \in \Sigma$ and $f(-,-) = 0$, where R denotes the set of real numbers and $\Sigma' = \Sigma \cup \{-\}$. The score for an alignment $\mathcal{M}$ is defined by

$$\mathrm{score}(\mathcal{M}) = \sum_{1 \le p < q \le k} \sum_{i=l}^{l} f(s'_p[i], s'_q[i])$$

where $s'_p[j]$ denotes the jth letter of s'_p. Then we define an *optimal alignment* to be an alignment with the maximum score. If we define $f(x,x) = 1$ and $f(x,-) = f(-,x) = -1$ for $x \in \Sigma$, $f(x,y) = -1$ for $x \neq y$, and $f(-,-) = 0$, the scores of $\mathcal{M}_1$ and $\mathcal{M}_2$ are both 3, and the score of $\mathcal{M}_3$ is -5. In this case, both $\mathcal{M}_1$ and $\mathcal{M}_2$ are optimal alignments. The alignment problem is to find an optimal alignment. It is called the *pairwise alignment* problem if $k = 2$, and otherwise, it is called the *multiple alignment* (multiple sequence alignment) problem.

An optimal alignment for two sequences can be computed in $O(n^2)$ time using a simple *dynamic programming* algorithm (1), where n is the larger length of the two input sequences. The following procedure gives the core part of the algorithm:

$$\begin{aligned} D[i][0] &= -i \cdot d, \quad D[0][j] = -j \cdot d \\ D[i][j] &= \max(D[i-1][j] - d, \quad D[i][j-1] - d, \\ &\quad D[i-1][j-1] + f(s_1[i], s_2[j])) \end{aligned}$$

where $D[i][j]$ corresponds to the optimal score between $s_1[1] \ldots s_1[i]$ and $s_2[1] \ldots s_2[j]$. An optimal alignment can also be obtained from this matrix by using the *traceback* technique (1). Many variants are proposed for pairwise alignment, among which local alignment (the Smith–Waterman algorithm) with affine gap costs is most widely used (1,3).

This algorithm is fast enough to compare two sequences. However, in the case of a *homology search* (search for homologous genes or proteins), it is required to find sequences in a database that are similar to a given sequence. For example, suppose that one determines a new DNA sequence of some gene in some organism and wants to know the function of the gene. He or she tries to find similar sequences in other organisms using a database (such as GenBank 5), which stores all known DNA sequences. If a similar sequence whose function is known is found, then he or she can infer that the new gene has a similar function. Thus, in a homology search, pairwise alignment between a query sequence and all sequences in a database should be performed. Since more than several hundreds of thousands of sequences are usually stored in a database, simple application of pairwise alignment would take a lot of time. Therefore, several heuristic methods have been proposed to speed up a database search, among which FASTA and BLAST are widely used (3). Most heuristic methods employ the following strategy: Candidate sequences having fragments (short length substrings) that are the same as (or very similar to) a fragment of the query sequence are first searched, and then

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

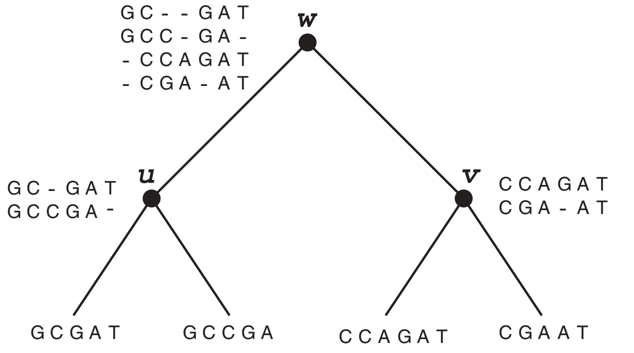

Figure 1. Progressive alignment. Pairwise sequence alignment is performed at nodes u and v, whereas profile alignment is performed at node w.

pairwise alignments are computed using these fragments as anchors. Using these methods, a homology search against several hundreds or thousands of sequences can be done in around a few minutes.

The dynamic programming algorithm above can be extended for cases of $k > 2$, but it is not practical because it takes ($O(n^k)$ time or more. Indeed, multiple alignment is known to be NP-hard if k is a part of the input (i.e., k is not fixed) (6). Thus, a variety of heuristic methods have been applied to multiple alignment that include simulated annealing, evolutionary computation, iterative improvement, branch-and-bound search, and stochastic methods (1,7).

The most widely used method employs the *progressive strategy*(1,8). In this strategy, we need an alignment between two profiles, where a profile corresponds to the result of an alignment. Alignment between profiles can be computed in a similar way to pairwise alignment: Each column is treated as if it were a letter in pairwise alignment. An outline of the progressive strategy used in CLUSTAL-W (8) is as follows (see also Fig. 1):

(i) Construct a distance matrix for all pairs of sequences by pairwise sequence alignment, followed by conversion of alignment scores into distances using an appropriate method.
(ii) Construct a rooted tree whose leaves correspond to input sequences, using a method for phylogenetic tree construction.
(iii) Progressively perform sequence–sequence, sequence–profile, and profile–profile alignment at nodes in order of decreasing similarity.

Although we have assumed that score functions were given, derivation or optimization of score functions is also important. Score functions are usually derived by taking log-ratios of frequencies (9). Since score functions obtained in this manner are not necessarily optimal, some methods have been proposed for optimizing score functions (10).

MOTIF DISCOVERY

It is very common that sequences of genes or proteins with a common biological function have a common pattern of sequences. For example, promoter regions of many genes in Eukaryotes have “TATAA” as a subsequence. Such a pattern is called a *motif* (more precisely, a sequence motif) (11,12). Motif discovery from sequences is important for inference of functions of proteins and for finding biologically meaningful regions (such as transcription factor binding sites) in DNA sequences. Although there are various ways of defining motif patterns, these can be broadly divided into *deterministic patterns* and *probabilistic patterns*(11).

Deterministic patterns are usually described using syntax similar to regular expressions. For example, “[AG]-x(2,5)-C” is a pattern matching any sequence containing a substring starting with A or G, followed by between two and five arbitrary symbols, followed by C. Deterministic patterns are usually discovered from positive examples (sequences having a common function) and negative examples (sequences not having the function). Although discovery of deterministic patterns is computationally hard (NP-hard) in general, various machine learning techniques have been applied (11).

Probabilistic patterns are considered to be more flexible than deterministic patterns, although deterministic patterns are easier to interpret. Probabilistic patterns are represented using statistical models. For example, *profiles* (also known as *weight matrices* or *position-specific score matrices*) and *hidden Markov models* are widely used (1). Here, we introduce profiles. A profile is a function $w(x, j)$ from $\Sigma \times [1\ldots L]$ to $\mathcal{R}$, where L denotes the length of subsequences corresponding to a motif, and $[1\ldots L]$ denotes the set of integers between 1 and L. It should be noted in this case that the lengths of motif regions (i.e., subsequences corresponding to a motif) must be the same and that gaps are not allowed in the motif regions. A profile can be represented by a two-dimensional matrix of size $L \cdot |\Sigma|$. A subsequence $s[i]\ldots s[i + L{-}1]$ of s is regarded as a motif if $\Sigma_{j=1,\ldots,L} w(s[i + j - 1], j)$ is greater than a threshold θ.

Various methods have been proposed in order to derive a profile from sequences $s_1, s_2, \ldots, s_k$ having a common function. One common approach is to select a subsequence t_i from each sequence s_i such that the relative entropy score (the average information content) is maximized (see Fig. 2). The relative entropy score is defined by

$$\frac{1}{L}\sum_{j=1}^{L}\sum_{a\in\Sigma} f_j(a)\log_2\frac{f_j(a)}{p(a)}$$

where $f_j(a)$ is the frequency of appearances of symbol a at the$j$th position in the subsequences (i.e., $f_j(a) = |\{i|t_i|[j] = a\}|/k$) and$p_a$ is the background probability of symbol a. In a simplest case, we may use $p(a) = \frac{1}{|\Sigma|}$.

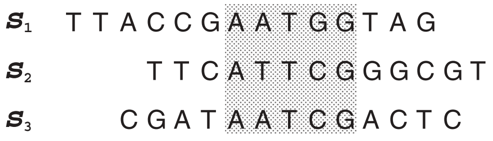

Figure 2. Motif discovery based on relative entropy score. Shaded regions correspond to t_1,t_2 and t_3 (L = 5).

Maximization of this relative entropy score is known to be NP-hard (13). On the other hand, several heuristic algorithms have been proposed based on statistical algorithms such as the expectation maximization (EM) method (14) and Gibbs sampling (12).

HIDDEN MARKOV MODELS

HMMs were originally developed in the areas of statistics and speech recognition. In the early 1990s, HMMs were applied to multiple sequence alignment (15) and protein secondary structure prediction (16). After that, the HMM and its variants were applied to solve various problems in bioinformatics. For example, HMMs have been applied to gene finding (identification of subsequences in DNA that encode genes), motif finding, and recognition of protein domains (1). One advantage of HMMs is that they can provide more detailed generative models for biological sequences than sequence alignment, although HMMs usually require longer CPU time than sequence alignment, and HMMs often need to be trained. Here, we briefly review the HMM and its application to bioinformatics. Readers interested in the details may refer to Ref. 1.

An HMM is defined by quadruplet (Σ, Q, A, E), where Σ is an alphabet (a set of symbols), $Q = \{q_0, \ldots, q_m\}$ is a set of states, $A = (a_{kl})$ is an $(m + 1) \times (m + 1)$ matrix of state transition probabilities, and $E = (e_k(b))$ is an $(m + 1) \times |\Sigma|$ matrix of emission probabilities. To be more precise, a_{kl} denotes the transition probability from state q_k to q_l, and $e_k(b)$ denotes the probability that a symbol b is emitted at state q_k. Θ denotes the collection of parameters of an HMM [i.e., $\Theta = (A, E)$], where we assume that Σ and Q are fixed based on the nature of the problem.

A *path*$\pi = \pi[1] \ldots \pi[n]$ is a sequence of (indices of) states. The probability that both π and a sequence $s = s[1] \ldots s[n]$ over Σ are generated under Θ is defined by

$$P(s, \pi | \Theta) = \prod_{i=1}^{n} a_{\pi[i-1]\pi[i]} e_{\pi[i]}(s[i]),$$

where $\pi[0] = 0$ is introduced as a fictitious state, a_{0k} denotes the probability that the initial state is q_k, and $a_{k0} = 0$ for all k.

There are three important algorithms for using HMMs: the *Viterbi algorithm*, the *forward algorithms*, and the *Baum–Welch algorithm*. The Viterbi algorithm computes the most plausible path for a given sequence. Precisely, it computes $\pi^*(s)$ defined by

$$\pi^*(s) = \arg\max_{\pi} P(s, \pi | \Theta)$$

when sequence s is given. The forward algorithm computes the probability that a given sequence is generated. It computes

$$P(s|\Theta) = \sum_{\pi} P(s, \pi | \Theta)$$

when sequence s is given. Both the Viterbi and forward algorithms are based on the dynamic programming technique. Each of these algorithms works in $O(nm^2)$ time for fixed Σ.

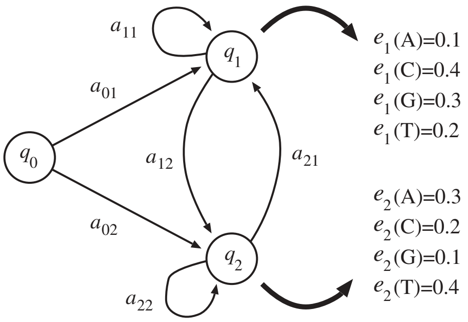

Figure 3. Example of an HMM.

Figure 3 shows an example of an HMM. Suppose that $a_{kl} = 0.5$ for all $k, l \, (l \neq 0)$. Then, for sequence $s =$ ATCGCT, we have $\pi^*(s)$-0221112 and $P(s, \pi^*|\Theta) = 0.5^6 \cdot 0.4^4 \cdot 0.3^2$.

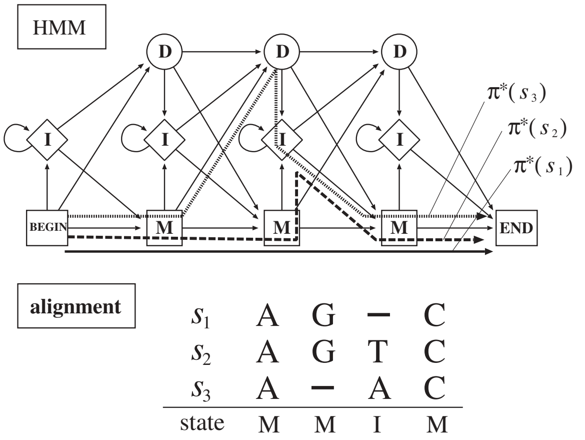
We assumed in both algorithms that Θ was fixed. However, it is often required to train HMMs from sample data. The Baum–Welch algorithm is used to estimate Θ when a set of sequences is given. Suppose that a set of k sequences $\{s_1, \ldots, s_k\}$ is given. The likelihood of observing these k sequences is defined to be $\prod_{j=1}^{k} P(s_j|\Theta)$ for each Θ. Based on the maximum likelihood method, we want to estimate Θ, which maximizes this product (likelihood). That is, the goal is to find an optimal set of parameters Θ^* defined by

$$\Theta^* = \arg\max_{\Theta} \prod_{j=1}^{k} P(s_j|\Theta)$$

However, it is computationally difficult to find an optimal set of parameters. Therefore, various heuristic methods have been proposed for finding a locally optimal set of parameters. Among them, the Baum–Welch algorithm is most widely used. It is a kind of EM algorithm, and it computes a locally optimal set of parameters using an iterative improvement strategy. How to determine the architecture of the HMM is also an important problem. Although several approaches were proposed to automatically determine the architectures from data (see Sections 3.4 and 6.5 of Ref. 1), the architectures are usually determined manually based on knowledge about the target problem.

HMMs are applied to bioinformatics in various ways. One common way is the use of *profile HMMs*. Recall that a profile is a function $w(x, j)$ from $\Sigma \times [1..L]$ to $\mathcal{R}$, where L denotes the length of a motif region. Given a sequence s, the score for s was defined by $\Sigma_{j=1,\ldots,L} w(s[j], j)$. Although profiles are useful for detecting short motifs, they are not so useful for detecting long motifs or remote homologs (sequences having weak similarities) because insertions or deletions are not allowed. A profile HMM is considered to be an extension of a profile in which insertions and deletions are allowed.

A profile HMM has a special architecture as shown in Fig. 4. The states are classified into three types: *match states* (M), *insertion states* (I), and *deletion states* (D). A match state corresponds to one position in a profile. A symbol b is emitted from a match state q_j with probability



s_1	A	G	–	C
s_2	A	G	T	C
s_3	A	–	A	C
state	M	M	I	M

Figure 4. Computation of multiple alignment using a profile HMM.

$e_j(b)$. A symbol b is also emitted from any insertion state q_i with probability $p(b)$, where $p(b)$ is the background frequency of occurrence of the symbol b. No symbol is emitted from any deletion state. Using a profile HMM, we can also obtain multiple alignment of sequences by combining $\pi^*(s_j)$ for all input sequences s_j. Although alignments obtained by profile HMMs are not necessarily optimal, they are meaningful from a biological viewpoint (1).

Many variants and extensions of HHMs have also been developed and applied in bioinformatics. For example, stochastic context-free grammar was applied to prediction of RNA secondary structures (1).

PROTEIN STRUCTURE PREDICTION

Protein structure prediction is the problem of a given protein sequence (target sequence), inferring its three-dimensional structure (17,18). This problem is important since determination of the three-dimensional structure of a protein is much harder than determination of its sequence, and the structure provides useful information on the function and interactions of the protein, which cannot be observed directly from the sequence. Various kinds of approaches exist for protein structure prediction (18), where the major approaches (to be explained below) include *ab initio, homology modeling, secondary structure prediction,* and *protein threading*.

Since many methods have been proposed, a type of contest or meeting called CASP (community-wide experiment on the critical assessment of techniques for protein structure prediction) has been held every two years since 1994 (18). CASP has been playing an important role in the progress of protein structure prediction technologies.

Ab Initio

This approach tries to predict protein structures based on basic principles of physics. For example, energy minimization and molecular dynamics have been applied. However, this approach is currently limited to prediction of small protein structures because it requires enormous computational power. A combination of an ab initio approach and a statistical approach has also been studied (19).

Homology Modeling

Two proteins tend to have similar structures if their sequences are similar enough (although there are exceptional cases). Based on this fact, we have an outline of the structure (backbone structure) from the result of a sequence alignment between the target sequence and the template sequence whose structure is known and that is similar enough to the target sequence. After obtaining a backbone structure, methods such as energy minimization or molecular dynamics are applied to predicting a detailed structure.

Secondary Structure Prediction

In secondary structure prediction, each amino acid of a protein structure is predicted to be one of three classes: α-helix, β-strand, or other, depending on its local shape. Since it is a simple classification problem, many methods in artificial intelligence have been applied. It is easy to see that random prediction (randomly output one of three classes) will achieve 33.3% accuracy. The best existing methods achieve 70~80% accuracy, some of which are based on artificial neural networks (20).

Protein Threading

It is useful in protein structure prediction to measure the compatibility between an input protein sequence and a known protein structure. For that purpose, we usually compute an *alignment between a sequence and a structure* (see Fig. 5). This problem is called *protein threading*. Many algorithms have been proposed for protein threading (3,18,21). Based on score functions, these can be grouped into two classes: threading with profiles and threading with pair score functions.

Threading with Profiles

The score function for this type of threading does not explicitly include the pairwise interaction preferences so that score functions are treated as profiles. A simple dynamic programming algorithm can be used to compute an optimal threading as in the case of pairwise sequence

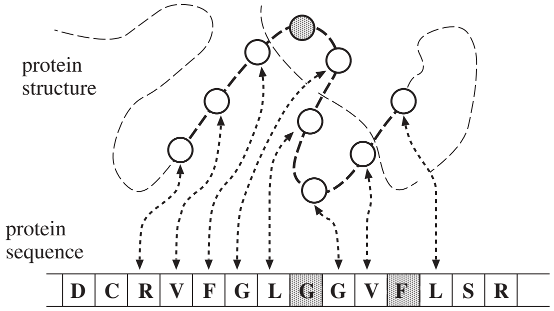


Figure 5. In protein threading, an alignment between a query sequence and a template structure is computed. Shaded parts correspond to gaps.

alignment. However, this method is not so useful unless there is a structure whose sequence has some similarity with an input sequence.

Threading with Pair Score Functions

The score function for this type of threading includes the pairwise interaction preferences. Since protein threading is proven to be NP-hard (22), various methods have been proposed based on heuristics, which include double dynamic programming, frozen approximation, Monte-Carlo sampling, and evolutionary computation (21). Although these methods are not guaranteed to find optimal solutions, several other methods have been proposed in which optimal solutions are guaranteed to be found under some assumptions (e.g., gaps are not allowed in α-helices or β-strands). The first practical algorithm with guaranteed optimal solutions was proposed by employing an elaborated branch-and-bound procedure (23). However, it could not be applied to large protein structures. In 2003, a protein threading method (with pairwise interaction preferences) formulated as a large-scale *integer programming* (IP) was proposed (21). The IP formulation is then relaxed to a linear programming (LP) problem. Finally, an optimal solution is obtained from the LP by using a branch-and-bound method. Surprisingly, the relaxed LP programs generated integral solutions (i.e., optimal solutions) directly in most cases.

From Generative to Discriminative Models

Most methods described in the previous sections are generative: Such objects as alignments and predicted structures are generated. On the other hand, many problems require discriminative approaches: It is required for predicting to which class a given object belongs. For that purpose, various techniques in pattern recognition, statistics, and artificial intelligence have been applied, including but not limited to, neural networks and decision trees. Among these techniques, *support vector machines* (SVMs) and kernel methods (24,25) are beginning to be recognized as one of the most powerful approaches to discriminative problems in bioinformatics (25,26), since the prediction accuracies are in many cases better than other methods and it is easy to apply SVMs; once a suitable kernel function is designed, efficient software tools for SVMs are available. Thus, in this section, we focus on SVMs and kernel methods (see also Fig. 6).

SVMs are basically used for binary discrimination. Let *POS* and *NEG* be the sets of *positive examples* and *negative examples* in a training set, where each example is represented as a point in d-dimensional Euclidean space. Then an SVM tries to find an optimal hyperplane h such that the distance between h and the closest point to h is the maximum (i.e., the margin is maximized) under the condition that all points in *POS* lie above h and all points in *NEG* lie below h. Once such h is obtained, a new test data point is predicted as positive (respectively negative) if it lies above h (respectively below h). If h does not exist, which completely separates *POS* from *NEG*, it is required to optimize the *soft margin*, which is a combination of the margin and the classification error. In order to apply an SVM effectively, it is important to design a *kernel function* suitable for an application problem, where a kernel takes two objects (e.g., two sequences) as inputs and provides a measure of similarity between these objects. Kernel functions can also be used in principal component analysis (PCA) and canonical correlation analysis (CCA) (25–27). In the rest of this section, we briefly review the kernel functions developed for biological sequence analysis.

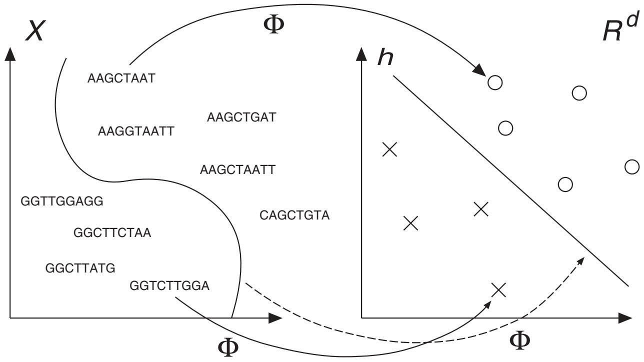

Figure 6. Kernel function and support vector machine. In the right figure, circles denote positive examples and crosses denote negative examples.

We consider a space $\mathcal{X}$ of objects. For example, $\mathcal{X}$ can be a set of DNA or protein sequences. We also consider a *feature map* ϕ from $\mathcal{X}$ to $\mathcal{R}^d$, where $d \in \{1,2,3,\ldots\}$ (we can even consider infinite-dimensional space (Hilbert space) instead of $\mathcal{R}^d$). We define a kernel K from $\mathcal{X} \times \mathcal{X}$ to $\mathcal{R}$ by

$$K(x,y) = \phi(x) \cdot \phi(y)$$

where $\phi(x) \cdot \phi(y)$ is the inner product between vectors $\phi(x)$ and $\phi(y)$. It is known that if a function K from $\mathcal{X} \times \mathcal{X}$ to $\mathcal{R}$ is symmetric [i.e., $K(x,y) = K(y,x)$] and positive definite (i.e., $\Sigma_{i=1}^{n}\Sigma_{j=1}^{n} a_i a_j K(x_i,x_j) \geq 0$ holds for any $n > 0$, for any $(a_1,\ldots,a_n) \in \mathcal{R}$, and for any $(x_1,\ldots,x_n) \in \mathcal{X}^n$), K is a valid kernel (i.e., some $\phi(x)$ exists such that $K(x,y) = \phi(x) \cdot \phi(y)$).

In bioinformatics, it is important to develop kernel functions for sequence data. One of the simplest kernel functions for sequences is the *spectrum kernel* (28). Let k be a positive integer. We define a feature map $\phi_k(x)$ from a set of sequences over Σ to $\mathcal{R}^{|\Sigma^k|}$ by

$$\phi_k(x) = (occ(s,x))_{s \in \Sigma^k}$$

where $occ(s, x)$ denotes the number of occurrences of substring s in string x. The k-spectrum kernel is then defined as $K(x,y) = \phi_k(x) \cdot \phi_k(y)$. Although the number of dimensions of $\mathcal{R}^{|\Sigma^k|}$ is large, we can compute $(K(x,y)$ efficiently (in $(O(kn)$ time) using a data structure named *suffix trees* without computing $\phi_k(x)$ (28). Here, we consider the example case of $k = 2$ and $\Sigma = \{A, C\}$. Then we have $\phi_2(x) = (occ(AA,x), occ(AC,x), occ(CA,x), occ(CC,x))$. Thus, for example, we have $K(ACCAC, CCAAAC) = 4$ since $\phi_2(ACCAC) = (0,2,1,1)$ and $\phi_2(CCAAAC) = (2,1,1,1)$. The spectrum kernel was extended to allow small mismatches (*mismatch kernel*) (29) and to use motifs in place of substrings (*motif kernel*) (30).

Several methods have been proposed that combine HMMs with SVMs. The *SVM-Fisher kernel* is one such kernel (31). To use the SVM-Fisher kernel, we first train a profile HMM with positive training data using the Baum–Welch algorithm. Then we compute a feature vector for each input sequence s as follows. Let m be the number of match states in the profile HMM. $E_i(a)$ denotes the expected number of times that $a \in \Sigma$ is observed in the ith match state for s, $e_i(a)$ denotes the emission probability of $a \in \Sigma$, and θ_{al} is the coordinate corresponding to a of the lth ($l \in \{1,\ldots,9\}$) Dirichlet distribution (1). It is known that $E_i(a)$ can be computed using the forward and backward algorithms (1,3). Then the feature vector $\phi_F(s)$ is defined by

$$\phi_F(s) = \left(\sum_{a \in \Sigma} E_i(a)[\frac{\theta_{al}}{e_i(a)} - 1] \right)_{(l,q_i) \in \{1,\ldots,9\} \times Q_{\mathrm{MATCH}}}$$

which is finally combined with the radial basis function kernel. As another approach to combining HMMs and SVMs, the local alignment kernel was developed based on the pair HMM model (a variant of the HMM) (32).

Kernels for other objects have also been proposed. The *marginalized kernel* was developed based on the expectation with respect to hidden variables (33). The marginalized kernel is defined in a very general way, and thus, it can be applied to nonsequence objects. For example, the marginalized graph kernel was developed and applied to classification of chemical compounds (34).

ANALYSIS OF GENE EXPRESSION PATTERNS

Genetic information stored in genes is used to synthesize proteins. Each gene usually encodes one or a few kinds of proteins. Genes are said to be *expressed* if a certain amount of corresponding proteins are synthesized. *DNA microarray* and *DNA chip* technologies enabled observation of expression levels of several thousands of genes simultaneously. Precisely, the amount of mRNA (messenger RNA) corresponding to each gene is estimated by observing the amount of cDNA that is obtained from mRNA via reverse transcription. Since proteins are synthesized from mRNA, the amount of mRNA estimated via DNA microarray or DNA chip is considered to approximately indicate the expression level of the gene. Analysis of gene expression patterns and time-series data of gene expression patterns has recently become an important topic in bioinformatics. Although various problems have been considered, this section focuses on the three important problems of *clustering of gene expression patterns, classification of tumor types* using gene expression patterns, and *inference of genetic regulatory networks*.

Clustering of Gene Expression Patterns

This problem is important for classification and prediction of functions of genes because it is expected that genes with similar functions have similar gene expression patterns (35,36). Suppose that we have a vector of gene expression levels $(g_i(1), g_i(2), \ldots, g_i(t))$ for each gene, where $g_i(j)$ denotes the gene expression level (real number) of the ith gene under the jth environmental constraint or at the jth time step. We would like to divide a set of several thousands genes into several or several tens of clusters according to similarities of vectors of gene expression levels (see Fig. 7). Clustering of real vectors is a well-studied topic in artificial intelligence and statistics, and many methods have been proposed. Various clustering methods have been applied to clustering of gene expression patterns, which include hierarchical clustering, self-organizing maps, k-means clustering, and EM-clustering (35–37).

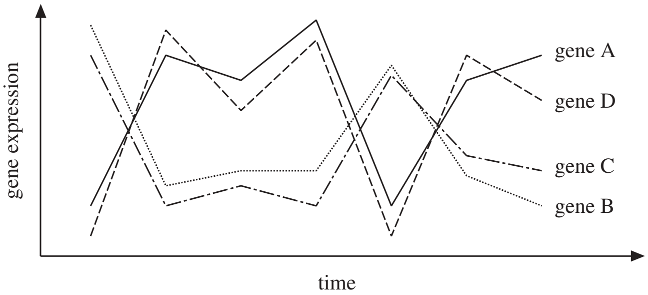

Figure 7. Clustering of gene expression patterns. In this case, genes are clustered into two groups: {A,D} and {B,C}.

Classification of Tumor Types

This problem may be the most important because it has many potential applications in medical and pharmaceutical sciences. Suppose that we have expression patterns for samples of tumor cells from patients and we would like to classify samples into more detailed tumor classes. Golub et al. considered two problems: *class discovery* and *class prediction* (38). Class discovery defines previously unrecognized tumor subtypes, whereas class prediction assigns particular tumor samples to predefined classes.

Golub et al. applied the *self-organizing map* (a kind of clustering method) to class discovery. In this case, they considered a vector $\mathbf{g}_j = (g_1^j, g_2^j, \ldots, g_m^j)$ for each patient, where g_i^j denotes the gene expression level of the ith gene of the sample obtained from the jth patient. They classified the set of samples into a few classes based on similarities of vectors. They also employed *weighted voting* for class predictions, where the weight for each gene was learned from training samples and each test sample was classified according to the sum of the weights.

In their experiments, not all genes were used for weighted votes, but only several tens of genes relevant to class distinction were selected and used. Use of selected genes seems better for several reasons. For example, cost for measurement of gene expression levels will be much lower if only selected genes are used. Golub et al. called these selected genes *informative genes*. Although they used a simple method to select genes, many methods have been proposed for selecting informative genes. Using terminologies in artificial intelligence, class discovery, class prediction, and selection of informative genes correspond to clustering, learning of discrimination rules, and feature selection, respectively. Many methods have been developed for these three problems in artificial intelligence (37,39–41).

Although it is still unclear which method is the best for tumor classification, the SVMs explained here have been effectively applied to class prediction (40,41). For example, consider the case of predicting whether a given sample belongs to a particular tumor class. We regard gene expression profile $\mathbf{g}_j$ corresponding to the jth sample as an example (i.e., a point in m-dimensional Euclidean space), where $\mathbf{g}_j$ is regarded as a positive example if the sample belongs to the tumor class, and as a negative example otherwise. Then we can simply apply an SVM to this problem, where many variants and extensions, which include multiple tumor class prediction, have been proposed (40,41). SVMs can also be applied to selection of informative genes in combination with *recursive feature elimination*(39,42). In this method, genes are ranked based on the weight (effect on classification) of each gene, and the gene with the smallest rank is recursively removed, where SVM-learning is executed at each recursive step.

Inference of Genetic Regulatory Networks

In order to understand the detailed mechanism of organisms, it is important to know which genes are expressed, when they are expressed, and to what extent. Expressions of genes are regulated through genetic regulatory systems structured by networks of interactions among DNA, RNA, proteins, and chemical compounds. Gene expression data are expected to be useful for revealing these genetic regulatory networks. Therefore, many studies have been done in order to infer the architectures of genetic regulatory networks from gene expression data. Usually, mathematical models of networks are required to infer genetic regulatory networks. Extensive studies have been done using such models as Boolean networks, Bayesian networks, and differential equations (4,43–46).

Here we briefly describe the Boolean network model and its relation with the Bayesian network model. The Boolean network is a very simple model (47). Each gene corresponds to a node in a network. Each node takes either 0 (inactive) or 1 (active), and the states of nodes change synchronously according to regulation rules given as Boolean functions. In a Boolean network, the state of node v_i at time t is denoted by $v_i(t)$, where $v_i(t)$ takes either 0 or 1. A node v_i has k_i incoming nodes $v_{i1}, \ldots, v_{ik_i}$, and the state of v_i at time $t + 1$ is determined by

$$v_i(t+1) = f_i(v_{i_1}(t), \ldots, v_{i_{k_i}}(t))$$

where f_i is a Boolean function with k_i input variables. This rule means that gene v_i is controlled by genes $v_{i_1}, v_{i_2}, \ldots, v_{i_k}$.

For example, consider a very simple network in which there three nodes exist (i.e., genes) v_1, v_2, v_3, and the regulation rules are given as follows:

$$\begin{aligned} v_1(t+1) &= v_2(t), \\ v_2(t+1) &= v_1(t) \wedge v_3(t), \\ v_3(t+1) &= \overline{v_1(t)}, \end{aligned}$$

where $x \wedge y$ means the conjunction (logical AND) of x and y, and $\bar{x}$ means the negation (logical NOT) of x. Suppose that the states of genes at time 0 are $(v_1(0), v_2(0), v_3(0)) = (1, 1, 1)$. Then the states of genes change as follows:

$$(1,1,1) \Rightarrow (1,1,0) \Rightarrow (1,0,0) \Rightarrow (0,0,0) \Rightarrow (0,0,1) \Rightarrow (0,0,1) \Rightarrow \cdots$$

This sequence of state transitions corresponds to time-series data of gene expression patterns.

Under this model, inference of a gene regulatory network is defined as a problem of inferring regulation rules (i.e., input genes and Boolean functions) for all genes from a set of state transition sequences (43). Although gene regulation rules are deterministic in Boolean networks, the Boolean network model was extended to the probabilistic Boolean network model (48), in which multiple Boolean functions can be assigned to one gene and one Boolean function is randomly selected for each gene at each time step according to some probability distribution. Probabilistic Boolean networks are almost equivalent to dynamic Bayesian networks with a binary domain (49). In practice, Bayesian networks have been more widely applied to inference of genetic networks than Boolean networks since Bayesian networks are considered to be more flexible. Furthermore, many variants of Bayesian networks and their inference algorithms have been proposed for modeling and inference of genetic networks (43–46).

BIOLOGICALLY INSPIRED NEURAL COMPUTATION

THE BIOLOGICAL NEURON

In order to fully understand the relationship of artificial neural network components to their biological analogues, an overview of the biological neuron and its function within networks of interconnected neurons is presented here. In particular, the electrical behavior of the neuron membrane, the influence of synaptic junctions, and the computational aspects of simple neural networks are presented.

It should be emphasized that there is no mathematical model that exactly describes the behavior of the biological neuron. Instead, there is a plethora of models and algorithms, some of which are closer to the true biological behavior than others, as verified by experimentation. Moreover, as a general rule, those models that are more true to neuron physiology, henceforth called *biological*, have more computationally demanding solutions than those that are less physiologically accurate. Hence, the more simplified models, including the perceptron and its derivative models, will henceforth be called *computational*.

Neurons

Nerve cells (or neurons) are fundamental components of the human nervous system. They relay and process information that governs our movement and perception. Moreover, the number of neurons in the human brain itself is estimated to be on the order of 10^{11}(1). Recently, glial cells, which provide physical support to neurons in the brain and outnumber the neurons by a ratio of 10:1, have also been reported to perform some computational tasks through chemical signaling (2). However, their influence shall be omitted here for practical purposes.

The physical dimensions of neurons vary significantly depending on the location and function of the particular neuron [see Fig. 1(3)]. However, all neurons are encapsulated by a thin membrane, in the order of 50 nm in thickness separating an inner axoplasm from the outer environment. Also, all neurons can be thought of as being comprised of three components: the soma, or cell body of the neuron, typically spheroidal in shape; the dendrites, or thin extensions of the cell body that receive input stimuli; and the axon, a larger and longer extension of the cell body that transports information to other neurons in the form of electrical pulses. Moreover, typical neurons in the human brain have a soma from 4 μm to 100 μm in diameter and an axon from several millimeters to over a meter in length, as in the case of some motor neurons that extend down the spine.

The excitable nerve cells differ from other cells in that they communicate with each other through a distinct use of electrical and chemical signaling. That is, local changes in electric potential and current density of the cell membrane propagate along the neuronal cell conveying information in an *intra*cellular manner, whereas chemicals called neurotransmitters are emitted from one cell and affect the electrical behavior of adjacent cells, thus conveying information in an *inter*cellular manner.

Given the unique electrical and chemical behavior of neurons, it is possible to envision how groups of neurons are capable of executing computational tasks. In fact, it is well established that neurons are responsible for the detection and interpretation of exogenous stimuli (through sensation), as well as the regulation of muscle contractions (or movement). For example, in the human retina, sensory stimuli (light waves) are converted to electrical impulses by photo-receptor cells. Then, networks of neurons process the exogenous information through nonlinear methods such as lateral inhibition (4). Also, impulses originating from motor neurons in the basal ganglia can activate muscle cell contractions, thus governing movement in humans and nonhuman primates (4).

Electrical Behavior

The electrical behavior of neurons is due to the concentration gradient and movement of specific ions across the cell membrane. In particular, the electric potential across the membrane (or transmembrane potential V_m) changes in proportion to the presence of positive ions within the cell. Also, as ions are transported across the membrane, they effectively establish a transmembrane current I_m. Moreover, at equilibrium conditions, $V_m \approx -70\,\text{mV}$ and $I_m \approx 0$.

The forces that transport the ions across the cell membrane are due to diffusion, permeability, and a biological mechanism of active transport. In particular, a biological "ion pump" actively transports ions across the membrane in order to maintain a particular concentration gradient for each ion. Also, when the permeability of the membrane to a particular ion changes, the diffusion forces establish a transmembrane current for that ion. Moreover, when V_m is below some threshold V_{th}, the relation between V_m and I_m is practically linear with constant permeability, whereas when V_m approaches V_{th}, ion permeability begins to change with respect to time, thus defining a time-varying and nonlinear relationship between V_m and I_m that lasts for a finite duration.

The nonlinear behavior of the neuron consists of a chain reaction of shifts in permeability that governs the influx and exit of charged ions across the cell membrane over time. That is, first the sodium (Na^+) permeability increases for a brief instant (roughly 1 ms in duration) causing Na^+ ions to diffuse into the cell from the higher concentration of Na^+ outside the cell, thus raising V_m. Next, the potassium (K^+) permeability immediately increases followed by a mass exit of K^+ ions from the higher K^+ concentration inside the cell, which, in turn, pulls V_m down to a hyperpolarized state V_{hyp} until the K^+ permeability returns to equilibrium. At the same time, the ion pump mechanism is constantly restoring the concentrations of Na^+ and K^+ to the original levels.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

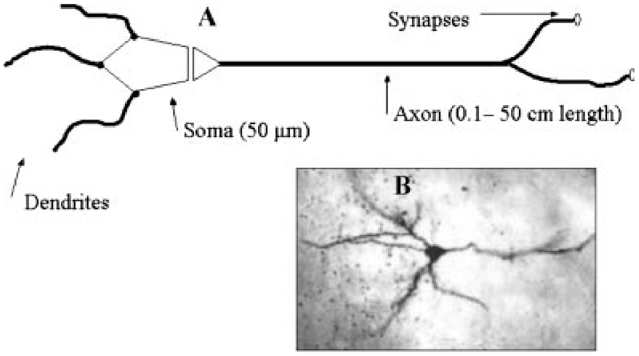

Figure 1. Graphic illustration of a neuron (A). Image of a pyramidal neuron from the cerebral cortex (B) from Ref. 3.

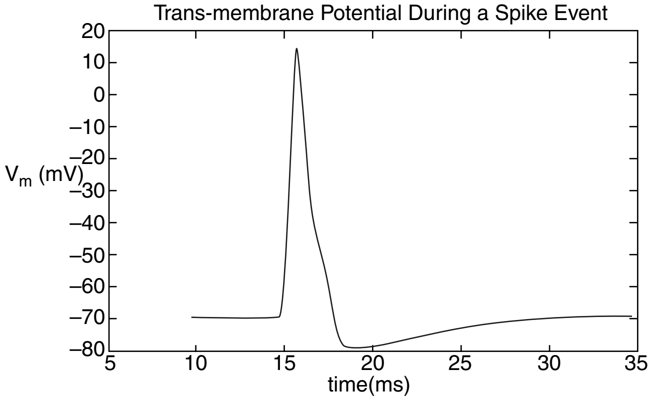

Figure 3. A typical action potential waveform.

Figure 2 illustrates the behavior of the cell membrane when a Na$^+$ channel is open while a K$^+$ channel is closed. Also, relative concentrations of Na$^+$ and K$^+$ are shown.

The course that V_m follows throughout the duration of the nonlinear behavior is characterized by three phases. Namely, these phases are the depolarization, repolarization, and hyperpolarization. In particular, during depolarization, V_m suddenly increases from its equilibrium to roughly 20 mV due to the influx of Na$^+$. Then, the membrane immediately enters the repolarization phase, where V_m suddenly decreases due to the exit of K$^+$, which is then followed by hyperpolarization, where V_m swings below −70 mV to roughly −80 mV. Together, the three phases comprise an "action potential" waveform or "spike" illustrated in Fig. 3. Moreover, the action potential duration is roughly 2 ms for the depolarization and repolarization phases, whereas the hyperpolarization phase lasts somewhat longer. Furthermore, due to the closed Na$^+$ channels immediately after depolarization, it is virtually impossible to elicit a new action potential event in the neuron. This effect is called inactivation and its duration is the *absolute refractory period*. However, during the period of hyperpolarization, it is possible, although somewhat difficult, to achieve threshold as compared with rest conditions. This process is called de-inactivation and the duration is the *relative refractory period* (1).

It is believed that the action potential is generated at the point where the axon meets the neuron soma, a region dubbed "axon hillock." Subsequently, ion currents entering the cell force adjacent locations of the cell membrane to depolarize, thus propagating the action potential across the cell axon at roughly 1 m/s (10 m/s in myelinated cells), depending on the dimensions of the cell.

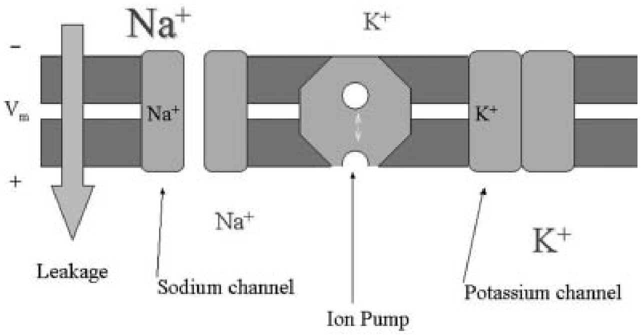

Figure 2. Ion permeability in a neuron membrane.

For a more rigorous mathematical description of the nerve cell dynamics, the interested reader may study the "core conductor" model, which pairs the Hodgkin–Huxley equations with the "transmission line" or "cable equations" (4,5).

Synaptic Transmission

The synaptic junction is the computational link between adjacent neurons. It regulates communication between adjacent neurons through short-term and long-term processes. The long-term processes are believed to regulate learning ability, whereas short-term processes are involved in the transmission and processing of real-time information.

In the short-term, communication at the synapse is achieved through the release of neurotransmitters by one neuron, and the effect on ion permeability that those neurotransmitters have in the membrane of adjacent neurons. In particular, when the action potential waveform travels along the length of the axon, then branches into a dendritic branch, it finally terminates at a synaptic junction where biochemical processes not yet well understood cause the release or exocytosis of neurotransmitters into a space between the presynaptic neuron and postsynaptic neuron. Next, as the neurotransmitters come into contact with the postsynaptic membrane, they alter the ionic permeability of that membrane and cause an inflow or outflow of current, depending on the type of neurotransmitter and the particular ion channels affected on the postsynaptic neuron. Moreover, depending on whether the resulting net membrane current is inward or outward, the synaptic connection is said to be *excitatory* or *inhibitory*.

From a systems perspective, the synapse acts as an integrator because of the first-order response of induced local postsynaptic current upon arrival of a presynaptic action potential. Moreover, this result is likely because of the slowly decaying amount of neurotransmitter released in response to the arrival of the action potential. In particular, the impulse response of the system can be modeled as

$$I_m(t) = \frac{J}{\tau_s} e^{-(t-t_k)/\tau_s} u(t - t_k) \tag{1}$$

where $I_m(t)$ represents the local current induced by the synapse over time, J represents the strength or efficacy of the synapse, τ_s represents the decay constant, t_k is the time of the incident spike, and $u(t)$ represents the unit step function (6). Furthermore, notice how Equation (1) omits the effect of action potential intensity and instead focuses only on the time of incidence t_k of the incoming spike.

Random processes within the presynaptic membrane cause spontaneous release of neurotransmitter even in the absence of an incident spike. Moreover, Fatt and Katz have shown that neurotransmitter is actually released in bundles where the number of bundles follows a Poisson process. Thus, the cumulative effect of this release over many synapses is to cause occasional random spike generation in the postsynaptic membrane.

FROM BIOLOGY TO COMPUTER SCIENCE

Simplifications of the biological model of the neuron can produce the early "perceptron" models and threshold units that influenced the vast proliferation of artificial neural networks in the latter part of the twentieth century. In particular, a linear relationship can be established between the summation of synaptic activity in a neuron and the frequency of presynaptic spike trains. Also, a distinct nonlinear function can be established between the resulting spike frequency of a particular neuron and the summation of its synaptic contributions.

From Synapse to Summation

As shown previously, synapses integrate the spikes and collectively cause an aggregation of positive charge in the cell body of the neuron. This temporal and spatial integration is known as "summation" in neuroscience literature. There are also inhibitory synapses that retain the temporal integration, but elicit an *exit* of positive charge from the postsynaptic membrane, thus contributing a negative component to the overall summation.

The temporal integration is described by Equation (1) above. Moreover, solving Equation (1) with respect to local postsynaptic transmembrane current I_l for some synapse l during the arrival of a presynaptic spike train of frequency f shows a near-linear relationship between I_l and f. In particular, assuming the decay rate τ_s of Equation (1) is large compared with the duration of an action potential, the response of I_l with respect to the presynaptic transmembrane potential is just an impulse response

$$h(t) = \begin{Bmatrix} \frac{J}{\tau_s} e^{-\frac{t}{\tau_s}} & \text{for } t \geq 0 \\ 0 & \text{otherwise} \end{Bmatrix} \tag{2}$$

Next, assuming there is an arrival of a spike train of frequency f, or an interarrival time of $\Delta t = 1/f$, also assuming the spike train has a long duration (ignoring transients), the input can be represented as

$$s(t) = \sum_{n=-\infty}^{\infty} \delta(t - n\Delta t) \tag{3}$$

Thus, in a linear system sense, the local postsynaptic current that will result is given by the convolution equation

$$I_l(t) = \int_{-\infty}^{+\infty} h(T - t)s(T)dT \tag{4}$$

Furthermore, solving for $I_l(t)$ yields

$$I_l(t) = \frac{J}{\tau_s} \frac{e^{\frac{1}{\tau_s}(t - \lceil \frac{t}{\Delta t} \rceil \Delta t)}}{1 - e^{-\frac{\Delta t}{\tau_s}}} \tag{5}$$

As can be gleaned from Equation (5), the dependence of I_l on time t is constrained within limits that depend on τ_s. In particular, the range of I_l can be described as

$$\frac{J}{\tau_s\left(e^{+\frac{\Delta t}{\tau_s}} - 1\right)} < I_l < \frac{J}{\tau_s\left(1 - e^{-\frac{\Delta t}{\tau_s}}\right)} \tag{6}$$

Furthermore, taking the limit as $\tau_s \to \infty$ yields the remarkable result that

$$I_l = \frac{J}{\Delta t} = Jf \tag{7}$$

Which can be thought of as a neural rate-coding theorem in that it shows a linear relationship between the incident spike frequency at a synapse and the resulting induced local current in the postsynaptic neuron membrane. Moreover, it is noteworthy that the synaptic efficacy J retains the same value and meaning in the transition from the biological model in Ref. 6 to the computational realm of the perceptron. Also, it is evident that as τ_s becomes larger, the dependency of I_l on f becomes stronger than its dependency on t. Thus, the temporal variations of the incident spike train become less significant with larger τ_s as Fig. 4 illustrates.

In turn, the "spatial" integration that is achieved by a neuron is simply the aggregate effect of all the synapses connected to the neuron. In mathematical terms, using the linear relation shown in Equation (7), the total transmembrane current due to synaptic connections can be described as

$$I_s = \sum_{l=1}^{L} J_l f_l \tag{8}$$

where J_l and f_l represent the efficacy and incident spike frequency of a particular synapse l.

The results of this section suggest that the mechanism of summation used in popular models of artificial neural networks is closely related to the more biological model of the synapse, as has been alluded to often in the scientific literature. That is, the overall effect of synaptic connections

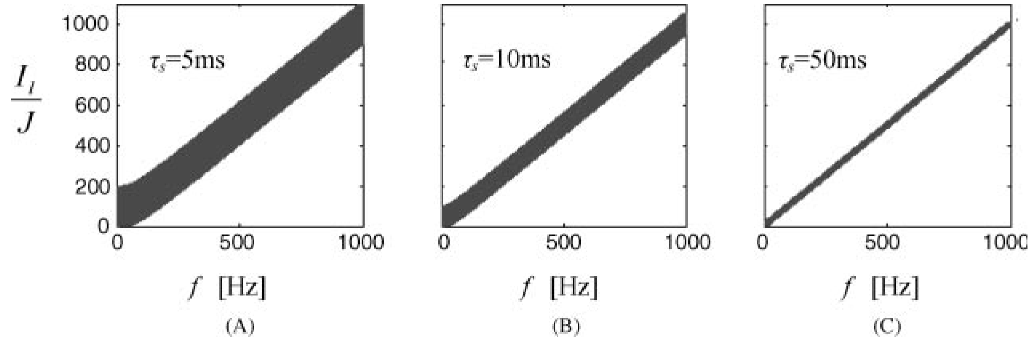

Figure 4. The shaded regions show the possible range of local current at a given frequency of an incident spike train for $\tau_s = 5\,\mathrm{ms}$ (A), $\tau_s = 10\,\mathrm{ms}$ (B), $\tau_s = 50\,\mathrm{ms}$ (C). Moreover, the values of current are normalized with respect to J. As can be seen, the relationship between postsynaptic local current I_l and incident spike frequency f is approximately linear with an uncertainty that grows inversely proportional to the synaptic decay rate τ_s.

on a neuron can be described by a linear relationship—the weighted sum of the incident spiking frequencies, where each weight represents the efficacy of a particular synapse. Also, the decay rate of a synapse affects the accuracy or fuzziness of the relationship in that relatively larger decay rates constrain the time-varying aspects of the effect. Moreover, practical ranges for τ_s that were used in this study were 5 ms, 10 ms, and 50 ms, similar to the synaptic types found in Ref. 6.

From Voltage-Gated Channels to Activation Functions

As described previously, the voltage-gated behavior of the neuron membrane establishes a threshold between the linear and nonlinear modes of operation. In particular, when the transmembrane voltage V_m is sufficiently less than the threshold V_{th}, the relationship between V_m and the transmembrane current I_m is practically a linear one. However, when V_m reaches V_{th}, a nonlinear event known as the action potential is generated.

The biological model describes the dynamics of the neuron behavior with respect to time. However, what is the relationship between the biological model and the computational model of the perceptron? In other words, how can the perceptron model be derived from the biological analogue?

The analysis can begin by describing the subthreshold dynamics of the neuron membrane. In particular, given nominal membrane resistance R_m and capacitance C_m, the linear model relating V_m to the total transmembrane current I_m is

$$R_m C_m \frac{dV_m}{dt} + V_m - R_m I_m = 0 \tag{9}$$

For the case when I_m consists of a step function with amplitude $\bar{I}_m$, and V_{rest} is V_m at $t = 0$, Equation (9) can be solved for V_m yielding the result

$$V_m(t) = V_{rest} + \bar{I}_m R_m \left(1 - e^{-\frac{t}{R_m C_m}}\right) \tag{10}$$

At this point, a change of variables can make the derivations simpler. In particular, introducing the relative transmembrane voltage $\Delta V_m = V_m - V_{rest}$ into Equation (1) yields

$$\Delta V_m = \bar{I}_m R_m \left(1 - e^{-\frac{t}{R_m C_m}}\right) \tag{11}$$

Now, introducing the relative threshold $\Delta V_{th} = V_{th} - V_{rest}$, and replacing t with Δt, the time required to reach threshold is

$$\Delta t = -R_m C_m \ln\left(1 - \frac{\Delta V_{th}}{\bar{I}_m R_m}\right) \tag{12}$$

It is apparent that Δt will be finite for only certain values of $\bar{I}_m$. In particular, the minimum value of $\bar{I}_m$ required to achieve threshold (called the rheobase current) (5) is

$$I_{rh} = \frac{\Delta V_{th}}{R_m} \tag{13}$$

The implications for the spike frequency $f = \Delta t^{-1}$ are that f remains essentially zero until I_s (the summation current) surpasses the rheobase current. Furthermore, this implication confirms the older perceptron models with the "hard-limiting" function, or the activation function with a discontinuity. However, what are the exact values of f as I_s extends past the rheobase current?

To answer this question, Equation (12) may seem like the likely candidate. However, this equation predicts that f will grow unboundedly with I_s, a relation that is not, in fact, practical. In contrast, a more realistic scenario includes the refractory period t_{ref} of the neuron. The reason is that t_{ref} plays a significant role in bounding the upper limits of spike frequency f that are attainable by a neuron.

As stated previously, t_{ref} is caused by the inactivation of ion channels in the cell membrane and the prolonged opening of the K+ channels. Specifically, when V_m swings to V_{hyp} during hyperpolarization, any activating current has to be strong enough to drive V_m from V_{hyp} to V_{th}, which is a greater leap than driving V_m from V_{rest} to V_{th}(1).

For all practical purposes, this activity would mean that ΔV_{th} is nearly infinite during the inactivation phase of the sodium channels, and then decays exponentially from

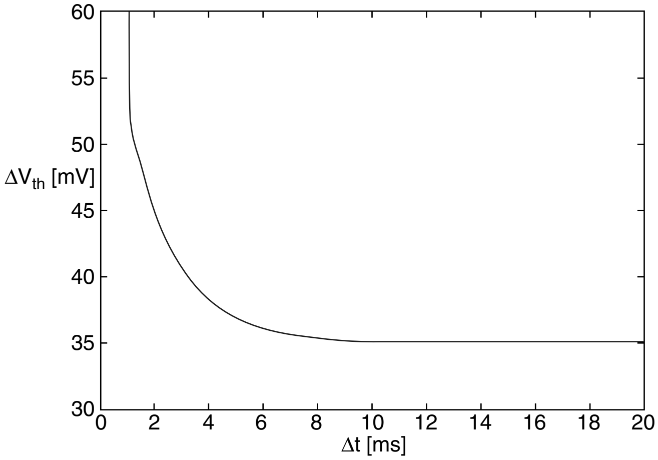

Figure 5. The relative threshold ΔV_{th} as a function of the time elapsed Δt since depolarization for $\alpha = 575.6$, $v_\Theta = 35\,\text{mV}$, $V_o = 66.6\,\text{mV}$, $T_{abs} = 1\,\text{ms}$, and $A = 3.2 \times 10^{-16}$.

ΔV_{hyp} to its nominal value as the potassium channels close. Moreover, this kind of description is closely in keeping with the models of threshold voltage mentioned in Ref. 4. In particular, assuming the inactivation phase of the sodium channels ends at time T_{abs}, a very steep function of Δt could model ΔV_{th} when $t < T_{abs}$. Then, for $t > T_{abs}$, the relation could be a decaying exponential. Thus, if v_Θ is ΔV_{th} at rest and A is a constant chosen to keep the curve continuous, then

$$\Delta V_{th}(\Delta t) = \left\{ \begin{array}{ll} v_\Theta + \dfrac{A}{\Delta t^{10}}, & 0 \leq \Delta t < T_{abs} \\ v_\Theta + (v_0 - v_\Theta)e^{-\alpha \Delta t}, & T_{abs} < \Delta t \\ v_\Theta, & \text{otherwise} \end{array} \right\} \tag{14}$$

Figure 5 shows a graphic representation of Equation (14) for appropriate values of v_Θ, T_{abs}, and α.

Substituting Equation (14) into Equation (12) yields a relation that cannot easily be solved for Δt. However, numerical methods can be used to obtain a consistent answer. Thus, using the ALOPEX algorithm (15), the end result is a series of points describing the relation of Δt to I_s. Furthermore, inverting this result yields a relation of f to I_s (shown in Fig. 6) that is in keeping with the "activation function" of the perceptron.

The activation function is a central theme of the perceptron and most of the derivative artificial neuron models in that it limits the possible output levels of a neuron. In this sense, it is the defining factor that places artificial neurons and neural networks into the category of nonlinear adaptive systems (8).

A popular approximation to the activation function of a neuron is the sigmoidal function. For example, using the sigmoidal function, the output of a neuron given the summation I_s is

$$F(I_s) = \frac{2}{\left(1 + e^{-\beta I_s}\right)} - 1 \tag{15}$$

Figure 6 shows the results of a numerical solution with a sigmoidal function optimized to fit the numerical solution.

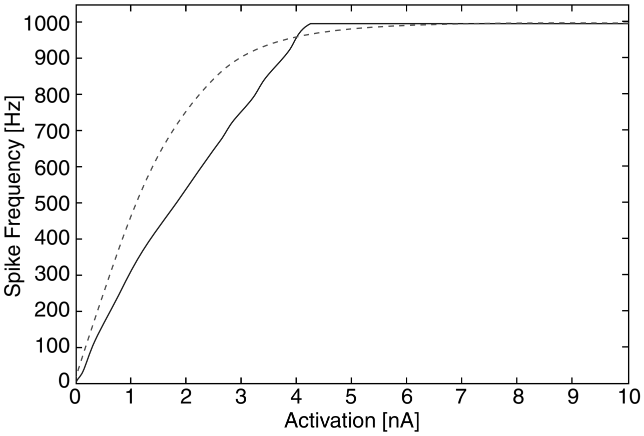

Figure 6. Activation function (solid) and sigmoid (--). Sigmoid parameter was $\beta = 0.99 \times 10^9$. Subthreshold neuron parameters were $R_m = 414\,\text{M}\Omega$ and $C_m = 78.5\,\text{pF}$ for a neuron of diameter 50 μm.

Rate-Coding in Neurons and Networks

The synapse can be thought of as a *decoder* of spike trains into levels of activity, whereas the neuron itself is viewed as a modulator or *encoder* of aggregate synaptic activity into a spike train. This aspect of neuron function has been called *rate-coding* because the information transmitted by a particular neuron is thought to be carried by the firing rate itself. Also, pulse frequency modulation (PFM) has been used to characterize this model (4). Accordingly, Fig. 7 shows the decoding, summation, and spike generation aspects of a neuron where $H_e(S)$ and $H_i(S)$ are transfer functions of excitatory and inhibitory synapses, respectively, and the component labeled "H-H" denotes a Hodgkin–Huxley-type spike generation mechanism.

From Synaptic Plasticity to Learning Algorithms

The cornerstone of the theory on synaptic plasticity is the "Neurophysiological Postulate," made by Donald Hebb in 1949 (9,10), which states

> When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic changes take place in one or both cells such that A's efficiency as one of the cells firing B, is increased.

A simple mathematical description of this postulate is suggested by Haykin et al. (11). In particular, given the

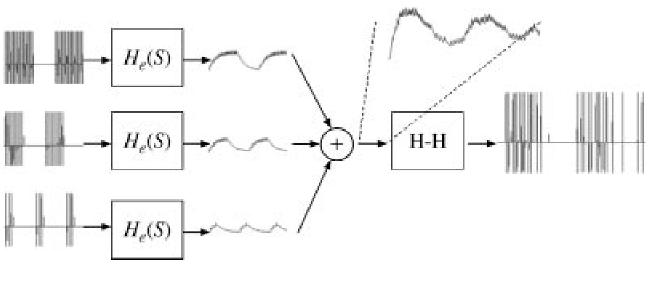

Figure 7. A neuron as a pulse frequency modulator.

activity in two adjacent neurons is $x_a(t)$ and $x_b(t)$ and a "learning rate" parameter is η, then the change in synaptic efficacy would be

$$\Delta\theta_{ab}(t) = x_a(t)x_b(t) \tag{16}$$

However, the value representing synaptic efficacy θ_i can potentially grow without bound. Thus, to curb this behavior, Oja introduced a learning rule that will guarantee that the norm of θ_is will have unity magnitude (12). In particular, given the output of a neuron is V and the input to synapse i is ξ_i, then

$$\Delta\theta_i = \eta V(\xi_i - V\theta_i) \tag{17}$$

Both the Hebbian and Oja rules are considered to be in the category of "unsupervised" learning in that a network of such neurons adjusts itself to encode or interpret the data at the input. However, when the synaptic weights of a network are modified to minimize some external cost function, the learning rules are in the category of "supervised" learning (13).

One such learning rule is the "perceptron learning rule," introduced by Rosenblatt (14). In this case, given the desired output ζ_k of neuron k and some threshold N, the weight of synapse i is updated as

$$\Delta\theta_{k,i} = \eta \mathrm{U}\left(N - \zeta_k \sum_j \theta_{k,j}\xi_{k,j}\right)\zeta_k\xi_{k,i} \tag{18}$$

where U is the unit step function.

A similar innovation on this theme of supervised learning is the ALOPEX algorithm that introduces stochastic components in the updating of synaptic weights in order to minimize a global cost function (15). In particular, given global error E_n at iteration n, zero-mean random variable $r_{i,n}$, and rate parameters γ and σ, the algorithm can be described in the following steps

$$\Delta E_n = E_n - E_{n-1} \tag{19}$$

$$\Delta\theta_{i,n+1} = \gamma\Delta E_n \Delta\theta_{i,n} + \sigma r_{i,n} \tag{20}$$

THE PERCEPTRON AND OTHER NEURAL NETWORKS

The derivations of synaptic summation and the neuron activation function outlined above show how the perceptron model, introduced by Rosenblatt (14), is very similar to the more biological descriptions of the neuron and its synapses. In particular, using the standard notation for perceptrons, the output of some neuron i with synaptic weights given by w_{ik}, inputs ξ_k, and threshold μ_i, is given by

$$O_i = g\left(\sum_k w_{ik}\xi_k - \mu_i\right) \tag{21}$$

Here, the activation function $g(\bullet)$ can be thought of as the activation function derived from Equations (12) and (14), whereas the argument of $g(\bullet)$ is the summation mentioned in Equation (8). Also, the threshold can be thought of as the rheobase current mentioned in Equation 13.

For a "hard-limiting" activation function, the summation can be thought of as being sufficiently large so that the transition of $g(\bullet)$ from zero to peak (~1000 Hz) is negligible. In this case, the model resembles the McCulloch–Pitts (16) unit, so that, for some neuron unit i at iteration n and threshold μ_i, the next output is given as

$$O_i(n+1) = U\left(\sum_j w_{ij}O_j(n) - \mu_i\right) \tag{22}$$

where U($\bullet$) is the unit step function.

In 1982, Hopfield (17) popularized another neuron model that was originally developed by Cragg and Temperley in 1954 and later modified by Caianiello in 1961. Moreover, it is similar to the McCulloch–Pitts model except that the step function is replaced by the signum function and the threshold is dropped from the equation. In this manner, the dynamics of a network of such neurons are described by equations that are familiar in statistical mechanics. In particular, the output of a single neuron i is

$$S_i = sgn\left(\sum_j w_{ij}S_j\right) \tag{23}$$

Networks composed of Hopfield units are known as "associative memories" because of their ability to associate an unknown input to some stored information. Also, the stored patterns are known as "attractors" because of the trajectory that an unknown input will follow until it reaches the correct association (12).

Three-Dimensional Neural Networks

A three-dimensional, time-dependent (though synchronized) artificial neural network (ANN) is presented with the purpose to better simulate a complex biological system and thereby be useful in the understanding of how memories are stored and recollected. In emulating the biological model, this ANN also functions to aid in visualizing how neural damage of various kinds affects mental activity.

The ANN is three-dimensional and time-dependent (yet synchronized). It differs from the classic pattern recognition system in four ways:

1. It is a three-dimensional network (3D-NN), rather than a one-dimensional neural network. In this sense, it consists of two-dimensional planes of neurons stacked atop one another in the third dimension. The connectivity of a network is determined by this 3D configuration, with neurons that are closer to one another having a greater chance of being connected to one another.
2. The network is dependent on time. It takes one unit of testing time for neurotransmitters to jump across any synapse. The exception to this role is the

connections going from the external stimuli to the receptor neurons, which transmit signals instantaneously; these connections do not represent a synaptic gap, but rather the detection of external stimuli.

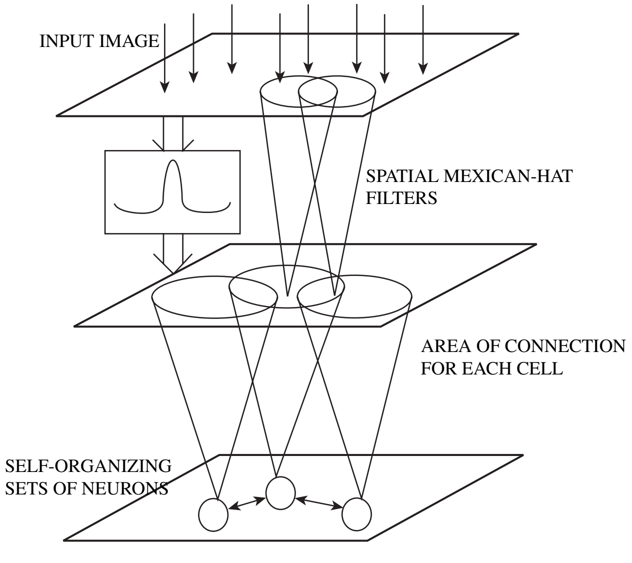
3. The connections can act in lateral and feedback manners, as well as a feed-forward manner (which is the type presented most often in the classic ANN). Lateral and feedback connections are present within the biological system, and these here help to make the network more flexible and closer to the biological model (See Fig. 1).
4. The classic ANN has the purpose of pattern recognition. The 3D-NN can be trained in an unsupervised manner, however, via a version of Hebb's rule, where external stimuli may or may not be present, and the network generates particular sets of weights in response. Without the introduction of known templates, it tries to simulate learning templates for the first time, as a child does in real life. This creation of memories is then used in conjunction with a pattern recognition system when recollection of these memories is desired.

Damage of the network can be assessed by destroying neurons or connections within specific areas and then visualizing how the activity of the entire network is affected. Various conditions can be simulated. For example, a stroke or concussion is modeled by destroying neurons within a finite area on a certain layer. Parkinson's disease is simulated by destroying connections between specific layers (such as the destruction of inhibition in this condition that can lead to tremors). Dementia is simulated by damaging connection strengths with random noise.

This type of neural network allows analysis of these conditions through visualization of the activity of the network at various times and places. Through such visualization, the ANN attempts to aid in greater understanding of its biological counterpart. An example of such a network is given in Fig. 8, where we show the concept of the ANN, where predefined areas of the first layer (in physiological terms these areas are the so-called Receptive Fields), are connected to neurons in the second layer after their output has undergone some filtering. The outputs of the second-layer neurons connect to the third layer and so on. This network, however, differs from the classic perceptron network in two main points: each neuron can send an output to any neuron in the previous layers or the next layers and, in addition, it can make connections laterally (i.e., with neurons on the same plane); and information is transferred in quanta of time from one layer to the next.

Figure 9 shows this propagation of signals from layer to layer and for six consecutive times. The columns correspond to time intervals (1 through 6) (Fig. 9 a, b, c) and rows correspond to neuronal layers (1 though 3). The X, Y coordinates specify the position of a neuron on the plane, whereas the Z coordinate indicates the activity of the neuron.

The reader should notice that at $t = 1$ (Fig. 9a), only the first layer has activity, because this layer is where the stimulus is originating. The second and third layers do not have any activity. At $t = 2$ (Fig. 9a), the activity has also reached the second layer, whereas at $t = 3$ (Fig. 9a), all three layers show some activity. Because of the feedback connectivity as well as the lateral connections, the distribution of activity on each plane is not changing in a linear manner (Fig. 9 b, c).



INPUT IMAGE
SPATIAL MEXICAN-HAT FILTERS
AREA OF CONNECTION FOR EACH CELL
SELF-ORGANIZING SETS OF NEURONS

Figure 8. Schematic representation of a 3D-neural network. Stimulus is applied on the first layer. Neurons can connect to any other neuron on any level, with specified connection strengths, gains, and timing characteristics such as delays.

The network, as in the classic ANNs, consists of an input (stimulus) layer, layers of neurons, and connections. The stimulus layer can contain as many different stimuli as desired. Each stimulus consists of a specified number of nodes, each of which shall have a specified activation. The neural layers all contain the same number of neurons, but the spatial locations of neurons on each plane are random and unique to that plane. The neurons themselves can have activation functions (AFs) of four different types. The linear AF takes the form $y_j = \tau \sum_i x_i w_{ij}$, where y_j is the output of neuron j, x_i is the output of neuron i at the beginning of a connection that terminates at neuron j, w_{ij} is the connection strength between these two neurons, and τ is the slope of the AF. The sigmoid is expressed as $y_j = \frac{2}{1+\exp\left[-\frac{\left(\sum_i x_i w_{ij}\right)}{\tau}\right]} - 1$; the multiplier of 2 and subtraction of 1 function to give the sigmoid bounds of -1 and 1, with an input of 0 giving 0 output; without these two factors, the bounds are 0 and 1, which is a reasonable scenario, but an input of 0 creates an output of 1/2, which then propagates through the network, creating output even though there is no initial stimulus, which is unacceptable. The biological neuron uses a threshold-type activation function, which the sigmoid mimics, except for the addition of a continuous first derivative. The linear AF is useful in making a network simple, as it is then easier to trace what one knows an output should be. In trying to simulate the biological system, however, the sigmoid is more accurate. Unfortunately, the exponential in the sigmoid can only

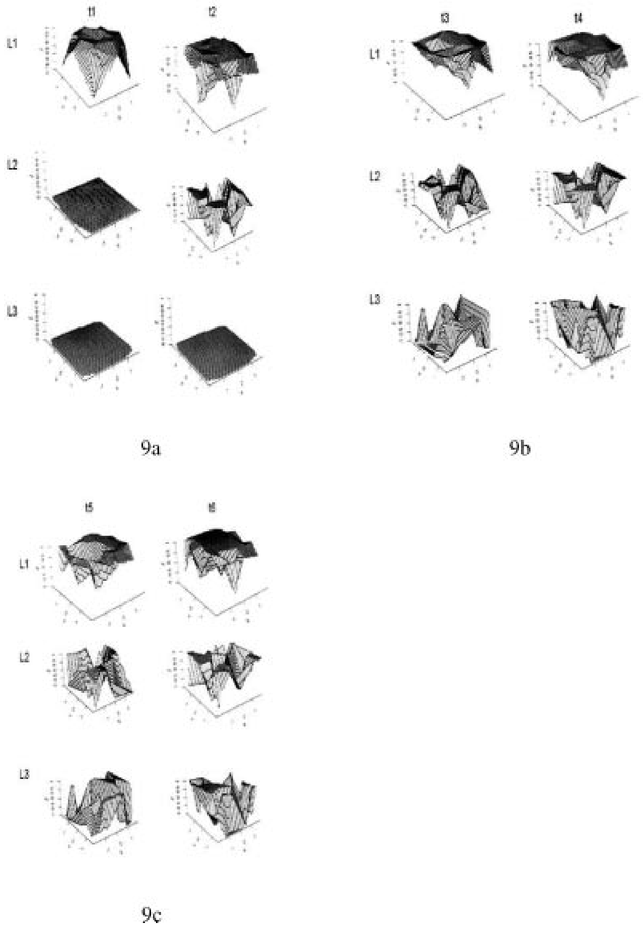


Figure 9. Progress of the workings of the 3D spatiotemporal neural network. Columns correspond to time slots. Rows indicate layers of neurons in a planar form, with given X, Y coordinates for neuronal positions on the plane. The Z axis represents the activity of neurons at that time. Notice that at $t = 1$, layers 2 and 3 have not received any inputs yet and therefore have no activity, At $t = 2$, layer 2 has some activity but layer 3 does not.

handle arguments up to a finite size, and too great an input will cause the network to fail; luckily, however, this problem usually only occurs when the stimuli are given activation that exceeds normal values, and it is easily controlled; because neural outputs are limited to a maximum of 1 (apart from the activation of input layer nodes), this overflow is only a problem when a neuron has too large a receptive field (greater than 1000 inputs, maybe), which then inundates this neuron with a greater input than the exponential function can handle. A problem with the linear AF manifests itself when feedback and lateral connections are introduced into a network; in this case, a signal, via these non-feed-forward connections, can grow indefinitely, and the output of a neuron possibly can, over time, approach infinity. A linear AF, however, can be given bounds of minimum and maximum activation. Bounding the linear AF is effective in preventing the unwanted blowup of activation seen in unbounded linear nets with feedback. A fourth type of AF is the step function, with which a neuron will fire with an output of 1 if the input exceeds a certain threshold, and it will remain inactive (output of 0) if the input is less than this threshold. The step function emulates the biological system in the closest fashion, but it does not give as much flexibility in neural outputs as the linear and sigmoid functions do, because the step function lacks the intermediate values otherwise possible.

Connections can stem from the input layer to any number of other layers, and also among all other layers. The only limitation on connections is that, with respect to the stimulus layer, only feed-forward connections may exist, which is biologically reasonable. Among all other layers, feed-forward, feedback, and lateral connections are viable. Connections are created on the basis of a connective neighborhood. The radius of this neighborhood may represent one of two things, either it is the boundary of the circle within which all neurons are connected to (by the neuron of origination) or it is the standard deviation of a Gaussian probability curve, with closer neurons having a greater probability of being connected. The initial weights of these connections are random, except for the synapses between the inputs and the first neural layer, which can either be initially random (and thereafter trained along with the other synapses) or initially (and thereafter) a constant 1.

Testing the network simply consists of exposing it to specified stimuli and allowing the network to run through a specified number of time units. The external stimuli can be either constant in value (with a delay for activation, if desired) or dynamic. The dynamic input is a sine curve, which varies the intensity of the nodes in a stimulus sinusoidally as a function of time. Testing the ANN will generate activation of neural layers.

Training the ANN can be done in one of two ways: unsupervised or supervised. The former uses predetermined stimuli, but it does not match these stimuli with known memories of any sort. A set of stimuli are presented to the network, and the outputs of all neurons are calculated. Then, the weights are updated according to a specified training rule. With the new synaptic strengths, the network is then run through again while being presented with the desired stimulus. The weights are again changed. This process continues iteratively for the desired number of iterations. It is seen that one iteration of training here is equal to one unit of network running time (as opposed to the case of supervised training, below, where one iteration of training usually consists of many time units of running through the network).

During unsupervised training, as during testing, the input layer can be either static or dynamic. Static inputs can be either homogeneous (each node in a stimulus taking the same value) or heterogeneous. Dynamic inputs can be sinusoidal (as in the testing case) or prespecified. Many training rules are available for the purpose of updating weights without supervision.

Supervised training requires stimuli-output pairs to be known, where the stimuli are the features of a specific template, and the ANN matches these features with the output neural layer corresponding to this same template. This layer must take a known form, after a specified amount of running time, for specific stimuli. The ALOPEX training algorithm then proceeds to iteratively alter the connection strengths of the network until the introduction of a certain set of stimuli creates the correct scenario of activation for the output layer. The activation of the output layer (to correspond to a specific set of features) can be set in one of two ways. One is to specify areas of output neurons to be active (positive) when a certain template is introduced, with other output neurons having negative activation. The other way for the output layer to be set is by creating data files of the activation of this layer via the testing of the network. In this latter case, a network can be trained in an unsupervised manner, and this trained network is then tested with the same stimuli used to train it, thus creating a data file containing the activation of the output neural layer after a preset amount of time. This data file can then be used as the desired activation of the output layer in a supervised network, and ALOPEX will try to force an identical network to attain this activation when the same stimuli are introduced.

Supervised training can try to take many different stimuli-output pairs and match them up in the same network, which may be used to simulate the recollection of stored memories when situations encountered are similar to those that brought about such a memory in the first place. As in most pattern recognition ANNs, however, convergence problems limit the applicability of this ANN in its desired task.

Damage to a network is a concern that may be visualized in like manner. A network can be damaged by deactivation of a group of connections between specified layers. Taking all connections away from a particular layer in effect kills all neurons on that layer. Another option is to destroy connections only within specified areas on two layers, or to simply add a Gaussian noise to all weights.

A network damaged as described earlier is easily visualized or retrained in the same manner as before and, by doing so, the effects of damage on neural activity become apparent.

These ANNs, although they are three-dimensional and time-dependent, behave in a synchronized manner, as do their classic counterparts. It may be of use, for future development, to construct nets that transmit signals in a manner where the time it takes a signal to propagate from one neuron to the next is proportional to the distance between these two neurons. Hardware ANNs do so naturally, but a digital one can be constructed in a manner where it is also possible. A synchronized ANN is still viable for this application if the time increments are very small and a signal takes a number of time units proportional to this distance to travel across the synapse. Would this method better simulate the biological system? Might it also better simulate the biological model if a frequency-modulated signal is simulated? These have been questions for future research that can prove their validity.

Biologically Inspired Modular Neural Networks

The idea of building modular networks comes from the analogy with biological systems, in which a brain (as a common example) consists of a series of interconnected substructures, like auditory, vestibular, and visual systems, which, in turn, are further structured on more functionally independent groups of neurons. Each level of signal processing performs its unique and independent purpose, such that the complexity of the output of each subsystem depends on the hierarchical level of that subsystem within the whole system. For instance, in the striate cortex (area 17), simple cells provide increased activity when a bar or slit of light stimulates a precise area of the visual field at a precise orientation. Their output is further processed by complex neurons, which respond best to straight lines moving through the receptive field in a particular direction with a specific orientation. The dot-like information from ganglion and Lateral Geniculate (LG) cells is, therefore, transformed in the occipital lobe into information about edges and their position, length, orientation, and movement. Although this information represents a high degree of abstraction, the visual association areas of the occipital lobe serve as only an early stage in the integration of visual information.

The usage of modular neural networks is most beneficial when there are cases of missing pieces of data. As each module takes its input from several others, a missing connection between modules would not significantly alter that module's output.

The anticipation is that the greater the number of features per input module, the more advantageous is the usage of modular neural networks in case of missing features. One possible application of this approach can be used in face recognition, when certain parts of a face image (like nose or eyes) are not available for some images (20).

For further improvement of the algorithm, different schemes can be used to compute the local or global error factor in the ALOPEX optimization (see Appendix 1), as well as a more reliable way for adjusting the noise with respect to the global error.

As stated earlier, one type of modular neural network is a multilayer perceptron that is not fully connected. However, just deleting random connections does not make a modular neural network. Haykin (21) defines a modular neural network as follows:

> A neural network is said to be modular if the computation performed by the network can be decomposed into two or more modules (subsystems) that operate on distinct inputs without communicating with each other. The outputs of the modules are mediated by an integrating unit that is not permitted to feed information back to the modules. In particular, the integrating unit both (1) decides how the outputs of the modules should be combined to form the final output of the system, and (2) decides which modules should learn which training patterns.

The idea of modular neural networks is analogous to biological systems (22). Our brain has many different subsystems that process sensory inputs and then feed these results to other central processing neurons in the brain. For instance, consider a person who meets someone they have not seen in a long time. To remember the identity of this person, multiple sensory inputs may be processed. Foremost perhaps is the sense of sight whereby one processes what the person looks like. That may not be enough to recognize the person, as the person may have changed over the course of a number of years. However, their looks coupled with the person's voice, the sensory input from the ears may be enough to provide an identity. If those two are not enough, perhaps the person wears a distinctive cologne or perfume that the olfactory senses will process and add an input to the central processing. In addition, the sense of touch may also provide more information if the person has a firm handshake or soft hands. In this way, our biological system makes many different observations each processed first by some module and then the results sent to be further processed at a central location. Indeed, there may be several layers of processing before a final result is achieved.

In addition to different modules processing the input, the same sensor may process the input in two different ways. For example, the ears process the sound of a person's voice. The pitch, tonality, volume, and speed of a person's voice are all taken into account when one is identifying someone. However, perhaps more important is what that person says. For instance, they may tell you their name—a piece of data that is highly critical to identification. These data would be passed to the central processing to be used to match that name with the database of peoples' names that one has previously met. It is easy to postulate that what someone says is processed differently, and perhaps feeds to a different module in the next layer, than how they say it, even though the same raw data are used.

Although the concept of a modular neural network is based on biological phenomena, it also makes sense from a purely practical viewpoint. Many real-world problems have a large amount of data points. Using this large number of points as input to a fully connected multilayer perceptron results in a very large number of weights. Just blindly trying to train a network with this approach most often results in poor performance of the network, not to mention long training times because of slow convergence (23). Sometimes there are feature extraction methods, which will reduce the number of data points. However, as was the case in this project, there are times when even then the amount of data is large. As it is desirable to have the minimum number of weights that will yield good performance, a modular neural network may be a good solution. Each module is effectively able to compress its data and extract subfeatures, which then are used as input to a fully connected neural network. Without this modularity, the number of weights in the network would be far greater.

SUMMARY

Biologically inspired neural networks in computational intelligence have been proven to be more efficient in pattern recognition tasks (24). Several examples exist that prove the notion of "every neuron connected to every neuron in the network" might not be the best approach. The feed-forward approach with a huge number of inputs and many layers of neurons does not seem to be the best and most efficient way of doing computations, simply because the number of weights that have to be optimized is prohibitively large.

We presented new types of architectures that have the ability of overcoming the above-mentioned shortcomings. In addition, mathematical models of certain biological events and processes were also presented.

COGNITIVE SYSTEMS AND COGNITIVE ARCHITECTURES

INTRODUCTION

Cognitive systems refer to computational models and systems that are in some way inspired by human (or animal) cognition as we understand it, which is a broad class of systems, not always well defined or clearly delineated. There is a variety of forms of cognitive systems. They have been developed for a variety of different purposes and in a variety of different ways. We will describe two broad categories below.

In general, computational cognitive modeling explores the essence of cognition through developing computational models of mechanisms (including representations) and processes of cognition, thereby producing realistic cognitive systems. In this enterprise, a cognitive architecture is a domain-generic and comprehensive computational cognitive model that may be used for a wide range of analysis of behavior. It embodies generic descriptions of cognition in computer algorithms and programs. Its function is to provide a general framework to facilitate more detailed computatonal modeling and understanding of various components and processes of the mind. Cognitive architectures occupy a particularly important place among all kinds of cognitive systems, as they aim to capture all basic structures and processes of the mind, and therefore are essential for broad, multiple-level, multiple-domain analyses of behavior. Developing cognitive architectures has been a difficult task. In this article, the importance of developing cognitive architectures, among other cognitive systems, will be discussed, and examples of cognitive architectures will be given.

Another common approach toward developing cognitive systems is the logic-based approach. From the logical point of view, a cognitive system is first and foremost a system that, through time, adopts and manages certain attitudes toward propositions, and reasons over these propositions, to perform the actions that will secure certain desired ends. The most important propositional attitudes are *believes that* and *knows that.* (Our focus herein will be on the latter. Other propositional attitudes include *wants that* and *hopes that*.) A propositional attitude is simply a relationship holding between an agent (or system) and one or more propositions, where propositions are declarative statements.

We can think of a cognitive system's life as being a cycle of sensing, reasoning, acting; sensing, reasoning, acting; . . ., and so on. In a cognitive system, this cycle repeats *ad infinitum*, presumably with goal after goal achieved along the way. In a logic-based cognitive system, the knowledge at the heart of this cycle is represented as formulas in one or more logics, and the reasoning in question is also regimented by these logics.

The eventual objective of cognitive systems research is to construct physically instantiated cognitive systems that can perceive, understand, and interact with their environment, and evolve and learn to achieve human-like performance in complex activities (often requiring context-specific knowledge). The readers may look into Refs. 1–4 for further information.

COGNITIVE ARCHITECTURES

In this section, we describe cognitive architectures. First, the question of what a cognitive architecture is is answered. Next, the importance of cognitive architectures is addressed. Then an example cognitive architecture is presented.

What is a Cognitive Architecture?

As mentioned earlier, a cognitive *architecture* is a comprehensive computational cognitive model, which is aimed to capture the essential structure and process of the mind, and can be used for a broad, multiple-level, multiple-domain analysis of behavior (5,6).

Let us explore this notion of architecture with an analogy. The architecture for a building consists of its overall framework and its overall design, as well as roofs, foundations, walls, windows, floors, and so on. Furniture and appliances can be easily rearranged and/or replaced and therefore they are not part of the architecture. By the same token, a cognitive architecture includes overall structures, essential divisions of modules, essential relations between modules, basic representations and algorithms within modules, and a variety of other aspects (2,7). In general, an architecture includes those aspects of a system that are relatively invariant across time, domains, and individuals. It deals with componential processes of cognition in a structurally and mechanistically well-defined way.

In relation to understanding the human mind (i.e., in relation to cognitive science), a cognitive architecture provides a concrete framework for more detailed computational modeling of cognitive phenomena. Research in computational cognitive modeling explores the essence of cognition and various cognitive functionalities through developing detailed, process-based understanding by specifying corresponding computational models of mechanisms and processes. It embodies descriptions of cognition in concrete computer algorithms and programs. Therefore, it produces runnable computational models of cognitive processes. Detailed simulations are then conducted based on the computational models. In this enterprise, a cognitive architecture may be used for broad, multiple-level, multiple-domain analyses of cognition.

In relation to building intelligent systems, a cognitive architecture specifies the underlying infrastructure for intelligent systems, which includes a variety of capabilities, modules, and subsystems. On that basis, application

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

systems may be more easily developed. A cognitive architecture also carries with it theories of cognition and understanding of intelligence gained from studying human cognition. Therefore, the development of intelligent systems can be more cognitively grounded, which may be advantageous in many circumstances (1,2).

Existing cognitive architectures include Soar (8), ACT-R (9), CLARION (6), and many others.

For further (generic) information about cognitive architectures, the readers may turn to the following websites:

http://act-r.psy.cmu.edu/

http://sitemaker.umich.edu/soar/home

Why Are Cognitive Architectures Important?

For cognitive science, the importance of cognitive architectures lies in the fact that they are beneficial to understanding the human mind. In understanding cognitive phenomena, the use of computational simulation on the basis of cognitive architectures forces one to think in terms of process and in terms of detail. Instead of using vague, purely conceptual theories, cognitive architectures force theoreticians to think clearly. They are, therefore, critical tools in the study of the mind. Researchers who use cognitive architectures must specify a cognitive mechanism in sufficient detail to allow the resulting models to be implemented on computers and run as simulations. This approach requires that important elements of the models be spelled out explicitly, thus aiding in developing better, conceptually clearer theories. It is certainly true that more specialized, narrowly scoped models may also serve this purpose, but they are not as generic and as comprehensive and thus they are not as useful (1).

An architecture serves as an initial set of assumptions to be used for further computational modeling of cognition. These assumptions, in reality, may be based on either available scientific data (for example, psychological or biological data), philosophical thoughts and arguments, or ad hoc working hypotheses (including computationally inspired such hypotheses). An architecture is useful and important precisely because it provides a comprehensive initial framework for further modeling in a variety of task domains. Different cognitive architectures, such as Soar, ACT-R, or CLARION, embody different sets of assumptions (see an example later).

Cognitive architectures also provide a deeper level of explanation. Instead of a model specifically designed for a specific task (often in an ad hoc way), using a cognitive architecture forces modelers to think in terms of the mechanisms and processes available within a generic cognitive architecture that are not specifically designed for a particular task, and thereby to generate explanations of the task that are not centered on superficial, high level features of a task (as often happens with specialized, narrowly scoped models), that is, to generate explanations of a deeper kind. To describe a task in terms of available mechanisms and processes of a cognitive architecture is to generate explanations centered on primitives of cognition as envisioned in the cognitive architecture (e.g., ACT-R or CLARION), and therefore such explanations are deeper explanations. Because of the nature of such deeper explanations, this style of theorizing is also more likely to lead to unified explanations for a large variety of data and/or phenomena, because potentially a large variety of tasks, data, and phenomena can be explained on the basis of the same set of primitives provided by the same cognitive architecture. Therefore, using cognitive architectures leads to comprehensive theories of the mind (5,6,9), unlike using more specialized, narrowly scoped models.

Although the importance of being able to reproduce the nuances of empirical data from specific psychological experiments is evident, broad functionality in cognitive architectures is also important (9), as the human mind needs to deal with the full cycle that includes all of the following: transducing signals, processing them, storing them, representing them, manipulating them, and generating motor actions based on them. There is clearly a need to develop generic models of cognition that are capable of a wide range of functionalities to avoid the myopia often resulting from narrowly-scoped research (in psychology in particular).

In all, cognitive architectures are believed to be essential in advancing the understanding of the mind (5,6,9). Therefore, developing cognitive architectures is an important enterprise in cognitive science.

On the other hand, for the fields of artificial intelligence and computational intelligence (AI/CI), the importance of cognitive architectures lies in the fact that they support the central goal of AI/CI—building artificial systems that are as capable as human beings. Cognitive architectures help us to reverse engineer the best existing intelligent system—the human mind. They constitute a solid basis for building intelligent systems, because they are well motivated by, and properly grounded in, existing cognitive research. The use of cognitive architectures in building intelligent systems may also facilitate the interaction between humans and artificially intelligent systems because of the similarity between humans and cognitively based intelligent systems.

It is also worth noting that cognitive architectures are the antithesis of "expert systems": Instead of focusing on capturing performance in narrow domains, they are aimed to provide broad coverage of a wide variety of domains (2). Business and industrial applications of intelligent systems increasingly require broad systems that are capable of a wide range of intelligent behaviors, not just isolated systems of narrow functionalities. For example, one application may require the inclusion of capabilities for raw image processing, pattern recognition, categorization, reasoning, decision making, and natural language communications. It may even require planning, control of robotic devices, and interactions with other systems and devices. Such requirements accentuate the importance of research on broadly scoped cognitive architectures that perform a wide range of cognitive functionalities across a variety of task domains (as opposed to more specialized systems).

An Example of a Cognitive Architecture

An Overview. As an example, we will describe a cognitive architecture: CLARION. It has been described extensively in a series of previous papers, including Refs. 6,10–12. The reader is referred to these publications for further details.

Those who wish to know more about other cognitive architectures in existence (such as ACT-R or Soar) may want to see Refs. 8 and 9.

CLARION is an integrative architecture, consisting of a number of distinct subsystems, with a dual representational structure in each subsystem (i.e., implicit versus explicit representations; more later). Its subsystems include the action-centered subsystem (the ACS), the nonaction-centered subsystem (the NACS), the motivational subsystem (the MS), and the meta-cognitive subsystem (the MCS). The role of the action-centered subsystem is to control actions, regardless of whether the actions are for external physical movements or for internal mental operations. The role of the nonaction-centered subsystem is to maintain general knowledge (either implicit or explicit). The role of the motivational subsystem is to provide underlying motivations for actions in terms of providing impetus and feedback (e.g., indicating whether outcomes are satisfactory). The role of the meta-cognitive subsystem is to monitor, direct, and modify the operations of the action-centered subsystem dynamically as well as the operations of all the other subsystems.

Each of these interacting subsystems consists of two “levels” of representation (i.e., a dual representational structure): Generally, in each subsystem, the top level encodes explicit knowledge and the bottom level encodes implicit knowledge. The distinction of implicit and explicit knowledge has been amply argued for before (6,13–15). The two levels interact, for example, by cooperating in actions, through a combination of the action recommendations from the two levels respectively, as well as by cooperating in learning through a bottom-up and a top-down process (to be discussed below). See Fig. 1.

It has been intended that this cognitive architecture satisfy some basic requirements as follows. It should be able to learn with or without a priori domain-specific knowledge to begin with (unlike most other existing cognitive architectures) (11,13). It also has to learn continuously from ongoing experience in the world (as indicated by Refs. 16 and 17, and others, human learning is often gradual and ongoing). As suggested by Refs. 13 and 14, and others, there are clearly different types of knowledge involved in human learning. Moreover, different types of learning processes are involved in acquiring different types of knowledge (9,11,18). Furthermore, it should include both situated actions/reactions and cognitive deliberations (6). It should be able to handle complex situations that are not amenable to simple rules. Finally, unlike other existing cognitive architectures, it should more fully incorporate motivational processes as well as meta-cognitive processes. Based on the above considerations, CLARION was developed.

Some Details. ***The Action-Centered Subsystem.*** First, let us look into the action-centered subsystem (the ACS) of CLARION. The overall operation of the action-centered subsystem may be described as follows:

1. Observe the current state x.
2. Compute in the bottom level the Q-values of x associated with each of all the possible actions a_i's: $Q(x, a_1)$, $Q(x, a_2)$, ..., $Q(x, a_n)$.

selection
regulation
MS
MCS

Figure 1. The CLARION architecture.

3. Find out all the possible actions ($b_1, b_2, \ldots, b_m$) at the top level, based on the input x (sent up from the bottom level) and the rules in place.
4. Compare or combine the values of the selected a_is with those of b_js (sent down from the top level), and choose an appropriate action b.
5. Perform the action b, and observe the next state y and (possibly) the reinforcement r.
6. Update Q-values at the bottom level in accordance with the *Q-Learning-Backpropagation* algorithm.
7. Update the rule network at the top level using the *Rule-Extraction-Refinement* algorithm.
8. Go back to Step 1.

In the bottom level of the action-centered subsystem, implicit reactive routines are learned: A Q-value is an evaluation of the “quality” of an action in a given state: $Q(x, a)$ indicates how desirable action a is in state x (which consists of some sensory input). An action may be chosen in any state based on Q-values in that state. To acquire the Q-values, the *Q-learning* algorithm (19) may be used, which is a reinforcement learning algorithm (see the articles on learning algorithms in this encyclopedia). It basically compares the values of successive actions and adjusts an evaluation function on that basis. It thereby develops reactive sequential behaviors or reactive routines [such as navigating through a body of water or handling daily activities, in a reactive way (6,12)]. Reinforcement learning is implemented in modular (multiple) neural networks. Due to such networks, CLARION is able to handle very complex situations that are not amenable to simple rules.

In the top level of the action-centered subsystem, explicit symbolic conceptual knowledge is captured in the form of explicit symbolic rules; see Ref. 12 for details. There are many ways in which explicit knowledge may be learned, including independent hypothesis-testing learning and “bottom-up learning” as discussed below.

Humans are generally able to learn implicit knowledge through trial and error, without necessarily using a priori knowledge. On top of that, explicit knowledge can be acquired also from ongoing experience in the world, possibly through the mediation of implicit knowledge (i.e., bottom-up learning; see Refs. 6,18, and 20). The basic process of bottom-up learning (which is generally missing from other existing cognitive architectures and distinguishes CLARION from others) is as follows: If an action implicitly decided by the bottom level is successful, then the agent extracts an explicit rule that corresponds to the action selected by the bottom level and adds the rule to the top level. Then, in subsequent interaction with the world, the agent verifies the extracted rule by considering the outcome of applying the rule: If the outcome is not successful, then the rule should be made more specific and exclusive of the current case; if the outcome is successful, the agent may try to generalize the rule to make it more universal (21).[1] After explicit rules have been learned, a variety of explicit reasoning methods may be used. Learning explicit conceptual representation at the top level can also be useful in enhancing learning of implicit reactive routines at the bottom level (11).

Although CLARION can learn even when no a priori or externally provided explicit knowledge is available, it can make use of it when such knowledge is available (9,22). To deal with instructed learning, externally provided knowledge, in the forms of explicit conceptual structures such as rules, plans, categories, and so on, can 1) be combined with existent conceptual structures at the top level, and 2) be assimilated into implicit reactive routines at the bottom level. This process is known as top-down learning (12).

The Non-action-Centered Subsystem. The nonaction-centered subsystem (NACS) may be used for representing general knowledge about the world (23), for performing various kinds of memory retrievals and inferences. The nonaction-centered subsystem is under the control of the action-centered subsystem (through its actions).

At the bottom level, “associative memory” networks encode nonaction-centered implicit knowledge. Associations are formed by mapping an input to an output (such as mapping “2 + 3” to “5”). For example, the regular backpropagation learning algorithm can be used to establish such associations between pairs of inputs and outputs (24).

On the other hand, at the top level of the nonaction-centered subsystem, a general knowledge store encodes explicit nonaction-centered knowledge (25). In this network, chunks are specified through dimensional values (features).[2] A node is set up in the top level to represent a chunk. The chunk node connects to its corresponding features (represented as individual nodes) in the bottom level of the nonaction-centered subsystem (25). Additionally, links between chunks encode explicit associations between pairs of chunks, known as associative rules. Explicit associative rules may be formed (i.e., learned) in a variety of ways (12).

Different from most other existing cognitive architectures, during reasoning, in addition to applying associative rules, similarity-based reasoning may be employed in the nonaction-centered subsystem. During reasoning, a known (given or inferred) chunk may be automatically compared with another chunk. If the similarity between them is sufficiently high, then the latter chunk is inferred (12,25).

As in the action-centered subsystem, top-down or bottom-up learning may take place in the nonaction-centered subsystem, either to extract explicit knowledge in the top level from the implicit knowledge in the bottom level or to assimilate explicit knowledge of the top level into implicit knowledge in the bottom level.

The Motivational and the Meta-Cognitive Subsystem. The motivational subsystem (the MS) is concerned with why an

[1] The detail of the bottom-up learning algorithm can be found in Ref. 10.

[2] The basic form of a chunk is as follows: *chunk-id*$_i$: (dim_{i_1}, val_{i_1})(dim_{i_2}, val_{i_1}) ...... (dim_{i_n}, val_{i_n}), where *dim* denotes a particular state/output dimension and *val* specifies its corresponding value. For example, *table-1:* (*size*, *large*) (*color*, *white*) (*number-of-legs*, *four*) specifies a large, four-legged, white table.

agent does what it does. Simply saying that an agent chooses actions to maximizes gains, rewards, reinforcements, or payoffs leaves open the question of what determines these things. The relevance of the motivational subsystem to the action-centered subsystem lies primarily in the fact that it provides the context in which the goal and the reinforcement of the action-centered subsystem are set. It thereby influences the working of the action-centered subsystem, and by extension, the working of the nonaction-centered subsystem.

A dual motivational representation is in place in CLARION. The explicit goals (such as "finding food") of an agent (which is tied to the working of the action-centered subsystem) may be generated based on internal drive states (for example, "being hungry"; see Ref. 12 for details).

Beyond low level drives (concerning physiological needs),[3] there are also higher level drives. Some of them are primary, in the sense of being "hard-wired".[4] Although primary drives are built-in and relatively unalterable, there are also "derived" drives, which are secondary, changeable, and acquired mostly in the process of satisfying primary drives.

The meta-cognitive subsystem (the MCS) is closely tied to the motivational subsystem. The meta-cognitive subsystem monitors, controls, and regulates action-centered and nonaction-centered processes for the sake of improving performance (26,27). Control and regulation may be in the forms of setting goals for the action-centered subsystem, setting essential parameters of the action-centered subsystem and the nonaction-centered subsystem, interrupting and changing ongoing processes in the action-centered subsystem and the nonaction-centered subsystem, and so on. Control and regulation can also be carried out through setting reinforcement functions for the action-centered subsystem. All of the above can be done on the basis of drive states and/or goals in the motivational subsystem. The meta-cognitive subsystem is also made up of two levels: the top level (explicit) and the bottom level (implicit).

Accounting for Cognitive Data. Like some other cognitive architectures (ACT-R in particular), CLARION has been successful in accounting for and explaining a variety of psychological data. For example, a number of well-known psychological tasks have been simulated using CLARION that span the spectrum ranging from simple reactive skills to complex cognitive skills. The simulated tasks include serial reaction time tasks, artificial grammar learning tasks, process control tasks, categorical inference tasks, alphabetic arithmetic tasks, and the Tower of Hanoi task (6). Among them, serial reaction time and process control tasks are typical implicit learning tasks (mainly involving implicit reactive routines), whereas Tower of Hanoi and alphabetic arithmetic are high level cognitive skill acquisition tasks (with a significant presence of explicit processes). In addition, extensive work has been done on a complex minefield navigation task, which involves complex sequential decision making (10,11). Work has also been done on an organizational decision task (28), and other social simulation tasks, as well as meta-cognitive tasks. While accounting for various psychological data, CLARION provides explanations that shed new light on cognitive phenomena.

In all of these cases of simulations, the use of the CLARION cognitive architecture forces one to think in terms of process, and in terms of details, as envisaged in CLARION. The use of CLARION also provides a deeper level of explanations. It is deeper because the explanations were centered on lower level mechanisms and processes (1,6). Due to the nature of such deeper explanations, this approach is also likely to lead to unified explanations, unifying a large variety of data and/or phenomena. For example, all the afore-mentioned tasks have been explained computationally in a unified way in CLARION.

LOGIC-BASED COGNITIVE SYSTEMS

We now give an account of logic-based cognitive systems, mentioned in broad strokes earlier.

Logic-Based Cognitive Systems in General

At any time t during its existence, the cognitive state of a cognitive system S consists in what the system knows at that time, denoted by Φ_S^t. (To ease exposition, we leave aside the distinction between what S knows versus what it merely believes.) We assume that as S moves through time, what it knows at any moment is determined, in general, by two sources: information coming directly from the external environment in which S lives, through the transducers in S's sensors that turn raw sense data into propositional content, and from reasoning carried out by S over its knowledge.

For example, suppose you learn that Alvin loves Bill, and that everyone loves anyone who loves someone. Your goal is to determine whether or not everyone loves Bill, and whether or not Katherine loves Dave. The reasoning needs to be provided in the form of an explicit series of inferences (which serves to guarantee that the reasoning in question is "surveyable").

Your knowledge (or *knowledge base*) now includes that Alvin loves Bill. (It also includes 'Everyone loves anyone who loves someone'.) You know this because information impinging upon your sensors has been transduced into propositional content added to your knowledge base. We can summarize the situation at this point is as follows:

$$\Phi_S^{t_{n+1}} = \Phi_S^{t_n} \cup \{\texttt{Loves(alvin,bill)}\}$$

Generalizing, we can define a ternary function *env* from timepoint-indexed knowledge bases, and formulas generated by *trans* applied to raw information hitting sensors, to a new, augmented knowledge base at the next timepoint. So we have:

$$\Phi_S^{t_{n+1}} = env(\Phi_S^{t_n}, trans(raw))$$

where $trans(raw) = \texttt{Loves(alvin,bill)}$.

[3] Low level drives include, for example, *need for food, need for water, need to avoid danger,* and so on (12).

[4] A few high level drives include: *desire for domination, desire for social approval, desire for following social norms, desire for reciprocation, desire for imitation* (of certain other people), and so on (12).

Now consider the second source of new knowledge, viz., reasoning. On the basis of reasoning over the proposition that Alvin loves Bill, we know that someone loves Bill, that someone loves someone, that someone whose name starts with ‘A’ loves Bill, and so on. These additional propositions can be directly deduced from the single one about Alvin and Bill; each of them can be safely added to your knowledge base.

Let $\mathcal{R}[\Phi]$ denote an augmentation of Φ via some mode of reasoning $\mathcal{R}$. Then your knowledge at the next timepoint, t_{n+2}, is given by

$$\Phi_S^{t_{n+2}} = \mathcal{R}[env(\Phi_S^{t_n}, trans(raw))]$$

As time flows on, the environment’s updating, followed by reasoning, followed by changes the cognitive system makes to the environment (the system’s actions), define the cognitive life of S.

But what is $\mathcal{R}$, and what is the structure of propositions returned by *trans*? This point is where logic enters the stage. In a logic-based cognitive system, propositions are represented by formulas in a logic, and a logic provides precise machinery for carrying out reasoning.

Knowledge Representation in Elementary Logic

In general, when it comes to any logic-based system, three main components are required: one is syntactic, one is semantic, and one is metatheoretical in nature.

The syntactic component includes specification of the alphabet of a given logical system, the grammar for building well-formed formulas (wffs) from this alphabet, and, more importantly, a proof theory that precisely describes how and when one formula can be inferred from a set of formulas. The semantic component includes a precise account of the conditions under which a formula in a given system is true or false. The metatheoretical component includes theorems, conjectures, and hypotheses concerning the syntactic component, the semantic component, and connections between them.

The simplest logics to build logic-based cognitive systems are the propositional calculus and the predicate calculus (or first-order logic, or just FOL).

The alphabet for propositional logic is an infinite list

$$p_1, p_2, \ldots, p_n, p_{n+1}, \cdots$$

of propositional variables and the five familiar truth-functional connectives $\neg$, $\rightarrow$, $\leftrightarrow$, $\wedge$, $\vee$. (The connectives can at least provisionally be read, respectively, as ‘not,’ ‘implies’ (or ‘if then’), ‘if and only if,’ ‘and,’ and ‘or.’) To say that ‘if Alvin loves Bill, then Bill loves Alvin, and so does Katherine,’ we could write

$$a_l \rightarrow (b_1 \wedge k_l)$$

where b_l and k_l are the propositional variables.

We move up to first-order logic when we allow the quantifiers $\exists x$ (‘there exists at least one thing x such that …’) and $\forall x$ (‘for all x …’); the first is known as the *existential* quantifier, and the second is known as the *universal*. We also allow a supply of variables, constants, relations, and function symbols. Using this representation, the proposition that ‘Everyone loves anyone who loves someone’ is represented as

$$\forall x \forall y (\exists z Loves(y,z) \rightarrow Loves(x,y))$$

Deductive Reasoning

The hallmark of deductive reasoning is that if the premises are true, then that which is deduced from them must be true as well. In logic, deduction is formalized in a *proof theory*. Such theories (versions of which were first invented and presented by Aristotle) are often designed not to model the reasoning of logically untrained humans, but rather to express ideal, normatively correct human deductive reasoning targeted by the logically trained. To canvass other proof theories explicitly designed to model the deductive reasoning of logically untrained humans, interested readers may consult Ref. 29.

A number of proof theories are possible (for either of the propositional or predicate calculi). When the goal is to imitate human reasoning and to be understood by humans, the proof theory of choice is *natural deduction* rather than *resolution*. The latter approach to reasoning (whose one and only rule of inference, in the end, is that from $\varphi \vee \psi$ and $\neg \varphi$ one can infer ψ), while used by a number of automated theorem provers (e.g., Otter, which, along with resolution, is presented in Ref. 30), is generally impenetrable to humans.

On the other hand, suppositional reasoning is at the heart of natural deduction. For example, one such common suppositional technique is to assume the opposite of what one wishes to establish, to show that from this assumption some contradiction (i.e., an absurdity) follows, and to then conclude that the assumption must be false. The technique in question is known as *reductio ad absurdum,* or indirect proof, or proof by contradiction. Another natural rule is that to establish that some conditional of the form $\varphi \rightarrow \psi$ (where φ and ψ are any formulas in a logic L), it suffices to suppose φ and derive ψ based on this supposition. With this derivation accomplished, the supposition can be discharged, and the conditional $\varphi \rightarrow \psi$ established. The needed conclusion from the previous example (i.e., whether or not everyone loves Bill, and whether or not Katherine loves Dave) follows readily from such reasoning. (For an introduction to natural deduction, replete with proof-construction and proof-checking software, see Ref. 31.)

Nonmonotonic Reasoning

Deductive reasoning is monotonic. That is, if φ can be deduced from some knowledge base Φ of formulas (written $\Phi \vdash_D \phi$), then for any formula $\psi \notin \Phi$, it remains true that $\Phi \cup \{\psi\} \vdash_D \phi$ In other words, when $\mathcal{R}$ is deductive in nature, new knowledge never invalidates prior reasoning.

This process is not how human cognition works in real life. For example, at present, I know that my house is standing. But if, later in the day, while away from my home and working at RPI, I learn that a vicious tornado passed over RPI, and touched down in the town of Brunswick where my house is located, I have new information that probably leads me to at least suspend judgment as to whether or not my house still stands. Or to take the much-used example from AI, if I know that Tweety is a bird, I will probably deduce that Tweety can fly, on the strength of a general principle saying that birds can fly. But if I learn that Tweety is a penguin, the situation must be revised: that Tweety can fly should now not be in my knowledge base. Nonmonotonic reasoning is the form of reasoning designed to model, formally, this kind of *defeasible* inference.

There are many different logic-based approaches that have been designed to model defeasible reasoning—default logic, circumscription, argument-based defeasible reasoning, and so on. (The *locus classicus* of a survey can be found in Ref. 32.) In the limited space available in the present chapter, we can only briefly explain one of these approaches—argument-based defeasible reasoning, because it seems to accord best with what humans do as they adjust their knowledge through time.

Returning to the tornado example, what is the argument that supports the belief that the house stands (while one sits within it)? Here is Argument 1:

(1) I perceive that my house is still standing.
(2) If I perceive ϕ, ϕ holds.
$\therefore$(3) My house is still standing.

Later on, we learned that the tornado had touched down in Brunswick, and devastating damage to some homes has come to pass. At this point (t_2), if one was pressed to articulate the current position on (3), one might offer something like this (Argument 2):

(4) A tornado has just (i.e., at some time between t_1 and t_2) touched down in Brunswick, and destroyed some houses there.
(5) My house is located in Brunswick.
(6) I have no evidence that my house was *not* struck to smithereens by a tornado that recently passed through the town in which my house is located.
(7) If a tornado has just destroyed some houses in town T, and house h is located in T, and one has no evidence that h is not among the houses destroyed by the tornado, then one ought not to believe that h was not destroyed.
$\therefore$(8) I ought not to believe that my house is still standing (i.e., I ought not to believe (3).

The challenge is to devise formalisms and mechanisms that model this kind of mental activity through time. The argument-based approach to nonmonotonic reasoning does this. Although the details of the approach must be left to outside reading (33), it should be easy enough to see that the main point is to allow one argument to shoot down another (and one argument to shoot down an argument that shoots down an argument, which revives the original, etc.), and to keep a running tab on which propositions should be believed at any particular time.

Argument 2 above rather obviously shoots down Argument 1. Should one then learn that only two houses in Brunswick were leveled, and that they are both located on the other side of the town, Argument 2 would be defeated by a third argument, because this third argument would overthrow (6). With Argument 2 defeated, (3) would be reinstated, and back in my knowledge base. Notice that this ebb and flow in argument-versus-argument activity is far more than just straight deductive reasoning. (Logic can be used to model nondeductive reasoning that is not only nonmonotonic, but also inductive, abductive, probabilistic, model-based, and analogical, but coverage of these modes of inference is beyond the scope of the present entry). For coverage of the inductive and probabilistic modes of reasoning, see Ref. 34. For coverage of model-based reasoning, which is not based solely on purely linguistic formulas, but rather on models, which are analogous to states of affairs or situations on which linguistic formulas are true or false (or probable, indeterminate, etc.), see Ref. 35.

Modal Logics

Logics can be used to represent knowledge, but advanced logics can also be used to represent knowledge about knowledge, and reasoning about knowledge about knowledge. Modeling such knowledge and reasoning is important for capturing human cognition, and in light of the fact that heretofore the emphasis in psychology of reasoning has been on modeling simpler reasoning that does not involve modals, the level of importance only grows. Consider the Wise Man Puzzle below as an illustration of modal reasoning to be captured:

> Suppose there are three wise men who are told by their king that at least one of them has a white spot on his forehead; actually, all three have white spots on their foreheads. We assume that each wise man can see the others' foreheads but not his own, and thus each knows whether the others have white spots. Suppose we are told that the first wise man says, "I do not know whether I have a white spot," and that the second wise man then says, "I also do not know whether I have a white spot." Now we would like to ask you to attempt to answer the following questions:
>
> 1. Does the third wise man now know whether or not he has a white spot?
> 2. If so, what does he know, that he has one or doesn't have one?
> 3. And, if so, that is, if the third wise man does know one way or the other, provide a detailed account (showing all work, all notes, etc.; use scrap paper as necessary) of the reasoning that produces his knowledge.

The logic able to answer these questions is a modal propositional epistemic logic; we refer to it simply as $\mathcal{L}_{KT}$. This logic is produced by adding to the propositional calculus the modal operators $\Box$ (traditionally interpreted as "necessarily") and $\Diamond$ (traditionally interpreted as "possibly"), with subscripts on these operators to refer to cognitive systems. Because we are here concerned with what cognitive systems believe and know, we will focus on the box, and will rewrite $\Box_\alpha$ as $\mathbf{K}_\alpha$ [i.e., cognitive system α knows (something)]. So, to represent that 'Wise man A knows he doesn't have a white spot on his forehead,' we can write $\mathbf{K}_A$ ($\neg$White(A)). Here's the grammar for $\mathcal{L}_{KT}$.

1. All wffs in the propositional calculus are wffs.
2. If ϕ is a closed wff, and α is a constant, then $\Box_\alpha\phi$ is a wff. Since we are here concerned with doxastic matters, that is, matters involving believing and knowing, we say that $\mathbf{B}_\alpha\phi$ is a wff, or, if we are concerned with 'knows' rather than 'believes,' that $\mathbf{K}_\alpha\phi$ is a wff.
3. If ϕ and ψ are wffs, then so are any strings that can be constructed from ϕ and ψ by the usual propositional connectives (e.g., $\rightarrow, \Lambda, \ldots$).

Next, here are some key axioms and rules of inference:

K $\Box(\phi \rightarrow \psi) \rightarrow (\Box\phi \rightarrow \Box\psi)$

T $\Box\phi \rightarrow \phi$

LO ("logical omniscience") Where $\Phi = \{\phi_1, \phi_2, \ldots, \phi_n\}$, from $\Phi \vdash_D \psi$ and $\mathbf{K}_\alpha\phi_1$, $\mathbf{K}_\alpha\phi_2, \ldots$ infer $\mathbf{K}_\alpha\psi$

The first rule says that if one knows a conditional, then if one knows the antecedent of the conditional, one knows the consequent. The second says that if one knows some proposition, that proposition is true. The inference rule LO says that the agent α knows that which can be deduced from what she knows. This rule of inference, without restrictions placed on it, implies that if a knows, say, the axioms of set theory (which are known to be sufficient for deductively deriving all of classical mathematics from them), α knows all of classical mathematics, which is not cognitively plausible. Fortunately, LO allows for the introduction of parameters that more closely match the human case. For example LO^n would be the rule of inference according to which α knows the consequences of what she knows, as long as the length of the derivations (in some fixed proof theory) of the consequences does not exceed n steps.

To ease exposition, we restrict the solution to the two-wise man version. In this version, the key information consists in these three facts:

1. A knows that if A does not have a white spot, B will know that A does not have a white spot.
2. A knows that B knows that either A or B has a white spot.
3. A knows that B does not know whether or not B has a white spot.

Here is a proof in $\mathcal{L}_{KT}$ that solves this problem:

1. $\mathbf{K}_A(\neg\text{White(A)} \rightarrow \mathrm{K}_{\mathrm{B}}(\neg\text{White(A)}))$ (first fact)
2. $\mathbf{K}_A(\mathbf{K}_B(\neg\text{White(A)} \rightarrow \text{White(B)}))$ (second fact)
3. $\mathbf{K}_A(\neg\mathbf{K}_B(\text{White(B)}))$ (third fact)
4. $\neg\text{White(A)} \rightarrow \mathbf{K}_B(\neg\text{White(A)})$ 1, T
5. $\mathbf{K}_B(\neg\text{White(A)} \rightarrow \text{White(B)})$ 2, T
6. $\mathbf{K}_B(\neg\text{White(A)}) \rightarrow \mathbf{K}_B(\text{White(B)})$ 5, K
7. $\neg\text{White(A)} \rightarrow \mathbf{K}_B(\text{White(B)})$ 4, 6
8. $\neg\mathbf{K}_B(\text{White(B)}) \rightarrow \text{White(A)}$ 7
9. $\mathbf{K}_A(\neg\mathbf{K}_B(\text{White(B)}) \rightarrow \text{White(A)})$ 4–8, 1, LO
10. $\mathbf{K}_A(\neg\mathbf{K}_B(\text{White(B)})) \rightarrow \mathbf{K}_A(\text{White(A)})$ 9, K
11. $\mathbf{K}_A(\text{White(A)})$ 3, 10

The foregoing solution closely follows that provided by Ref. 32; this solution lacks a formal semantics for the inference rules in question. For a fuller version of a solution to the arbitrarily iterated n-wise man version of the problem, replete with a formal semantics for the proof theory used, and a real-life implementation that produces a logic-based cognitive system, running in real time, that solves this problem; see Ref. 36.

Examples of Logic-Based Cognitive Systems

There are many logic-based cognitive systems that have been engineered. It is important to know that they can be physically embodied, have to deal with rapid-fire interaction with the physical environment, and still run efficiently.

For example, Amir and Maynard-Reid (37) built a logic-based robot able to carry out clerical functions in an office environment; similar engineering has been carried out in Ref. (38). For a set of recent examples of readily understood, small-scale logic-based cognitive systems doing various things that humans do; see Ref. 39.

There is insufficient space to put on display an actual logic-based cognitive system of a realistic size here. So see the afore-mentioned references for further details.

CONCLUDING REMARKS

In recent decades, the research on cognitive systems has progressed to the extent that we can start to build computational systems that mimic the human mind to some degree, although there is a long way to go before we can fully understand the architecture of the human mind and thereby develop computational cognitive systems that replicate its full capabilities.

Some example cognitive systems have been presented here. Yet, it is still necessary to explore more fully the space of possible cognitive systems (40,41), to further advance the state of the art in cognitive systems, in cognitive modeling, and in cognitive science in general. It will also be necessary to enhance the functionalities of cognitive systems so that they can be capable of the full range of intelligent behaviors. Many challenges and issues need to be addressed (1,2). We can expect that the field of cognitive systems will have a significant and meaningful impact on cognitive science and on computer science both in terms of understanding cognition and in terms of developing artificially intelligent systems. The goal of constructing embodied systems that can perceive, understand, and interact with their environment to achieve human-like performance in various activities drives this field forward.

DIMENSIONALITY REDUCTION

INTRODUCTION

A dimension refers to a measurement of a certain aspect of an object. Dimensionality reduction is the study of methods for reducing the number of dimensions describing the object. Its general objectives are to remove irrelevant and redundant data to reduce the computational cost and avoid data over-fitting (1) and to improve the quality of data for efficient data-intensive processing tasks such as pattern recognition and data mining. Dimensionality reduction is an effective solution to the problem of “curse of dimensionality.” When the number of dimensions increases linearly, experiments have shown that the required number of examples for learning increases exponentially (2). Figure 1 shows an example of the curse of dimensionality.

In practice, researchers and practitioners interchangeably use dimension, feature, variable, and attribute. Similarly, we will interchangeably use object, example, vector, and instance. Consider an application in which a system processes data (speech signal, images, or patterns in general) in the form of a collection of vectors. For a particular application, it is more often than not that a subset of features is relevant, and in some cases, a large number of features are irrelevant. This problem can be caused by factors such as (i) many dimensions will have variation smaller than the measurement noise and thus will be *irrelevant*, and (ii) many dimensions will be correlated (through linear combinations or functional dependence) to others and thus will be *redundant*. Therefore, in many situations, it is recommended to remove the irrelevant and redundant dimensions, producing a more economical representation of the data (6).

Dimensionality reduction is a research area at the intersection of several disciplines, including statistics, databases, data mining, text mining, pattern recognition, machine learning, artificial intelligence, visualization, and optimization. Each of these areas has a way of looking at the problem. For example, in pattern recognition the problem of dimensionality reduction is to extract a small set of features that recovers most of the variability of the data. In text mining, however, the problem is defined as selecting a small subset of words or terms (not new features that are combination of words or terms). Use of this important technique also varies with the application domain. Examples of applications of dimensionality reduction techniques include mining of text documents, gene structure discovery, image processing, statistical learning, and exploratory data analysis. Different applications need to be treated with different techniques. Depending on the application, new features may be extracted as in the case of exploratory analysis, or a small subset of original features are selected as in the case of gene structure discovery.

Dimensionality reduction has been a subject of much research currently and over the past several decades [some good overviews are available (7–10)]. In particular, the pioneering work of Sammon (11) has given inspiration to today’s information processing systems. Sammon, in the late 1970s, combined dimensionality reduction with issues such as classification and interactive visual data analysis. Recently, there is a renewed interest in this topic due to massive data of large dimensionality created in data mining, data warehousing, and knowledge discovery applications. Other applications such as genome project, text mining, and web mining also require efficient dimensionality reduction methods.

Dimensionality reduction methods can be grouped in various ways: (i) feature selection or feature extraction, (ii) linear or nonlinear, (iii) supervised or unsupervised, and (iv) local or global. Dimensionality reduction methods are often classified into feature selection or feature extraction. In feature selection, a subset of original features are selected in the end. In feature extraction, new features are extracted using some mapping (linear or nonlinear) from the original set of features. Linear methods such as principal components analysis (PCA) use a linear mapping to extract new features from original features (9). Similarly, nonlinear methods such as Sammon’s mapping (7), locally linear embedding (12), and ISOMAP (13) use a nonlinear mapping to extract new features. Supervised methods can take advantage of any class information present in the data, whereas unsupervised methods do not use this class information. One limitation of the supervised methods is that characteristic variables that describe examples of infrequent classes tend to be easily removed as a result of dimensionality reduction making use of the class distribution. Typically, supervised dimensionality reduction methods can be further divided into local or global methods. In a local method, features are selected for each category of the class feature; in the case of a global method, features are selected for all categories. Among these different ways of categorizing dimensionality reduction methods, we will mainly describe various methods of dimensionality reduction methods in terms of feature extraction or feature selection.

In the following two sections, we introduce the basic concepts and key techniques of feature extraction and selection, respectively. We then discuss some dimensionality reduction methods in practice.

FEATURE EXTRACTION

Feature extraction can be defined as follows: Given a set of features $S = \{v_1, v_2, \ldots, v_D\}$, find a new set of features S' derived from a linear or nonlinear mapping of S. The cardinality of $|S'| = d$ and $J(S') \geq J(T)$ for all derived set of features T with $|T| = d$, where J is the evaluation function. Here d or some other parameter that can determine d

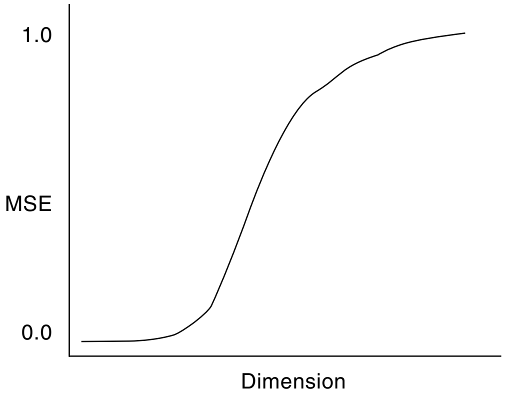

Figure 1. An example of curse of dimensionality: MSE is the mean-squared error of a 1-nearest neighbor rule (3, 4). Each dimension is generated uniformly on $[-1, 1]$. As the dimensionality increases, the MSE increases very sharply until it levels off at 1.0. This happens as early as dimensionality $= 10$. See Ref. 5 for further details.

(e.g., a threshold eigen value) is usually specified by the user.

When all existing features are recombined to yield new features, then we are dealing with feature extraction. Hence a mapping is defined that transforms any original D dimensional feature vector into a new d-dimensional feature vector. Ideally the mapping conserves or even enhances the discriminatory information while reducing the dimensionality of the feature vector. Mapping can be linear or nonlinear. Figure 2 depicts this pictorially. The following descriptions of a sample of classic feature extraction methods will bring out the methodical difference between feature transformation and selection (Fig. 3).

Principal Components Analysis (PCA)

It is the most widely used linear feature extraction method (14). It is also called the Karhunen–Loeve transform in signal processing literature. The class information is not taken into consideration in this method. The objective of this method is to find a set of d orthogonal basis vectors that maximally captures the relationship between the original dimensions. It can be shown that the *jth* principal component direction is along an eigenvector direction of the global covariance matrix $C = \frac{1}{N-1}\sum_{j=1}^{N}[(x_j - \mu)^T(x_j - \mu)]$ of the feature vector x and its global mean μ. The first d eigenvectors e_j then define a $D \times d$ matrix M with the eigenvectors as columns that transforms the original sample x to the extracted sample $y = M^T x^T$.

The eigenanalysis can be done using standard mathematical software, e.g., Ref. 15. PCA is an information conserving transform. Using all d' ($d \leq d' \leq D$) nonzero eigenvectors conserves the information contained in the

Figure 3. Procedures for PCA, LDA, and Sammon mapping.

orthogonal features. The new features are orthogonal to each other, and there is no covariance (and correlation) between any two features. The variance of the new feature y_j is the eigenvalue λ_j. The original feature vector can be reconstructed as $x = My^T$. The truncation of those eigenvectors, which are associated with the smallest eigenvalues, does not incur a large information loss (approximate loss: $\epsilon = \sum_{j=d+1}^{d'} \lambda_j$). PCA can therefore be used as an information-conserving, correlation-eliminating, and dimensionality reduction feature extraction method.

The process of determining most influential features having maximum eigenvalues is called singular value decomposition (SVD). Another method similar to PCA is called latent semantic indexing (LSI). LSI has been successfully used in information retrieval for clustering documents. Below we give brief descriptions of some applications using PCA and LSI.

Linear Discriminative Analysis (LDA)

Unlike PCA, LDA considers the class information. The only difference between PCA and LDA is the matrix that is considered. LDA uses a within-scatter matrix of all c classes: $S_W = \sum_{i=1}^{c} \sum_{j=1}^{N_i} [(x_j - \mu_i)^T (x_j - \mu_i)]$, and a between-scatter matrix: $S_B = \sum_{i=1}^{c} [(\mu_i - \mu)^T (\mu_i - \mu)]$, where N_i is the number of objects within class i, μ_i is the common mean of class i, and μ is the mixture mean of all classes. Then at most $d = c - 1$ nonzero eigenvectors, associated with the largest eigenvalues of the matrix $S_W^{-1} S_B$, define the $D \times d$ feature extraction matrix M. This transformation maximizes the between-class scatter while minimizing the within-class scatter (i.e., maximize $\frac{det(S_B)}{det(S_W)}$), where $det(.)$ denotes determinant of a square matrix. Such a transformation should retain class separability while reducing the variation due to other sources. The objective of LDA is to perform dimensionality reduction while preserving as much of the class discriminatory information as possible. It seeks to find directions along which the classes are best separated. LDA works well if the data have a multivariate normal distribution.

Sammon Map

Sammon map is an example of a nonlinear feature extraction method, whereas the above methods are all linear [7]. It is mainly used for two-dimensional (2-D) visualization of high-dimensional data. The nonlinear mapping can be performed for any dimensionality $d < D$. Sammon's algorithm uses the gradient descent technique to minimize an error function in order to map from D to d dimensions. The error function is given as

$$E = \frac{1}{\sum_{j=1}^{N-1} \sum_{k=j+1}^{N} \delta_{jk}} \sum_{j=1}^{N-1} \sum_{k=j+1}^{N} \frac{\delta_{jk} - d_{jk}^2}{\delta_{jk}}$$

where δ_{jk} is the distance between two points in the extracted d-dimensional space and d_{jk} is the distance between two points in the original D-dimensional space. The mapping attempts to fit N points in the lower space, such that their inter-point distances approximate the corresponding distances in the higher space. In Ref. 16, the linear feature extraction method PCA is compared with nonlinear methods such as Sammon's mapping, multidimensional scaling (17), and self-organizing mapping (18) using texture data. Results clearly show that classification performance improves, particularly for small values of d, by using nonlinear methods compared with that of linear methods such as PCA. The reason being, performing nonlinear feature extraction provides a better characterization of the data in a smaller number of features.

FEATURE SELECTION

Feature selection can be defined as follows: Given a set of features $S = \{v_1, v_2, \ldots, v_D\}$, find a subset S' of S with $|S'| = d$ such that $J(S') \geq J(T)$ for all $T \subset S$, $|T| = d$, where J is the evaluation function. Here d is usually specified by the user.

A feature selection algorithm requires the following ingredients: a generation or search strategy, an evaluation method, a stopping criterion, and/or a validation method (19–22). See Fig. 4 for a block diagram showing relationships between these components. The search or generation strategy decides the way in which combinations of features are tested for a certain goodness. As exhaustive search is usually prohibitive, alternative strategies must be employed. The evaluation or selection function assesses the goodness of a set of features and provides a ranking possibility for the selection process. The stopping criterion is of less importance. Usually a predefined number of features to be selected decides the stopping of search procedures. Validation is not part of the selection process, but it is nonetheless carried out to check the validity of the

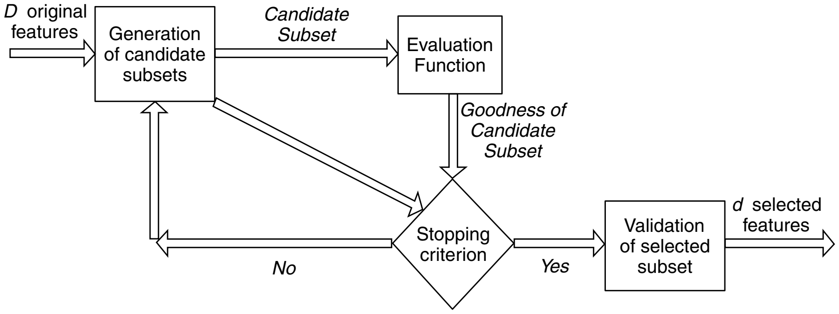

Figure 4. Feature selection process.

selected features. In the following we briefly discuss the most important search strategies and evaluation criteria.

Generation/Search Procedure

With a total of D features, there are 2^D candidate feature subsets to be searched. This is number huge even for moderate D. In the literature, there are different approaches for solving this problem, namely, complete, heuristic, and random.

Complete Search. Schlimmer (23) argues that just because the search must be complete does not mean that it must be exhaustive. Different heuristic functions are used to reduce the search space without jeopardizing the chances of finding the optimal subset. The branch-and-bound method (24) is one such method that guarantees optimality if the features obey monotonocity. Unfortunately many often-used evaluation criteria such as classifier error rate are not monotonic.

Heuristic Search. In each iteration of this method, all remaining features yet to be selected are considered for selection. This is called sequential forward selection. When the search is backward, it is called sequential backward selection. There are also combinations of these two approaches such as beam search (25).

Random Search. It searches randomly and usually stops after a maximum number of iterations. This has advantages over the heuristic method in that, unlike the heuristic methods, it is less likely to be trapped in local optima (26).

Evaluation Functions

An evaluation function or selection criterion $J()$ aims at finding the best set of features in the reduced dimensionality d from the set of all features. Hence the best set S' maximizes the criterion function over all other possible combinations of d features. Some important evaluation functions are briefly described here.

Distance Measure. It is also known as a separability, divergence, or discrimination measure. For a two-class problem, a feature f_i is preferred to another feature f_j if f_i induces a greater difference between the two-class conditional probabilities than f_j (27).

Information Measure. These measures typically determine the information gain from a feature that is the difference between the prior uncertainty and the expected posterior uncertainty using the feature. The feature giving higher information gain is selected (28).

Dependence Measures. It quantifies the ability of a feature to predict the value of the class variable. An example is the correlation coefficient. If feature f_i has a higher correlation with the class variable than feature f_j, then feature f_i is preferred (29).

Consistency Measures. These measures prefer a consistent hypothesis definable over as few features as possible. A feature set is consistent if for the same set of values for the feature set the class variable does not change (26).

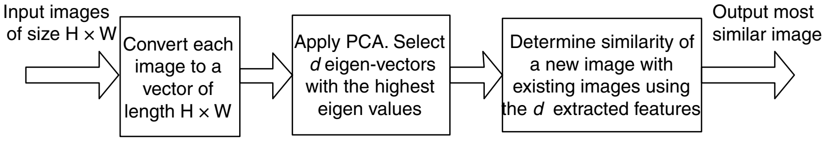
Classifier Error Rate Measure. The above four types of criteria are typically known as *filter* type, whereas the classifier error rate is known as *wrapper* type. The classifier that will be used after feature selection is also used to select the features. The feature set giving the minimum classifier error rate is selected. More details on wrapper methods are given in Ref. 30.

Feature Selection for Unsupervised Learning

The above discussion is mostly for supervised learning where class information is available. Lately, feature selection has been attempted for unsupervised learning, and among different unsupervised learning, it has been mostly applied to clustering and visualization.

In the last several years, several methods for feature selection for clustering are proposed, most of which are wrapper in approach. Here a clustering algorithm is used to evaluate the candidate feature subsets. Wrapper methods can be categorized based on whether they select features for the whole data (global type) or for each cluster separately (local type). The global type assumes a subset of features to be more important than others for the whole data, whereas the local type assumes each cluster to have a subset of important features. In the case of global type, a feature selection method is run over the whole data, whereas for local type, first clustering is done over the data using all features and then important features are selected for each cluster separately using a feature selection method.

Selecting a set of features for unsupervised learning such as clustering is arguably more difficult than selecting for supervised learning such as classification because of the absence of any class information in the former. This is also the reason for extensive research being conducted for feature selection for classification compared with that for clustering. The difficult part is to evaluate the candidate subsets and compare against each other to select the optimal subset of features. First of all, quantifying the quality of clustering is far less straightforward and less accurate than classification. On top of it, one must compare the quality of clustering across varying dimensionality to select the optimal subset of features. So, one requires evaluation methods that are invariant to varying dimensionality. Examples of such methods used in various research work are trace measure (31,32), visualization (32,33), ranking of features and user selects several of the most important features (31,32,34–37), Bayesian statistical estimation framework (38), and entropy (31,39). These methods are of the global type. Examples of local methods are Manhattan distance (40) and dense regions (41).



Input images of size H × W
Convert each image to a vector of length H × W
Apply PCA. Select d eigen-vectors with the highest eigen values
Determine similarity of a new image with existing images using the d extracted features

DIMENSIONALITY REDUCTION IN PRACTICE

In this section we discuss some applications of feature extraction and selection methods.

Uses of Feature Extraction Methods

Uses of PCA in Regression Analysis. PCA can be used in regression analysis in several ways (9). If the independent variables are highly correlated, then they can be transformed to principal components (PCs) and the PCs can be used as the independent variables. If we do not want to transform the independent variables, then the PCs can be used indirectly to improve the precision of the regression parameter estimates associated with the independent variables. PCA can also be used as a diagnostic tool to detect multicolinearities among the independent variables. Multicolinearity means that one or more independent variables are essentially linear combinations of other independent variables.

Using PCs to detect Outlying and Influential Observations. A major advantage of PCA is that if the first two PCs account for a substantial portion of the total variation, then we can approximate the distribution of the observations in the variable space by plotting the PCs (9). This 2-D representation of the D-dimensional observations can be used in several ways. The plot can be examined for outlying observations or for influential observations, or it can be used to see whether the observations can be visually clustered. Outlying observations are observations that lie at a considerable distance from the bulk of the observations or do not conform to the general pattern the observations exhibit. Outlying observations are called influential observations if their deletion from a particular analysis leads to different results.

Use of PCs in Cluster Analysis. If the first two or three PCs account for a substantial proportion of the total variation, then we can also use the plots to visually identify clusters (9). A *cluster* is a group of observations that are “closer” to each other than they are to observations in other clusters or groups. Many clustering algorithms are used to cluster data (42). No significant advantage exists in transforming the original observations to principal components before the clustering because the same information is contained in the original and in the transformed data. That is, for any distance function, the distances among examples computed from principal components are equal to the corresponding distances computed from the original variables using an equivalent but different distance function. The only advantage of employing PCs in cluster analysis is to be able to plot the components and visually search for clusters of observations. PCs can also be used to verify the clusters determined on the basis of another clustering algorithm. We can see whether the defined clusters are homogeneous, distinct, and aesthetically appealing to the eye. Clustering algorithms will define clusters even if none exist, i.e., even if the observations are evenly spread throughout the variable space. For this reason, a plot of the data on the first two PCs can be informative if they account for a large portion of the total variance.

Application to Computer Vision. PCA is used in computer vision to find patterns and to compress the images (43).

PCA for Finding Patterns. An example of its application to face recognition is as follows (Fig. 5). Say we have 20 images. Each image is H pixels high by W pixels wide. For each image we can create an image vector of $H \times W$ dimensions. We can then put all images together in one big image-matrix as follows:

$$\begin{pmatrix} ImageVec1 \\ ImageVec2 \\ . \\ . \\ ImageVec20 \end{pmatrix}$$

which gives us a starting point for the PCA analysis. Once PCA is performed, we have original data in terms of the eigenvectors found from the covariance matrix. Why is this useful? Say we want to do facial recognition, and so our original images were of peoples faces. Then, the problem is, given a new image, whose face from the original set is it? The way this is done in computer vision is to measure the difference between the new image and the original images, not along the original axes, but along the new axes derived from the PCA analysis. It turns out that these new axes work much better for recognizing faces, because the PCA analysis has extracted these new axes *based on their ability to capture the variability among the images*. In a way, the PCA analysis can identify the statistical patterns in the data. As all vectors have $H \times W$ dimensions, we will get $H \times W$ eigenvectors. In practice, one can leave out most of the less significant eigenvectors and the recognition still performs well.

PCA for Image Compression. Using PCA for image compression is also known as the Hotelling or Karhunen–Loeve (KL) transform. If there are 20 images, each with $H \times W$

pixels, one can form $H \times W$ vectors, each with 20 dimensions. Each vector consists of all intensity values from the same pixel from each picture. Notice that this factor is different from the previous example. By performing PCA on this, one gets 20 eigenvectors because each vector is 20-D. To compress the data, one then chooses to transform the data only using, say five eigenvectors. This gives a final dataset with only five dimensions, which has saved three quarters of the space. However, when the original data are reproduced, the images have lost some information. This compression technique is said to be lossy because the decompressed image is not exactly the same as the original.

Applications of PCA to Microarray Gene Expression Data. Each data point produced by a DNA microarray hybridization experiment represents the ratio of expression levels of a particular gene under two different experimental conditions. The result, from an experiment with n genes on a single chip, is a series of n expression-level ratios. Typically, the numerator of each ratio is the expression level of the gene in the varying condition of interest, whereas the denominator is the expression level of the gene in some reference condition. The data from a series of m such experiments may be represented as a gene expression matrix, in which each of the n rows consists of an m-element expression vector for a single gene. The expression measurement is positive if the gene is induced (turned up) with respect to the reference state and negative if it is repressed (turned down).

A PCA analysis of DNA microarray data can consider the genes as variables or the experiments as variables or both. When genes are variables, the analysis creates a set of "principal gene components" that indicate the features of genes that best explain the experimental responses they produce. When experiments are the variables, the analysis creates a set of "principal experiment components" that indicate the features of the experimental conditions that best explain the gene behaviors they elicit. When both experiments and genes are analyzed together, there is a combination of these affects. In Ref. 44, the authors considered the experiments as variables. They applied PCA to the publicly released yeast sporulation dataset (45). They found that most variance ($> 90\%$) in the sporulation dataset is contained in the first two principal components, which allows most information to be visualized in two dimensions.

Application of SVD to Document Indexing. Regular keyword searches approach a document collection with a kind of accountant mentality: A document contains a given word or it does not, with no middle ground. We create a result set by looking through each document in turn for certain keywords and phrases, tossing aside any document that does not contain them, and ordering the rest based on some ranking system.

LSI adds an important step to the document indexing process (46). In addition to recording which keywords a document contains, the method examines the document collection as a whole, to see which other documents contain some of those same words. LSI considers documents that have many words in common to be semantically close, and ones with few words in common to be semantically distant. This simple method correlates surprisingly well with how a human being, looking at content, might classify a document collection. When one searches an LSI-indexed database, the search engine looks at similarity values it has calculated for every content word and returns the documents that it thinks best fit the query. Because two documents may be semantically very close even if they do not share a particular keyword, LSI does not require an exact match to return useful results. Where a plain keyword search will fail if there is no exact match, LSI will often return relevant documents that do not contain the keyword at all. For example, searching for "Saddam Hussain" can return documents on Iraq which has no mention of "Saddam Hussain" in it.

The first step in doing LSI is culling all those extraneous words from a document, leaving only *content words* likely to have semantic meaning. Using this list of content words and documents, we can now generate a term-document matrix. This is a very large grid, with documents listed along the horizontal axis, and content words along the vertical axis. For each content word in our list, we go across the appropriate row and put an "X" in the column for any document where that word appears. If the word does not appear, we leave that column blank. The key step in LSI is decomposing this matrix using SVD. LSI works by projecting this large, multidimensional space down into a smaller number of dimensions. A typical term space might have tens of thousands of dimensions and be projected down into fewer than 150. In this reduction, information is lost, and content words are superimposed on one another. What we are losing is noise from our original term-document matrix, revealing similarities that were latent in the document collection. Similar things become more similar, whereas dissimilar things remain distinct. This reductive mapping is what gives LSI its seemingly intelligent behavior of being able to correlate semantically related terms. We are really exploiting a property of natural language, namely that words with similar meaning tend to occur together.

Uses of Feature Selection Methods

Image Retrieval. Feature selection is applied in Ref. 47 to content-based image retrieval. Recent years have seen a rapid increase of the size and amount of image collections from both civilian and military equipment. However, we cannot access or make use of the information unless it is organized so as to allow efficient browsing, searching, and retrieval. Content-based image retrieval (48) is proposed to efficiently handle large-scale image collections. Instead of being manually annotated by text-based keywords, images would be indexed by their own visual contents (features), such as color, texture, and shape. One of the biggest problems to make content-based image retrieval truly scalable to large-sized image collections is still the curse of dimensionality (5). As suggested in Ref. 48, the dimensionality of the feature space is normally of the order of 10^2. Dimensionality reduction is a promising approach to solve this problem. The image retrieval system proposed in Ref. 47 performs feature selection, and these features are then used to index images for efficient retrieval.

Customer Relationship Management (CRM). A case of feature selection is presented in Ref. 49 for customer relationship management. In this context, each customer means a big revenue and the loss of one will likely trigger a significant segment to defect; it is imperative to have a team of highly experienced experts monitor each customer's intention and movement based on massively collected data. A set of key indicators, proven useful in predicting potential defectors, is used by the CRM team. The problem is that it is difficult to find new indicators describing the dynamically changing business environment among many possible features. The machine-recorded data are simply too enormous for any human expert to browse and obtain any insight from. Feature selection is employed to search for possible new indicators. They are later presented to experts for scrutiny. This approach considerably improves the team's efficiency in finding new changing indicators.

Intrusion Detection. As network-based computer systems play increasingly vital roles in modern society, they have become the targets of our enemies and criminals. The security of a computer system is compromised when an intrusion takes place. Intrusion detection is often used as one way to protect computer systems. In Ref. 50, Lee et al. proposed a systematic data mining framework for analyzing audit data and constructing intrusion detection models. Under this framework, a large amount of audit data is first analyzed using data mining algorithms to obtain the frequent activity patterns. These patterns are then used to guide the selection of system features as well as for the construction of additional temporal and statistical features for another phase of automated learning. Classifiers based on these selected features are then inductively learned using the appropriately formatted audit data. These classifiers can be used as intrusion detection models because they can classify whether an observed system activity is "legitimate" or "intrusive." Feature selection plays an important role in building such classification models for intrusion detection.

Genomic Analysis. Structural and functional data from analysis of the human genome has increased many fold in recent years, presenting enormous opportunities and challenges for data mining. In particular, gene expression microarray is a rapidly maturing technology that provides the opportunity to assay the expression levels of thousands or tens of thousands of genes in a single experiment. These assays provide the input to a wide variety of data mining tasks, including classification and clustering. However, the number of instances in these experiments is often severely limited. In Ref. 51, for example, Xing et al. used a case involving only 38 training data points in a 7130-dimensional space to exemplify the above situation, which is becoming increasingly common in molecular biology applications. In this extreme case of very few observations on a large number of features, Xing et al. investigated the possible use of feature selection on a microarray classification problem. All classifiers tested in the experiments performed significantly better in the reduced feature space than in the full feature space.

Text Categorization. Text categorization is the problem of automatically assigning predefined categories to free text documents (52,53). This problem is of great practical importance given the massive volume of online text available through the World Wide Web, e-mails, and digital libraries. A major characteristic, or difficulty of text categorization problems, is the high dimensionality of the feature space. This dimensionality is prohibitively high for many mining algorithms. Therefore, it is highly desirable to reduce the original feature space without sacrificing categorization accuracy. In Ref. 54, different feature selection methods are evaluated and compared with reduced high-dimensional space in text categorization problems. It is reported that the methods under evaluation can effectively remove 50–90% of the terms while maintaining the categorization accuracy.

CONCLUSIONS AND FUTURE DIRECTIONS

As computers become increasingly powerful, many applications can produce massive data of high dimensionality. Dimensionality reduction is an efficient way of dealing data with high dimensionality. The purpose is to reduce the data so that computational load decreases and patterns of better quality can be extracted by pattern recognition and data mining algorithms. In this article, we described the concepts of feature extraction and feature selection and briefly introduced some representative methods. We then presented in brief some cases of dimensionality reduction to illustrate its application to many problem domains. The need for dimensionality reduction techniques presents new challenges, and novel methods are expected to be developed.

Some research directions in dimensionality reduction are as follows:

1. Feature extraction.
   a. Study how to sparsify the resulting matrix after transformation so that the connection between the extracted features and original features can become evident.
   b. Investigate how to make use of both labeled and unlabeld data in feature extraction.
2. Feature selection.
   a. Unsupervised feature selection remains a challenging task.
   b. Study efficient methods to detect interacting features (may still be slower than sequential forward heuristic methods but faster than exhaustive methods). and
3. Investigate how to maximally take advantage of both feature extraction and selection methods.

EVOLUTIONARY LEARNING

INTRODUCTION

Over the last three decades, evolutionary computation has become popular in various applications such as optimization and machine learning. Examples include scheduling problems, routing problems, game playing, and robot navigation. Here, several different ways are described in which evolutionary algorithms can be applied to machine learning tasks, which are related to the disciplines of engineering and computer science.

Four main types of evolutionary algorithms (EAs) exist, although in recent years a more unified approach has been attempted (1):

- Genetic algorithms
- Genetic programming (described in the section entitled "Genetic Programming")
- Evolutionary programming
- Evolution strategies

The above algorithms are based on the principles of a Darwinian natural selection system, which includes the following characteristics:

- A population of individuals, i.e. candidate solutions to the underlying problem.
- Genetic operators (e.g., crossover, mutation) that modify the population of solutions dynamically when applied to them.
- A fitness function that is used to measure how good or bad an individual is. Fitter solutions have a higher probability to survive and to contribute to children who inherit some characteristics. Populations evolve and their average fitness (goodness of solutions or effectiveness) is improved over time.

Genetic algorithms (GAs) adopt a string representation of individuals. Frequently, this takes the form of binary strings. Populations of such strings evolve by applying mutation (random modification of a gene within the string) and crossover (exchange the successive genes of two parent individuals, to maximize the fitness of two created offsprings) (2). GAs are general-purpose algorithms because, in theory at least, they can be applied to any domain.

Evolutionary programming (EP) employs mutation only as the means to derive a new N-membered population from an existing population of N members (3). Individuals (possibly mutated) are selected probabilistically to contribute to the next generation. Traditionally, EP was used to evolve finite state machines, but more recently it has been applied to other structures and domains.

An evolution strategy (ES) concentrates on numerical optimization problems. Individuals are encoded as real number vectors. Initially, $(1 + \lambda)$-ES models were used. One parent produces λ children using mutation, and the fittest of the $(1 + \lambda)$ parent-offspring individuals is selected to be the parent in the next generation. ES uses an adaptive mutation operator. According to this technique, each gene i is mutated using a Gaussian (normal) distributed perturbation $G(0, \sigma_i)$ with a mean of zero and a standard deviation of σ_i that evolves over time. Every individual that requires N genes by the problem definition is encoded with a total of $2N$ genes. The additional N genes represent the variances σ_i of the original genes required by the problem. ES can also be used with a $(\mu + \lambda)$ model, in which μ parents are selected to produce λ children and the fittest μ individuals from the $(\mu + \lambda)$ parents/children are selected in a deterministic fashion to participate in the new generation. More recent ES approaches use recombination (crossover) operators as well.

More details about the various aspects of EAs can be found in this encyclopedia.

The following sections describe some common approaches for the application of EAs to machine learning problems.

EVOLVING NEURAL NETWORKS

EAs can be used to train neural networks in the following ways:

- Adapt the weights of a network.
- Find the right topology of a network, in terms of how many hidden units per layer, the number of hidden layers, connectivity of the net (which nodes connect to which others).
- Derive a learning algorithm.

Artificial neural networks are biologically inspired structures that can learn from experience and generalize from trained examples to unseen ones. Artificial neural networks have been applied in many diverse fields.

One of the most popular neural network architectures is the multilayer perceptron (see also the encyclopedia's articles on Perceptrons and Feedforward Neural Nets). Such a network is shown in Fig. 1. A number of nodes (neurons) are arranged in layers, which include one input layer and one output layer with one or more hidden layers in between. Nodes are connected via links called weights. The output o_j of each node j in the network is given by Equation (1), or a similar "sigmoidal" function, where its input *net* is given by (2):

$$f(\text{net}) = \frac{1}{1 + e^{-\text{net}}} \tag{1}$$

$$\text{net}_j = \sum_i w_{ij} o_i \tag{2}$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

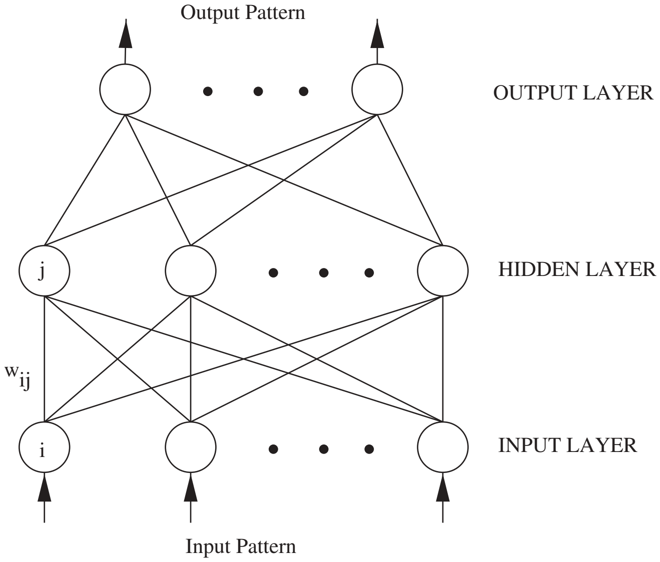

Figure 1. An example of a multilayer feedforward neural network.

The above network is a example of supervised learning, in which several training data exist in the form of inputs and corresponding correct outputs. The multilayer perceptron should learn (i.e., find appropriate values for the weights) the input–output behavior described by the training data, and also should generalize well in unseen data (i.e., data not inside the training set).

A learning algorithm is responsible to adapt the learning parameters (weights) of a neural network. One of the most widely used learning algorithms for the multilayer perceptron is the backpropagation algorithm. In its basic form, backpropagation is based on gradient descent optimization, although more advanced optimization algorithms such as conjugate gradient can be applied as well (4). The aim of backpropagation is to minimize the training error, which is defined as:

$$E = \frac{1}{2}\sum_{p}\sum_{k}(t_{pk} - o_{pk})^2 \tag{3}$$

where k, p belong to the sets of output nodes and training patterns, respectively. The values o_{pk} and t_{pk} are the actual network outputs and the training set target outputs, respectively, of the node k in the output layer for the training pattern p.

Gradient descent algorithms suffer from the local minima problem, which is something that can be avoided if EAs are used to learn the network weights instead.

A typical way to evolve the weights of a neural network is to use GA individuals. These individuals encode all weights of the network in the form of a string that contains real numbers. Thus, a chromosome $a_1a_2\ldots a_n$ represents a network that has n weights, for which the first weight has the value a_1 the second weight has the value a_2, and the n-th weight is equal to a_n.

The initial population of the GA could initialize weights randomly with values from a selected range, for example, between −1 and 1. Mutation can be performed by selecting a hidden or an output node and adding random values (e.g., in the range −1 to 1) to its incoming weights (5). The crossover operator can be defined as the probabilistic selection of two parents who produce a single offspring by copying the incoming weights of a randomly selected non input parent node to the corresponding node of the child. This operation is repeated for all hidden and output nodes of the offspring.

For example, in Fig. 2, the offspring inherits the incoming weights for nodes 4 and 5 from *Parent 2*, whereas the incoming weights for node 3 are coming from *Parent 1*.

The network that will be used in an application is chosen as the network that performs best (based on the training and the generalization error) in the last generation of the GA.

The topology of a feedforward neural network (number of hidden nodes or layers and the connectivity) can also be determined using a GA. For example, a matrix such as the one shown in Fig. 3 describes the connectivity of a neural network (6). One (1) specifies that a connection is present between two nodes and zero (0) stands for no connection. Notice that the matrix is not symmetric because the network is feedforward and no recurrent connections exist, for example, node 1 propagates a signal (value) to node 3, but node 3 does not send a signal to node 1.

To apply a GA for connectivity evolution, the connectivity matrix must be translated to a linear chromosome. This translation can be done by placing all the rows of

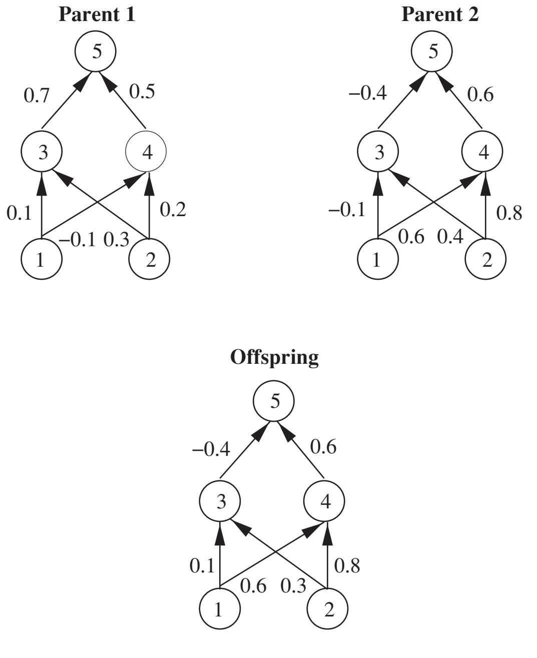

Figure 2. The crossover operator for the evolution of the weights of a multilayer perceptron. For each hidden and output node of the offspring, its incoming weights are coming from a randomly selected parent (all the weights of a single node are inherited from the same parent).

$$\begin{array}{r|ccccc} \textbf{from node:} & \textbf{1} & \textbf{2} & \textbf{3} & \textbf{4} & \textbf{5} \\ \textbf{to node: 1} & 0 & 0 & 0 & 0 & 0 \\ \textbf{2} & 0 & 0 & 0 & 0 & 0 \\ \textbf{3} & 1 & 1 & 0 & 0 & 0 \\ \textbf{4} & 1 & 1 & 0 & 0 & 0 \\ \textbf{5} & 0 & 0 & 1 & 1 & 0 \end{array}$$

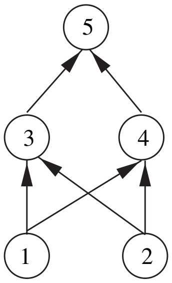

Figure 3. The connectivity of the network on the right is described using the matrix on the left. The matrix can be encoded as the chromosome 0000000000110001100000110.

the matrix next to each other within a string. Thus, the matrix in Fig. 3 corresponds to the chromosome 0000000000110001100000110.

The initial population of the GA is created using randomly selected chromosomes that correspond to networks with different connectivity. Then, the backpropagation algorithm is applied to each net, and the fitness of each trained network is measured according to the error in the training set given by Equation (3) and the error of a test set. The next generation of the GA is evolved by applying mutation and crossover genetic operations. The mutation can be defined as the flipping of bits in an individual. The crossover operator selects a row index k and exchanges the rows between 1 and k in two parents to create two children. The neural network that performs best in the last generation is designated as the best overall solution.

Similar approaches can determine the number of hidden nodes and layers in a network. In such cases, the GA chromosome could be a binary string, that when decoded gives the number of hidden nodes per layer.

Finally, GAs can be used to evolve the learning algorithm, which is the rule that determines the updates of weights after the presentation of training data to the net. One simple approach (see Ref. 6 for a detailed description) is to try to evolve a learning rule whose inputs are the activation function a_i of node i the training signal t_j (correct output of node j), the current output o_j of node j, and the current weight w_{ij} between nodes i, j. The output of the learning rule is the weight update, which, in this simple case, consists of the weighted sum of all the inputs and the pairwise products of the inputs:

$$\begin{aligned} \Delta w_{ij} = \eta(&k_1 w_{ij} + k_2 a_1 + k_3 o_j + k_4 t_j + k_5 w_{ij} a_i \\ &+ k_6 w_{ij} o_j + k_7 w_{ij} t_j + k_8 a_i o_j + k_9 a_i t_j \\ &+ k_{10} o_j t_j) \end{aligned} \tag{4}$$

where η (the learning rate) and the coefficients $k_m, m = 1, 2, \ldots 10$ are evolved using a GA.

Note that in all the approaches described in this section, the chosen network is the network that performs best in the last generation (or across all generations). However, this does not mean that the generalization ability of such a network is the best possible. A different approach is described in Ref. 7, where all (or the top n) individuals (networks) of the last population (generation) are used to determine the final output. For example, in a classification task where each network predicts the class that the input (s) belongs to, all the networks of the last population are considered to be voting toward a class, and the majority of votes is treated as the final prediction. Another possibility for combining the outputs of the individuals in the final generation is to form a weighted sum of their outputs.

A detailed review of various techniques to evolve artificial neural networks can be found in Ref. 8.

REINFORCEMENT LEARNING

In many problems, supervised learning is not possible because no explicit teacher exists [i.e., no pairs of data exist to describe the input(s) and the corresponding correct output(s)] For example, a robot that navigates in an environment is trying to achieve certain goals such as locating targets and avoiding obstacles. The problem can be complicated more by assuming that the environment is unknown or that changes over time.

Although in these situations no information exists about the perfect action that the robot (agent) should take while being in a specific state, the agent can estimate its own performance, as it receives reward or penalty feedback signals by the environment from time to time. The agent should learn to take appropriate actions based on the feedback. Rewards and penalties are referred to geherally as rewards, because a penalty can be seen as a negative reward.

This type of problem is known as *reinforcement learning*. The reinforcement learning problem is the learning of behavior by trial and error without an explicit teacher (9) (see Fig. 4). Some reinforcement learning architectures not only use trial and error for the learning agent, but also use a learned model of the environment (world). Note that some people refer to the learning agent as the *animat*.

Reinforcement learning can be seen commonly as a control task, because at every step the agent must take an appropriate control action so as to maximize the received rewards in the long term (10). Rewards in reinforcement learning are numeric scalar values, and although, this

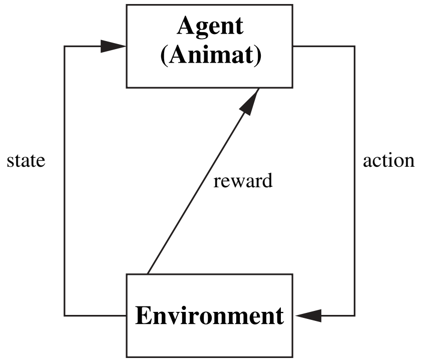

Figure 4. The reinforcement learning problem. The goal is to maximize the total reward in the long term.

seems limiting, a large number of applications exist for which the goals include numeric scalar rewards. For example (9):

- Foraging: rewards are positive for finding food, and negative for energetic motion.
- Classic control problems, such as pole-balancing.
- Recycling robot: rewards are positive for dropping soda cans in the recycling bin, negative for colliding with objects, and are more negative for bumping hard into objects.
- Game playing, such as chess.

When considering the above example applications, it becomes apparent that in many cases the rewards are not continuous; a reward might not be received at every single step, but only from time to time, or in the very end. In games such as chess, the only reward (win or lose) is received in the very end of the match, and the agent does not receive "explicit" indicative signals of how well or bad it functions during the match. In this case, the agent's goal is to learn a policy $\pi: S \rightarrow A$ that maps states to actions. The optimal policy π^* is defined as the policy that achieves the maximum cumulative reward.

To solve the reinforcement learning problem, algorithms operate in either the value or the policy space. Thus, reinforcement learning algorithms search the value or the policy space. Examples of such algorithms include value iteration, policy iteration, Q-learning, and $TD(\lambda)$ (11).

Value function methods attempt to approximate the value function $V^{\pi^*}(s)$, which gives the expected cumulative reward for the optimal policy from any state s. The value function for a policy π (not necessarily the optimal policy) is defined as:

$$V^{\pi}(s_t) = \sum_{i=0}^{h} r_{t+i} \tag{5}$$

where r_i is the reward received at time step t and assumes that h is a finite value that describes the total number of steps [if $h = \infty$, a discount rate should be included in the above formula as well (11)]. Then the optimal policy is calculated as:

$$\pi^* = \arg\max_{\pi} V^{\pi}(s), \quad \forall s \tag{6}$$

Policy-space methods search directly for the optimal policy. EAs can be used to search for the optimal policy in the policy space. An individual in the population represents a policy explicitly.

To illustrate how an EA can be applied to reinforcement learning problems, consider the following task (12):

1. An agent in the grid shown in Fig. 5 moves from state to state by selecting either of the two actions: move right (R) or move down (D).

	a	b	c	d	e
1	0	2	1	−1	1
2	1	1	2	0	2
3	3	−5	4	3	1
4	1	−2	4	1	2
5	1	1	2	1	1

Figure 5. A simple grid-world reinforcement learning problem. The dotted line indicates one of the optimum paths.

2. The initial position (state) of the agent is a1 and it receives the reward indicated when visiting each state.
3. The agent keeps moving until it moves off the grid world.
4. The goal is to learn a policy that returns the highest cumulative reward. For example, a policy that moves the agent in the sequences R, D, R, D, D, R, R, D is an optimal policy (not a unique one in this case) because it achieves the optimal score of 17.

A direct way to apply a GA to the above problem would be to choose a chromosome representation that contains $n = 25$ genes that correspond to each state of the grid. A gene contains a value that corresponds to the action that the chromosome (policy) should take from that state. For example, the chromosome shown in Fig. 6 represents a policy that takes the actions R at state a1, D at state a2, R at state a3, and so on. The initial population of the GA can be created randomly and the standard mutation and crossover genetic operators can be applied to the described representation of a policy to evolve several generations according to a defined fitness.

The fitness of an individual in this problem could be defined naturally as the total reward received when the sequence of actions described by the individual (policy) is applied until the agent moves off the grid. In more complex problems, in which a generalization capability of the agent

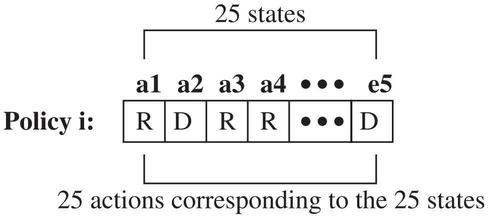

Figure 6. Genetic algorithm policy representation for the problem of Fig. 5.

would be desired (i.e., the agent should be able to receive the maximum reward even when starting from different positions, or placed in a new grid), the fitness should include a number of different test cases, which measure the total efficiency of the individual.

For problems where the state space is very large, the above representation is be feasible. In these situations, the chromosome representation could be modified so each gene represents a "region" of similar states and the gene value corresponds to a common action associated with these states. An extension of that would be to have a condition–action rule in each gene, so that the condition expresses a predicate that matches a set of states (12). The set of states that trigger an action must be defined according to a "similarity" function of states.

COEVOLUTION

Traditional EAs involve individuals in a population that try to adapt in a fixed environment (or a number of static environments). The performance of an individual is measured using an absolute fitness function, and the evolutionary process derives highly fit solutions based on the defined fitness function after a number of generations.

However, many problems exist for which a fitness function is difficult or impossible to define, for example, the task of evolving a game player such as in chess. One could attempt to define the fitness function as the number of wins/losses when the computerized solution plays against a human player. This approach is difficult because a human player might not be available, or, in the case where one is the evolved individuals will learn to play well only with the available human opponent(s), and they will not be able to play well (generalize) against other opponents (unless the human players improve through time) (1).

A second case in which a fitness function cannot be defined is when different individuals perform different subtasks and several individuals must cooperate to solve the whole problem.

A third case involves situations in which it is infeasible to evaluate an individual because of an extremely large number of test cases (1). For example, an individual that represents some software cannot be evaluated against all possible inputs.

The above problem of being unable to define (easily or not at all) a fitness function can be addressed by considering the *coevolution* process found in nature. Natural predators and preys evolve simultaneously, and they adapt to the characteristics of each other. Preys (e.g., organisms) evolve their characteristics to defend against predators (e.g., parasites). Then, predators evolve to circumvent the new defenses of the preys (organisms) and so on.

EAs apply coevolution using populations that compete with each other. For example, let us consider the case of two populations. Initially, both populations are likely to be unfit. Then, individuals of the first population try to adapt to the environment that consists of the second population. To do so, all the individuals of the first population are evaluated against all the individuals of the second population, and a new generation of the first population is created. Then, all the individuals of the second population are evaluated against those of the first one, and a new generation for the second population evolves.

According to this process, for two competing populations *A, B*, the efficiency of an individual in *A* is assessed with a relative fitness function that is defined as its performance when measured against the individuals of the *B*, and vice versa. The fitness is relative, not absolute, because the individuals of the other population continue to change.

In the case of chess, two populations of computerized chess players could be coevolved. Because the fitness of both populations increases, the coevolutionary system will continue to evolve players with higher performance over time.

Another example of coevolution are robots that are able to navigate in different environments (therefore generalize well in unknown environments). One of the populations could consist of the actual robots and the second population could consist of the different environments. Both the robots and the environments evolve over time. To make sure that robots do not "forget" how to behave in older population environments, the fitness of the robot should also take into account its past performance. A limited version of this approach (only one environment with different starting positions) is demonstrated in Ref. 13.

As a special case, some coevolutionary systems could involve a single population. Individuals compete with other individuals within the same population.

CLASSIFIER SYSTEMS

Often, EAs are used in machine learning tasks in the form of *classifier systems*. Broadly speaking, a classifier system is a system whose interaction with the environment creates a chain of "internal" events (classifiers) of the form

$$\textit{if}\ \text{condition}\ \textit{then}\ \text{activate} \tag{7}$$

that triggers a chain of external events implicitly.

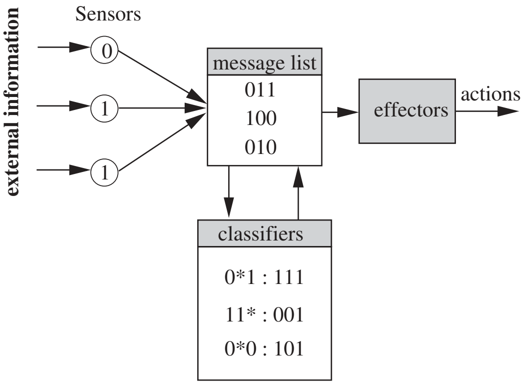

Figure 7. A simple classifier system.

Figure 7 shows a typical simple classifier system. A set of sensors detects information flowing into the system from the external environment. This information depends on the previous outputs of the classifier system. The sensors are able to decode the input to one or more messages, which are posted to the message list.

The messages in the message list can activate the classifiers that have the from of a string rule. If a message matches the first part of a classifier (i.e., the part before the colon : in Fig. 7), the classifier is activated and posts a new message in the message list. For example, given the classifiers in Fig. 7, if a message 011 arrives in the message list, it will activate the classifier 0*1: 111, which will post the new message 111 in the message list. Certain messages can trigger an effector in the effector system (Fig. 7), which will cause an external action to be directed toward the enviroment.

Note that at any instant, more than one classifier can be activated (as a message can be matched by any number of them). In this case, the classifiers compete against each other to designate a winner. The algorithm behind this is known as the *bucket brigade* algorithm (14).

From time to time, new rules (classifiers) must be derived (learned) and this is done by means of a GA. More details about classifier systems can be found in Ref. 2.

GENETIC PROGRAMMING

Genetic programming (GP) (15) aims at the automatic discovery of computer programs. GP is based on a more powerful representation than GAs because every individual in the population is a computer program. The characteristics of computer programs (such as conditionals, loops, assignments, variables, functions) are present in each individual in the population.

GP is an effective evolutionary tool in machine learning applications because it creates computer programs automatically that solve tasks encoded by the fitness function.

The representation of a GP computer program is done through the use of trees. For example, in Fig. 8, the tree shown represents the single program statement

$$\text{if}\, x > y \quad \text{then} \quad a := 10 \tag{8}$$

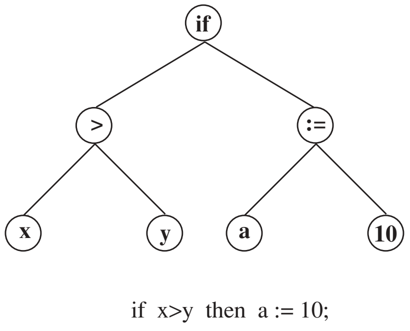

Figure 8. In genetic programming, the representation of a computer program is a tree.

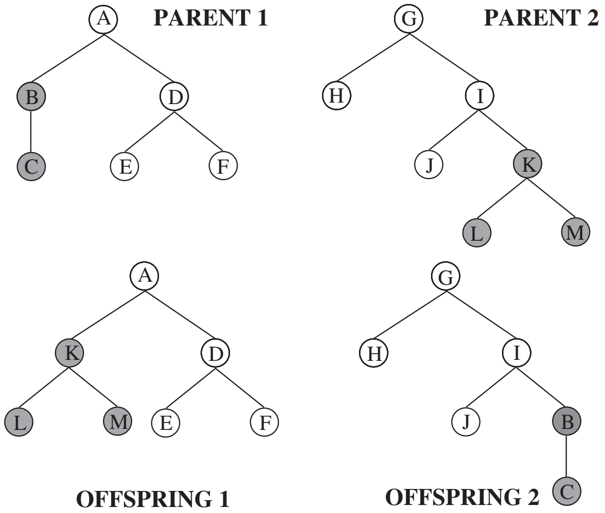

Figure 9. The crossover operator in genetic programming.

Only when the evaluation of the first subtree (i.e., $x > y$) is true is the second subtree of the root node executed (i.e., $a := 10$). This tree representation is equivalent to the parse trees that compilers construct internally to represent a given program.

The application of GP follows the same steps as GAs. The genetic operators used commonly are reproduction, crossover, and mutation.

Reproduction selects an individual from the current generation based on its fitness and copies it to the next generation. Crossover is performed by choosing two points randomly in the probabilistically selected parents and swapping the parent subtrees that are defined by these points (Fig. 9). Note that, unlike GAs, the GP crossover contributes more to different shapes and sizes of the trees (programs) in the population. Thus, sufficient diversity exists in the population and the phenomenon of premature convergence (2) is unlikely to occur. Mutation is performed by choosing a node randomly in the chosen individual and by replacing the subtree that starts at this node with a randomly generated tree.

A tree in the population is composed of functions and terminals chosen from the function set F and the terminal set T, respectively. The function set may include arithmetic or Boolean operations, conditional operators (such as *if-then-else*), iteration functions (e.g., *while*), operators that create statements similar to those found in programming languages, and any functions that are associated closely with the problem domain. The terminal set consists of state variables and inputs and possibly constants (numbers, boolean constants or the random generator R that returns a random value in a prespecified range).

The function and terminal sets should satisfy the *closure* and *sufficiency* properties. The closure property requires that any function in the function set accepts as an argument any terminal from the terminal set and any value returned by any other function. Thus, each function should be closed for any combination of arguments that it may receive. For example, the normal division arithmetic operator always returns a number, unless it is dividing by zero. To be consistent with the closure property, the division function must be redefined to return an “acceptable” value when the denominator is zero. The sufficiency property requires that the sets of functions and terminals that are provided to GP can express a solution to the problem under consideration. A solution cannot be expected to be found if the functions or terminals provided are “incomplete”.

An important issue in the application of GP is the creation of the initial population. Usually, creation is done randomly, after setting a maximum initial depth of each individual (tree). The depth is defined as the length of the longest nonbacktracking path from the root to a leaf. The practical application of GP indicates that the initial population generative method of *ramped half-and-hcdf* gives satisfactory results as it creates enough diversity in the initial population. According to this method, an equal number of individuals for each depth (up to the maximum) is created. Half of the individuals are full trees (trees for which the length of every nonbacktraddng path between the root and any leaf is equal to the prespecified maximum depth) and half are of variable shape (15).

To obtain a solution to a problem, one might need to run GP multiple times, (with different initial conditions, i.e., initial population), because the starting point in a search can lead to different results. This procedure is also appropriate for the application of other EAs.

GP has been applied successfully in a variety of “lear ing” tasks, which include control, game playing, and electrical circuit design.

HYBRID SYSTEMS

EAs can be combined with other techniques to form hybrid systems that can be applied to machine learning tasks. It is common to create hybrid systems of evolutionary techniques and other “soft-computing” approaches such as neural networks and fuzzy logic. Such hybrid systems have discrete operational modules, one of which is using EAs while the other module(s) are based on different nonevolutionary approaches (e.g., neural networks).

Consider the general control problem in which an agent (e.g., a robot) must make decisions and take actions while operating in a completely unknown environment. Assuming that the environment does not change frequently (or it changes slowly enough), the neurogenetic architecture which is an example of a hybrid solution, could be applied to this problem (10).

The neurogenetic architecture consists of two separate steps:

1. Learn a model of the unknown environment using a neural network. This task could be done offline (the agent is not using the model for decisions until the model’s training is complete) or online (depending on the complexity of the environment and the learning rate of the neural network algorithm applied).
2. The model learned is used by a GA, to help the agent in making optimum decisions according to its targets.

At each time step, the agent is using the model of the world to predict the next state of the system given specific candidate input actions. The agent does not actually attempt these actions, but it considers the possible state that it will encounter if it takes several different actions. A GA is used as an optimizer, which ”tells“ the agent which of the candidate actions is optimum. It is only then that the agent applies the optimum action to the real world, and the next step of the agent must be considered.

The application of such an approach can use a single step model prediction (”myopic“ optimization) or multistep prediction of the state of the model at some point in the future. As seen in the section entitled, “Reinforcement Learning”, in the general rainforcement learning problem, the long term behavior should be optimized. However, in certain dynamic systems, even the ”myopic“ approach can result in long-term optimization.

EXPERT SYSTEMS

INTRODUCTION

In the early 1970s, substantial interest existed in studying decisions by experts that did not use statistical or other mathematical tools and in determining whether and how such decisions could be modeled in a computer. In particular, researchers were interested in investigating conceptual and symbolic methods appropriate for modeling physician and other expert decision making [e.g., Shortliffe (1)]. From this environment, the notion of an expert system evolved.

The concept of expert systems is almost magical: Simply capture human expertise and put it into a computer program. Rather than worry about a person, a computer program that includes all relevant and appropriate knowledge could be developed and shipped around the world. For example, Rose (2) reported that Southern California Edison (SCE) had an expert whose troubleshooting had helped keep a dam safe. However, SCE was afraid their expert would retire or quit, and they worried that he might "get hit by a bus." As a result, SCE planned on using an expert system to try to "clone" one of their engineers, in a computer program that captured his expertise.

With such hype, it is probably not surprising that, unfortunately, expert systems never lived up to their hype. Bobrow et al. (3) noted that the term "expert" may have created unrealistic expectations about what a computer program could do. Unfortunately, as noted by Business Week (4) "... grandiose promises of problem solving 'expert in a box' proved illusory." However, the term "expert" also generated "commercial" hopes for a discipline that had been academically based [e.g., Shortliffe (1)].

As a result, that same *Business Week* article also noted that expert systems had proliferated rapidly throughout finance in business applications, which was being used for a range of activities such as market analysis to credit evaluation. From the early to mid 1970s to the mid 1980s, expert systems application base seemed almost universal. Since then, expert systems have been applied to just about every conceivable discipline, ranging from chemistry to medicine to business.

The term expert system apparently began to be replaced by the term "knowledge-based system" in the mid 1980s to mid 1990s [e.g., Hayes-Roth (5) and Davis (6)]. The shift began to remove the need for labeling a system with "expert," and reduce the hype, but still would require that the system be "knowledge based." This name shift put less direct pressure on developers to build systems that were equivalent to experts, but it also was sign of a commercial and research shift away from expert systems and an evolution to other forms of problem solving approaches.

Purpose and Scope

The purpose of this article is to review key concepts in expert systems across the lifecycle of expert system development. As a result, we will analyze the choice of the application area for system development, gathering knowledge through so-called knowledge acquisition, choosing a knowledge representation, building in explanation, and verifying and validating the system.

Although it would be easy to focus only on the technical issues, a key finding in the expert systems literature was noted as businesses actually began to implement expert systems [e.g., Barker and O'Connor (7)]: "... To successfully develop and provide ongoing support for expert systems and to integrate them into the fabric of one's business, ... one must attend to the needs of the business and to human resource and organizational issues as well as to technical issues." One of the first developers of expert systems, E. Feigenbaum, was quoted as saying [Lyons (8)], "I'm not interested in theoretical concepts. I like to see my work used in the real world." Accordingly, we will not only consider technical issues, but also some nontechnical organizational and people issues, along with the applications.

Expert systems were a key part of pioneering artificial intelligence efforts to model human behavior. Expert systems have led to substantial additional and emerging research. Accordingly, this article briefly investigates some additional and emerging issues.

Finally, in an article of this type it is inevitable that some key works and important researchers are omitted. As space is limited, some topics that might be addressed are not. The author apologizes in advance for any such omissions.

Outline of this Article

This article proceeds in the following manner. This first section has provided an introduction and statement of purpose and scope. The second section investigates expert systems and human reasoning, while the third section analyzes the structural nature of an "expert system." The fourth section provides some definitions of an expert system. The following two sections analyze some characteristics of expert system applications and investigate some expert system applications. Then, the following five sections trace expert systems through the lifecycle of choosing an application that is likely to work, knowledge acquisition, knowledge representation, explanation, and verification and validation of the system. The final three sections investigate, respectively, expert system strengths and limitations, extensions, and emerging issues, followed by a brief conclusion.

EXPERT SYSTEMS AND HUMAN REASONING

Initially, computer scientists were interested in capturing nonquantitative decision-making models in a computer, and they used expert systems to generate those models

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

[e.g., Shortliffe (1)]. What were some basic assumptions about human reasoning that drove expert systems? Perhaps the initial primary assumptions were:

- Experts know more than nonexperts.
- People use information and knowledge based on their past experience.
- People use heuristics.
- People use specific, a priori rules to solve problems.
- People use focused knowledge to solve problems.

Experts Know More Than Nonexperts

Expert systems assume that experts know more or at least something different than nonexperts in a field. Accordingly, expert systems assume that experts are differentiated from nonexperts by what knowledge they have. As a result, capturing that expert knowledge can potentially change the knowledge of nonexperts.

People use Past Experience

People use their past experience (actions, education, etc.) as the basis of how to solve problems. As a result, system developers interested in building systems to solve problems can consult with people to try to capture that past experience, and they use it to solve problems where that experience could be used.

People use Heuristics

Heuristics are so-called "rules of thumb." Often, past experience is captured and summarized in heuristics. Rather than optimize every decision, people [e.g., Simon (9)] use heuristics that they have found from past experience to drive them toward good, feasible solutions. To solve complex problems, expert systems assume that it is possible to capture those heuristics in a computer program and assemble them for reuse.

People use Rules

Much everyday and business problem solving seems based on rules. For example, when choosing a wine for dinner, simple rules such as "if the dinner includes a red meat then the wine should be red," help guide dinners to the choice of a wine. People use rules to solve problems. As noted by Clancey (10), rules were recognized as a simple and uniform approach to capture heuristic information. Heuristics and other knowledge are captured and kept in a rule-based form. If people use rules, then computer programs could use those same rules to solve problems.

Problem Solving Requires Focused Knowledge

Expert systems researchers [e.g., Feigenbaum (8)] note that one view of human intelligence is that it requires knowledge about *particular* problems and how to solve those particular problems. Accordingly, one approach to mimicking human intelligence is to generate systems that solve only particular problems.

STRUCTURAL NATURE OF EXPERT SYSTEMS

Because it was assumed that human problem solvers used rules and knowledge could be captured as rules, rule bases and their processing were the critical component of expert systems. Accordingly, the structure of a classic expert system was designed to meet those needs. Ultimately, expert systems were composed of five components: data/database, user interface, user, knowledge base/rule base, and an inference engine to facilitate analysis of that knowledge base.

Data

The data used by the system could include computer-generated data, data gathered from a database, and data gathered from the user. For example, computer-generated data might derive from an analysis of financial statement data as part of a program to analyze the financial position of a company. Additional data might be gathered selectively straight from an integrated database. Furthermore, the user might be required to generate some assessment or provide some required data. Typically, initial expert systems required that the user provide key inputs to the system.

User Interface

Because the user typically interacted with the system and provided it with data, the user interface was critical. However, an expert system user interface could take many forms. Typically, the system would display a question, and the user would select one or more answers from a list, as in a multiple choice test. Then, the system would go to another question and ultimately provide a recommended solution. In some cases, the user would need to analyze a picture or a movie clip to answer the questions.

User

In any case, in a classic expert system, the user is a key component to the system, because it is the user who ultimately provides environmental assessments, generates inputs for the system, and as a result, disambiguates the questions provided by the system to gather data from the user. Research has found that different user groups (e.g., novice or expert) given the same interrogation by the system would provide different answers. As a result, generating that user interface and building the system for a particular type of user are critical.

Knowledge Base/Rule Base

The knowledge base typically consisted of a static set of "if . . . then . . ." rules that was used to solve the problem. Rules periodically could be added or removed. However, the knowledge needed for solving the particular problem could be summarized and isolated. In addition, the very knowledge that was used to solve an inquiry also could be used to help explain why a particular decision was made. (Some researchers include explanation facility as its own component.) Accordingly, gathering, explaining, and verifying and validating that knowledge is the focus of the rest of this discussion.

Inference Engines

Inference engines facilitate use of the rule base. Given the necessary information as to the existing conditions provided by the user, inference engines allow processing of a set of rules to arrive at a conclusion by reasoning through the rule base. For example with the system "if a then b," and "if b then c" would allow us to "reason" that a led to b and then to c. As rule-based systems became the norm, the inference engine saved each developer from doing the same thing, and allowed developers to focus on generation of the knowledge base. Developers became referred to as knowledge engineers. Ultimately, data was gathered, combined, and processed with the appropriate knowledge to infer the matching solution.

Expert System Software

Because the expert system components were distinct, software could be designed to allow developers to focus on problem solution rather than building the components themselves. As a result, a wide range of so-called "expert system shells" were generated, for example [e.g., Richter (11)], EMYCIN [from MYCIN, Buchanan and Shortliffe (12)], ART (Automated Reasoning Tool by Inference Corporation), M.4 [http://www.teknowledge.com/, (13)] or Exsys (http://www.exsys.com/).

WHAT IS AN EXPERT SYSTEM?

The term expert system has been applied broadly to several systems apparently for many different reasons. At various points in time, the term "expert system" has implied a type of knowledge representation, a system to perform a particular task, the level of performance of the system.

Rule-Based Knowledge Representation

As noted above, people seemed to use rules to reason to conclusions, and experts were recognized as supplying rules that would be used to guide others through task solution. As a result, most so-called "expert systems" probably were "rule-based systems." Researchers had observed that this type of reasoning apparently was used by people to solve problems. So-called experts seemed to reason this way, so the systems were "expert."

Activity/Task of the System

Another rationale for labeling a system an "expert system," was because the system performed a specific task that human experts did. Experts seem to structured reasoning approaches that could be modeled to help solve various problems (e.g., choosing a wine to go with dinner).

Level of Performance of the System

One perspective was that a system was an "expert system" if it performed a task at the level of a "human expert." For example, Buchanan and Feigenbaum (14) argue that the DENDRAL system functioned at the same level as a human expert.

System Dependence

However, although the system was expert, it was generally still dependent on people for environmental assessments of conditions and corresponding data input. Expert systems were dependent on the user for a range of activities and thus dependent on the user. For example, as noted in Hart et al. (15, p. 590) "... facts recorded in databases often require interpretation." As a result, most self proclaimed expert systems typically provided an interactive consultation that meant the system was still dependent on people.

Definitions

Accordingly, over the years, the term expert systems has been defined several ways, including the following:

- A program that uses available information, heuristics, and inference to suggest solutions to problems in a particular discipline. (answers.com)
- "The term expert systems refer to computer programs that apply substantial knowledge of specific areas of expertise to the problem solving process." [Bobrow et al. (3, p. 880)]
- "... the term expert system originally implied a computer-based consultation system using AI techniques to emulate the decision-making behavior of an expert in a specialized, knowledge-intensive field." [Shortliffe (1, p. 831)]

As a result, we will call a system an expert system when it has the following characteristics:

- a rule-based approach is used to model decision making knowledge, and those rules may include some kind of factor, to capture uncertainty
- interacts with a user from whom it gathers environmental assessments, through an interactive consultation (not always present)
- designed to help facilitate solution of a particular task, typically narrow in scope
- generally performs at the level of an informed analyst

CHARACTERISTICS OF EXPERT SYSTEM APPLICATIONS

Because expert systems related to the ability of a computer program to mimic an expert, expert systems were necessarily about applications and about comparing human experts and systems. Often, the initial goal of expert systems at some level was to show that the system could perform at the same level as a person. But as they put these systems in environments with people, we began to realize several key factors. First, typically, for a rule-base to solve the problem, the problem will need to be structurable. Second, systems may support or replace humans. Third, one of the key reasons that a system might replace a human is the amount of available time to solve the problem, not just knowledge.

Structured versus Unstructured Tasks

Expert systems and their rule-based approaches rely on being able to structure a problem in a formal manner. Rules provided a unifying and simple formalism that could be used to structure a task. Thus, although the problem may not have had sufficient data to be analyzed statistically, or could not be optimized, information still facilitated structuring the problem and knowledge about the problem in a formal manner.

Support versus Replace

Expert systems were often recognized as a vehicle to replace human experts [e.g., Rose (2)]. Many systems apparently were designed initially to replace people. However, in many decision-making situations, the focus was on providing a decision maker with support. For example, as noted by Kneale (16) in a discussion of an accounting system ExperTAX, the expert system is not designed to replace accountants, but instead to enhance and support advice for people.

Available Time

Another important issue in the support versus replace question was how much time was available to make the decision. If a problem needed to be solved in real time, then perhaps support was out the question, particularly if many decisions must be made. Furthermore, even if the system was to support an expert, perhaps it could provide insights and knowledge so the expert did not need to search for information elsewhere.

APPLICATIONS

Because of its focus on modeling and mimicking expertise, ultimately, the field of expert systems has been application oriented. Many applications of expert systems exist in a wide range of areas, including chemical applications, medical diagnosis, mineral exploration, computer configuration, financial applications and taxation applications. Applications have played an important role in expert system technology development. As expert system technologies and approaches were applied to help solve real world problems, new theoretical developments were generated, some of which are discussed below.

Chemical Applications

Some early applications of expert systems took place in this arena [e.g., Buchanan and Feigenbaum (14)]. DENDRAL and Meta-DENDRAL are programs that assist chemists with interpreting data. The DENDRAL programs use a substantial amount of knowledge about mass spectrometry to help with the inference as to what a compound may be. The output from the program is a detailed list with as much detail as the program can provide. Ultimately, Buchanan and Feigenbaum (14) argued that the program had a level of performance equal to a human expert.

Medical Diagnosis Expert Systems

Medicine was one of the first applications of expert systems. By 1984, Clancey and Shortliffe (17) presented a collection of papers that covered the first decade of applications in this domain. Shortliffe (1) briefly summarized some contributions of medical expert systems to medicine. MYCIN was a success at diagnosing infectious diseases. Present illness program (PIP) generated hypotheses about disease in patients with renal disease. INTERNIST-1 was a system designed to assist diagnosis of general internal medicine problems. Since that time, substantial research has occurred in medical expert systems. One of the critical developments associated with medical expert system was using uncertainty on rules [e.g., (18)], which is discussed additionally below.

Geology Advisor

In geology, an expert system was developed to assist in the analysis of drilling site soil samples for oil exploration. PROSPECTOR I and II [(McCammon (19)] were built with over 2,000 rules capturing information about the geologic setting and kinds of rocks and minerals, to help geologists find hidden mineral deposits. PROSPECTOR I [Duda et al. (20) and Hart et al. (15)] was developed along with an alternative representation of uncertainty on rules that garnered substantial attention and is discussed further below.

Computer Configuration

Configuration was one of the first major industrial applications of expert systems. Perhaps the best known configuration expert system was XCON, also known as R1 [e.g., Barker and O'Connor (7)]. XCON was touted as the first expert system in daily production use in an industry setting. At one point in time, XCON was only one of many expert systems in use in at the former computer manufacturer "Digital" to configure hardware and software. As an expert system, XCON was used to validate the customer orders for technical correctness (configurability) and to guide order assembly. Barker and O'Connor (7) also describe many other expert systems that were in use at Digital Equipment Corporation (DEC) during the same time as XCON, including

- XSEL, which was used interactively to assist in the choice of saleable parts for a customer order
- XFL, which was used to diagram a computer room floor layout for the configuration under consideration
- XNET, which was used to design local area networks to select appropriate components

Not surprisingly, these industrial applications had very large knowledge bases. For example, as of September 1988, XCON had over 10,000 rules; XSEL had over 3500 rules; XFL had over 1800 rules; and XNET, a prototype, had roughly 1700 rules.

Taxation Applications at the IRS

Beckman (21) reviewed and summarized the taxation applications expert systems literature, and he provided a focus on applications at the Internal Revenue Service (IRS). Throughout the IRS's involvement in artificial intelligence starting in 1983, the IRS focused on the ability of the technology to help solve real-world problems. As reported by Beckman (21), many expert system projects were developed and tested, including the following. A "tax return issue identification" expert system was designed to help identify individual tax returns with "good audit potential." A "reasonable cause determination" expert system was developed because it was found that the error rate by people was too high. As a result, the system was designed to improve the consistency and quality of so-called "reasonable cause determinations." An "automated under-reporter" expert system that was designed to help tax examiners assess whether individual taxpayers properly reported income.

Auditing and Accounting

The fields of auditing and accounting have generated a substantial literature of applications. The notion behind the development of many such systems was inviting: Auditors and accountants used rules to solve many problems they faced. Expert systems were used to model judgment decisions made by the participants. Brown et al. (22) provide a recent survey of the field.

CHOOSING AN APPLICATION

Two basic perspectives exist on choosing an application to build an expert system. Prerau (23), Bobrow et al. (3), and others have analyzed what characteristics in the domain were important in the selection of a problem around which to build an expert system. Their perspective was one of how well the needs of the domain met the needs of the technology: choose the right problem so that the expert system technology can blossom. Alternatively, Myers et al. (24) and others have viewed it from the business perspective, stressing the need for making sure that the system was in an area that was consistent with the way the company was going to run their business: Make sure the expert system application meets the objectives of the company developing it. In any case, many issues were suggested as conditions that needed to be considered when the domain and expert system application were aligned, including the following issues.

Art and Science

Hart et al. (15, p. 590) note that "Mineral exploration is perhaps as much an art as science, and the state of this art does not admit the construction of models as rigorous and complete, as, say, those of Newtonian mechanics." If a scientific model exists, then a rule-based approach is not needed; the scientific model can be used.

Expertise Issues

Because expert systems are dependent on human experts as a source of their knowledge, experts must work on the project. For example, Prerau (23) notes the importance of having access to an expert from which expertise can be gathered, and the expert must have sufficient time to spend on the project development. Other concerns such as willingness to work on the project also must be considered.

Benefit

In addition, the task should be one that provides enough returns to make it worthwhile. There is no sense in building a system if the value to the builders does not exceed the costs.

Testability

Because the system is to be categorized as an expert system, the system must perform appropriately. This task requires that the results are testable.

KNOWLEDGE ACQUISITION

Early expert systems research was not so much concerned with knowledge acquisition or any other issues, per se. Instead the concern was mostly about the ability of the system to mimic human experts. However, over time as more systems demonstrated the feasibility of capturing expertise, greater attention was paid to knowledge acquisition.

In general, expert system expertise was solicited initially in a team environment, in which programmers and the expert worked hand-in-hand to generate the system. Faculty from multiple disciplines were often coauthors on research describing the resulting systems. However, as the base of applications broadened, it became apparent that interviews with experts, which were designed to try and elicit the appropriate knowledge, was generally the most frequently used approach. Prerau (25) notes the importance of getting step-by-step detail, and that using some form of "quasi-English if-then rules" to document the findings. However, many other creative approaches exist for gathering knowledge from experts, including the following applications.

ExperTAX

One particularly innovative approach was used by Coopers and Lybrand in the development of their expert system "ExperTAX" [e.g., Shpilberg et al. (26) and Kneale (16)] The goal of the project was to try and understand how partners in a professional services firm analyzed tax planning problems. Ultimately, to gather the knowledge necessary to solve a particular tax problem, they had a team of three expert partners behind a curtain. On the other side of the curtain was a beginner, with many documents. While videotaping the process, the partners guided the beginner toward a solution. The camera captured what questions were asked, what documents were needed, and what information was used. Ultimately, each partner spent a total of over 50 hours working on the system.

Problems with Gathering Knowledge from Experts

Various problems have been reported associated with gathering knowledge from experts. First, knowledge is power. As a result, unfortunately, experts do not always have incentives to cooperate. For example, one consultant noted in Orlikowski (27, p. 246) as to why expert consultants at one company were not interested in participating in knowledge acquisition,

> "Power in this firm is your client base and technical ability . . . It is definitely a function of consulting firms. Now if you put all of this in a . . . database, you will lose power. There will be nothing that's privy to you, so you will lose power. It's important that I am selling something that no one else has. When I hear people talk about the importance of sharing expertise in the firm, I say, 'Reality is a nice construct.' "

As a result, it has been suggested that experts may withhold secrets [e.g., (2)].

Second, as noted in Rose (2), experts often do not consciously understand what they do. As a result, any attempt to interview them will not result in the quality or quantity of knowledge that is necessary for a system to work. In an example discussed in Rose (2), SCE had their programmers study dam safety and construction engineering before the knowledge acquisition. Then the programmers met one-on-one with the expert in a windowless conference room. Their first meeting lasted seven hours. They captured all interaction using a tape recorder. Unfortunately, the attempts to build the system ran into difficulties. Early versions of the program indicated problems. Virtually every scenario ended with the recommendation to pack the problem wet area with gravel and keep it under observation. They narrowed the focus to a single dam in an effort to generate sufficient detail and insights. However, even after months of work, the knowledge base had only 20 different rules.

KNOWLEDGE REPRESENTATION

Several forms of knowledge representation exist in artificial intelligence. However, expert systems typically refer to so-called rule-based systems. However, some extensions to deterministic rules have been developed to account for uncertainty and ambiguity.

"If . . .then . . ." Rules

"If . . . then . . ." rules are the primary type of knowledge used in classic expert systems. As noted above those rules are used to capture heuristic reasoning that experts apparently often employ. However, over time researchers began to develop and integrate alternative forms of knowledge representation, such as frame-based or case-based reasoning, into their systems. Systems that included multiple types of knowledge sometimes were referred to as hybrid systems or labeled after a particular type of knowledge representation (e.g., case-based).

Uncertain Knowledge

Unfortunately, not all statements of knowledge are with complete certainty. One approach to capturing uncertainty of knowledge was to use some form of probability on each of the rules. As expert systems were developed, many different approaches were generated, which often depended on the particular application. For example, Buchanan and Shortliffe (12, p. 248) for rules of the sort "if e then h," generated certainty factors (CF) for a medical expert system. MYCIN attributes a "meaning" to different certainty factors [Buchanan and Shortliffe (12, p. 91)]. The larger the weight, the greater the belief in the specific rule. If $CF = 1.0$, then the hypothesis is "known to be correct." If $CF = -1.0$ then that means that the hypothesis ". . . has been effectively disproven." "When $CF = 0$ then there is either no evidence regarding the hypothesis or the supporting evidence is equally balanced by evidence suggesting that the hypothesis is not true."

Duda et al. (20) and Hart et al. (15) developed a different approach for Prospector, which is an expert system designed to aid geological exploration. They used the specification of "if E then H (to degree S,N)." S and N are numeric values that represent the strength of association between E and H. S is called a sufficiency factor, because a large S means that a high probability for E is sufficient to produce a high probability of H; N is called a necessity factor, because a small value of N means that a high probability for E is necessary to produce a high probability of H, where $S = P(E \mid H)/P(E \mid H')$ and $N = P(E' \mid H)/P(E' \mid H')$. S and N are likelihood ratios. This approach was extended to include the reliability of the evidence [e.g., (28)].

In addition to probability-based approaches, additional approaches emerged and found their way into expert systems. For example, fuzzy sets [Zadeh (29)] and Dempster-Shafer belief functions [Shafer (30)] were used to provide alternative approaches.

Interaction of Knowledge Acquisition and Representation

Unfortunately, it does not seem that knowledge acquisition and representation are independent of each other. For example, recent research (31) illustrates that the two are tightly intertwined. An empirical analysis of logically equivalent but different knowledge representations can result in different knowledge being gathered. That is, soliciting knowledge in one knowledge representation can generate knowledge perceived as different than a logically equivalent one. As a result, if the developer wants "if . . . then . . ." rules, then they should use those rules as the form of knowledge in the acquisition process and throughout system development.

EXPLANATION

Researchers developed techniques so that given complex rule bases or other structured forms of knowledge representation systems could analyze the knowledge to find a solution. However, a human user of the system might look at the systems and not understand "why" that particular solution was chosen. As a result, it became important for systems to provide an explanation as to why they chose a particular solution.

Importance of Explanation Facilities

Arnold et al. (32) did an empirical analysis of the use of an explanation facility. They found that novice and expert users employed the explanation capabilities differently. In addition, they found that users were more likely to follow a recommendation if an explanation was given. As a result, explanation is an important strand of expert system research, which includes the following approaches.

Trace Through the Rules

Perhaps the first approach toward generating a system that could provide an explanation for the choice was to generate a trace of the rules. The trace was simply a listing of which rules were executed in generating the solution. Much research on explanation leveraged knowledge and context from the specific application area. Although primitive, this approach still provided more insight into why a decision was made, as compared with probability or optimization approaches.

Model-Based Reasoning

In general, explanation is facilitated by the existence of a model that can be used to illustrate why a question is being asked or why a conclusion was drawn. One model-based domain that has gathered a lot of attention is the financial model of a company that depends on several accounting relationships. This financial model has been investigated by many researchers as a basis of explaining decisions [e.g., (33)].

Dialog-Based Systems

Quilici (34) had an interesting approach to explanation, suggesting that in the long-run expert systems must participate in dialogs with their users. Quilici suggested that providing a trace was not likely to be enough, but instead the system needed to know when and how to convince a user. This task would require that the system understand why its advice was not being accepted.

Explanation as to what Decisions were Made in Building the Program

Swartout (35) argued that as part of explanation, a system needs to explain what its developers did and why. Accordingly, he built XPLAIN to provide the user with insights about decisions made during creation of the program to get insight into the knowledge and facilitate explanation.

VERIFICATION AND VALIDATION

As noted above, one factor that makes a system an expert system, is the level of performance of a system. As a result, perhaps more than any other type of system, verification and validation that some system functions at a particular level of expertise is important in establishing the basic nature of the system. Accordingly, an important set of issues is ensuring that the system developed works appropriately and that the knowledge contained in the system is correct. Assuring those conditions is done using verification and validation.

Verification

Verification is more concerned with the syntactical issues. As noted by O’Keefe et al. (36), verification refers to building the system right. Verification refers to making sure that the technology has been implemented correctly. Accordingly, verification is concerned that the structural nature of the “if. . . then . . .” rules is appropriate. For example, verification is concerned that no loops existed in the rule base (“if a then b” and “if b then a”) or that no rules conflict (e.g., “if a then b,” “if a then c”). Preece and Shinghal (37) examine these structural issues in greater detail. Verification also is concerned that any weights on rules have been performed correctly. For example, O’Leary (38) provides many approaches to help determine whether expert system weights on the rules have been put together appropriately or whether any anomalies should be investigated.

Validation

Validation is concerned more with the semantic issues. As noted by O’Keefe et al. (36) validation refers to building the right system. O’Leary (39) lays out some critical issues regarding validation of expert systems and ties his approach to a structure based on research methods. O’Leary (39) suggests that some of the key functions of validation, all consistent with the nature of expert systems, are

- ascertaining what the system knows, does not know or knows incorrectly
- ascertaining the level of decision making expertise of the system
- analyzes the reliability of the system.

Although O’Leary (39) is concerned with the theory and basic guidelines, he provides (40) several practical methods for expert system validation.

EXPERT SYSTEM STRENGTHS AND LIMITATIONS

Unfortunately, the mere term “expert” has put much pressure that the system performs at an appropriate level. This label is both a strength and a weakness. This section lists some other strengths and limitations of expert systems.

Strengths

Expert systems have provided the ability to solve real problems using the manipulation of syntactic and semantic information, rather than quantified information, providing a major change in the view as to what computer could do. In particular, if the problem being posed to the system is one for which rule based knowledge is effective, then the system is likely to provide a recommended solution.

Furthermore, expert systems can be integrated with other computer-based capabilities. As a result, they can do substantial “pre-analysis” of the data. For example, in the case of financial systems, financial ratios can be computed and analyzed, saving much time and effort.

Limitations

However, some limitations are associated with expert systems. One of the biggest “complaints” against expert systems has been the extent to which they are limited in scope and that the systems do not know their limitations. Classic expert systems have rules that focus only on the problems that it is designed to solve, which results in their limited scope. Generally expert systems do not know when a problem being posed by the user is outside of scope of the system.

Furthermore, as noted by *Business Week* (4), from a practical perspective, expert systems "... require complex and subtle interactions between machines and humans, each teaching and learning from other." Rather than being static, systems and people need to learn and change to accommodate each other.

In addition, Clancey (10) was an early investigator who noted that people, other than the authors of the rules, may have difficulty modifying the rule set. Clancey (10) also had concerns with the basic rule formalism for capturing knowledge. For example, Clancey noted "... the view that expert knowledge can be encoded as a uniform ... set of if/then associations is found to be wanting."

Getting and keeping up-to-date knowledge is another potential limitation. For example, in the area of U.S. taxation, the tax rules change every year. Some rules are new and some rules are no longer valid. Such rule-base changes are not unusual in any setting where technology is involved that must change often more than once a year. For example, imagine developing a system to help someone choose the right mobile phone.

Finally, a primary limitation to expert systems is illustrated by comment from Mike Ditka, a hall of fame American Football player. On a radio interview on Los Angeles Area radio (September 18, 2007), while talking about evaluating football players, he noted "... the intangibles are more important than the tangibles." Viewed from the perspective of expert systems, this quote suggests that although we can capture (tangible) knowledge, that other (intangible) knowledge is available, but not captured, and in many cases that additional knowledge may be the most important.

EXTENSIONS TO EXPERT SYSTEMS AND EMERGING RESEARCH ISSUES

The basic model of the expert system presented to this point is one where knowledge is gathered from a single expert and that knowledge is categorized as "if ... then ..." rules, as a basis for mapping expertise into a computer program. However, some extensions have occurred to that basic model, including the following ideas.

Multiple Experts or Knowledge Bases

Ng and Abramson (41) discussed a medical system named "Pathfinder" that was designed around multiple experts. Rather than having the system designers try to merge knowledge gathered from multiple experts into a single knowledge base, the design concept was to allow the system to put together knowledge from the multiple experts when it needed it.

Knowledge from Data

Gathering knowledge from experts ultimately became known as a "bottle neck." In some cases data was available, so rather than capturing what people said they did, an analysis of the data found what they actually did. Some researchers began to try to get knowledge from data, rather than going through classic interview processes. Ultimately, the focus on generating knowledge from data ended up creating the notion and field of knowledge discovery.

Neural nets also provided a vehicle to capture knowledge about data. Ultimately, neural nets have been used to create rules that are used in expert systems and expert systems have been built to try to explain rules generated from neural networks.

Alternative Forms of Knowledge Representation

As researchers studied reasoning and built systems they found that rules apparently were not the only way that people thought, or the ways that the researchers could represent knowledge. For example, one line of reasoning suggested that people used cases or examples on which to base their reasoning. As another example, researchers built frame-based reasoning systems. Frames allow researchers to capture patterns, that allow heuristic matching, for example, as was done with GRUNDY [Rich (42)]. As a result, case-based reasoning and other forms of knowledge representation helped push researchers to forms of knowledge representation beyond rules in an attempt to match the way that people use knowledge [Hayes (43)].

Alternative Problem Solving Approaches

Knowledge representation not only changed, but also other types of problem solving approaches were used. For example, as noted by Shortliffe (1, p. 831), "The term (expert systems) has subsequently been broadened as the field has been popularized, so that an expert system's roots in artificial intelligence research can no longer be presumed ... any decision support system (is) an expert system if it is designed to give expert level problem specific advice ..."

Expertise

Because expert systems were intent on capturing human expertise in a computer program, a need existed to better understand expertise and what it meant to be an expert. As a result, since the introduction of expert systems, substantial additional research is needed in the concept of expertise, not just how expertise can be mapped into a computer program.

Uncertainty Representation

Generating expert systems for different domains ended up facilitating the development of several approaches for representing uncertainty. However, additional research has focused on moving toward Bayes' Nets and influence diagrams [e.g., Pearl (44)] and moving away from the MYCIN certainty factors and the Prospector likelihood ratios.

The Internet and Connecting Systems

Generally, the expert system wave came before the Internet. As a result, the focus was on systems for a specific computer and not networked computers. As a result, limited research was available on networks of expert systems. However, since the advent of the Internet, expert system concepts were extended to knowledge servers (e.g., Reference 45) and multiple intelligent agents. In addition, technologies such as extensible markup language (XML) are now used to capture information containing rules and data and to communicate it around the world (e.g., xpertrule.com).

Ontologies

Furthermore, developers found that as expert systems grew or were connected and integrated with other systems that more formal variable definition was necessary. Large variable sets needed to be controlled and managed carefully, particularly in multilingual environments. As a result, extending those expert system capabilities led to some work on ontologies.

Embedded Intelligence versus Stand-Alone Systems

Increasingly, rather than highly visible stand alone applications, rule-based intelligence was built into other production applications. Because the systems were not stand alone expert systems, users did not even "see" the embedded expertise: People don't go check on what the expert system has to say—programs now are just more intelligent. For example, fixing spelling errors and grammar errors in Microsoft Word requires a certain amount of intelligence.

Business Rules

As another form of evolution, businesses are interested in so-called "business rules." As might be anticipated, business rules assume that businesses use rules in their interaction with other businesses. Rather than wait for people to make decisions, business rules capture those decision making capabilities. Business rules have virtually all of the same concerns as we saw in expert system rules in terms of knowledge acquisition, knowledge representation, verification and validation, and so on.

CONCLUSION

Expert systems have provided an important starting point for understanding and mimicking human expertise. However, they were only a start. Expert systems focused on heuristic decision making and rules, which are generally manifested in "if-then" rules, possibly employing weights on the rules to capture uncertainty or ambiguity. Expert system provided the foundations on which many other developments have been made.

FUZZY MODELING FUNDAMENTALS

This article introduces the basic concepts, notation, and basic operations for fuzzy sets that are needed in fuzzy modeling. Because research on fuzzy set theory has been underway for over 30 years now, it is practically impossible to cover all aspects of current developments in this area. Therefore, the main goal of this article is to provide an introduction to and a summary of the basic concepts and operations that are relevant to the study of fuzzy sets. We introduce in this article the definition of linguistic variables and linguistic values and explain how to use them in fuzzy rules, which are an efficient tool for quantitative modeling of words or sentences in a natural or artificial language. By interpreting fuzzy rules as fuzzy relations, we describe different schemes of fuzzy reasoning, in which inference procedures based on the concept of the compositional rule of inference are used to derive conclusions from a set of fuzzy rules and known facts. Fuzzy rules and fuzzy reasoning are the basic components of fuzzy inference systems, which are the most important modeling tool, based on fuzzy set theory.

The "fuzzy inference system" is a popular computing framework based on the concepts of fuzzy set theory, fuzzy if-then rules, and fuzzy reasoning (1). It has found successful applications in a wide variety of fields, such as automatic control, data classification, decision analysis, expert systems, time series prediction, robotics, and pattern recognition (2). Because of its multidisciplinary nature, the fuzzy inference system is known by numerous other names, such as "fuzzy expert system" (3), "fuzzy model" (4), "fuzzy associative memory" (5), and simply "fuzzy system."

The basic structure of a fuzzy inference system consists of three conceptual components: a "rule base," which contains a selection of fuzzy rules; a "data base" (or "dictionary"), which defines the membership functions used in the fuzzy rules; and a "reasoning mechanism," which performs the inference procedure on the rules and given facts to derive a reasonable output or conclusion. In general, we can say that a fuzzy inference system implements a nonlinear mapping from its input space to output space. This mapping is accomplished by several fuzzy if-then rules, each of which describes the local behavior of the mapping. In particular, the antecedent of a rule defines a fuzzy region in the input space, whereas the consequent specifies the output in the fuzzy region.

In what follows, we shall first introduce the basic concepts of fuzzy sets and fuzzy reasoning. Then, we will introduce and compare the three types of fuzzy inference systems that have been employed in various applications. Finally, we will address briefly the features and problems of fuzzy modeling, which is concerned with the construction of fuzzy inference systems for modeling a given target system. In this article, we will assume that all fuzzy sets, fuzzy rules, and operations are of type-1 category, unless otherwise specified.

FUZZY SET THEORY

Let X be a space of objects and x be a generic element of X. A classic set A, $A \subseteq X$, is defined by a collection of elements or objects $x \in X$, such that each x can either belong or not belong to the set A. By defining a "characteristic function" for each element $x \in X$, we can represent a classic set A by a set of order pairs (x,0) or (x,1), which indicates $x \notin A$ or $x \in A$, respectively.

Unlike the aforementioned conventional set, a fuzzy set (6) expresses the degree to which an element belong to a set. Hence, the characteristic function of a fuzzy set is allowed to have values between 0 and 1, which denotes the degree of membership of an element in a given set.

Definition 1. Fuzzy sets and membership functions. If X is a collection of objects denoted generically by x, then a "fuzzy set" A in X is defined as a set of ordered pairs:

$$A = \{(x, \mu_A(x)) \mid x \in X\} \tag{1}$$

where $\mu_A(x)$ is called "membership function" (MF) for the fuzzy set A. The MF maps each element of X to a membership grade (or membership value) between 0 and 1.

Obviously, the definition of a fuzzy set is a simple extension of the definition of a classic set in which the characteristic function is permitted to have any values between 0 and 1. If the values of the membership function $\mu_A(x)$ is restricted to either 0 or 1, then A is reduced to a classic set and $\mu_A(x)$ is the characteristic function of A. This function can be observed with the following example.

Example 1. Fuzzy set with a discrete universe of discourse X. Let X = {Tijuana, Acapulco, Cancun} be the set of cities one may choose to organize a conference in. The fuzzy set A = "desirable city to organize a conference in" may be described as follows:

$$A = \{(\text{Tijuana}, 0.5), (\text{Acapulco}, 0.7), (\text{Cancun}, 0.9)\}$$

In this case, the universe of discourse X is discrete—in this example, three cities in Mexico. Of course, the membership grades listed above are quite subjective; anyone can come up with three different values according to his or her preference.

Corresponding to the ordinary set operations of union, intersection and complement, fuzzy sets have similar operations, which were initially defined in Zadeh's seminal paper (6). Before introducing these three fuzzy set operations, first we shall define the notion of containment, which plays a central role in both ordinary and fuzzy sets. This definition of containment is a natural extension of the case for ordinary sets.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Definition 2. Containment. The fuzzy set A is "contained" in fuzzy set B (or, equivalently, A is a "subset" of B) if and only if $\mu_A(x) \leq \mu_B(x)$ for all x. Mathematically,

$$A \subseteq B \Leftrightarrow \mu_A(x) \leq \mu_B(x) \tag{2}$$

Definition 3. Union. The "union" of two fuzzy sets A and B is a fuzzy set C, written as C = A∪B or C = A OR B, whose MF is related to those of A and B by

$$\mu_C(x) = \max(\mu_A(x),\ \mu_B(x)) = \mu_A(x) \vee \mu_B(x) \tag{3}$$

Definition 4. Intersection. The "intersection" of two fuzzy sets A and B is a fuzzy set C, written as C = A∩B or C = A AND B, whose MF is related to those of A and B by

$$\mu_C(x) = \min(\mu_A(x),\ \mu_B(x)) = \mu_A(x) \wedge \mu_B(x) \tag{4}$$

Definition 5. Complement or Negation. The "complement" of a fuzzy set A, denoted by A (⌉A, NOT A), is

$$\mu_A(x) = 1 - \mu_A(x) \tag{5}$$

As mentioned earlier, a fuzzy set is completely characterized by its MF. Because most fuzzy sets in use have a universe of discourse X consisting of the real line R, it would be impractical to list all the pairs defining a membership function. A more convenient and concise way to define a MF is to express it as a mathematical formula. First we define several classes of parameterized MFs of one dimension.

Definition 6. Triangular MFs. A "triangular MF" is specified by three parameters {a, b, c} as follows:

$$y = \text{triangle}(x; a, b, c) = \begin{cases} 0, & x \leq a \\ (x-a)/(b-a), & a \leq x \leq b \\ (c-x)/(c-b), & b \leq x \leq c \\ 0, & c \leq x \end{cases} \tag{6}$$

The parameters {a,b,c} (with $a < b < c$) determine the x coordinates of the three corners of the underlying triangular MF. Figure 1 (b) illustrates a triangular MF defined by triangle(x; 10, 20, 40).

Definition 7. Trapezoidal MFs. A "trapezoidal MF" is specified by four parameters {a, b, c, d} as follows:

$$\text{traezoid}(x; a, b, c, d) = \begin{cases} 0, & x \leq a \\ (x-a)/(b-a), & a \leq x \leq b \\ 1, & b \leq x \leq c \\ (d-x)/(d-c), & c \leq x \leq d \\ 0, & d \leq x \end{cases} \tag{7}$$

The parameters {a, b, c, d} (with $a < b \leq c < d$) determine the x coordinates of the four corners of the underlying trapezoidal MF. Figure 1 (b) illustrates a trapezoidal MF defined by trapezoid(x; 10, 20, 40, 75).

Because of their simple formulas and computational efficiency, both triangular MFs and trapezoidal MFs have been used extensively, especially in real-time implementations. However, because the MFs are composed of straight line segments, they are not smooth at the corner points specified by the parameters. In the following, we introduce other types of MFs defined by smooth and nonlinear functions.

Definition 8. Gaussian MFs. A "Gaussian MF" is specified by two parameters {c, σ}:

$$\begin{array}{lcl} & & -1\dfrac{(x-c)^2}{\sigma} \\ \text{gaussian}(x; c, \sigma) & = & e^2 \end{array} \tag{8}$$

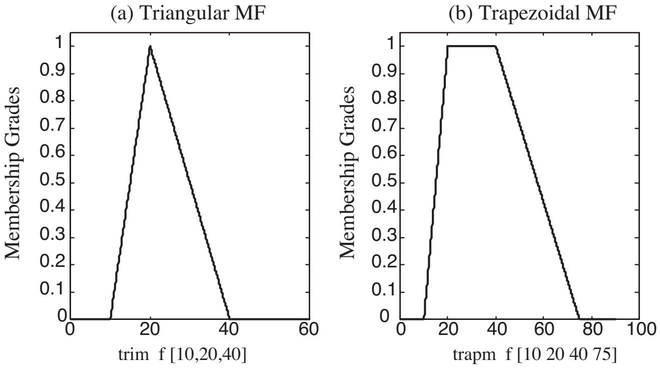
A "Gaussian" MF is determined completely by c and σ; c represents the MFs center and σ determines the MFs width. Figure 2 (a) plots a Gaussian MF defined by gaussian (x; 50, 20).

Definition 9. Generalized bell MFs. A "generalized bell MF" is specified by three parameters {a, b, c}:

$$\text{bell}(x; a,\ b,\ c) = \frac{1}{1 + |(x-c)/a|^{2b}} \tag{9}$$

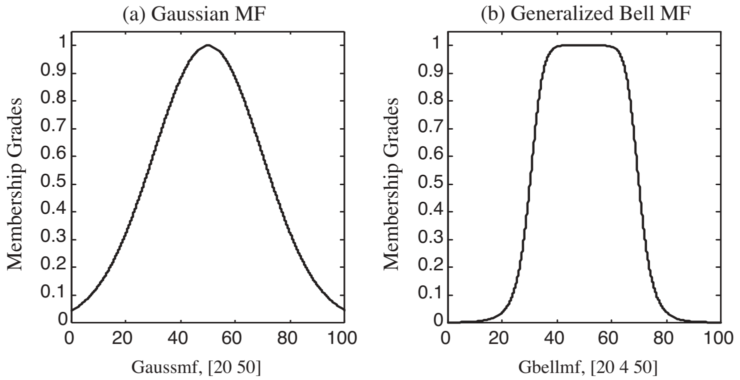
where the parameter b is usually positive. We can note that this MF is a direct generalization of the Cauchy distribution used in probability theory, so it is also referred to as the "Cauchy MF." Figure 2 (b) illustrates a generalized bell MF defined by bell (x; 20, 4, 50).

Although the Gaussian MFs and bell MFs achieve smoothness, they cannot specify asymmetric MFs, which are important in certain applications. Next we define the sigmoidal MF, which is either open left or right.



(a) Triangular MF (b) Trapezoidal MF

Figure 1. Examples of two types of parameterized MFs.



(a) Gaussian MF (b) Generalized Bell MF

Figure 2. Examples of two classes of parameterized continuous MFs.

.

Definition 10. Sigmoidal MFs. A "Sigmoidal MF" is defined by the following equation:

$$\mathrm{sig}(x;\ a,\ c) = \frac{1}{1+\exp[-a(x-c)]} \tag{10}$$

where a controls the slope at the crossover point $x = c$.

Depending on the sign of the parameter "a," a sigmoidal MF is inherently open right or left and thus is appropriate for representing concepts such as "very large" or "very negative." Figure 3 shows two sigmoidal functions $y_1 = \mathrm{sig}(x;\ 1,\ -5)$ and $y_2 = \mathrm{sig}(x;\ -2,\ 5)$.

FUZZY RULES AND FUZZY REASONING

In this section, we introduce the concepts of the extension principle and fuzzy relations, which extend the notions of fuzzy sets introduced previously. Then we give the definition of linguistic variables and linguistic values and show how to use them in fuzzy rules. By interpreting fuzzy rules as fuzzy relations, we describe different schemes of fuzzy reasoning. Fuzzy rules and fuzzy reasoning are the backbone of fuzzy inference systems, which are the most important modeling tool based on fuzzy set theory.

Fuzzy Relations

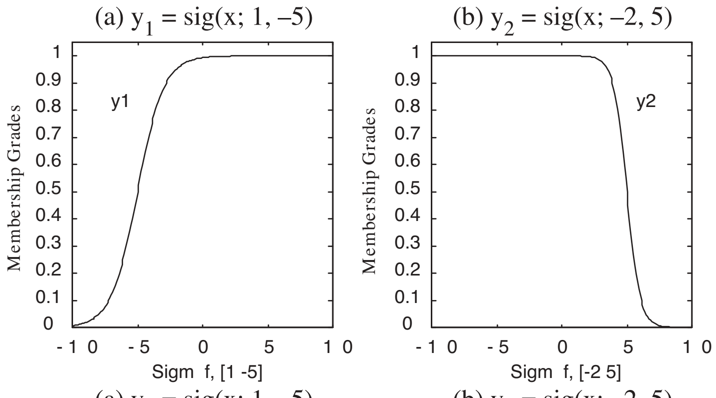
The "extension principle" is a basic concept of fuzzy set theory that provides a general procedure for extending crisp domains of mathematical expressions to fuzzy domains. This procedure generalizes a common one-to-one mapping of a function f to a mapping between fuzzy sets. More specifically, lets assume that f is a function from X to Y and A is a fuzzy set on X defined as

$$A = \mu_A(x_1)/x_1 + \mu_A(x_2)/x_2 + \cdots + \mu_A(x_n)/x_n$$

Then the extension principle states that the image of fuzzy set A under the mapping f can be expressed as a fuzzy set B,

$$B = f(A) = \mu_A(x_1)/y_1 + \mu_A(x_2)/y_2 + \cdots + \mu_A(x_n)/y_n$$

where $y_i = f(x_i)$, $i = 1, \ldots, n$. In other words, the fuzzy set B can be defined through the values of f in $x_1, x_2, \ldots, x_n$. If



(a) $y_1 = \mathrm{sig}(x;\ 1, -5)$ (b) $y_2 = \mathrm{sig}(x;\ -2, 5)$

Figure 3. Two sigmoidal functions y_1 and y_2.

f is a many-to-one mapping, then $x_1, x_2 \in X, x_1 \neq x_2$ exists, such that $f(x_1) = f(x_2) = y^*, y^* \in Y$. In this case, the membership grade of B at $y = y^*$ is the maximum of the membership grades of A at $x = x_1$ and $x = x_2$, because $f(x) = y^*$ may result from $x = x_1$ or $x = x_2$. More generally speaking, we have

$$\begin{aligned} \mu_B(y) &= \max \mu_A(x) \\ x &= f^1(y) \end{aligned}$$

A simple example of this concept is shown below.

Example 2. Application of the extension principle to fuzzy sets. Lets suppose we have the following fuzzy set with discrete universe

$$A = 0.2/-2 + 0.5/-1 + 0.7/0 + 0.9/1 + 0.4/2$$

and lets suppose that we have the following mapping

$$y = x^2 + 1$$

After applying the extension principle, we have the following result

$$\begin{aligned} B &= 0.2/5 + 0.5/2 + 0.7/1 + 0.9/2 + 0.4/5 \\ B &= 0.7/1 + (0.2 \vee 0.4)/5 + (0.5 \vee 0.9)/2 \\ B &= 0.7/1 + 0.4/5 + 0.9/2 \end{aligned}$$

where $\vee$ represents "max."

Binary fuzzy relations are fuzzy sets in X × Y which map each element in X × Y to a membership grade between 0 and 1. In particular, unary fuzzy relations are fuzzy sets with one-dimensional MFs; binary fuzzy relations are fuzzy sets with two-dimensional MFs, and so on. Here we will restrict our attention to binary fuzzy relations. A generalization to *n*-ary fuzzy relations is not so difficult.

Definition 11. Binary fuzzy relation. Let X and Y be two universes of discourse. Then

$$\mathcal{R} = \{((x, y), \mu_{\mathcal{R}}(x, y))|(x, y) \in X \times Y \tag{11}$$

is a binary fuzzy relation in X × Y.

Example 3. Binary fuzzy relations. Let X = {1, 2, 3} and Y = {1, 2, 3, 4, 5} and $\mathcal{R}$ = "y is slightly greater than x." The MF of the fuzzy relation $\mathcal{R}$ can be defined (subjectively) as

$$\mu_{\mathcal{R}}(x, y) = \begin{cases} (y - x)/(y + x), & \text{if} \quad y > x \\ 0, & \text{if} \quad y \leq x \end{cases} \tag{12}$$

This fuzzy relation $\mathcal{R}$ can be expressed as a relation matrix in the following form:

$$\mathcal{R} = \begin{pmatrix} 0 & 0.333 & 0.500 & 0.600 & 0.666 \\ 0 & 0 & 0.200 & 0.333 & 0.428 \\ 0 & 0 & 0 & 0.142 & 0.250 \end{pmatrix}$$

where the element at row *i* and column *j* is equal to the membership grade between the *i*th element of X and *j*th element of Y.

Other common examples of binary fuzzy relations are the following:

- x is similar to y (x and y are objects)
- x depends on y (x and y are events)
- If x is big, then y is small (x is an observed reading and y is the corresponding action)

The last example, "If x is A, then y is B," is used repeatedly in fuzzy systems. We will explore fuzzy relations of this type in the following section.

Fuzzy relations in different product spaces can be combined through a composition operation. Different composition operations have been proposed for fuzzy relations; the best known is the max-min composition proposed by Zadeh in 1965 (6).

Definition 12. Max-min composition. Let $\Re_1$ and $\Re_2$ be two fuzzy relations defined on X × Y and Y × Z, respectively. The "max-min composition" of $\Re_1$ and $\Re_2$ is a fuzzy set defined by

$$\begin{aligned} \Re_1 \circ \Re_2 = \{[(x, z), \max, \min(\mu_{\Re_1}(x, y), \\ \mu_{\Re_2}(y, z))]|x \in X,\ y \in Y,\ z \in Z\}y \end{aligned} \tag{13}$$

When $\Re_1$ and $\Re_2$ are expressed as relation matrices, the calculation of the composition $\Re_1 \circ \Re_2$ is almost the same as matrix multiplication, except that × and + are replaced by the "min" and "max" operations, respectively. For this reason, the max-min composition is called the "max-min product."

Fuzzy Rules

As was pointed out by Zadeh in his work on this area (7), conventional techniques for system analysis are intrinsically unsuited for dealing with humanistic systems, whose behavior is strongly influenced by human judgment, perception, and emotions. This finding is a manifestation of what might be called the "principle of incompatibility": "As the complexity of a system increases, our ability to make precise and yet significant statements about its behavior diminishes until a threshold is reached beyond which precision and significance become almost mutually exclusive characteristics" (7). It was because of this belief that Zadeh proposed the concept of linguistic variables (8,9) as an alternative approach to modeling human thinking.

Definition 13. Linguistic variables. A "Linguistic variable" is characterized by a quintuple (x, T(x), X, G, M) in which x is the name of the variable; T(x) is the "term set" of x-that is, the set of its "linguistic values" or "linguistic terms"; X is the universe of discourse, G is a "syntactic rule" which generates the terms in T(x); and M is a "semantic rule" which associates with each linguistic value A its meaning M(A), where M(A) denotes a fuzzy set in X.

Definition 14. Concentration and dilation of linguistic values. Let A be a linguistic value characterized by a fuzzy set membership function $\mu_A(.)$. Then, A^k is interpreted as a modified version of the original linguistic value expressed as

$$A^k = \int_X [\mu_A(x)]^k/x \tag{14}$$

In particular, the operation of "concentration" is defined as

$$\mathrm{CON}(A) = A^2 \tag{15}$$

whereas that of "dilation" is expressed by

$$\mathrm{DIL}(A) = A^{0.5} \tag{16}$$

Conventionally, we take CON(A) and DIL(A) to be the results of applying the hedges "very" and "more or less," respectively, to the linguistic term A. However, other consistent definitions for these linguistic hedges are possible and well justified for various applications.

Following the definitions given before, we can interpret the negation operator NOT and the connectives AND and OR as

$$\begin{aligned} \mathrm{NOT}(A) &= \rceil A = \int_X [1 - \mu_A(x)]/x \\ A\ \mathrm{AND}\ B &= A \cap B = \int_X [\mu_A(x) \wedge \mu_B(x)]/x \\ A\ \mathrm{OR}\ B &= A \cup B = \int_X [\mu_A(x) \vee \mu_B(x)]/x \end{aligned} \tag{17}$$

respectively, where A and B are two linguistic values whose meanings are defined by $\mu_A(.)$ and $\mu_B(.)$.

Definition 15. Fuzzy If-Then Rules. A "fuzzy if-then rule" (also known as "fuzzy rule," "fuzzy implication," or "fuzzy conditional statement") assumes the form

$$\textbf{if}\ x\ \text{is}\ A\ \textbf{then}\ y\ \text{is}\ B \tag{18}$$

where A and B are linguistic values defined by fuzzy sets on universes of discourse X and Y, respectively. Often "x is A" is called "antecedent" or "premise," while "y is B" is called the "consequence" or "conclusion."

Examples of fuzzy if-then rules are widespread in our daily linguistic expressions, such as the following:

- If pressure is high, then volume is small.
- If the road is slippery, then driving is dangerous.
- If the speed is high, then apply the brake a little.

Before we can employ fuzzy if-then rules to model and analyze a system, first we have to formalize what is meant by the expression "if x is A then y is B," which is sometimes abbreviated as A → B. In essence, the expression describes a relation between two variables x and y; this suggests that a fuzzy if-then rule is defined as a binary fuzzy relation R on the product space X ^{x} Y. Generally speaking, there are two ways to interpret the fuzzy rule A → B. If we interpret A → B as A "coupled with" B then

$$R = A \to B = A \times B = \int_{x\ x\ y} \mu_A(x) * \mu_B(y)/(x, y)$$

where * is an operator for intersection (10). On the other hand, if A → B is interpreted as A "entails" B, then it can be written as one of two different formulas:

- Material implication:

$$R = A \to B = \rceil A \cup B \tag{19}$$

- Propositional Calculus:

$$R = A \to B = \rceil A \cup (A \cap B) \tag{20}$$

Although these two formulas are different in appearance, they both reduce to the familiar identity $A \to B \equiv \rceil A \cup B$ when A and B are propositions in the sense of two-valued logic.

Fuzzy reasoning, also known as approximate reasoning, is an inference procedure that derives conclusions from a set of fuzzy if-then rules and known facts. The basic rule of inference in traditional two-valued logic is "modus ponens," according to which we can infer the truth of a proposition B from the truth of A and the implication A → B. This concept is illustrated as follows:

premise 1 (fact):	x is A,
premise 2 (rule):	if x is A then y is B,
consequence (conclusion):	y is B.

However, in much of human reasoning, modus ponens is employed in an approximate manner. This concept is written as:

premise 1 (fact):	x is A′
premise 2 (rule):	if x is A then y is B,
consequence (conclusion):	y is B′

where A′ is close to A and B′ is close to B. When A, B, A′ and B′ are fuzzy sets of appropriate universes, the foregoing inference procedure is called "approximate reasoning" or "fuzzy reasoning"; it is also called "generalized modus ponens" (GMP), because it has modus ponens as a special case.

Definition 16. Fuzzy reasoning. Let A, A′, and B be fuzzy sets of X, X, and Y, respectively. Assume that the fuzzy implication A → B is expressed as a fuzzy relation R on X ^{x} Y. Then the fuzzy set B induced by "x is A′" and the fuzzy rule "if x is A then y is B" is defined by

$$\begin{aligned} \mu_{B'}(y) &= \max_X \min[\mu_{A'}(x), \mu_R(x, y)] \\ &= V_X[\mu_{A'}(x) \wedge \mu_R(x, y)] \end{aligned} \tag{21}$$

Now we can use the inference procedure of fuzzy reasoning to derive conclusions provided that the fuzzy implication A → B is defined as an appropriate binary fuzzy relation.

Single Rule with Single Antecedent. This rule is the simplest case, and the formula is available in Equation (21). Another simplification of the equation yields

$$\begin{aligned}\mu_{B'}(y) &= [\vee_X(\mu_{A'}(x) \wedge \mu_A(x))] \wedge \mu_B(y)\\ &= \omega \wedge \mu_B(y)\end{aligned}$$

In other words, first we find the degree of match ω as the maximum of $\mu_{A'}(x) \wedge \mu_A(x)$, then the MF of the resulting B′ is equal to the MF of B clipped by ω. Intuitively, ω represents a measure of degree of belief for the antecedent part of a rule; this measure gets propagated by the if-then rules and the resulting degree of belief or MF for the consequent part should be no greater than ω.

Multiple Rules with Multiple Antecedents. The process of fuzzy reasoning or approximate reasoning for the general case can be divided into four steps:

1. Degrees of compatibility: Compare the known facts with the antecedents of fuzzy rules to find the degrees of compatibility with respect to each antecedent MF.
2. Firing strength: Combine degrees of compatibility with respect to antecedent MFs in a rule using fuzzy AND or OR operators to form a firing strength that indicates the degree to which the antecedent part of the rule is satisfied.
3. Qualified (induced) consequent MFs: Apply the firing strength to the consequent MF of a rule to generate a qualified consequent MF.
4. Overall output MF: Aggregate all the qualified consequent MFs to obtain an overall output MF.

FUZZY INFERENCE SYSTEMS

In this section, we describe the three types of fuzzy inference systems that have been widely used in the applications. The differences between these three fuzzy inference systems lie in the consequents of their fuzzy rules, and thus their aggregation and defuzzification procedures differ accordingly.

The “Mamdani fuzzy inference system” (10) was proposed as the first attempt to control a steam engine and boiler combination by a set of linguistic control rules obtained from experienced human operators. Figure 4 is an illustration of how a two-rule Mamdani fuzzy inference system derives the overall output z when subjected to two numeric inputs x and y.

In Mamdani’s application, two fuzzy inference systems were used as two controllers to generate the heat input to the boiler and throttle opening of the engine cylinder, respectively, to regulate the steam pressure in the boiler and the speed of the engine. Because the engine and boiler take only numeric values as inputs, a defuzzifier was used to convert a fuzzy set to a numeric value.

Defuzzification

Defuzzification refers to the way a numeric value is extracted from a fuzzy set as a representative value. In general, five methods exist for defuzzifying a fuzzy set A of a universe of discourse Z, as shown in Fig. 5 (Here the fuzzy set A is usually represented by an aggregated output MF, such as C′ in Fig. 4). A brief explanation of each defuzzification strategy follows.

- Centroid of area z_{COA}:

$$z_{COA} = \frac{\int_z \mu_A(z) z dz}{\int_z \mu_A(z) dz} \tag{22}$$

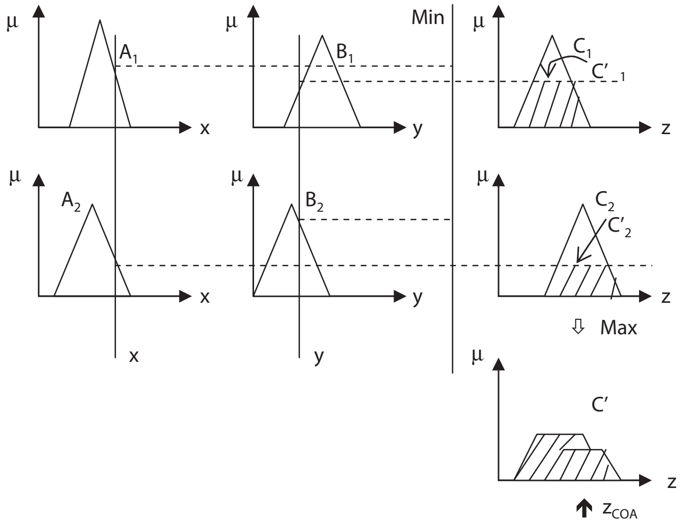


Figure 4. The Mamdani fuzzy inference system using the min and max operators.

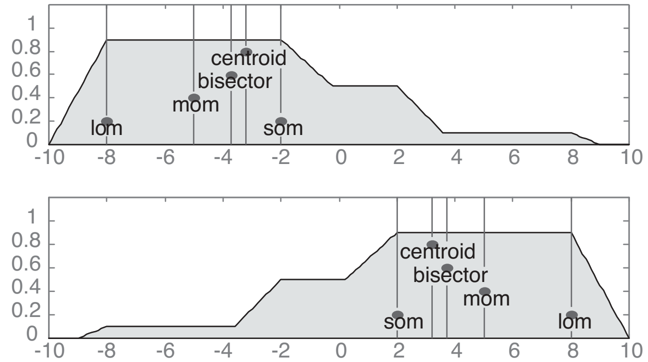

Figure 5. Various defuzzification methods for obtaining a numeric ouput.

where $\mu_A(z)$ is the aggregated output MF. This example is the most widely adopted defuzzification strategy, which is reminiscent of the calculation of expected values of probability distributions.

- Bisector of area z_{BOA}: z_{BOA} satisfies

$$\int_{\alpha}^{Z_{BOA}} \mu_A(z)dz = \int_{z^{BOA}}^{\beta} \mu_A(z)dz \tag{23}$$

where $\alpha = \min\{z|z \in Z\}$ and $\beta = \max\{z|z \in Z\}$.

- Mean of maximum z_{MOM}: z_{MOM} is the average of the maximizing z at which the MF reach a maximum μ^*. Mathematically,

$$z_{MOM} = \frac{\int_{z'} zdz}{\int_{z'} dz} \tag{24}$$

where $z\prime = \{z|\mu_A(z) = \mu*\}$. In particular, if $\mu_A(z)$ has a single maximum at $z = z^*$, then $z_{MOM} = z^*$. Moreover, if $\mu_A(z)$ reaches its maximum whenever $z \in [z_{left}, z_{right}]$ then $z_{MOM} = (z_{left} + z_{right})/2$.

- Smallest of maximum z_{SOM}: z_{SOM} is the minimum (in terms of magnitude) of the maximizing z.
- Largest of maximum z_{LOM}: z_{LOM} is the maximum (in terms of magnitude) of the maximizing z. Because of their obvious bias, z_{SOM} and z_{LOM} are not used as often as the other three defuzzification methods.

The calculation needed to carry out any of these five defuzzification operations is time consuming unless special hardware support is available. Furthermore, these defuzzification operations are not easily subject to rigorous mathematical analysis, so most studies are based on experimental results. This result leads to the propositions of other types of fuzzy inference systems that do not need defuzzification at all; two systems will be described in the following. Other more flexible defuzzification methods can be found in several more recent papers (11,12).

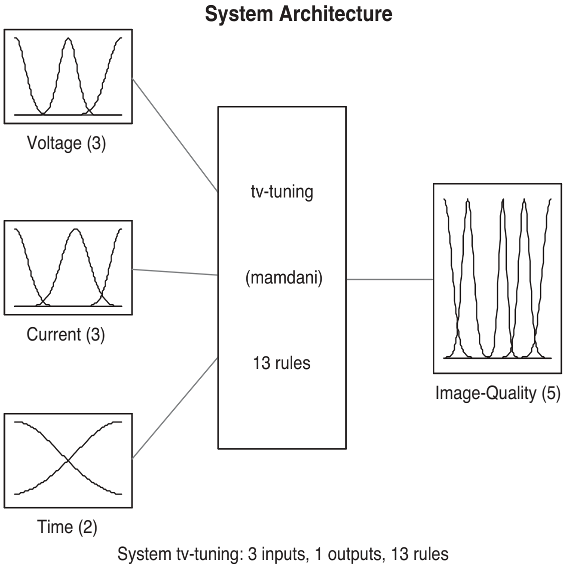

Figure 6. Architecture of the fuzzy system for quality evalution.

We will give a simple example to illustrate the use of the Mamdani fuzzy inference system. We will consider the case of determining the quality of a image produce by a Television as a result of controlling the electrical tuning process based on the input variables: voltage, current, and time (13). Automating the electrical tuning process during the manufacturing of televisions results in increased productivity and reduction of production costs, as well as increasing the quality of the imaging system of the television. The fuzzy model will consist of a set of rules relating these variables, which represent expert knowledge in the electrical tuning process of televisions. In Fig. 6 we show the architecture of the fuzzy system relating the input variables (voltage, current, and time) with the output variable (quality of the image), which was implemented by using the MATLAB Fuzzy Logic Toolbox. We show in Fig. 7 the fuzzy rule base, which was implemented by using the “rule

editor" of the same toolbox. In Fig. 8 we can appreciate the membership functions for the image-quality variable. We show in Fig. 9 the membership functions for the voltage variable. We also show in Fig. 10 the use of the "rule viewer" of MATLAB to calculate specific values. Finally, in Fig. 11 we show the nonlinear surface for the Mamdani model.

Sugeno Fuzzy Models

The "Sugeno fuzzy model" (also known as the "TSK fuzzy model") was proposed by Takagi, Sugeno, and Kang in an effort to develop a systematic approach to generating fuzzy rules from a given input-output data set (4,14). A typical fuzzy rule in a Sugeno fuzzy model has the form:

$$\textbf{if } \mathrm{x \text{ is } A} \textbf{ and } \mathrm{y \text{ is } B} \textbf{ then } \mathrm{z} = \mathrm{f(x, y)}$$

where A and B are fuzzy sets in the antecedent, whereas z = f(x,y) is a traditional function in the consequent. Usually f(x,y) is a polynomial in the input variables x and y, but it can be any function as long as it can appropriately describe the output of the model within the fuzzy region specified by the antecedent of the rule. When f(x,y) is a first-order polynomial, the resulting fuzzy inference system is called a "first-order Sugeno fuzzy model." When f is constant, we then have a "zero-order Sugeno fuzzy model," which can be viewed either as a special case of the Mamdani inference system, in which each rule's consequent is specified by a fuzzy singleton; or a special case of the Tsukamoto fuzzy model (to be introduced next), in which each rule's consequent is specified by a MF of a step function center at the constant.

Figure 12 shows the fuzzy reasoning procedure for a first-order Sugeno model. Because each rule has a numeric output, the overall output is obtained via "weighted average," thus avoiding the time-consuming process of defuzzification required in a Mamdani model. In practice, the weighted average operator is sometimes replaced with the "weighted sum" operator (that is, $w_1z_1 + w_2z_2$ in Fig. 12) to reduce computation further specially, in the training of a fuzzy inference system. However, this simplification could lead to the loss of MF linguistic meanings unless the sum of firing strengths (that is, Σw_i) is close to unity.

Unlike the Mamdani fuzzy model, the Sugeno fuzzy model cannot follow the compositional rule of inference strictly in its fuzzy reasoning mechanism. This result poses some difficulties when the inputs to a Sugeno fuzzy model are fuzzy. Specifically, we can still employ the matching of fuzzy sets to find the firing strength of each rule. However, the resulting overall output via either weighted average or weighted sum is always crisp; this finding is counterintuitive because a fuzzy model should propagate the fuzziness from inputs to outputs in an appropriate manner. Without the use of the time-consuming defuzzification procedure,

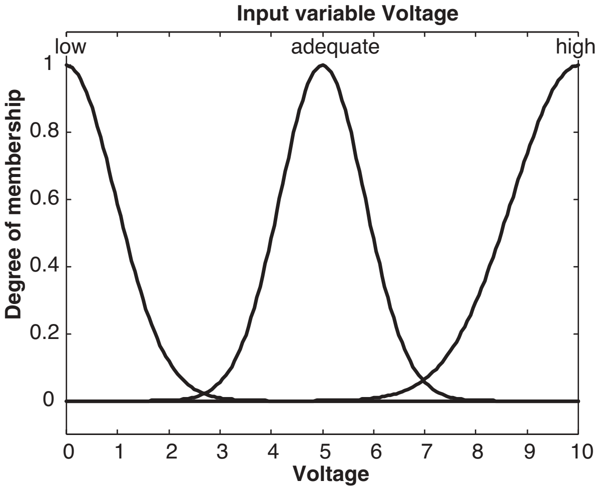

Figure 9. Gaussian membership functions for the voltage linguistic variable.

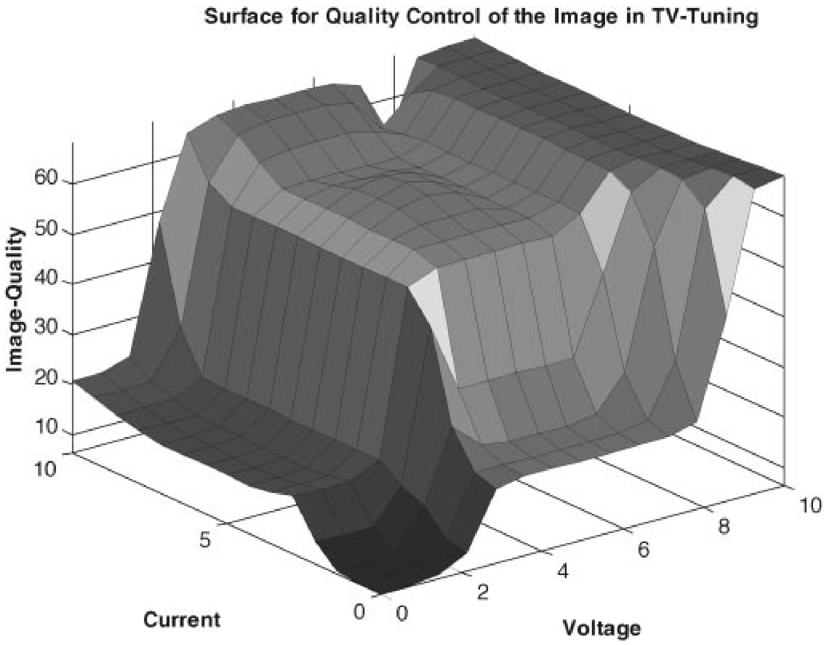

Figure 11. Nonlinear surface of the Mamdani fuzzy model.

the Sugeno fuzzy model is by far the most popular candidate for sample-data-based modeling.

We will give a simple example to illustrate the use of the Sugeno fuzzy inference system. We will consider again the television example (i.e., determining the quality of the images produced by the television depending on the voltage and current of the electrical tuning process). In Fig. 13 we show the architecture of the Sugeno model for this example. We show in Fig. 14 the fuzzy rule base of the Sugeno model. We also show in Fig. 15 the membership functions for the current input variable. In Fig. 16 we show the nonlinear surface of the Sugeno model.

Finally, we show in Fig. 17 the use of the "rule viewer" of the Fuzzy Logic Toolbox of MATLAB. The rule viewer is used when we want to evaluate the output of a fuzzy system using specific values for the input variables. In Fig. 17, for example, we give a voltage of 5 volts, a current intensity of 5 Amperes, and a time of production of 5 seconds, and obtain as a result a quality of 92.2%, which is excellent. Of course, this example only illustratives the potential use of fuzzy logic in this type of application.

Tsukamoto Fuzzy Models. In the "Tsukamoto fuzzy models" (15), the consequent of each fuzzy if-then rule is represented by a fuzzy set with a monotonical MF, as shown in

Fig. 18. As a result, the inferred output of each rule is defined as a numeric value induced by the rule firing strength. The overall output is taken as the weighted average of each rule's output. Figure 18 illustrates the reasoning procedure for a two-input–two-rule system.

Because each rule infers a numeric output, the Tsukamoto fuzzy model aggregates each rule's output by the method of weighted average and thus avoids the time-consuming process of defuzzification. However, the Tsukamoto fuzzy model is not used often because it is not as transparent as either the Mamdani or Sugeno fuzzy models. Because the reasoning method of the Tsukamoto fuzzy model does not follow strictly the compositional rule of inference, the output is always crisp even when the inputs are fuzzy.

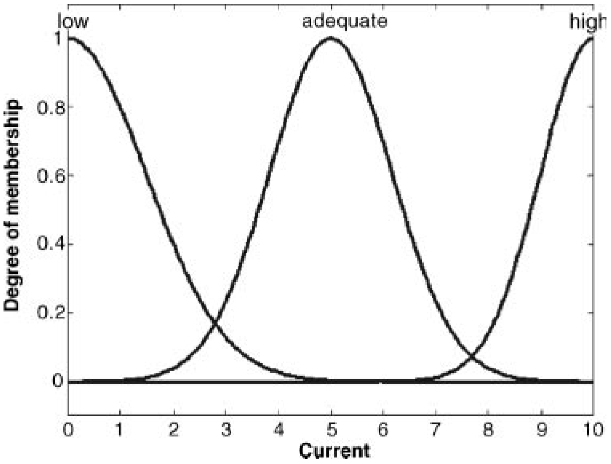

Figure 15. Membership functions for the current linguistic variable.

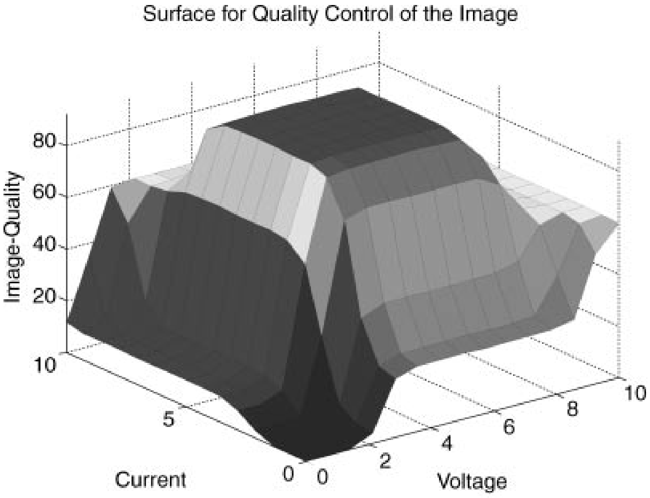

Figure 16. Nonlinear surface for the Sugeno fuzzy model for quality evaluation.

Certain common issues surround all the three fuzzy inference systems introduced previously, such as how to partition an input space and how to construct a fuzzy inference system for a particular application. We will examine these issues in more detail in the following Section.

Input Space Partitioning

Now it should be clear that the main idea of fuzzy inference systems resembles that of "divide and conquer"— the antecedent of a fuzzy rule defines a local fuzzy region, whereas the consequent describes the behavior within the region via various constituents. The consequent constituent can be a

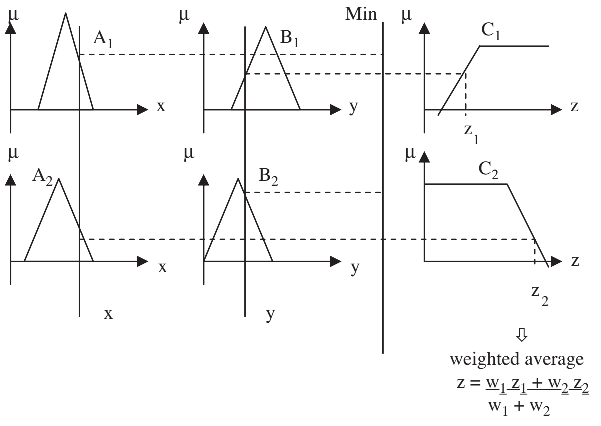

Figure 18. The Tsukamoto fuzzy model.

consequent MF (Mamdani and Tsukamoto fuzzy models), a constant value (zero-order Sugeno model), a linear equation (first-order Sugeno model), or a nonlinear equation (higher-order Sugeno models). Different consequent constituents result in different fuzzy inference systems, but their antecedents are always the same. Therefore, the following discussion of methods of partitioning input spaces to form the antecedents of fuzzy rules is applicable to all three types of fuzzy inference systems.

- Grid partition: This partition method is often chosen in designing a fuzzy controller, which usually involves only several state variables as the inputs to the controller. This partition strategy needs only a small number of MFs for each input. However, it encounters problems when we have many inputs. For instance, a fuzzy model with 12 inputs and 2 MFs on each input would result in $2^{12} = 4096$ fuzzy if-then rules, which is prohibitively large. This problem, which is usually referred to as the "curse of dimensionality," can be alleviated by other partition strategies.
- Tree partition: In this method, each region can be uniquely specified along a corresponding decision tree. The tree partition relieves the problem of an exponential increase in the number of rules. However, more MFs for each input are needed to define these fuzzy regions, and these MFs do not usually bear clear linguistic meanings. In other words, orthogonality holds roughly in X × Y, but not in either X or Y alone.
- Scatter partition: By covering a subset of the whole input space that characterizes a region of possible occurrence of the input vectors, the scatter partition can also limit the number of rules to a reasonable amount. However, the scatter partition is usually dictated by desired input-output data pairs and thus, in general, orthogonality does not hold in X, Y, or X × Y. This result makes it hard to estimate the overall mapping directly from the consequent of each rule's output.

FUZZY MODELING

In general, we design a fuzzy inference system based on the past known behavior of a target system. The fuzzy system is then expected to reproduce the behavior of the target system. For example, if the target system is a human operator in charge of a electrochemical reaction process, then the fuzzy inference system becomes a fuzzy logic controller that can regulate and control the process (Castillo and Melin, 2001) (16). Another example could the human recognition using fuzzy logic (17).

Let us now consider how we might construct a fuzzy inference system for a specific application. Generally speaking, the standard method for constructing a fuzzy inference system, which is a process usually called "fuzzy modeling," has the following features:

- The rule structure of a fuzzy inference system makes it easy to incorporate human expertise about the target system directly into the modeling process. Namely, fuzzy modeling takes advantage of "domain knowledge" that might not be employed easily or directly in other modeling approaches.
- When the input–output data of a target system is available, conventional system identification techniques can be used for fuzzy modeling. In other words, the use of "numerical data" also plays an important role in "fuzzy modeling," just as in other mathematical modeling methods.

Conceptually, fuzzy modeling can be pursued in two stages, which are not totally disjoint. The first stage is the identification of the "surface structure," which includes the following tasks:

1. Select relevant input and output variables.
2. Choose a specific type of fuzzy inference system.
3. Determine the number of linguistic terms associated with each input and output variables.
4. Design a collection of fuzzy if-then rules.

Note that to accomplish the preceding tasks, we rely on our own knowledge (common sense, simple physical laws, and so on) of the target system, information provided by human experts who are familiar with the target system, or simply trial and error.

After the first stage of fuzzy modeling, we obtain a rule base that can more or less describe the behavior of the target system by means of linguistic terms. The meaning of these linguistic terms is determined in the second stage, the identification of "deep structure," which determines the MFs of each linguistic term (and the coefficients of each rule's output in the case that a Sugeno model is used). Specifically, the identification of deep structure includes the following tasks:

1. Choose an appropriate family of parameterized MFs.
2. Interview human experts familiar with the target systems to determine the parameters of the MFs used in the rule base.

3. Refine the parameters of the MFs using regression and optimization techniques.

Tasks 1 and 2 assume the availability of human experts, while task 3 assumes the availability of a desired input–output data set. When a fuzzy inference system is used as a controller for a given plant, then the objective in task 3 should be changed to that of searching for parameters that will generate the best performance of the plant.

SUMMARY

In this article, we have presented the main ideas underlying fuzzy logic and we have only started to point out the many possible applications of this powerful computational theory. We have discussed in some detail fuzzy set theory, fuzzy reasoning and fuzzy inference systems. At the end, we also gave some remarks about fuzzy modeling. In the following chapters, we will show how fuzzy logic techniques (in some cases, in conjunction with other methodologies) can be applied to solve real world complex problems.

GENETIC ALGORITHMS

FOUNDATIONS OF GENETIC ALGORITHM

The original form of genetic algorithms (GAs) was described by Goldberg (1). GAs are stochastic search techniques based on the mechanism of natural selection and natural genetics. The central theme of research on GA is to keep a balance between exploitation and exploration in its search to the optimal solution for survival in many different environments. Features for self-repair, self-guidance, and reproduction are the rules in biologic systems, whereas they barely exist in the most sophisticated artificial systems. GA has been theoretically and empirically proved to provide a robust search in complex search spaces. Many research papers and dissertations have established the validity of GA approach in function optimization problems and application problems (2–4).

GAs, differing from conventional search techniques, start with an initial set of random solutions called *population*. Each individual in the population is called a *chromosome*, representing a solution to the problem at hand. A chromosome is a string of symbols, usually but not necessarily, a binary bit string. The chromosomes *evolve* through successive iterations, called *generations*. During each generation, the chromosomes are *evaluated*, using some measures of *fitness*. To create the next generation, new chromosomes, called *offspring*, are generated by either merging two chromosomes from the current generation using a *crossover* operator and/or modifying a chromosome using a *mutation* operator. A new generation is formed by selecting some parents, according to the fitness values, and offspring, and rejecting others so as to keep the *population size* constant. Fitter chromosomes have higher probabilities of being selected. After several generations, the algorithms converge to the best chromosome, which hopefully represents the optimum or suboptimal solution to the problem. In general, GAs have five basic components, as summarized by Michalewicz (5):

1. A genetic representation of potential solutions to the problem.
2. A way to create a population (an initial set of potential solutions).
3. An evaluation function rating solutions in terms of their fitness.
4. Genetic operators that alter the genetic composition of offspring (crossover, mutation, selection, etc.).
5. Parameter values that genetic algorithms use (population size, probabilities of applying genetic operators, etc.).

Figure 1 shows a general structure of GA. Let $P(t)$ and $C(t)$ be parents and offspring in the current generation t, and the general implementation structure of GA is described as follows:

Implementation of Genetic Algorithm

For implementing GA, several GA components should be considered. First, *genetic representation* of a solution is decided. Second, the *fitness evaluation* of the solution using the objective functions subjected to constraints is used. Last, *genetic operators* such as crossover operator, mutation operator, and selection methods are applied to the population of GA. These implementation processes are repeated until the predefined generation number is satisfied or the optimal solution is reached. The detailed implementation logics and procedures of GA are suggested in the following subsections.

Genetic Representation. How to encode a solution of the problem into a chromosome is a key issue for GAs. The issue has been investigated from many aspects, such as mapping characters from genotype space to phenotype space when individuals are decoded into solutions and the metamorphosis properties when individuals are manipulated by genetic operators.

Classification of Encodings. In Holland's work, encoding is carried out by using binary strings (6). The binary encoding for function optimization problems is known to have severe drawbacks because of the existence of Hamming cliffs; i.e., pairs of encodings have a large Hamming distance while belonging to points of minimal distance in phenotype space. For example, the pair of 01111111111 and 10000000000 belongs to neighboring points in phenotype space (points of minimal Euclidean distance) but has maximum Hamming distance in genotype space. To cross the Hamming cliff, all bits have to be changed at once. The probability that crossover and mutation will occur to cross it can be very small. In this sense, the binary code does not preserve locality of points in the phenotype space.

For many problems from the computer science and engineering world, it is nearly impossible to represent their solutions with the binary encoding. During the last ten years, various encoding methods have been created for particular problems to have an effective implementation of GAs. According to the symbols used as the alleles of a gene, the encoding methods can be classified as binary encoding, real number encoding, integer/literal permutation encoding, and a general data structure encoding; According to the structure of encodings, the encoding methods also can be classified into the following two types: one-dimensional encoding and multidimensional encoding; According to what kinds of contents are encoded into the encodings, the encoding methods can also be divided as solution only and solution + parameters.

Properties of Encodings. When a new encoding method is given, usually it is necessary to examine whether we can

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

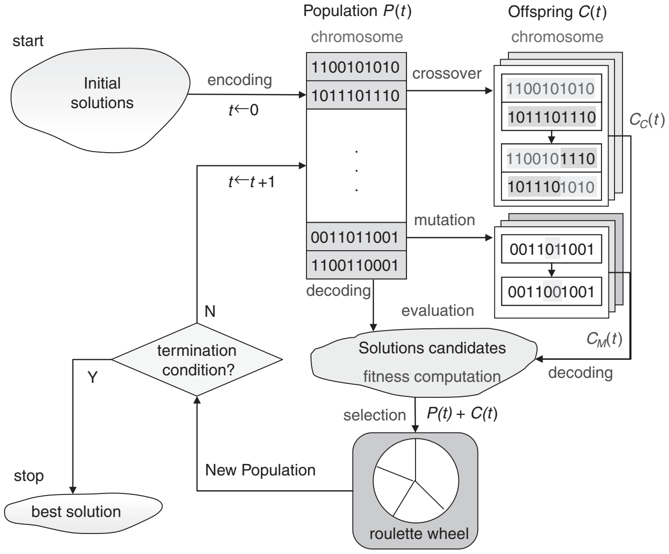

Figure 1. The general structure of genetic algorithms.

build an effective genetic search with the encoding. Several principles have been proposed to evaluate an encoding (7,8):

1. Space: Chromosomes should not require extravagant amounts of memory.
2. Time: The time complexities of evaluating, recombining, and mutating chromosomes should be small.
3. Feasibility: All chromosomes, particularly those generated by simple crossover (i.e., one-cut point crossover) and mutation, should represent feasible solutions.
4. Uniqueness: The mapping from chromosomes to solutions (decoding) may belong to one of the following three cases: 1-to-1 mapping, n-to-1 mapping, and 1-to-n mapping. The 1-to-1 mapping is the best one among three cases, and 1-to-n mapping is the most undesired one.
5. Heritability: Offspring of simple crossover (i.e., one-cut point crossover) should represent solutions that combine substructures of their parental solutions.
6. Locality: A mutated chromosome should usually represent a solution similar to that of its parent.

Initialization. In general, two ways exist to generate the initial population, heuristic initialization and random initialization, by using an encoding procedure satisfying system constraints and/or a boundary condition. Although the mean fitness of the heuristic initialization is already high so that it may help GAs to find solutions faster. Unfortunately, in most large-scale problems, for example, network design problems, it may just explore a small part of the solution space, and it is difficult to find global optimal solutions because of the lack of diversity in the population.

Fitness Evaluation. Fitness evaluation is to check the solution value of the objective function subjected to constraints by using a decoding procedure. In general, the objective function provides the mechanism evaluating each individual. However, its range of values varies from problem to problem. To maintain uniformity over various problem domains, we may use the fitness function to normalize the objective function to a range of 0 to 1. The normalized value of the objective function is the fitness of the individual, and the selection mechanism uses it to evaluate the individuals of the population.

When GAs are used to search, the population undergoes evolution with fitness and forms a new population. At that time, in each generation, relatively good solutions are reproduced and relatively bad solutions are killed so that the offspring composed of the good solutions are reproduced. To distinguish between the solutions, an evaluation function (also called fitness function) plays an important role in the environment, and scaling mechanisms are also necessary to be applied in objective function for being fitness function.

Genetic Operators. When GAs are used, both the search direction to optimal solution and the search speed should be considered as an important factor, in order to keep a balance between exploration and exploitation in search space. In general, the exploitation of the accumulated information resulting from a GA search is done by the selection mechanism, whereas the exploration to new regions of the search space is accounted for by genetic operators.

The genetic operators mimic the process of heredity of genes to create new offspring at each generation. The operators are used to alter the genetic composition of individuals during representation. In essence, the operators perform a random search and cannot guarantee to yield an improved offspring. Three common genetic operators exist: crossover, mutation, and selection.

Crossover. Crossover is the main genetic operator. It operates on two chromosomes at a time and generates offspring by combining both chromosomes' features. A simple way to achieve crossover would be to choose a random cut-point and to generate the offspring by combining the segment of one parent to the left of the cut-point with the segment of the other parent to the right of the cut-point (e.g., one-cut point, two-cut point, multi-cut-point, or uniform crossover). This method works well with the bit string representation. The performance of GAs depends to a great extend on the performance of the crossover operator used (e.g., partial-mapped crossover, order crossover, or position-based crossover) (2).

Mutation. Mutation is a background operator that produces spontaneous random changes in various chromosomes. A simple way to achieve mutation would be to alter one or more genes. In GAs, mutation serves the crucial role of either 1) replacing the genes lost from the population during the selection process so that they can be tried in a new context or 2) providing the genes that were not present in the initial population. Many different mutation operators are available for different genetic representations. Such as replacement mutation works well with the bit string representation, the uniform mutation, boundary mutation, dynamic mutation, and so on work well with the real number representation; several mutation operators work well for integer and string representations (e.g., inversion mutation, insertion mutation, displacement mutation, and swap mutation).

Selection. A selection (reproduction) operator is intended to improve the average quality of the population by giving the high-quality chromosomes a better chance to get copied into the next generation. Selection provides the driving force in a GA. With too much force, a genetic search will terminate prematurely, whereas with too little force, evolutionary progress will be slower than necessary. Typically, a lower selection pressure is indicated at the start of the genetic search in favor of a wide exploration of the search space, whereas a higher selection pressure is recommended at the end in order to narrow the search space. The selection directs the genetic search toward promising regions in the search space. During the past two decades, many selection methods have been proposed, examined, and compared. One of the common proportional selections is the so-called *Roulette wheel selection*, and other selection types like *Tournament selection, Elitist selection, (μ,λ) selection*, and $(\mu + \lambda)$ *selection* are deterministic procedures that select the best chromosomes from parents and offspring.

Major Advantages of Genetic Algorithm

GA has received considerable attention regarding their potential as a novel optimization technique. Three major advantages exist when applying GA to optimization problems:

Adaptability. GA does not have much mathematical requirements about the optimization problems. Because of the evolutionary nature, GA will search for solutions without regard to the specific inner workings of the problem. GA can handle any kind of objective functions and any kind of constraints, i.e., linear or nonlinear, defined on discrete, continuous, or mixed search spaces.

Robustness. The use of evolution operators makes GA very effective in performing global search (in probability), whereas most of conventional heuristics usually perform local search. It has been proved by many studies that GA is more efficient and more robust in locating an optimal solution and reducing a computational effort than other conventional heuristics.

Flexibility. GA provides us with a great flexibility to hybridize with domain-dependent heuristics to make an efficient implementation for a specific problem.

ADAPTATION OF GENETIC ALGORITHMS

Since GAs are inspired from the idea of evolution, it is natural to expect that the adaptation is used not only for finding solutions to a given problem but also for tuning GAs to the particular problem. During the past few years, many adaptation techniques have been suggested and tested to obtain an effective implementation of GAs to real-world problems. In general, two kinds of adaptations exist: 1) adaptation to problems and 2) adaptation to evolutionary processes.

The difference between these two adaptations is that the first one advocates modifying some components of GAs, such as representation, crossover, mutation, and selection to choose an appropriate form of the algorithm to meet the nature of a given problem. The second one suggests a way to tune the parameters of the changing configurations of GAs while solving the problem. According to Herrera and Lozano, the later type of adoption can be divided even more into the following classes (9): adaptive parameter settings, adaptive genetic operators, adaptive selection, adaptive representation, and adaptive fitness function.

Among these classes, the parameter adaptation has been studied extensively in the past ten years because the strategy parameters such as mutation probability, crossover probability, and population size are key factors in the determination of the exploitation versus exploration tradeoff.

Structure Adaptation

The structure adaptation technique aims at adapting the GA's structure or problem's structure to obtain an effective implementation of GAs to the problems. GAs were first created as a kind of generic and weak method featuring binary encoding and binary genetic operators. This approach requires a modification of an original problem into an appropriate form suitable for GAs. The approach includes a mapping between potential solutions and binary representation, taking care of decoding or repair procedures. For complex problems, such an approach usually fails to provide successful applications.

To overcome such problems, various nonstandard implementations of GAs have been created for particular problems. This approach leaves the problem unchanged and adapts GAs by modifying a chromosome representation of a potential solution and by applying appropriate genetic operators.

But in general, it is not a good choice to use the whole original solution of a given problem as the chromosome because many real problems are too complex to have a suitable implementation of GAs with the whole solution representation. Generally, the encoding methods can be either direct or indirect. In the direct encoding method, the whole solution for a given problem is used as a chromosome. For a complex problem, however, such a method will make almost all conventional genetic operators unusable because many offspring will be infeasible or illegal. On the contrary, in the indirect encoding method, just the necessary part of a solution is used as a chromosome. Solutions then can be generated by a decoder. A decoder is a problem-specific and determining procedure to generate a solution according to the permutation and/or the combination of the items produced by GAs. With this method, the GAs will focus their search solely on the interesting part of solution space.

A third approach is to adapt both GAs and the given problem. A common feature of combinatorial optimization problems is to find a permutation and/or a combination of some items associated with side constraints. If the permutation and/or combination can be determined, a solution then can be derived with a problem-specific procedure. With this third approach, GAs are used to evolve an appropriate permutation and/or combination of some items under consideration, and a heuristic method is subsequently used to construct a solution according to the permutation and combination.

Parameter Adaptation

The behaviors of GAs are characterized by the balance between exploitation and exploration in the search space. The balance is affected strongly by the strategy parameters such as population size, maximum generation, crossover probability, and mutation probability. How to choose a value to each parameter and how to find the values efficiently are very important and promising areas of research of GAs. A recent survey on adaptation techniques is given by Herrera and Lozano (9) and by Hinterding, et al. (10).

Usually, fixed parameters are used in most applications of GAs. The values for the parameters are determined with a set-and-test approach. Because a GA is an intrinsically dynamic and adaptive process, the use of constant parameters is thus in contrast to the general evolutionary spirit. Therefore, it is a natural idea to try to modify the values of strategy parameters during the run of the algorithm. It is possible to do this in various ways: 1) by using some rule; 2) by taking feedback information from the current state of search; or 3) by employing some self-adaptive mechanism. Gen and Cheng surveyed various adaptive methods using fuzzy logic controlled (FLC) (3). Subbu, et al. suggested a fuzzy logic controlled GA (FLC-GA), and the FLC-GA uses a fuzzy knowledge-base developed (11). This scheme can adaptively adjust the rates of crossover and mutation operators. Song, et al. used two FLCs (12): one for the crossover rate and the other for the mutation rate. These parameters are considered as the input variables of GAs and are also taken as the output variables of the FLC. Yun and Gen proposed an extended FLC-GA method based on the basic concept of Song, et al.'s method (13). A detailed survey is introduced in Ref. 14.

MULTIOBJECTIVE GENETIC ALGORITHM

Optimization deals with the problems of seeking solutions over a set of possible choices to optimize certain criteria. If only one criterion can be taken into consideration, it becomes a single objective optimization problem, which have been studied extensively for the past 50 years. If more than one criterion must be treated simultaneously, we have multiple objective optimization problems (15,16). Multiple objective problems develop in the design, modeling, and planning of many complex real systems in the areas of industrial production, urban transportation, capital budgeting, forest management, reservoir management, layout and landscaping of new cities, energy distribution, and so on. It is easy to find that almost every important real-world decision problem involves multiple and conflicting objectives that need to be tackled while respecting various constraints, leading to overwhelming problem complexity. The multiple objective optimization problems have been receiving growing interest from researchers with various background since early 1960 (17). Several scholars have made significant contributions to the problem. Among them, Pareto is perhaps one of the most recognized pioneers in the field (18). Recently, GAs have received considerable attention as a novel approach to multiobjective optimization problems, resulting in a fresh body of research and applications known as evolutionary multiobjective optimization (EMO).

Basic Concepts of Multiobjective Optimizations

A single objective optimization problem is usually given in the following form:

$$\max \quad z = f(x) \tag{1}$$

$$\text{s.t.} \quad g_i(x) \le 0, \qquad i = 1, 2, \ldots, m \tag{2}$$

where $x \in R^n$ is a vector of n decision variables, $f(x)$ is the objective function, and $g_i(x)$ are inequality constraint m functions, which form the area of feasible solutions. We usually denote the feasible area in decision space with the set S as follows:

$$S = \{x \in R^n | g_i(x) \le 0, \qquad i = 1, 2, \ldots, m, x \ge 0\} \tag{3}$$

Without loss of generality, a multiple objective optimization problem can be formally represented as follows:

$$\max \quad \{z_1 = f_1(x), z_2 = f_2(x), \cdots, z_q = f_q(x)\} \tag{4}$$

$$\text{s.t.} \quad g_i(x) \le 0, \qquad i = 1, 2, \ldots, m \tag{5}$$

Sometimes, we graph the multiple objective problem in both decision space and criterion space. S is used to denote the feasible region in the *decision space*, and Z is used to denote the feasible region in the *criterion space*.

$$\begin{aligned} Z = \{z \in R^q | z_1 = f_1(x), z_2 = f_2(x), \cdots, z_q \\ = f_q(x), \quad x \in S\} \end{aligned} \tag{6}$$

where $x \in S$ is a vector of values of q objective functions. In the other words, Z is the set of images of all points in S. Although S is confined to the nonnegative region of R^n, Z is not confined necessarily to the nonnegative region of R^q.

Nondominated Solutions

In principle, multiple objective optimization problems are very different from single objective optimization problems. For the single objective case, one attempts to obtain the best solution, which is absolutely superior to all other alternatives. In the case of multiple objectives, there does not exist necessarily such a solution that is the best with respect to all objectives because of incommensurability and conflict among objectives. Therefore, a set of solutions usually exists for the multiple objective cases that cannot be simply compared with each other. Such kind of solutions are called *nondominated solutions* or *Pareto optimal solutions*, for which no improvement in any objective function is possible without sacrificing on at least one of the other objective functions. For a given nondominated point in the criterion space Z, its image point in the decision space S is called *efficient* or *noninferior*. A point in S is efficient if and only if its image in Z is nondominated.

Definition 1. For a given point $z_0 \in Z$, it is nondominated if and only if another point $z \in Z$ does not exist such that for the maximization case,

$$z_k > z_k^0, \qquad \text{for some } k \in \{1, 2, \ldots, q\} \tag{7}$$

$$z_l > z_l^0, \qquad \text{for all } l \neq k \tag{8}$$

where z_0 is a dominated point in the criterion space Z with q objective functions.

Definition 2. For a given point $x_0 \in S$, it is efficient if and only if another point $x \in S$ does not exist such that for the maximization case,

$$f_k(x) > f_k(x_0), \qquad \text{for some } k \in \{1, 2, \ldots, q\} \tag{9}$$

$$f_1(x) \geq f_1(x_0), \qquad \text{for all } l \neq k \tag{10}$$

where x_0 is an inefficient in the decision space S with q objective functions.

Features of Genetic Search. The inherent characteristics of GAs demonstrate why genetic search is possibly well suited to the multiple objective optimization problems. The basic feature of GAs is the multiple directional and global search by maintaining a population of potential solutions from generation to generation. The *population-to-population* approach is hopeful to explore all Pareto solutions.

GAs do not have much mathematical requirements about the problems and can handle any kind of objective functions and constraints. Because of their evolutionary nature, the GAs can search for solutions without regard to the specific inner workings of the problem. Therefore, it is more hope for solving much complex problems than the conventional methods.

Because GAs, as a kind of meta-heuristics, provide us a great flexibility to hybridize with conventional methods into their main framework, we can take both advantages of the GAs and the conventional methods to make much more efficient implementations for the problems. The ingrowing research on applying GAs to the multiple objective optimization problems present a formidable theoretical and practical challenge to the mathematical community (3).

Fitness Assignment Mechanism

GAs are essentially a kind of meta-strategy methods. When applying the GAs to solve a given problem, it is necessary to refine on each major component of GAs, such as *encoding methods*, *recombination operators*, *fitness assignment*, *selection operators*, *constraints handling*, and so on, in order to obtain a best solution to the given problem. Because the multiobjective optimization problems are the natural extensions of constrained and combinatorial optimization problems, so many useful methods based on GAs developed during the past two decades. One of special issues in the multiobjective optimization problems is fitness assignment mechanism. Since the 1980s, several fitness assignment mechanisms have been proposed and applied in multiobjective optimization problems (3,19). Although most fitness assignment mechanisms are just a different approach and suitable to different cases of multiobjective optimization problems, to understanding the development of multiobjective GAs, we classify algorithms according to proposed years of different approaches:

Type 1: Vector Evaluation Approach. Vector evaluated genetic algorithm (veGA) (20) is the first notable work to solve multiobjective problems in which it uses a vector fitness measure to create the next generation (20). The selection step in each generation becomes a loop. Each time through the loop the appropriate fraction of the next generation, or subpopulation, is selected on the basis of each objective. The entire population is shuffled thoroughly to apply crossover and mutation operators, which is performed to achieve the mating of individuals of different subpopulations.

Type 2: Pareto Ranking + Diversity. ***Multiobjective Genetic Algorithm (21).*** Fonseca and Fleming proposed a multiobjective genetic algorithm (moGA) in which the rank of a certain individual corresponds to the number of individuals in the current population by which it is dominated. Based on this scheme, all the nondominated individuals are assigned rank 1, whereas dominated ones are penalized according to the population density of the corresponding region of the tradeoff surface.

Nondominated Sorting Genetic Algorithm (22). Srinivas and Deb also developed a Pareto ranking-based fitness assignment and called it the nondominated sorting genetic algorithm (nsGA). In each method, the nondominated solutions constituting a nondominated front are assigned the same dummy fitness value. These solutions are shared with their dummy fitness values (phenotypic sharing on the decision vectors) and are ignored in the other classification process. Finally, the dummy fitness is set to a value less than the smallest shared fitness value in the current nondominated front. Then the next front is extracted. This procedure is repeated until all individuals in the population are classified.

Type 3: Weighted Sum + Elitist Preserve. ***Random-Weight Genetic Algorithm (23).*** Ishibuchi and Murata proposed a weighted-sum based fitness assignment method, called a random-weight genetic algorithm (rwGA), to obtain a variable search direction toward the Pareto frontier. The weighted-sum approach can be viewed as an extension of methods used in the multiobjective optimizations to GAs. It assigns weights to each objective function and combines the weighted objectives into a single objective function. In rwGA, each objective $f_k(x)$ is assigned a weight $w_k = r_k/\sum_{j=1}^{q} r_j$, where r_j is a non-negative random number between [0, 1] with q objective functions. And the scalar fitness value is calculated by summing up the weighted objective value $w_k{\cdot}f_k(x)$. To search for multiple solutions in parallel, the weights are not fixed and can move uniformly the sample area toward the whole frontier.

Strength Pareto Evolutionary Algorithm II(24). Zitzler and Thiele proposed a strength Pareto evolutionary algorithm (spEA) (25) and an extended version spEA II (24) that combines several features of previous (moGAs) in a unique manner. The fitness assignment procedure is a two-stage process. First, the individuals in the external nondominated set P' are ranked. Each solution $i \in P$, is assigned a real value $s_i \in [0, 1)$, called *strength*; s_i is proportional to the number of population members $j \in P$ for which $i > j$. Let n denote the number of individuals in P that are covered by i, and assume N is the size of P. Then s_i is defined as $s_i = n/(N+1)$. The fitness f_i of objective i is equal to its strength: $f_i = s_i$. Afterward, the individuals in the population P are evaluated. The fitness of an individual $j \in P$ is calculated by summing the strengths of all external nondominated solutions $i \in P$, that cover j. The fitness is $f_j = 1 + \sum_{i \in (i>j)} s_i$, where $f_j \in [1, N)$.

Adaptive-Weight Genetic Algorithm (3). Gen and Cheng proposed another weight sum-based fitness assignment method, called the adaptive-weight genetic algorithm (awGA), which uses some useful information from the current population to readjust weights to obtain a search pressure toward the Pareto frontier. When considering the maximization problem with q objectives, we define two extreme points: the maximum extreme point $z^+ = \{z_1^{\max}, z_2^{\max}, \ldots, z_q^{\max}\}$ and the minimum extreme point $z^- = \{z_1^{\min}, z_2^{\min}, \ldots, z_q^{\min}\}$ in each generation. Each objective k is assigned a weight $w_k = 1/(z_k^{\max} - z_k^{\min})$. And the scalar fitness value is calculated by $\sum_{k=1}^{q}(f_k(x) - z_k^{\min})/(z_k^{\max} - z_k^{\min})$.

As show in Fig. 2, the hyperplane divides the criteria space Z into two half spaces: One half space contains the positive ideal point, denoted as Z^+, and the other half space contains the negative ideal point, denoted as Z^-. All examined Pareto solutions lie in the space Z^+, and all points lie in the Z^+ have larger fitness values than the points in the space Z^-. As the maximum extreme point approximates to the positive ideal point along with the evolutionary progress, the hyperplane will gradually approach to the positive ideal point. Therefore, awGA can readjust its weights according to the current population to obtain a search pressure toward to the positive ideal point.

Nondominated Sorting Genetic Algorithm II (26). Deb et al. suggested a nondominated sorting-based approach, called a nondominated sorting genetic algorithm II (nsGA II) (19,27), which alleviates the three difficulties: computational complexity, nonelitism approach, and the need for specifying a sharing parameter. The nsGA II was advanced from its origin, nsGA. In nsGA II, a nondominated sorting approach is used for each individual to create Pareto rank, and a crowding distance assignment method is applied to implement density estimation. In a fitness assignment between two individuals, nsGA II prefers the point with a lower rank value, or the point located in a region with fewer numbers of points if both points belong to the same front. Therefore, by combining a fast nondominated sorting approach, an elitism scheme and a parameterless sharing method with the original nsGA, nsGA II claims to produce a better spread of solutions in some testing problems.

Interactive Adaptive-Weight Genetic Algorithm (28). Lin and Gen proposed an interactive adaptive-weight genetic algorithm (i-awGA), which is an improved adaptive-weight fitness assignment approach with the consideration of the disadvantages of weighted-sum approach and Pareto ranking-based approach. They combined a penalty term to the fitness value for all of dominated solutions. First, calculate the adaptive weight $w_i = 1/(z_i^{\max} - z_i^{\min})$ for each objective $i = 1, 2, \ldots, q$ by using awGA. Afterward, calculate the penalty term $p(v_k) = 0$, if v_k is a nondominated solution in the nondominated set P. Otherwise $p(v_{k'}) = 1$ for a dominated solution $v_{k'}$. Last, calculate the fitness value of each chromosome by combining the method as follows and they adopted roulette wheel selection as supplementary

Performance Measures

Let S_j be a solution set ($j = 1, 2, \ldots, J$). To evaluate the efficiency of the different fitness assignment approaches, we have to define explicitly measures evaluating closeness of S_j from a known set of the Pareto-optimal set S^*. For example, the following common three measures are considered that are used already in different moGA studies. They provide a good estimate of convergence if a reference set for S^* (i.e., the Pareto optimal solution set or a near-Pareto optimal solution set) is chosen.

Number of Obtained Solutions $|S_j|$. Evaluate each solution set depend on the number of obtained solutions.

Ratio of Nondominated Solutions $R_{NDS}(S_j)$. This measure simply counts the number of solutions that are members of the Pareto optimal set S^*. The $R_{NDS}(S_j)$ measure can be written as follows:

$$R_{NDS}(S_j) = \frac{|S_j - \{x \in S_j | \exists r \in S^* : r < x\}|}{|S_j|} \qquad (12)$$

where $r < x$ means that the solution x is dominated by the solution r. The $R_{NDS}(S_j) = 1$ means all solutions are members of the Pareto-optimal set S^*, and $R_{NDS}(S_j) = 0$ means no solution is a member of the S^*. It is an important measure that although the number of obtained solutions $|S_j|$ is large, if that the ratio of nondominated solutions $R_{NDS}(S_j)$ is 0, it may be the worst result. The difficulty with the above measures is that although a member of S_j is Pareto-optimal, if that solution does not exist in S^*, it may not be counted in $R_{NDS}(S_j)$ as a non-Pareto-optimal solution. Thus, it is essential that a large set for S^* is necessary in the above equations.

Average Distance $\mathbf{D1_R}(S_j)$. Instead of finding whether a solution of S_j belongs to the set S^*, this measure finds an average distance of the solutions of S_j from S^*, as follows:

$$\text{D1}_\text{R}(S_j) = \frac{1}{|S^*|} \sum_{r \in s^*} \min\{d_{rx} | x \in S_j\} \qquad (13)$$

where d_{rx} is the distance between a current solution x and a reference solution r in the two-dimensional normalized objective space. f_i means the objective function for each objective $i = 1, 2, \ldots, q$.

$$d_{rx} = \sqrt{\sum_{i=1}^{q} (f_i(r) - f_i(x))^2} \qquad (14)$$

The smaller the value of $\text{D1}_\text{R}(S_j)$ is, the better the solution set S_j is. This measure explicitly computes a measure of the closeness of a solution set S_j from the set S^*.

Reference Set S^*. For making a large number of solutions in the reference set S^*, the first step calculates the solution sets with special GA parameter settings and a much longer computation time by each approach that is used in comparison experiments, and the second step combine these solution sets to calculate the reference set S^*. In the future, a combination of small but reasonable GA parameter settings for comparison experiments will be conducted, and thus ensure the effectiveness of the reference set S^*.

OVERALL PROCEDURE OF GENETIC ALGORITHM

The $P(t)$ and $C(t)$ are parents and offspring, respectively, in current generation t; the implementation structure of GA with combining the adaptive method and the multiobjective fitness assignment method is described as follows:

```
procedure: adaptive multiobjective GA
input: problem data, GA parameters
output: Pareto optimal solutions $E$
begin
    $t \leftarrow 0$; // $t$: generation number
    initialize $P(t)$ by encoding routine;        // $P(t)$: population of individuals
    calculate objectives $z_i(P)$, $i=1,\ldots,q$ by decoding routine;
    create Pareto $E(P)$;
    evaluate $eval(P)$ by fitness assignment routine;
    while (not terminating condition) do
        create $C(t)$ from $P(t)$ by crossover routine;        // $C(t)$: offspring
        create $C(t)$ from $P(t)$ by mutation routine;
        calculate objectives $z_i(C)$, $i=1,\ldots,q$ by decoding routine;
        update Pareto $E(P, C)$;
        evaluate $eval(P, C)$ by fitness assignment routine;
        auto-tuning GA parameters by parameter adaptive routine;
        select $P(t+1)$ from $P(t)$ and $C(t)$ by selection routine;
        $t \leftarrow t + 1$;
    end
    output Pareto optimal solutions $E(P, C)$
end
```

GA-Based Applications

GAs are powerful and broadly applicable stochastic search and optimization techniques. The major reason is that the advantages (adaptability, robustness, and flexibility) of GAs are very useful for applying the GAs to many complex problems that are very difficult to solve by conventional techniques. However, most problems of computer science and engineering are optimization problems subject to complex constraints. Simple GAs usually do not produce successful applications for these thorny optimization problems. Therefore, a method to tailor GAs to meet the nature of these problems is one of the major focuses of research into computer science and engineering-oriented genetic algorithms.

Combinatorial Optimizations

Combinatorial optimization studies problems that are characterized by a finite number of feasible solutions. An important and widespread area of applications concerns the efficient use of scarce resources to increase productivity. Typical problems include knapsack, set-covering, bin-packing, quadratic assignment, minimum spanning tree, machine scheduling, sequencing and balancing, cellular manufacturing design, vehicle routing, facility location and layout, traveling salesman problem, and so on (2).

Minimum Spanning Tree Models. The minimum spanning tree (MST) problem is one of the best-known network optimization problems used for designing backbone networks. Let G be a weighted, connected, undirected graph with node set V and edges E. A spanning tree on G is a maximal, acyclic subgraph of G; that is, it connects all of G's nodes and contains no cycles. A spanning tree's cost is the sum of the costs of its edges; a spanning tree with the smallest possible cost is a MST on G. Recently, researchers have described GAs for several kinds of constrained MST-related problems: capacitated MST (29), degree-constrained MST (30), stochastic MST (31), quadratic MST (32), probabilistic MST (33), multicriteria MST (34), and leaf-constrained MST (35) etc.

Genetic Representations. Lin and Gen (36) summarized the several kinds of classification of encoding methods as: (1) Characteristic vectors-based encoding [binary-based encoding (37,38), random key-based encoding (39,40)], (2) edge-based encoding (41,42), and (3) node-based Encoding [Prüfer number-based encoding (43), predecessor-based encoding (44)]. Furthermore, Lin and Gen propose a node-based encoding method, PrimPred-based encoding, that adopted Prim's algorithm in chromosome generating procedure (36).

Knapsack Models. Suppose that we want to fill up a knapsack by selecting some objects among various objects (generally called items). n different items are available, and each item j has a weight of w_j and a profit of p_j. The knapsack can hold a weight of at most W. The problem is to find an optimal subset of items so as to maximize the total profits subject to the knapsack's weight capacity. The profits, weights, and capacity are positive integers. The other extended knapsack models (multiple-choice knapsack model, multiconstraints knapsack model, etc.) are introduced in Ref. 45.

Binary-Based Encoding. A binary string is a natural representation of knapsack problem, where one means the inclusion and zero means the exclusion of one item from the knapsack. For example, a solution for the ten-item problem can be represented as $v_k = [0\ 1\ 0\ 1\ 0\ 0\ 0\ 0\ 1\ 0]$. It means that items 2, 4, and 9 are selected to be filled in the knapsack.

Order-Based Encoding. For a ten item problem, the kth chromosome $v_k = [2, 4, 9, 1, 3, 5, 7, 8, 6, 10]$ is an order of item for it to be filled into the knapsack. The same result (items 2, 4, and 9 are selected) can be decoded.

Set-Covering Model. The problem is a classic question in computer science and complexity theory. As input you are given several sets. They may have some elements in common. The problem is to select a minimum number of these sets so that the sets you have picked contain all the elements that are contained in any of the sets in the input. The sets can be formulated as an m-row/n-column zero–one matrix, and the objective is cover rows of the matrix by a subset of columns at minimal cost. Considering a vector $\boldsymbol{x}$ such that $x_j = 1$ if column j (with a cost $c_j > 0$) is in the solution and $x_j = 0$ otherwise ($j = 1, 2, \ldots, n$). The objective is to cover $A = [a_{ij}]$, $i = 1,2,\ldots,m, j = 1,2,\ldots,n$, a zero–one matrix by a subset of columns at minimal cost.

Column-Based Encoding. Column-based encoding is an n-bit binary string that is used for an n column problem. A value of 1 for the ith bit implies that column i is in the solution. For a six-column problem, the vector $x_1, x_{3,}$ and x_5 are selected by chromosome $v_k = [1\ 0\ 1\ 0\ 1\ 0]$.

Row-Based Encoding. The length of chromosome is equal to the number of rows for a given problem. The location of each gene corresponds to a row, and the encoded value of each gene is a column that covers that row.

Bin-Packing Model. The bin-packing problem consists of placing n objects into several bins (at most n bins). Each object has a weight ($w_i > 0$) and each bin has a limited bin capacity ($c_i > 0$). The objective is to find a best assignment of objects to bins such that the total weight of the objects in each bin does not exceed its capacity and the number of bins used is minimized.

Bin-Based Encoding. The position of a gene is used to represent an object, and the value of the gene is used to represent a bin in which the corresponding object is put it. For instance, the chromosome $v_k = [1\ 4\ 2\ 3\ 5\ 2]$ would encode a solution where the first object is in bin 1, the second is in bin 4, the third is in bin 2, the fourth is in bin 3, the fifth is in bin 5, and the sixth is in bin 2.

Object-Based Encoding. Encode the permutations of objects and then apply a decoder to retrieve the corresponding solution.

Group-Based Encoding. Chromosomes are item oriented, instead of being group oriented.

Traveling Salesman Model. The traveling salesman problem (TSP) is one of the most widely studied combinatorial optimization problems. Its statement is deceptively simple: A salesman seeks the shortest tour through n cities.

Permutation-Based Encoding. This direct representation is perhaps the most natural representation of a TSP, where cities are listed in the order in which they are visited. For example, a tour of a nine-city TSP: $3-2-5-4-7-1-6-9-8$ is represented simply as follows: v_k = [3 2 5 4 7 1 6 9 8]. This representation is also called as path-based encoding or order-based encoding.

Random Key-Based Encoding. This indirect representation encodes a solution with random numbers from (0,1). These values are used as sort keys to decode the solution. For example, a chromosome to a nine-city problem may be $v_k = [0.23\ 0.82\ 0.45\ 0.74\ 0.87\ 0.11\ 0.56\ 0.69\ 0.78]$, where position i in the list represents city i, and the random number in position i determines the visiting order of city i in a TSP tour. We sort the random keys in ascending order to get the following tour: $6-1-3-7-8-4-9-2-5$.

Genetic Operators. For permutation encoding, such as partial-mapped crossover, order crossover, or position-based crossover and inversion mutation, insertion mutation, or displacement mutation can be adopted. The detail description is introduced in Ref. 2.

Network Design Optimization

Network models are a fundamental issue in many disciplines, including applied mathematics, computer science, engineering, management, and operations research. Furthermore, because any system or structure may be considered abstractly as a set of elements, certain pairs of which are related in a special way, it has a representation as a network. Networks provide a useful way to modeling real-world problems, which are used extensively in many different types of systems, such as communications, mechanical, electronic, manufacturing, and logistics (46).

Shortest Path Model. The shortest path problem (SPP) is the heart of network optimization problems. Let $G = (N, A)$ be a directed network, which consists of a finite set of nodes $N = \{1, 2, \ldots, n\}$ and a set of directed arcs $A = \{(i,j), (k, l), \ldots, (s, t)\}$ connecting m pairs of nodes in N. Arc (i, j) is said to be incident with nodes i and j, and it is directed from node i to node j. Suppose that each arc (i, j) has been assigned to a nonnegative value c_{ij}, the cost of (i, j). The SPP is to find the minimum cost z from a specified source node 1 to another specified sink node n.

Variable-Length Encoding. Munemoto et al. proposed a variable-length encoding to construct the shortest path (47). Its element represents nodes included in a path between a designated pair of source and destination nodes. Ahn and Ramakrishna developed this variable-length encoding. A new crossover operator exchanges partial chromosomes (partial-routes), and the mutation introduces new partial chromosomes (partial-routes) (48).

Fixed-Length Encoding. Inagaki et al. proposed a *fixed (deterministic) length chromosome* (49). The chromosomes in the algorithm are sequences of integers, and each gene represents a node ID that is selected randomly from the set of nodes connected with the node corresponding to its locus number. All the chromosomes have the same (fixed) length. In the crossover phase, one gene (from two-parent chromosomes) is selected at the locus of the starting node ID and put in the same locus of an offspring. One gene is then selected randomly at the locus of the previously chosen gene's number. This process is continued until the destination node is reached.

Priority-Based Encoding. Gen et al. proposed a priority-based encoding method (50). As all know, a gene in a chromosome is characterized by two factors: locus, i.e., the position of gene located within the structure of chromosome, and allele, i.e., the value the gene takes. In this encoding method, the position of a gene is used to represent node ID and its value represents the priority of the node among the candidates to construct a path. A path can be determined uniquely by the encoding.

Random Key-Based Encoding. Gen and Lin proposed an extended version of priority-based encoding (51) in a real number string, i.e., random key-based encoding. It not only can be decoded a path by same decoding procedure with priority-based encoding, but also most crossover and mutation operators can be adopted, because the chromosome is represented by real number code.

Maximum Flow Model. In a capacitated network, the maximum flow problem (MXF) is to send as much flow as possible between two special nodes, a source node s and a sink node t, without exceeding the capacity of any arc. The MXF model and the shortest path model are complementary. The two problems differ because they capture different aspects: the shortest path problem model arc costs but not arc capacities and maximum flow problem model capacities but not costs. Taken together, the shortest path problem and the maximum flow problem combine all the basic ingredients of network models. As such, they have become the nuclei of network optimization.

Priority-Based Encoding. One specific difficulty of the MXF is the solution presented by various numbers of paths. Until now, for presenting a solution of MXF with various paths, the general idea of chromosome design is to add several shortest paths-based encoding to one chromosome. The length of these representations is variable depending on various paths, and most offspring is infeasible after crossover and mutation operations. Gen and Lin adopt the priority-based encoding that is an effective representation to present a solution with various paths (52). For decoding process, after a path is calculated by a given priority-based chromosome, we update the flow capacity for each arc on the network. Then we can obtain another new path by the same chromosome depending on the new network structure. By repeating this way, we can obtain a solution with various numbers of paths for MXF problem.

Bicriteria MXF/MCF Model. The MXF finds a solution that sends the maximum flow from a source node s to a sink node t. The minimum cost flow problem (MCF) determines a least cost shipment of a commodity through a network to satisfy demands at certain nodes from available supplies at other nodes. The bicriteria MXF/MCF model is an extended version considering the flow costs, flow capacities, and multiobjective optimization problems. This model provides a useful way for modeling real-world problems. For example, in a communication network, we want to find a set of links that consider the connecting cost (or delay) and the high throughput (or reliability) for increasing the network performance; in a manufacturing system, the two criteria under consideration are minimizing manufacturing cost and maximizing quality.

Priority-Based Encoding. Gen and Lin proposed an extended priority-based encoding for this bicriteria MXF/MCF model (28,53). They proposed a new crossover operator, called weight mapping crossover (WMX) and adopt insertion mutation, immigration operator, and interactive adaptive-weight fitness assignment to accelerate the evolutionary process.

Advanced Planning and Scheduling

The planning and scheduling of manufacturing systems always require resource capacity constraints, disjunctive constraints, and precedence constraints, because of the tight due dates, multiple customer-specific orders, and flexible process strategies. In this subsection, some hot topics in advanced planning and scheduling (APS) are introduced. These models mainly support the integrated, constraint-based, and planning of the manufacturing system to reduce lead times, lower inventories, increase throughput, and so on.

Job-Shop Scheduling Model. In the job-shop scheduling problem (JSP), we are given a set of jobs and a set of machines. Each machine can handle at most one job at a time. Each job consists of a chain of operations, each of which needs to be processed during an uninterrupted time period of a given length on a given machine. The objective is to find a schedule; that is, an allocation of the operations to time intervals on the machines that has a minimum duration required to complete all jobs (54).

Genetic Representations. Gen and Cheng gave the nine different representations for JSP in Ref. 2: operation-based encoding, job-based encoding, preference-list-based encoding, job-pair-relation-based encoding, priority-based encoding, disjunctive-graph-based encoding, completion-time-based encoding, machine-based encoding, and random key-based encoding. These representations can be classified into two basic encoding approaches: direct approach and indirect approach.

Flexible Job-Shop Scheduling Model. Flexible job shop is a generalization of the job shop and the parallel machine environment (55), which provides a closer approximation to a wide range of real manufacturing systems. In particular, a set of parallel machines exists with possibly different efficiency. The flexible job shop scheduling problem (fJSP) is to assign each operation to an available machine and to sequence the operations assigned on each machine to minimize the makespan, that is, the time required to complete all jobs.

Parallel Machine-Based Encoding. The chromosome is a list of machines placed in parallel. For each machine, we associate operations to execute. Each operation is coded by three elements: operation k, job i, and starting time t_{ikj}^{S} of operation o_{ik} on the machine j.

Parallel Job-Based Encoding. The chromosome is represented by a list of jobs. Information of each job is shown in the corresponding row where each case is constituted of two terms: machine j, which executes the operation and corresponding starting time ${t_{ikj}}^{\mathrm{S}}$.

Operations Machine-Based Encoding. Kacem et al. proposed an operations machine-based approach (56), which is based on a traditional representation called schemata theorem representation; it was first introduced in GAs by Holland (5).

Multistage Operation-Based Encoding. Gen and Zhang proposed a multistage operation-based encoding for fJSP (57,58). In the encoding process, all operations are defined as a multistage network denoting each operation as one stage. At each stage, available machines of each operation are defined as states. The length of chromosome is the number of operations. An integer number in the kth gene represents a machine number to which the operation k is assigned.

Resource-Constrained Project Scheduling Model. The objective of the resource-constrained project scheduling problem (rcPSP) is to schedule the activities such that precedence and resource constraints are obeyed and the makespan of the project is to be minimized. The resource constraints refer to limited renewable resources such as manpower, material, and machines that are necessary for carrying out the project activities (59).

Priority-Based Encoding. Gen and Cheng adopted priority-based encoding for this rcPSP (2). To improve the effectiveness of priority-based GA approach for large-scale rcPSP problems and extended resource-constrained multiple project scheduling problem, Kim et al. combined priority dispatching rules in priority-based encoding process (60,61).

Recently, some researchers have studied various algorithms for solving an rcPSP problem on a large scale. Their works have dealt with a variety of situations in which one or both of these types of constraints are relaxed, or at least simplified. And comparisons of eight different priority dispatching rules (minimum job slack, resource scheduling method, minimum late finish time, greatest resource demand, greatest resource utilization, shortest imminent operation, most jobs possible, and select jobs randomly) for an rc-PSP problem have been reported in previous studies

Assembly Line Balancing Model. Assembly line balancing problems (ALB) consist of distributing work required to assemble a product in mass or series production on an assembly line among a set of work stations. Several constraints and different objectives may be considered. The simple assembly line balancing problem consists of assigning tasks to workstations such that precedence relations between tasks and zoning or other constraints are met. The objective is to make the work content at each station most balanced. Two versions of the problem exist. The Type I simple assembly line balancing (sALB-I) problem, as described by Scholl, consists in finding an assignment of tasks to workstations such that the required number of workstations is minimized given a cycle time, i.e., the maximum work time of any workstation. The Type II simple assembly line balancing (sALB-II) problem consists in allocating tasks to a given number of workstations to minimize the cycle time.

Genetic Representations. GAs have been applied to solve various assembly line balancing problems (62–64). The genetic representations can be summarized as follows: 1) *Standard encoding* (65), the chromosome is defined as a vector containing the indexes of the stations to which the tasks are assigned; 2) *Order-based encoding* (66), the chromosomes are defined as a task sequence in feasible order; 3) *Priority-based encoding* (3), the chromosome represents the solution in an indirect manner: coding priority values of tasks and coding a sequence of priority rules and corresponding construction schemes; and 4) *Group encoding* (67), the encoding of each solution consists of two parts: The task part is identical to the standard encoding, and the group part contains a gene for each station.

Recently, Gao et al. proposed an innovative GA hybridized with local search for a robotic-based ALB problem (68). Based on different neighborhood structures, five local search procedures are developed to enhance the searchability of GA. The coordination between the local search procedures are well considered to escape from local optima and to reduce computation time.

Advanced Planning and Scheduling Model. The advanced planning and scheduling (APS) model includes a range of capabilities from finite capacity planning at the plant floor level through constraint-based planning to the latest applications of advanced logic for supply chain planning and collaboration (69). The objective of APS problem is usually to determine an optimal schedule with operation sequences for all the orders (jobs). That is, the problem we are treating can be defined as follows: A set of K orders are to be processed on N machines with alternative operations sequences and alternative machines for operations in the environment of the multiplant chain; we want to find an operations sequence for each job and a schedule in which jobs pass between machines and a schedule in which operations on the same jobs are processed such that it satisfies the precedence constraints and it is optimal with respect to the makespan minimization.

Moon–Kim–Gen's Approach. Several related works by Moon et al. (70) and Moon and Seo (71) have reported a GA approach especially for solving such kinds of APS problems. However, to derive a feasible complete schedule, they only considered the optimal operation sequence, but they selected the resources in terms of minimum processing time. That means, for machines assignment, they consider that the minimum processing time assignment is the optimal choosing strategy for the solution. However the transition time between plants and setup time between operations are ignored.

Multistage Operation-Based Encoding. Zhang and Gen proposed a multistage operation-based encoding for solving the APS problem (72,73). This encoding method considers both operation sequence and machine selection so that it is easy to present a solution of the problem. The chromosome presentation of multistage operation-based encoding consists of two parts: 1) priority-based encoding for operation sequence and 2) machine permutation encoding for machine selection.

AGV Dispatching Model in Manufacturing System. Automated guided vehicle (AGV) is a mobile robot used highly in industrial applications to move materials from point to point. AGV help to reduce costs of manufacturing and increase efficiency in a manufacturing system. For example, a flexible manufacturing system (FMS) is composed of various cells, also called working stations (or machine), each with a specific operation such as milling, washing, or assembly. Each cell is connected to the guide path network by a pickup/delivery (P/D) point where pallets are transferred from/to the AGVs. The objectives of AGV system are as follows: Minimize time required to complete all jobs (i.e., makespan), minimize vehicle travel times (empty or/and loaded), evenly distribute workload over AGVs, minimize total costs of movement, and minimize the time of labor that is handled after its due time (i.e., tardiness), minimize expected waiting times of loads, minimize the number of AGVs, and so on.

Priority-Based Encoding. Lin et al. adopted priority-based encoding for solving the AGV dispatching problem in FMS (74). In this encoding method, the position of a gene is used to represent task (AGV's transport) ID and its value is used to represent the priority of the task for constructing a sequence among candidates. A feasible sequence can be determined uniquely from this encoding by considering a task precedence constraint. After a generated task sequence, separate tasks occur to several groups for assigning different AGVs.

Logistics Network Optimization

It is said that logistics is the "last frontier for cost reduction" and the "third profit source" of enterprises, by Peter Deruke, an American management specialist (75). The interest in developing effective logistics system design models and efficient optimization methods has been stimulated by high costs of logistics and is potentially capable of securing considerable savings.

Transportation Models. The transportation problem (TP) was proposed originally by Hitchcock in 1941 (76). Since then the research on the problem has received a great deal of attention, and various variants of the basic transportation problem have been investigated. According to what kind of objective is used, the problem can be characterized as follows: 1) linear problem or nonlinear problem and 2) single objective problem or multiple objective problem. According to what kind of constraints is under consideration, the problem can be classified even more into 1) planar problem or solid problem and 2) balanced problem or unbalanced problem.

Matrix-Based Encoding. A matrix is perhaps the most natural representation of a solution for a transportation problem. The allocation matrix of a transportation problem can be written as follows:

$$X_k = \begin{bmatrix} x_{11} & x_{12} & \cdots & x_{1n} \\ x_{21} & x_{22} & \cdots & x_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ x_{m1} & x_{m2} & \cdots & x_{mn} \end{bmatrix} \qquad (15)$$

where X_k denotes the kth chromosome (solution) and the element of it, x_{ij} is the corresponding decision variable (5).

Prüfer Number-Based Encoding. The Prüfer number-based encoding incorporating this data structure of TP was proposed by Gen and Li (77). This GA uses the Prüfer number encoding based on a spanning tree, which is capable of representing all possible trees. Using the Prüfer number representation, the memory only requires $m + n - 2$ for a chromosome implementation. A transportation model has separable sets of nodes for plants and customers. From this point, Gen and Li designed a criterion for checking the feasibility of the chromosome.

Location Allocation Models. As an extension of TP, a location–allocation decision is a very important factor in logistics network design problems. It can be classified as 1) location problems, involve determining the location of one or more new DCs in one or more of several potential sites; 2) allocation problems, assume that the number and location of DCs are known as a priori and attempt to determine how each customer is to be served; and 3) location–allocation problems, involve determining not only how much each customer is to receive from each DC but also the number of DCs along with their locations and capacities.

Genetic Representation. In continuous location problems, a binary representation may result in locating two DCs that are very close to each other. Taniguchi et al. used a real number representation (78) where a chromosome consists of $m(x,y)$ pairs representing the sites of DCs to be located and p is the number of DCs. For instance, this is represented as $v = [(x_1,y_1),(x_2,y_2),\ldots,(x_i,y_i),\ldots,(x_m,y_m)]$, where the coordinate (x_i,y_i) denotes the location of the ith DC, $i = 1,\ldots, m$.

Multistage Logistics Network Models. For some real-world applications of logistics, it is often that the transportation problem is extended to satisfy several other additional constraints or is performed in several stages. A two-stage transportation problem (tsTP) model is proposed by Gen et al. (79), which minimize the total logistic system cost, including the opening cost of DCs and the shipping cost from plants to DCs, and from DCs to customers under the capacity constraints of plants and DCs. And some extended models of multistage logistics network are introduced in Refs. 80 and 81.

Priority-Based Encoding. Gen et al. proposed a new encoding method based on priority-based encoding (79). For each stage of transportation, a chromosome consists of priorities of sources and depots to obtain a transportation tree and its length is equal to total number of sources (m) and depots (n); i.e., $m + n$. The transportation tree corresponding with a given chromosome is generated by sequential arc appending between sources and depots. At each step, only one arc is added to the tree selecting a source (depot) with the highest priority and connecting it to a depot (source) considering minimum cost.

Flexible Logistics Network Models. Recently, with the constant demand to reduce transportation costs and improve customer service quality, design and optimization of logistics face more challenging issues, which is the improvement of the flexibility of logistics system; i.e., we want to change the traditional structure of the logistics: Plant-DC-Retailer-Customer, the use of direct shipment (Plant-Customer) as much as possible, or direct delivery (Plant-Retailer or DC-Customer). Lin et al. formulate a flexible multistage logistics network model by considering the direct shipment and direct delivery of logistics and inventory (82).

Genetic Representation. Lin et al. hybridized the priority-based encoding with random number-based encoding by dividing a chromosome into two segments (82). The first segment is encoded by using a priority-based encoding method that can escape the repairing mechanisms in the searching process of GA. The second segment of a chromosome consists of two parts: The first part with K loci containing the guide information about how to assign retailers in the network, and the other with length L including that information of customers. Each locus is assigned an integer in the range from 0 to 2.

Advanced Applications

Communication Network Models. The use of communication networks has increased significantly in the last decade because of the dramatic growth in the use of Internet for business and personal use. As the society trans-forms itself into an information society the network becomes the primary source for information creation, storage, distribution, and retrieval. The design and development of a reliable network to support the primary resource of an information society becomes a very critical activity. The reliability and service quality requirements of communication networks and the large investments in communication infrastructure have made it critical to design optimized networks that meet performance parameters. These factors have encouraged researchers to develop new models and methodologies for network design. GA and other evolutionary algorithms have been applied successfully to large and complex optimization problems in communication networks over the past decade, covering a variety of problem areas. Kampstra et al. gave an extensive literature survey, listing over 350 references on the use of GA and other evolutionary algorithms for solving communication network design problems (83).

Real-Time Tasks Scheduling Models. Real-time tasks can be classified into many kinds. Some real-time tasks are invoked repetitively. For example, one may wish to monitor the speed, altitude, and attitude of an aircraft every 100 ms. This sensor information will be used by periodic tasks that control the surfaces of the aircraft to maintain stability and other desired characteristics. In contrast, many other tasks are aperiodic, which occur only occasionally. Aperiodic tasks with a bounded interarrival time are called sporadic tasks. Critical (or hard real-time) tasks are those whose timely execution is critical. If the deadline is missed, catastrophes occur. Noncritical (or soft real-time) tasks are, as the name implies, not critical to the application. Gen and Yoo detailed survey GA-based approaches for various real-time tasks scheduling problems (84), such as a continuous soft real-time task scheduling problem on multiprocessor systems, real-time task scheduling in homogeneous multiprocessor systems, and real-time task scheduling in heterogeneous multiprocessor systems.

Reliability Optimization Models. In the broadest sense, *reliability* is a *measure of performance* of systems. As systems have grown more complex, the consequences of their unreliable behavior have become severe in terms of cost, effort, lives, and so on and the interest in assessing system reliability and the need for improving the reliability of products and systems have become very important. Reliability optimization problems concentrate on optimal allocation of redundancy components and optimal selection of alternative designs to meet a system requirement. Gen and Yun reported a survey GA-based approach for various reliability optimization problems (85), such as reliability optimization of redundant system, reliability optimization with alternative design, reliability optimization with time-dependent reliability, reliability optimization with interval coefficients, bicriteria reliability optimization, and reliability optimization with fuzzy goals.

GRANULAR COMPUTING

INTRODUCTION

Granular computing (GrC) is a term coined in 1997 as the name of an emerging and fast-growing research area in computer science and related fields (1,2). In its short history of 10 years, we have already witnessed a rapid development and extensive results (1,3–15).

A granule, the basic notion of granular computing, may be interpreted as one of the numerous small particles forming a larger unit. Collectively, they provide a representation of the unit with respect to a particular level of granularity. The central idea of the new paradigm of granular computing is the conceptualization and problem solving at different levels of granularity (12). On the one hand, one focuses on the suitable level of relevant conceptualizations without considering irrelevant lower level details. On the other hand, one changes granularity at different stages of problem solving.

The ideas of granular computing (i.e., problem solving under different granularity) have been explored in many fields, such as artificial intelligence, interval analysis, quantization, rough set theory, Dempster–Shafer theory of belief functions, divide and conquer, cluster analysis, machine learning, programming, databases, and many others (13,14). Although the subject matters and detailed formulations are different, the philosophy and the fundamental principles remain the same. The main objectives of granular computing are therefore to extract the commonality from a diversity of fields and to study systematically and formally such domain-independent principles (15,16). In particular, three perspectives of granular computing have been identified and studied (16). From the philosophical perspective, granular computing is a way of structured thinking (17). From the methodological perspective, granular computing is a general method of structured problem solving (15,16,18). From the computational perspective, granular computing is a new paradigm of structured information processing (3,4).

Granular computing is used as an umbrella term to cover theories, methodologies, techniques, and tools that make use of granules in problem solving (19). However, it should not be viewed as a simple collection of isolated, independent, or loosely connected pieces, nor as a simple restatement of existing results. One needs to re-examine, re-evaluate, reformulate, summarize, synthesize, combine, and extend results from existing studies in a unified framework. The introduction of granular computing provides such a broader context in which one can examine the inherent connections between concrete models and extract the abstract ideas and fundamental principles. Granular computing aims at a wider holistic view of problem solving, in contrast to narrow and fragmented views.

Bohm and Peat argued that science must go beyond a fragmented view of nature (20). Their argument is applicable to the study of granular computing. Therefore, we introduce and formulate granular computing as a way of thinking and a general method of problem solving that embraces a variety of concrete theories and methods.

EXEMPLAR MODELS OF GRANULAR COMPUTING

Historically speaking, the explicit consideration of granular computing is from the studies of the theories of fuzzy sets and rough sets (1,3,21–23). The concept of granular computing is developed based on the notion of information granulation first discussed by Zadeh in 1979 (24). Unfortunately, not much attention has been paid to information granulation until the publication of a seminal paper in 1997 (14). The attention to granular computing is also generated, to a large extent, by studies of rough set theory (25,26). It is through the study of this concrete model that one gains appreciation for the potential usefulness of granular computing in general (1,23).

Granular Computing in Fuzzy Set Theory

In his 1997 paper, Zadeh discussed a general framework of granular computing within the fuzzy set theory (14). Granules are constructed and defined based on the concept of generalized constraints. Relationships between granules are represented in terms of fuzzy graphs or fuzzy if-then rules. The associated computation method is known as computing with words (27).

Let X be a variable taking values in a universe U. A generalized constraint on the values of X can be expressed as $X\ isr\ R$, where R is a constraining relation, isr is a variable copula, and r is a discrete variable whose value defines the way in which R constrains X. Examples of constraints are equality, possibilistic, probabilistic, fuzzy, and veristic constraints. For example, an equality constraint, $r = e$, is given by $X\ ise\ R$, which means $X = R$. A possibilistic constraint, $r = blank$, is given by $X\,is\,R$, where R is a possibility distribution of X. With the introduction of generalized constraints, a granule is defined by a fuzzy set:

$$G = \{X | X\, isr\, R\} \tag{1}$$

Depending on the types of constraints, various classes of granules can be obtained. From simple granules, one may obtain Cartesian granules by considering combinations of constraints (14).

One may label granules by natural language words, which establishes a basis for computing with words. As one of the core components of fuzzy logic, computing with words deals with fuzzy if-then rules of the form:

$$if\, X\, isr_1\, A\, then\, Y\, isr_2\, B \tag{2}$$

where r_1 and r_2 may represent different types of constraints, although the same type is commonly used. A set

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

of fuzzy if-then rules can be interpreted in terms of a fuzzy graph. Inference can be carried out using fuzzy if-then rules or fuzzy graphs (14,27).

More results on granular computing using fuzzy sets can be found in, for example, references (1–3,6,8,,9,11,21,28).

Granular Computing in Rough Set Theory

Rough set theory is another generalization of classic sets based on the notion of indiscernibility (25,26). Granulation is a consequence of indiscernibility of objects. The loss of information through granulation implies that some subsets of the universe can only be approximately described.

Let $E \subseteq U \times U$ denote an equivalence relation on the universe U. The pair $apr = (U, E)$ is called an approximation space. The equivalence relation E partitions the set U into disjoint subsets known as the quotient set U/E. Each equivalence class may be viewed as a granule consisting of indistinguishable elements. It is also referred to as an equivalence granule. A particular semantic interpretation of equivalence relations is provided based on the notion of information tables. Two objects are equivalent if they have exactly the same value with respect to a set of attributes. Thus, an equivalence granule is characterized by the equality constraint (29).

An arbitrary set $X \subseteq U$ may not necessarily be a union of some equivalence classes, which implies that one may not be able to describe X precisely using the equivalence classes of E. In this case, one may characterize X by a pair of lower and upper approximations:

$$\begin{aligned} \underline{apr}(X) &= \bigcup_{[x]_E \subseteq X} [x]_E, \\ \overline{apr}(X) &= \bigcup_{[x]_E \cap X \neq \varnothing} [x]_E \end{aligned} \tag{3}$$

where $[x]_E = \{y | xEy\}$ is the equivalence class containing x. The lower approximation $\underline{apr}(X)$ is the union of all the equivalence granules that are subsets of X. The upper approximation $\overline{apr}(X)$ is the union of all the equivalence granules that have a nonempty intersection with X.

Based on the approximations of sets, one may perform data analysis and data mining tasks in information tables, such as attribute reduction, dependency analysis, and learning of decision rules (23). Many proposals have been made regarding granular computing within rough set theory. More results can be found in Refs. 1,5,13,23,29–33.

Granular Computing in a Wider Context

Granular computing using the theories of fuzzy and rough sets is restricted to a set-theoretic setting, where a granule is a crisp or fuzzy subset of a universe. Another set-theoretic model of granular computing is neighborhood systems, in which an element is associated with a family of neighborhoods (21,22,30,34,35). Although rough set theory considers partitions consisting of nonoverlapping granules, neighborhood systems can deal with both nonoverlapping and overlapping granules.

There is a need to study granular computing in broader contexts by moving beyond the set-theoretic setting (13,15–17). One may treat a granule as an abstract notion to be concretized in a particular domain. A granule is a small particle of a whole unit. Different sized granules lead to different levels of details, which, in turn, enables us to represent the whole using multiple levels, multiple resolutions, or hierarchies. Granular computing is, therefore, viewed as a way of thinking using multilevel granularity.

Depending on particular problems, one may consider granulated theories, granulated maps, granulated solutions, granulated plans, and so on. By considering granular computing in a wider context, one can extract the basic principles from a diversity of fields, including concept formation, clustering, abstraction, machine learning, data mining, programming, theorem proving, and many more (13,15,16). It is within this wider context that one can appreciate the power, effectiveness, flexibility, and general applicability of granular computing as a way of thinking and as a general method of problem solving.

GRANULAR COMPUTING AS A WAY OF THINKING

Problem solving in general is an extremely complex process and involves many different techniques. It might be difficult to give a universally effective method or to design a set of precise instructions for problem solving. Nevertheless, the basic processes and the systematic ways of thinking are common elements of problem solving, regardless of any particular problem to be solved. From the philosophical and conceptual points of view, granular computing concerns a way of thinking that underlies human problem solving. It is based on our perception of the world in multiple levels of granularity and our ability to solve a problem with differing granularity.

Granular Computing Models Human Problem Solving

Zadeh identified three basic and closely related concepts that underlie human cognition, namely, granulation, organization, and causation (14). Granulation decomposes the whole unit into parts (granules), organization integrates parts into the whole unit, and causation involves association of causes and effects. Yager and Filev argued that humans have developed a granular view of the world and objects that we perceive, measure, conceptualize, and reason are granular (28). It is evident that granulation plays a central role in human perception and problem solving.

Granular computing, therefore, reflects naturally the ways in which humans granulate information and reason with it. In fact, models of granular computing are the formalization of ideas and principles of human problem solving. The effectiveness, flexibility, and adaptivity of human problem solving suggest that such a formulation is rational and may lead to useful problem-solving theories and tools.

The basic ideas and principles of granular computing have been investigated under different names such as abstraction and granularity in artificial intelligence. Hobbs proposed a theory of granularity (12). The theory is motivated by the fact that humans view the world under various grain sizes and abstract only those things relevant to the present interests (12). Human intelligence and flexibility, to a large degree, depend on the ability to conceptualize the world at different granularity and to switch granularity. With the theory of granularity, we can map the complexities of the real world around us into simpler theories that are computationally tractable to reason in. Based on similar motivations, Giunchigalia and Walsh proposed a theory of abstraction (36). Abstraction can be thought of as the process that allows us to consider relevant materials and to forget irrelevant details that would get in the way of what we are trying to do. The theory of abstraction may be viewed as a model of granular computing that subsumes many existing studies.

Granular Computing is Motivated by Practical Needs

Human problem-solving skills may be considered as the result of a long time adaptation to the environments. The practical reasons that motivate human adaptation also motivate the study of granular computing.

In many situations, when a problem involves incomplete, uncertain, or vague information, it may be difficult to differentiate distinct elements and one is forced to consider granules (23,25,26). Both theories of fuzzy and rough sets can be interpreted based on the similarity of objects. They are motivated by the practical needs to describe physically existing and ill-defined granules.

In some situations, although detailed information may be available, it may be sufficient to use granules to have an efficient and practical solution. In fact, very precise solutions may not be required at all for many practical problems. It may also happen that the acquisition of precise information is too costly, and coarse-grained information reduces cost (14). These observations suggest a basic guiding principle of fuzzy logic: "*Exploit the tolerance for imprecision, uncertainty, and partial truth to achieve tractability, robustness, low solution cost, and better rapport with reality*" (14). This principle offers a more practical philosophy for real-world problem solving. Instead of searching for the optimal solution, one may search for good approximate solutions. One only needs to examine the problem at a finer granulation level with more detailed information when there is a need or benefit for doing so (19).

Through granulation and abstraction, irrelevant details are filtered out, which may enable us to observe high-level structures and organizations that may not be easily seen otherwise. Granulation leads to a high-level organization, which provides a remedy for our inability to grasp every detailed aspect of a large problem. For example, the granulation of ideas in a scientific paper produces an organization in terms of title, keywords, abstract, section headings, and subsection headings, which greatly improves the readability as well as our understanding of the paper (37).

The necessity of information granulation, as well as the simplicity and efficiency derived from information granulation, may account for the popularity of granular computing.

Granular Computing is Consistent with the Organization of Knowledge

Every concept is understood as a unit of thought consisting of two parts, the intension and the extension of the concept (38–40). The intension of a concept consists of all properties or attributes that are valid for all those objects to which the concept applies. The extension of a concept is the set of objects or entities that are instances of the concept. All objects in the extension have the same properties that characterize the concept. In other words, the intension of a concept is an abstract description of common features or properties shared by elements in the extension, whereas the extension consists of concrete examples of the concept. A concept is thus described jointly by its intension and extension. This formulation enables us to study concepts in a logic setting in terms of intensions and also in a set-theoretic setting in terms of extensions. The descriptions of granules characterize concepts from the intension point of view, whereas granules themselves characterize concepts from the extension point of view. Through the connections between extensions of concepts, one may establish relationships between concepts (41,42).

In characterizing human knowledge, one needs to consider two topics, namely, context and hierarchy (43). Knowledge is contextual and hierarchical. A context in which concepts are formed provides meaningful interpretation of the concepts. Knowledge is organized in a tower or a partial ordering. The base-level, or first-level, concepts are the most fundamental concepts, and higher level concepts depend on lower level concepts. To some extent, granulation and inherent hierarchical granulation structures reflect naturally the way in which human knowledge is organized. The construction, interpretation, and description of granules and granulations are of fundamental importance in the understanding, representation, organization, and synthesis of data, information, and knowledge.

GRANULAR COMPUTING AS A GENERAL METHOD OF PROBLEM SOLVING

The underlying ideas of granular computing have been used either explicitly or implicitly for solving a wide diversity of problems. To illustrate its effectiveness and flexibility as a general method of problem solving, a few examples are discussed.

One-Dimensional Granulation

In problem solving, it is common to represent a certain physical property based on a quantitative measure. A quantitative measure may be viewed as a homomorphism from a set of objects to the set of real numbers (44). The set of real numbers is a linear order under the relation $\leq$. Granular computing based on the granulation of a linear order is therefore useful in many applications.

Suppose $(L, \preceq)$ is linearly ordered set with a linear order $\preceq$. A useful granulation of L is given by considering intervals of L. Given two elements $a, b \in L$, a closed interval of L is defined by:

$$[a,b] = \{x \in L | a \preceq x \preceq b\} \tag{4}$$

which is a subset of L. One can lift operations on L to operations on intervals of L based on the concept of power algebras (19,45). Let $'$ be a unary operation and $\circ$ a binary operation on L. The lifted operations on intervals of L, also denoted by $'$ and $\circ$, are defined by:

$$\begin{aligned} [a,b]' &= \{x' | x \in [a,b]\}, \\ [a,b] \circ [c,d] &= \{x \circ y | x \in [a,b], y \in [c,d]\} \end{aligned} \tag{5}$$

for intervals $[a,b]$ and $[c,d]$. In general, the lifted operations on intervals may not be closed. That is, they may not produce intervals of L. Based on the relation $\preceq$, we can define four relations on intervals:

$$\begin{aligned} &[a,b]_* \preceq_* [c,d] \Leftrightarrow \forall x \in [a,b] \, \forall y \in [c,d] x \preceq y, \\ &[a,b]_* \preceq^* [c,d] \Leftrightarrow \forall x \in [a,b] \, \exists y \in [c,d] x \preceq y, \\ &[a,b]^* \preceq_* [c,d] \Leftrightarrow \exists x \in [a,b] \, \forall y \in [c,d] x \preceq y, \\ &[a,b]^* \preceq^* [c,d] \Leftrightarrow \exists x \in [a,b] \, \exists y \in [c,d] x \preceq y \end{aligned} \tag{6}$$

for intervals $[a,b]$ and $[c,d]$. Additional relations can be defined on intervals by considering $[a,b]$ and $[c,d]$ as two subsets of L. For example, we say that the two intervals overlap if $[a,b] \cap [c,d] \neq \varnothing$ and disjoin otherwise. Similarly, $[a,b]$ is a subinterval of $[c,d]$ if $[a,b] \subseteq [c,d]$.

Concrete models of granular computing based on 1-D granulation are interval analysis (46), temporal granulation, and reasoning (47–51).

1-D granulations can be easily extended into partially ordered sets, such as Boolean algebras and lattices. Interval set algebra is an example of such an extension (52).

High-Dimensional Granulation

1-D granulations can be extended to 2-D granulations by considering a pair of linear orders $(L_1, \preceq_1)$ and $(L_2, \preceq_1)$. In this case, we have the Cartesian product $L_1 \times L_2$. Corresponding to an interval, we define a granule as a rectangle in the 2-D space. If the 2-D space is an Euclidean space, we can define a distance function between two points. A granule can also be a circle with a particular radius.

Spatial granulation and reasoning is an example of 2-D granulation (48,53). Another example of 2-D granulation is the hierarchical coding and progressive transmission of images (55).

The idea of extending a 1-D granulation to a 2-D granulation can be applied to study high-dimensional granulations.

Top-Down Programming

The top-down programming is an effective technique to deal with the complex problem of programming, which is based on the notions of structured programming and stepwise refinement (55). The principles and characteristics of the top-down design and stepwise refinement, as discussed by Ledgard, et al. (55), provide a convincing demonstration that granular computing is a general method of problem solving.

According to Ledgard et al. (55), the top-down programming approach has the following characteristics:

Design in Levels. A level consists of a set of modules. At higher levels, only a brief description of a module is given. The details of a module are to be refined, divided into smaller modules, and developed in lower levels.

Initial Language Independence. The initial levels focus on expressions that are relevant to the problem solution, without explicit reference to machine- and language-dependent features.

Postponement of Details to Lower Levels. The higher levels concern critical and broad issues and the structure of the problem solution. The details such as the choice of specific algorithms and data structures are postponed to lower levels.

Formalization of Each Level. Before proceeding to a lower level, one needs to obtain a formal and precise description of the current level, which ensures a full understanding regarding the structure of the current sketched solution.

Verification of Each Level. The sketched solution at each level must be verified so that errors pertinent to the current level will be detected.

Successive Refinements. Top-down programming is a successive refinement process. Starting from the top level, each level is redefined, formalized, and verified until one obtains a complete program.

In terms of granular computing, program modules correspond to granules, and levels of the top-down programming correspond to different levels of granularity. One can immediately see that those characteristics also hold for granular computing in general.

Top-down programming offers a general top-down problem-solving method, which may be considered as the core of granular computing. The hierarchical organization of human knowledge makes the top-down approach an effective way of problem solving.

By observing the systematic way of top-down programming, some authors suggest that the similar approach can be used in developing, teaching, and communicating mathematical proofs (56,57). Leron proposed a structured method for presenting mathematical proofs (57). The main objective is to increase the comprehensibility of mathematical presentations and at the same time retain their rigor. The traditional linear fashion presents a proof step-by-step from hypotheses to conclusion. In contrast, the structured method arranges the proof in levels and proceeds in a top-down manner. Like the top-down, stepwise refinement programming approach, a level consists of short autonomous modules, each embodying one major idea of the proof to be further concretized in the subsequent levels. The top level is a very general description of the main line of the proof. The second level elaborates on the generalities of the top level by supplying proofs of unsubstantiated statements, details of general descriptions, and so on. For some more complicated tasks, the second level only gives a brief description and the details are postponed to the lower levels. The process continues by supplying more details of the higher levels until a complete proof is reached.

TWO BASIC ISSUES OF GRANULAR COMPUTING

The two related basic issues of granular computing are granulation and computing with granules (13,19). The former deals with the formation, representation, and interpretation of granules, whereas the latter deals with the use of granules in problem solving. They can be studied from the semantic and algorithmic aspects, respectively (4,19).

Semantic Studies versus Algorithmic Studies

The interpretation of granules focuses on the semantic side of granule constructions. It addresses the question of *why* two objects are put into the same granule. Typically, elements in a granule are drawn together by indistinguishability, similarity, proximity, or functionality (14). Furthermore, information granulation depends on the available knowledge. In the construction of granules, it is necessary to study criteria for deciding whether two elements should be put into the same granule based on available information. In other words, one must provide necessary semantic interpretations for notions such as indistinguishability, similarity, and proximity. It is also necessary to study granulation structures derivable from various granulations of the universe (13). The formation and representation of granules deal with algorithmic issues of granule construction. They address the problem of *how* to put two objects into the same granule. Algorithms need to be developed for constructing granules efficiently.

Computation with granules can be similarly studied from both the semantic and algorithmic aspects. On the one hand, one needs to interpret various relationships between granules such as closeness, dependency, and association, and to define and interpret operations on granules. On the other hand, one needs to design methodologies and tools for computing with granules such as approximation, reasoning, and inference.

Both the semantic and algorithmic aspects of granular computing are important. However, many existing methods of granular computing do not pay enough attention to the semantic aspect. It is equally, if not more, important to investigate semantic issues involved in granular computing. The results may provide not only interpretations and justifications for a particular granular computing model, but also guidelines that prevent possible misuses of the model. The results from algorithmic study may lead to efficient and effective granular computing methods and tools.

Granulation

The notion of granulation can be studied in many different contexts. A family of granules collectively is referred to as a granulation of a problem. The granulation of a problem, particularly the semantics of granulation, is domain- and application-dependent. Nevertheless, one can still identify some domain-independent issues (13).

Granulation Criteria. A granulation criterion deals with the semantic interpretation of granules and addresses the question of *why* two objects are put into the same granule.

Granulation Structures. It is necessary to study granulation structures derivable from various granulations of the universe. Two structures can be observed: the structure of individual granules and structure of a granulation. Multilevel granulations produce a natural hierarchical structure (53,58–60).

Granulation Methods. A granulation method addresses the problem of *how* to put two objects into the same granule. The construction process can be modeled as either top-down or bottom-up. A top-down process divides large granules, whereas a bottom-up process combines smaller granules. Both processes lead naturally to a hierarchical organization of granules and granulations (33,58).

Representation/Description of Granules. Another semantics-related issue is the interpretation of the results of a granulation method. Once constructed, it is necessary to describe, name, and label granules using certain languages.

Quantitative Characteristics of Granules and Granulations. One can associate quantitative measures to granules and granulations to capture their features.

These issues can be understood by examining a concrete example of granulation known as the cluster analysis (61), which can be done by simply changing granulation into clustering and granules into clusters. *Clustering structures* may be hierarchical or nonhierarchical, exclusive or overlapping. Typically, a similarity or distance function is used to define the relationships between objects. *Clustering criteria* may be defined based on the similarity or distance function and the required cluster structures. For example, one would expect strong similarities between objects in the same cluster and weak similarities between objects in different clusters. Many *clustering methods* have been proposed and studied, including the families of hierarchical agglomerative, hierarchical divisive, iterative partitioning, density search, factor analytic, clumping, and graph theoretic methods (62). Cluster analysis can be used as an exploratory tool to interpret data and find regularities from data (61). This process requires the active participation of experts to interpret the results of clustering methods and judge their significance. A good *representation* of clusters and their *quantitative characterizations* may make the task of exploration much easier.

Computing and Reasoning with Granules

A granulated view summarizes available information and knowledge about a problem. As a basic task of granular computing, one can examine and explore further relationships between granules at a lower level and relationships between granulations at a higher level (13).

Mappings Between Different Level of Granulations. In a granulation hierarchy, the connections between different levels of granulations can be described by mappings. Giunchglia and Walsh considered an abstraction as a mapping between a pair of formal systems in the development of a theory of abstraction (36). A mapping links different representations of the same problem at different levels of detail. One can classify and study different types of granulations by focusing on the properties of the mappings (36).

Granularity Conversion. A basic task of granular computing is to change views with respect to different levels of granularity. As we move from one level of detail to another, we need to convert the representation of a problem accordingly (36,49). A move to a more detailed view may reveal information that otherwise cannot be seen, whereas a move to a simpler view can improve the high-level understanding by omitting irrelevant details of the problem (12,14,36,49,60).

Property Preservation. Granulation allows different representations of the same problem in different levels of detail. It is naturally expected that the same problem must be consistently represented (49). A granulation and its related computing methods are meaningful only if they preserve certain desired properties (36,60).

Operators. The relationship between granules at different levels and conversion of granularity can be precisely defined by operators (49,59). They serve as the basic building blocks of granular computing. There are at least two types of operators that can be defined. One type deals with the shift from a fine granularity to a coarse granularity. A characteristic of such an operator is that it will discard certain details, which makes distinct objects no longer differentiable. Depending on the context, many interpretations and definitions are available, such as abstraction, simplification, generalization, coarsening, zooming-out, and so on (12,36,51,59,60,63,64). The other type deals with the change from a coarse granularity to a fine granularity. A characteristic of such an operator is that it will provide more details so that a group of objects can be further classified. They can be defined and interpreted differently, such as articulation, specification, expanding, refining, zooming-in, and so on (2,36,51,59,60,63,64). Other types of operators may also be defined. For example, with the granulation, one may not be able to exactly characterize an arbitrary subset of a fine-grained universe in a coarse-grained universe, which leads to the introduction of approximation operators in rough set theory (26,52).

Granular computing methods describe our ability to switch granularity in problem solving. Detailed and domain-specific methods can be developed by elaborating these issues with explicit reference to an application.

CONCLUSION

Granular computing is introduced from two perspectives: as a way of thinking and as a general method of problem solving. The former perspective concerns the philosophical investigation and conceptual formulation. The results suggest that a general method for problem solving can be described based on granular computing.

The introduction of granular computing provides a unified and general framework to integrate a number of fragmentary studies that either explicitly or implicitly adopt similar or the same ideas and principles. The fields that have strong influences on granular computing are the theories of fuzzy and rough sets, cognitive science, and artificial intelligence.

The subject of granular computing can be studied by using its own principles, namely, formulation and investigation at different levels of granularity. We focus on a high-level examination of granular computing, although some details are discussed. The significance of granular computing lies in its basic principles that are common to problem solving.

HOPFIELD NEURAL NETWORKS

The development of artificial neural networks has been motivated by the desire to find improved methods of solving problems that are difficult for traditional computing software or hardware. The success of early neural networks led to the claim that they could solve virtually any type of problem. Although this claim was quickly shown to be overly optimistic, research continued during the 1970s into the use of neural networks, especially for pattern association problems. The early 1980s marked the beginning of renewed widespread interest in neural networks. A key player in the increased visibility of, and respect for, neural networks is physicist John Hopfield of the California Institute of Technology. Together with David Tank of AT&T, Hopfield developed a group of recurrent networks that are known as Hopfield neural networks (HNNs). The first of these, the discrete Hopfield neural network (DHNN), was designed as content addressable memory (CAM). The continuous Hopfield neural network (CHNN) can also serve as a CAM, but it is most widely used for combinatorial optimization problems.

One reason that Hopfield's work caught the attention of the scientific community, and the public, was the close connection between the models and the successful development of neural network chips by researchers at AT&T and by Carver Mead and his coworkers. Hopfield's emphasis on practical implications made the engineering connection very strong. By making explicit the relationship between the HNN and electrical circuits, Hopfield opened the field of neural networks to an influx of physical theory. Although many concepts incorporated in the HNN had antecedents in earlier neural network research, Hopfield and Tank brought them together with both clear mathematical analysis and strong emphasis on practical applications (1).

ARTIFICIAL NEURAL NETWORKS

An artificial neural network (ANN) approach to problem solving is inspired by certain aspects of biological nervous systems. An ANN is composed of a large number of very simple processing elements (neurons). The neurons are interconnected by weighted pathways. The pattern of connection among the neurons is called the network architecture. At any time, a neuron has a level of activity, which it communicates to other neurons by sending it as a signal over these pathways. As the weights on the pathways contain much of the important information in the network, the information is distributed, rather than localized, as in traditional computers.

Architectures

One of the most basic distinctions between different types of neural networks is based on whether the network architecture allows for feedback among the neurons. A fully interconnected recurrent network is shown in Fig. 1.

Weights

In addition to the design of the ANN architecture, a major consideration in developing a neural network is the determination of the connection weights. For many networks, this is done by means of a training phase, in which known examples of the desired input–output patterns are presented to the network and the weights are adjusted according to a specified training algorithm. This is especially typical of feed-forward networks. In the standard Hopfield networks, the weights are fixed when the network is designed.

Network Operation

To use a neural network, after the weights are set, an input pattern is presented and the output signal of each neuron is adjusted according to the standard process for the specific ANN model. In general, each neuron sends its output signal to the other neurons to which it is connected; the signal is multiplied by the weight on the connection pathway; each neuron sums its incoming signals. Each neuron's output signal is a nonlinear function of its summed input. In a feed-forward network, these computations are performed one layer at a time, starting with the input units, and progressing through the network to the output units. For a recurrent network, such as an HNN, the updating of each neuron's activity level continues until the state of the net (the pattern of activations) converges. The process differs for the discrete and continuous forms of HNN; before discussing the details, we summarize the primary types of applications for which HNNs are used.

APPLICATIONS OF HOPFIELD NEURAL NETWORKS

Memory in biological systems is fundamentally different than in a traditional digital computer, in which information is stored by assigning an address, corresponding to a physical location, where the data are written. On the other hand, your memory of an event is a combination of many sights, sounds, smells, and so on. The idea of associative memory came from psychology rather than from engineering, but during the 1970s, much of the neural network research (especially work by James A. Anderson at Brown University and Teuvo Kohonon at the University of Helsinki) focused on the development of mathematical models of associative (or content addressable) memory. The use of an energy function analysis facilitates the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

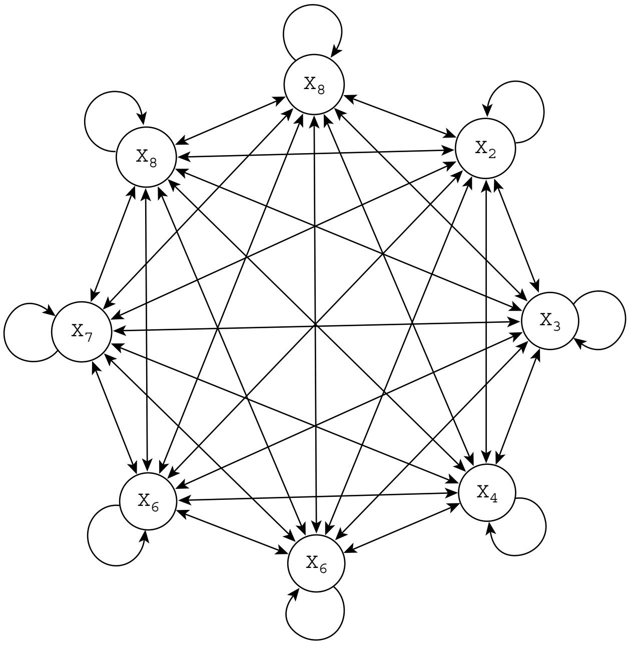

Figure 1. A fully interconnected network allows signals to flow between neurons.

understanding of associative memories that can be constructed as electronic “collective-decision circuits” (2).

The process used by biological systems to solve optimization problems also differs from that used in traditional computing techniques. Although no claim is made that neural network approaches to optimization problems directly model the methods used by biological systems, ANNs do have some potential advantages over traditional techniques for certain types of optimization problems. ANNs can find near-optimal solutions quickly for large problems. They can also handle situations in which some conditions are desirable but not absolutely required. Neural network solutions (and, in particular, HNN) have been investigated for many applications because of their potential for parallel computation and computational advantage when they are implemented with analog very large-scale integration (VLSI) techniques.

Many other forms of recurrent neural networks have also been developed. Networks with specific recurrent structure are used for problems in which the signal varies with time. Neural networks for the study of learning, perception, development, cognition, and motor control also use recurrent structures.

Associative Memory

One important use of an HNN is as an autoassociative memory, which can store (or memorize) a certain number of patterns. When a modified form of one of the stored patterns is presented as input, the HNN can recall the original pattern after a few iterations.

Before the weights of an associative memory neural net are determined, the patterns to be stored must be converted to an appropriate representation for computation. Usually each pattern is represented as a vector with components that are either 0 or 1 (binary form) or ±1 (bipolar form); the bipolar form is often computationally preferable for associative memory applications. The same representation is also used for patterns that are presented to the network for recognition.

Optimization

The second primary area of application for HNNs is combinatorial optimization problems. The use of a continuous HNN for solving optimization problems was first illustrated for the traveling salesman problem (TSP), a well-known but difficult optimization problem (3) and a task assignment problem (2). Since then, HNNs have been applied to optimization problems from many areas, including game theory, computer science, graph theory, molecular biology, VLSI computer-aided design, reliability, and management science. Many examples are included in Ref. 4.

The HNN approach is based on the idea that the network weights and other parameters can be found from an energy function; the network configuration (pattern of neuron activations) that produces a minimum of the energy function corresponds to the desired solution of the optimization problem. The appropriate choice of energy function for a particular problem has been the subject of much research.

DISCRETE HOPFIELD NETWORKS

The iterative autoassociative network developed by Hopfield (5,6) is a fully interconnected neural network, with symmetric weights and no self-connections, i.e., $w_{ij} = w_{ji}$ and $w_{ii} = 0$. In a DHNN, only one unit updates its activation at a time (this update is based on the signals it receives from the other units). The asynchronous updating of the units allows an energy (or Lyapunov) function to be found for the network. The existence of such a function forms the basis for a proof that the net will converge to a stable set of activations.

Operation

The primary considerations in using a DHNN are determining the network weights and updating the activations.

Setting the Weights. The earliest version of the DHNN used binary input vectors; later descriptions are often based on bipolar inputs. The weight matrix to store a pattern, represented as the column vector, $\mathbf{p} = (p_1,\ldots, p_i,\ldots p_n)^T$ is the matrix $\mathbf{P}\,\mathbf{P}^T - \mathbf{I}$. The matrix $\mathbf{pp}^T$ is known as the outer or matrix product of the vectors $\mathbf{p}$ and $\mathbf{p}^T$. Subtracting the identity matrix has the effect of setting the diagonal entries to 0, which is necessary to allow the network to reconstruct one of the stored patterns when a degraded or noisy form of the pattern is presented as input. The weight matrix $\mathbf{W}$ in which several patterns are stored is the sum of the individual matrices generated for each pattern.

Updating the Activations. To use a DHNN to recall a stored pattern, an input stimulus pattern $\mathbf{x}$ is presented to the network (one component to each neuron). Typically, the input is similar to one of the stored memories. Each neuron transmits its signal to all of the other neurons. The signal received by the ith neuron is $\sum_j x_j w_{ji}$; by the symmetry of the weights, this is also the ith row of the product $\mathbf{Wx}$. One neuron, chosen at random, updates its activation. Its activation is 1 if the signal it received was non-negative, i.e., if $\sum_j x_j w_{ji} \geq 0$; the activation is -1 if $\sum_j x_j w_{ji} < 0$. The new pattern is again broadcast to all neurons, and another neuron is chosen to update its activation. The process continues until the network reaches a stable state, a configuration of activations that does not change.

Example. To illustrate the use of a DHNN, consider the following simple example, adapted from Ref. 7. Suppose we wish to store the three bipolar patterns:

$$\begin{aligned} p_1 &= (\ 1 \quad 1 \quad 1 \quad 1 \quad 1)^{\mathrm{T}} \\ p_2 &= (\ 1 \ -1 \ -1 \quad 1 \ -1)^{\mathrm{T}} \\ p_3 &= (-1 \quad 1 \ -1 \ -1 \ -1)^{\mathrm{T}} \end{aligned}$$

The weight matrix to store these three patterns is $\mathbf{W}_1 + \mathbf{W}_2 + \mathbf{W}_3 = \mathbf{W}$:

$$\begin{array}{ccccc} 0 & 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 1 & 1 \\ 1 & 1 & 0 & 1 & 1 \\ 1 & 1 & 1 & 0 & 1 \\ 1 & 1 & 1 & 1 & 0 \end{array} + \begin{array}{ccccc} 0 & -1 & -1 & 1 & -1 \\ -1 & 0 & 1 & -1 & 1 \\ -1 & 1 & 0 & -1 & 1 \\ 1 & -1 & -1 & 0 & -1 \\ -1 & 1 & 1 & -1 & 0 \end{array}$$

$$+ \begin{array}{ccccc} 0 & -1 & 1 & 1 & 1 \\ -1 & 0 & -1 & -1 & -1 \\ 1 & -1 & 0 & 1 & 1 \\ 1 & -1 & 1 & 0 & 1 \\ 1 & -1 & 1 & 1 & 0 \end{array} = \begin{array}{ccccc} 0 & -1 & 1 & 3 & 1 \\ -1 & 0 & 1 & -1 & 1 \\ 1 & 1 & 0 & 1 & 3 \\ 3 & -1 & 1 & 0 & 1 \\ 1 & 1 & 3 & 1 & 0 \end{array}$$

We present as an input (or probe) vector $\mathbf{x} = (1, -1, -1, 1, 1)^T$, which differs from the second stored pattern in only the last component. To update the network, compute $\mathbf{Wx} = (4, -3, 4, 4, -2)^T$. If the third neuron is chosen, its activation will change from -1 to 1, because it received a signal of 4. Using the updated vector of activations, $(1, -1, 1, 1, 1)^T$ gives $\mathbf{Wx} = (6, 0, 4, 6, 4)^T$. If neuron 1, 3, 4, or 5 is chosen, its activity will not change, and eventually neuron 2 will be chosen. As we are using the convention that a neuron's activity is set to 1 if it receives a non-negative signal, neuron 2 will change its activation and the updated vector of activations becomes $(1, 1, 1, 1, 1)^T$, which is the first stored pattern, but not the stored pattern that is most similar to the probe. If the fifth neuron had been chosen for the first update (instead of the third neuron), the network would have reached the second stored pattern immediately.

This example illustrates both the operation of a DHNN for use as an associative memory and some of the issues that must be considered. These include questions concerning the circumstances under which convergence to a stable state is guaranteed, the question as to whether that stable state will be one of the stored patterns (and if so, will it be the closest pattern to the input?), and the relationship between the number of stored memories and the ability of the network to recall the patterns with little or no error.

Issues

The primary issues concerning the use of a DHNN are convergence and storage capacity.

Convergence. For any iterative process, it is important to understand its convergence characteristics. It can be shown that the general DHNN will converge to a stable limit point (pattern of activation of the units) by considering an energy function for the system. An energy function is a function that is bounded below and is a nonincreasing function of the state of the system. For a neural network, the state of the system is the vector of activations of the units. Thus, if an energy function can be found for an iterative neural network, the ANN will converge to a stable set of activations.

The general DHNN allows an external signal y_i to be maintained during processing, so that the total signal received by neuron X_i is $y_i + \sum_j x_j w_{ji}$. The threshold for determining whether a neuron is ON or OFF may be set to any desired constant θ_i; when chosen to update its activation, a unit will set its activation to ON if

$$y_i + \sum_j x_j w_{ji} \geq \theta_i$$

a unit will set its activation to OFF if

$$y_i + \sum_j x_j w_{ji} < \theta_i.$$

An energy function for the general DHNN described here is given by

$$\mathrm{E} = -0.5 \sum_{i \neq j} \sum_j x_i x_j w_{ij} - \sum_i x_i y_i + \sum_i \theta_i x_i \qquad (1)$$

If the activation of the net changes by an amount Δx_i, the energy changes by the corresponding amount

$$\Delta E = -\left[y_i + \sum_{i \neq j} x_j w_{ij} - \theta_i \right] \Delta x_i \qquad (2)$$

To show that $\Delta E \leq 0$, consider the two cases in which the activation of neuron X_i will change.

1. If X_i is ON, it will turn OFF if $y_i + \sum_j x_j w_{ji} < \theta_i$. This gives a negative change for x_i. As the quantity $\left[y_i + \sum_{i \neq j} x_j w_{ij} - \theta_i \right]$ in the expression for ΔE is also negative, we have $\Delta E < 0$.
2. On the other hand, if X_i is OFF, it will turn ON if $y_i + \sum_j x_j w_{ji} > \theta_i$. This gives a positive change for x_i. As $\left[y_i + \sum_{i \neq j} x_j w_{ij} - \theta_i \right]$ is positive in this case, the result is again that $\Delta E < 0$.

Therefore, the energy cannot increase. As the energy is bounded, the net must reach a stable equilibrium where the energy does not change with further iteration. This proof uses the fact that the energy change only depends on the change in activation of one unit, and that the weight matrix is symmetric. Setting the diagonal weights to 0 corresponds to the assumption that biological neurons do not have self-connections. From a computational point of view, zeroing out the diagonal makes it more likely that the network will converge to one of the stored patterns, rather than simply reproducing the input pattern.

Storage Capacity. In addition to knowing under what circumstances a Hopfield network is guaranteed to converge, it is also useful to understand how many patterns may be stored in, and recalled from, such a network. Although more patterns may be stored if the pattern vectors are orthogonal, that structure cannot be assumed in general. Therefore, most results are based on the assumption that the patterns to be stored are random. Hopfield found experimentally that P, the number of binary patterns that can be stored and recalled with reasonable accuracy, is given (approximately) by $P = 0.15\,n$, where n is the number of neurons. For a similar DHNN, using bipolar patterns, it has been found (7) that $P = \frac{n}{2\log_2 n}$.

CONTINUOUS HOPFIELD NETWORK

In contrast to the discrete form, the activations of the neurons in a continuous Hopfield net can take on a continuous range of values (most often between 0 and 1). The network dynamics are specified by differential equations for the change in activations. These differential equations are intimately connected to the underlying energy function for the network.

For a CHNN, we denote the internal activity of a neuron as u_i; its output signal is $v_i = g(u_i)$, where g is a monotonically nondecreasing function of the input signal received by unit U_i. Most commonly g is taken to be the sigmoid function $v = 0.5\ (1 + \tanh(\alpha\ u))$, which has range (0, 1). The parameter α controls the steepness of the sigmoid. The differential equations governing the change in the internal activity of each unit are closely related to the energy function that will be minimized as the network activations evolve. Either the evolution equation or the energy function may be specified and the other relationship derived from it. A standard form for the energy function is

$$E = 0.5 \sum_{i=1}^{n}\sum_{j=1}^{n} w_{ij}\, v_i v_j + \sum_{i=1}^{n} \theta_i\, v_i \tag{3}$$

the corresponding evolution equation is

$$\frac{d}{dt} u_i = -\frac{\partial E}{\partial v_i} = -\sum_{j=1}^{n} w_{ij}\, v_j - \theta_i \tag{4}$$

CHNNs that are used to solve constrained optimization problems have several standard characteristics. Each unit represents a hypothesis; the unit is ON if the hypothesis is true and OFF if the hypothesis is false. The weights are fixed to represent both the constraints of the problem and the function to be optimized. The solution of the problem corresponds to the minimum of the energy function. Each unit's activation evolves so that the energy function decreases.

In the next sections, we illustrate the use of CHNN for constraint satisfaction and constrained optimization, first for a very simple example, and then for the well-known N-queens and TSP problems.

Simple Example

To introduce the use of a CHNN, consider the network shown in Fig. 2, in which it is desired to have exactly one unit ON. The weights must be chosen so that the network dynamics correspond to reducing the energy function.

To have a network that converges to a pattern of activations that solves a specified problem, it is common to design the energy function so that its minimum will be achieved for a pattern of activations that solves the given problem. For this example, the energy function might be formulated as

$$E = \left[1 - \sum_i v_i\right]^2$$

so that its minimum value (0) is achieved when exactly one of the units is ON and the other two units each have activation of zero. Expanding the energy equation

$$E = 1 - 2v_1 - 2v_2 - 2v_3 + v_1^2 + v_1 v_2 + v_1 v_3 + v_2 v_1 + v_2^2 + v_2 v_3 + v_1 v_3 + v_2 v_3 + v_3^2$$

and comparing it with the standard form given in Equation 3, shows that $\theta_i = -2$, and $w_{ij} = 1$. (Note that there is a self-connection on each unit; this does not interfere with the convergence analysis for a CHNN.) The energy function could also be scaled by a positive constant factor, if desired.

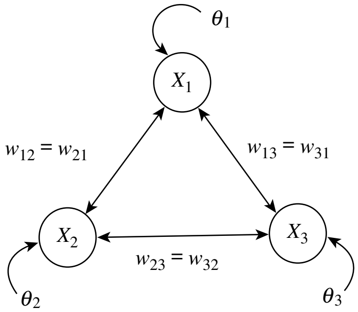

Figure 2. A simple Hopfield network to illustrate the interrelationship between the weights and the energy function.

The differential equations governing the change in the internal activity u_i for each neuron are given by

$$\frac{d}{dt}u_i = -\frac{\partial E}{\partial v_i} = 2[1-(v_1+v_2+v_3)]$$

The *N*-queens Problem

The problem of how to place 8 queens on an 8-by-8 chessboard in mutually nonattacking positions was proposed in 1848, and it has been widely studied since then. It is used as a benchmark for many methods of solving combinatorial optimization problems. In a neural network approach, one neuron is used for each square on the chessboard. The activation of the neuron indicates whether a queen is located on that square. As a queen commands vertically, horizontally, and diagonally, only one queen should be present on any row or column of the board. The arrangement of the neurons for a smaller 5-queens problem is shown in Fig. 3. For simplicity, connection pathways are shown for only one unit. To implement the energy function and evolution equations given below, the units in each row and each column are fully interconnected; similarly the units along each diagonal and each antidiagonal are also fully interconnected (4).

One example of a valid solution to the 5-queens problem is represented by the network configuration in which neurons U_{15}, U_{23}, U_{31}, U_{44}, and U_{52} are ON, and all others are OFF.

The constraints are as follows:

(a) One and only one queen is placed in each row.
(b) One and only one queen is placed in each column.
(c) At most one queen is placed on each diagonal.

An energy function can be constructed for this problem, as follows:

$$\begin{aligned} E = {} & \frac{C_1}{2}\sum_x\sum_i\sum_{j\neq i} V_{xi}V_{xj} + \frac{C_2}{2}\sum_i\sum_x\sum_{y\neq x} V_{xi}V_{yi} \\ & + \frac{C_3}{2}\sum_x\left[\sum_i V_{xi}-1\right]^2 + \frac{C_4}{2}\sum_i\left[\sum_x V_{xi}-1\right]^2 \\ & + \frac{C_5}{2}\sum_x\sum_i\sum_{1\leq x+k;i+k\leq N}(V_{xi}V_{x+k;i+k}) \\ & + \frac{C_6}{2}\sum_x\sum_i\sum_{1\leq x+k;i-k\leq N}(V_{xi}V_{x+k;i-k}) \end{aligned} \tag{5}$$

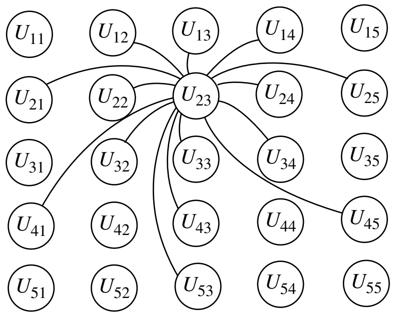

Figure 3. The arrangement of neurons for a 5-queens problem. Connection pathways are shown only for unit U_{23}.

(The inner summation in the last two terms runs over all values of k such that $x + k$ and $i + k$ are both between 1 and N.)

The first constraint is represented by the first and third terms in the energy function; the second constraint is represented by the second and fourth terms in the energy function; and the third constraint is represented by the fifth and sixth terms in the energy function (one term for the diagonal and one for the anti-diagonal).

The corresponding motion equation for unit U_{xi} is

$$\begin{aligned} \frac{dU_{xi}}{dt} = {} & -C_1\sum_{j\neq i}V_{xj} - C_2\sum_{y\neq x}V_{yi} - C_3\left[\sum_i V_{xi}-1\right] \\ & -C_4\left[\sum_x V_{xi}-1\right] - C_5\sum_x\sum_{1\leq x+k;i+k\leq N}V_{x+k;i+k} \\ & -C_6\sum_{1\leq x+k;i-k\leq N}V_{x+k;i-k} \end{aligned} \tag{6}$$

For further discussion of CHNN solutions to this problem, see Refs. 4 and 8.

The Traveling Salesman Problem

The TSP is a well-known example of a class of computationally hard problems for which the amount of time required to find an optimal solution increases exponentially as the problem size increases. In the TSP, every city in a given set of n cities is to be visited once and only once. A tour may begin with any city, and it ends by returning to the initial city. The goal is to find a tour that has the shortest possible length.

With a Hopfield network, the TSP is represented by an n-by-n matrix of neurons in which the rows of the matrix represent cities and the columns represent the position in the tour when the city is visited. For example, if unit U_{24} is ON for the TSP, it indicates that the second city is visited as the fourth stop on the tour. A valid solution is achieved when the network reaches a state of a permutation matrix, i.e., exactly one unit on in each row and each column. The arrangement of the neurons for a five-city TSP is shown in Fig. 4, with connection pathways shown only for unit U_{23}. A widely used energy function for the

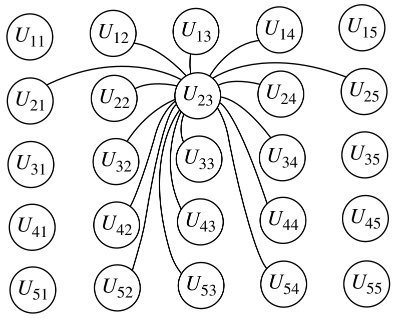

Figure 4. The arrangement of neurons for a five-city traveling salesman problem. Connection pathways are shown only for unit U_{23}.

TSP is

$$E = \frac{C_1}{2}\sum_x\sum_i\sum_{j\neq i}V_{xi}V_{xj} + \frac{C_2}{2}\sum_i\sum_x\sum_{y\neq x}V_{xi}V_{yi} + \frac{C_3}{2}\sum_x\left(\sum_i V_{xi} - 1\right)^2 + \frac{C_4}{2}\sum_i\left(\sum_x V_{xi-1}\right)^2 + \frac{C_5}{2}\sum_x\sum_{y\neq x}\sum_i D_{xy}V_{xi}(V_{y,i+1} + V_{y,i-1}) \qquad (7)$$

The first four terms in the energy function represent the validity constraints: The first term is minimized (zero) if each city is visited at most once. Similarly, the second term is zero if at most one city is visited at each stage in the tour. The third and fourth terms encourage each row and column in the network matrix to have one neuron ON. The fifth term gives the value of the corresponding tour length. This term represents the TSP objective function. It is desired to make its value as small as possible while maintaining the validity of the tour.

To guarantee convergence of the network, the motion dynamics are obtained from the energy function according to the relationship

$$\begin{aligned} du_{xi}/dt &= -\partial E/\partial V_{xi} \\ &= -C_1\sum_{j\neq i}V_{xj} - C_2\sum_{y\neq x}V_{yi} - C_3\left(\sum_j V_{xj} - 1\right) \\ &\quad -C_4\left(\sum_y V_{yi} - 1\right) - C_5\sum_{y\neq x}d_{xy}(V_{y,i+1} + V_{y,i-1}) \end{aligned} \qquad (8)$$

where the internal activation u and the output signal v for any unit are related by the sigmoidal function $v = 0.5\,(1 + \tanh(\alpha\, u))$.

For simulations, each neuron is updated using Euler's first-order difference equation:

$$u_{xi}(t + \Delta t) = u_{xi}(t) + \left(\frac{du_{xi}}{dt}\right)\Delta t$$

The neurons' activations are initialized with random values, and the activations are allowed to evolve according to the governing equations for the network dynamics. The activations are updated iteratively until the network converges; the final configuration of activations gives the network's solution to the TSP.

The choice of network parameters has a significant effect on the quality of solutions obtained. The relative sizes of the coefficients in the energy equation influence the network to either emphasize valid tours (at the expense of tour length) or to seek short tours (which may not be valid). A very steep sigmoid function may force the network to converge quickly (but not necessarily to a good solution), whereas a shallow slope on the sigmoid may result in the final activations not being close to 0 or 1.

Simulation Results. The energy function in the original presentation of a Hopfield network solution of the TSP was given as

$$E = \frac{A}{2}\sum_x\sum_i\sum_{j\neq i}v_{xi}v_{xj} + \frac{B}{2}\sum_i\sum_x\sum_{y\neq x}v_{xi}v_{yi} + \frac{C}{2}\left[N - \sum_x\sum_i v_{xi}\right]^2 + \frac{D}{2}\sum_x\sum_{y\neq x}\sum_i d_{xy}v_{xi}(v_{y,i+1} + v_{y,i-1}) \qquad (9)$$

The third term in this form of the energy function encourages N neurons to be on, but it does not try to influence their location. The original differential equation for the activity of unit U_{xi} was given by

$$\frac{d}{dt}u_{xi} = -\frac{u_{xi}}{\tau} - A\sum_{j\neq i}V_{xj} - B\sum_{y\neq x}v_{yi} + C\left[N - \sum_x\sum_i v_{xi}\right] - D\sum_{y\neq x}d_{xy}(v_{y,i+1} + v_{y,i-1}). \qquad (10)$$

The first term on the right-hand side of this equation is a decay term, which can be motivated by analogy to electrical circuits, but it does not have a corresponding term in the energy equation. The parameter values that Hopfield and Tank used, namely,

$$A = B = 500;\ C = 200, D = 500, N = 15, \alpha = 50, \text{ and } \tau = 1$$

give very little emphasis to the decay term, so the lack of corresponding energy term has relatively little significance. The parameter N must be taken to be larger than the actual number of cities in the problem to counterbalance the continuing inhibitory effect of the distance term; as the minimum of the distance component of the energy function is positive, the corresponding term in Equation (10) acts to try to turn a unit OFF even when there are no constraint violations.

Although Hopfield and Tank (3) reported a very high rate of success in finding valid tours (16/20 trials) with about one half of the trials producing one of the two shortest tours, other researchers have been unable to match these results. The coordinates of the Hopfield and Tank 10-city test problem were generated randomly; the same locations have been used as a benchmark for other neural network solutions. Many variations have been investigated, including alternative energy functions, methods of choosing parameter values, and procedures for setting the initial activations.

Wilson and Pawley (9) provide a detailed statement of the Hopfield–Tank algorithm, together with an analysis of their experiments. Using the Hopfield–Tank parameters, with $\Delta t = 10^{-5}$, they found 15 valid tours in 100 attempts; (45 froze and 40 failed to converge in 1000 epochs).

Wilson and Pawley tried several variations of the Hopfield and Tank algorithm, in attempting to obtain a success rate for valid tours that would approach that achieved by Hopfield and Tank. They experimented with different parameter values, different initial activity configurations, and imposing a large distance penalty for visiting the same city twice, none of which helped much. Fixing the starting city helped on the Hopfield–Tank cities, but not on other randomly generated sets of cities.

One variation that did improve the ability of the net to generate valid tours was a modification of the initialization procedure. The Willshaw initialization is based on the rationale that cities on opposite sides of a square probably should be on opposite sides of tour. The starting activity of each unit is biased to reflect this fact. Cities far from the center of the square received a stronger bias than those near the middle. The formula, in terms of the ith city and jth position, where the coordinates of the ith city are x_i, y_i:

$$\text{bias}(i,j) = \cos\left[\text{atan}\left(\frac{y_i - 0.5}{x_i - 0.5}\right) + \frac{2\pi(j-1)}{n}\right]$$
$$\sqrt{(x_i - 0.5)^2 + (y_i - 0.5)^2}$$

Although special analysis that relies on the geometry of the problem can improve the solution to the actual TSP, it does not generalize easily to other applications.

Issues

Proof of Convergence. For an energy function of the form of Equation (3), the Hopfield net will converge if the activations change according to the differential equation given in Equation (4), as the following simple calculations show. If $v_i = g(u_i)$ is monotonic nondecreasing, then $\dfrac{dv_i}{du_i} \geq 0$. As

$$\frac{dE}{dt} = \sum_i \frac{dv_i}{dt}\frac{\partial E}{\partial v_i} = -\sum_i \frac{dv_i}{dt}\frac{du_i}{dt} = -\sum_i \frac{dv_i}{du_i}\frac{du_i}{dt}\frac{du_i}{dt}$$

the energy is nonincreasing, as required.

In the original presentation of the CHNN (6), the energy function is

$$E = -0.5\sum_{i=1}^{n}\sum_{j=1}^{n} w_{ij} v_i v_j - \sum_{i=1}^{n} \theta_i v_i + \frac{1}{\tau}\sum_{i=1}^{n}\int_0^{v_i} g_i^{-1}(v)\, dv$$

If the weight matrix is symmetric and the activity of each neuron changes with time according to the differential equation:

$$\frac{d}{dt}u_i = -\frac{u_i}{\tau} + \sum_{j=1}^{n} w_{ij} v_j + \theta_i \qquad (11)$$

the net will converge. The argument is essentially the same as above.

Note that the weights must be symmetric for the equations given here to be valid. This symmetry follows from the fact that connections in a standard Hopfield are bidirectional; i.e., the connection from unit i to unit j, and the connection from unit j to unit i are the same connection. Results for asymmetrical Hopfield networks are discussed below.

Choice of Coefficients. The relative importance assigned to each of the terms in the energy function plays a very important role in determining the quality of the solutions obtained. A variety of experimental investigations into the appropriate coefficients have been reported. Theoretical results have also been obtained; the choice of energy function coefficients is discussed further in the section on recent developments.

Local Minima. One shortcoming of the CHNN, as with any optimization procedure that always moves in the direction of improving the solution, is convergence to a local optima that is not the global optimum. A Boltzmann machine incorporates a simulated annealing process into the updates, so that early in the iterations, each unit has a fairly high probability of not updating its activation in the manner dictated by the equations given for the DHNN. As the iterations progress, the "temperature" of the network is reduced, and at a lower temperature, the units become more closely controlled by the updating equations (10,11).

RECENT DEVELOPMENTS

Hopfield neural networks are being used for applications in many areas. Recent developments of both theoretical and practical importance can be found in journals such as *Neural Information Processing—Letters and Reviews* and *IEEE Transactions on Neural Networks*, or in conference proceedings, either for meetings that focus on neural network applications or for gatherings of researchers in a particular specialty. In the next sections, we consider some directions in which the basic Hopfield neural network model is being generalized. Methods of adapting the weights in HNN, both for CAM and for optimization problems, are being developed. Investigation into HNN with nonsymmetric weights is giving theoretical results for conditions under which such a network are guaranteed to converge. Research also continues into the determination of the storage capacity of the DHNN.

Adaptive Weights

Much of the neural network research has focused on networks in which either the activities of the neurons evolve or the strengths of the synapses (weights) adapt, but not both. However, a complete model of a biological process requires dynamical equations for both to specify the behavior of the system. On the other hand, applications of Hopfield networks to constrained optimization problems repeatedly illustrate the importance and difficulty of determining the proper weights to assure convergence to a good solution. Progress is being made in both of these areas.

Learning Patterns. Dong (12) has developed an energy function for a system in which both activations and weights are adaptive and has applied it to the study of the development of synaptic connection in the visual cortex. His dynamical equations for the activity of the neurons are essentially the same as given in Equation (11). The adaptation of the weights follows a differential form of Hebbian learning, based on the "recent" correlation of the activities of the neurons that are on either end of the weighted pathway; this leads to Hebbian learning with a decay term. The weights remain symmetric throughout the process, so that the convergence analysis follows an energy function approach as described previously.

As a simple example, consider two neurons and the weight w on the connection path between them. Dong's dynamical equations for this illustrative special case are as follows:

$$\begin{aligned} a\frac{du_1}{dt} &= -u_1 + w\,v_1 \\ a\frac{du_2}{dt} &= -u_2 + w\,v_2 \\ v &= f(g\,u) \\ b\frac{ds}{dt} &= -s + v_1 v_2 \\ w &= f(h\,s) \end{aligned}$$

The function f is piecewise linear, with a range between -1 and 1; i.e., $f(x) = -1$ if $x \le -1$, $f(x) = x$ if $-1 < x < 1$, $f(x) = 1$ if $x \ge 1$.

The energy function is

$$E(v_1, v_2, w) = -w\,v_1\,v_2 + \frac{1}{2g}v_1^2 + \frac{1}{2g}v_2^2 + \frac{1}{2h}\,w^2$$

The origin (0, 0, 0) is a stable point, corresponding to unlearned connections and no neuron activity. If the constants g and h are greater than 1, the configurations (1, 1, 1), (-1, -1, 1), (1, -1, -1), and (-1, 1, -1) are stable points. Each of these configurations has the property, which holds in general for stable points, that the weight on the connection is sign($v_i v_j$). The training of the network is conducted by presenting each pattern to be learned as the external input signal for a brief period of time and cycling through the patterns until the weights have converged. The behavior of the system during learning depends on the strength of the external input to the system relative to the size of the weights between neurons. When the input signals dominate, the network can learn several input patterns; for weaker input signals, the network ultimately chooses only one of the patterns to memorize. These ideas provide the basis for a model of the first stage of cortical visual processing in mammals.

Constrained Optimization. The appropriate choice of the weights in a Hopfield net for constrained optimization has been the subject of much experimental work. It is well known that using larger values for the coefficients of the constraint terms helps guide the network toward valid solutions, but it may result in poor quality solutions. On the other hand, increasing the value of the coefficient of the objective term helps to improve the quality of a solution, but it may result in an invalid solution because of a constraint violation.

Recently, Park and Fausett (8) introduced a method for determining the coefficients of the energy function (and thereby the weights) adaptively as the network evolves. As the network evolves in the direction of minimization of the total energy, each term in the energy function competes with the other terms to influence the path to be followed. To find good coefficients for the energy function, the components of the energy are monitored, and the coefficients are adapted, depending on how far each component of the energy function is to its goal (minimum value), until a balanced relationship among the coefficients is reached. Using a steepest ascent procedure with normalization, the coefficients are updated after every epoch of iteration until they reach a state of near equilibrium. Although this approach may seem counter-intuitive at first, it has the desired effect of increasing the coefficients of those terms that are contributing the most to the value of the energy function. It is those terms that most need to be reduced during network iteration. The final coefficient values are used to set the weight connections, and the network is run again to solve the problem.

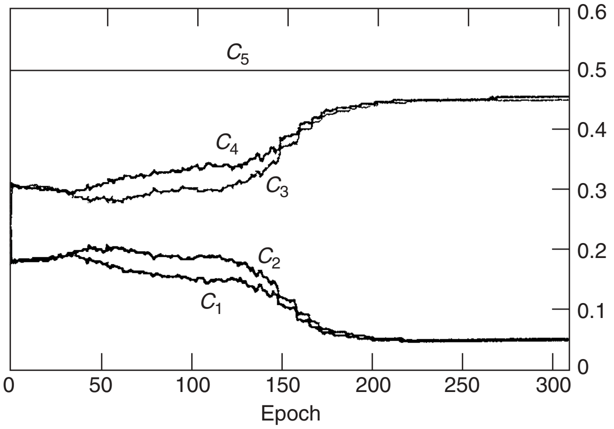

Figure 5. Evolution of coefficients on the constraint terms of the TSP; coefficient C_5 = 0.5.

A sample of the coefficient evolution for the 10-city TSP is illustrated in Fig. 5. In this example, the coefficient of the objective term (representing tour length) in the energy function is fixed as $C_5 = 0.5$; the other coefficients (on the constraint terms) evolve subject to the restriction that $C_1 + C_2 + C_3 + C_4 = 1$. When the network was rerun with the converged coefficients, 94% of the trials resulted in valid tours; the length of the generated tours ranged from 2.69 to 3.84, with a mean length of 2.83. The efficacy of this method is even more striking on larger problems. Although the results vary depending on the choice of the fixed value for the coefficient of the objective term, 20-city and 30-city problems (generated in a manner similar to that used by Hopfield and Tank for the 10-city problem) were successfully solved, with a high rate of valid solutions, for C_5 in the range of 0.2 to 0.5.

Storage Capacity

Another area of active research for Hopfield networks used as CAM is the storage capacity of the network. Many investigations are based on the assumption that the patterns are random (independent, identically distributed uniform random variables). The question is, how many patterns (vectors with components of $+1$ or -1) can be stored and retrieved (from a minor degradation of a stored pattern); a small fraction of errors may be allowed in the retrieved pattern. Hopfield suggested, based on numerical simulations, that P, the number of patterns that can be stored and retrieved, is given by $P = cn$, with $c = 0.15$.

More recently, martingale techniques have been applied (13) to a different joint distribution of the spins (patterns), extending the theoretical results to situations beyond those investigated previously (7). Assuming that the patterns have the same probability distribution, are orthogonal in expectation, and are independent, Francois shows that there are energy barriers (which depend on d, the acceptable fraction of errors in the reconstructed pattern) surrounding each memorized pattern. For almost perfect recall ($d = 1/n$), the storage capacity can be as large as $c = [2(1 + g) \ln n]^{-1}$ with $g > 2$. Other researchers have studied the effect of a noisy environment on the convergence of the network (13).

Stability Results

Investigations into the stability of more general Hopfield-type models have considered asynchronous updates for a continuous-valued, discrete-time Hopfield model (14). In general, stability arguments rely on sophisticated mathematical theory and are not easily summarized in a brief presentation.

One approach to the investigation of asynchronous updates is based on the Takeda–Goodman synchronous model:

$$x(k+1) = TF(x(k)) + (I - B)\,x(k) + u$$

where T is the interconnection matrix of the neural network (usually assumed symmetric), F is a diagonal nonlinear function (usually assumed monotonic, often sigmoidal), and u is a vector of inputs (assumed constant). With a few additional assumptions, the previous stability results have been extended by considering a class of desynchronizations (15).

Asymmetric Weights

The stability of asymmetric Hopfield networks is of practical interest, both for more general models (e.g., connectionist expert systems) and for the implementation of theoretically symmetric networks (because it is almost impossible to preserve the symmetry of the connections exactly in hardware).

Many results for nonsymmetric connections depend on the absolute value of the weights; however, these may be overly restrictive. For example, if $w_{ij} = -\,w_{ji}$ for all i, j, the network is absolutely stable, but results relying on absolute value considerations will not establish the fact. It has also been shown that if the largest eigenvalue of $\mathbf{W} + \mathbf{W}^T$ is less than 2, then the network is absolutely stable. A more convenient corollary of this result is that if

$$\sum_{i;j} (w_{ij} + w_{ji})^2 < 4$$

then the network is absolutely stable (16).

To study computational models based on asymmetric Hopfield-type networks, a classification theory for the energy functions associated with Hopfield networks has been introduced and convergence conditions deduced for several different forms of asymmetric networks. For example, two networks have been developed, using a triangular structure, to solve the maximum independent set of a graph problem. Although this problem can be solved with a standard Hopfield network, the triangular network is a more simple and efficient procedure. See Ref. 17 for details.

SUMMARY AND CONCLUSIONS

Hopfield neural networks comprise a rich and varied realm of the overall field of artificial neural networks. Applications can be found in many areas of engineering. Continuing investigation into the theoretical and practical considerations governing the convergence properties of the networks provides a firm foundation for the use of Hopfield models and their extension to more generalized settings. Work continues on differences in performance that may occur when the networks are implemented with fully parallel (asynchronous) updating of the activations.

INTELLIGENT AGENT

INTRODUCTION

“Agent” has different meanings in different contexts. In many dictionaries, there are about 10 items listed for “agent.” In computer science, an agent is referred to as a program that acts on a user or other programs, which is akin to its original meaning in dictionaries. If an agent can demonstrate some special features like learning, reasoning, and decision making, it may be called an intelligent agent. This article tries to provide an insight into what intelligent agent is for general readers in the context of computer science in general and artificial intelligence in particular.

The concept of agent can be traced back to the 1980s in the computer science and artificial intelligence communities. Agent systems are evolved from distributed artificial intelligence and distributed problem solving as well as parallel artificial intelligence (1). However, there is still no universally accepted definition of the term “agent.” One definition, which is adopted from Ref. 2, is attracting more and more attention. This definition states that, an intelligent agent is a computer system that is situated in some environment, and that is capable of autonomous action in this environment in order to meet its design objectives. This definition implies that the agent possesses the following minimal characteristics (30):

- Autonomy: Agents operate without the direct intervention of humans or others and have some kinds of control over their internal states.
- Social ability: Agents interact with other agents (and possibly humans) via some kinds of agent communication languages.
- Reactivity: Agents perceive their environment and respond in a timely fashion to changes that occur in it.
- Proactivity: Agents do not simply act in response to their environment; they can exhibit goal-directed behavior by taking the initiative.

Multiagent systems are systems composed of multiple interacting agents. Agents (adaptive or intelligent agents and multiagent systems) constitute one of the most prominent and attractive technologies in computer science at the beginning of this new century. Agent and multiagent system technologies, methods, and theories are currently contributing to many diverse domains. These domains include information retrieval, user interface design, robotics, electronic commerce, computer-mediated collaboration, computer games, education and training, smart environments, ubiquitous computers, and social simulation.

This technology, is not only very promising but also emerging as a new way of thinking, a conceptual paradigm for analyzing problems and for designing systems, for dealing with complexity, distribution, and interactivity, and perhaps a new perspective on computing and intelligence.

Agent-based computing has been a source of technologies to several research areas, both theoretical and applied. These areas include distributed planning and decision making, automated auction mechanisms, and learning mechanisms. Moreover, agent technologies have drawn from, and contributed to, a diverse range of academic disciplines, in the humanities, the sciences, and the social sciences. The fundamental research issues in agent technologies include multiagent planning, agent communication languages, coordination mechanisms, matchmaking architectures and algorithms, information agents and basic ontologies, sophisticated auction mechanism design, negotiation strategies, and learning.

Agent technologies are a natural extension of current component-based approaches and have the potential to greatly impact the lives and work of all of us. Accordingly, this area is one of the most dynamic and exciting in computer science today. Some application domains where agent technologies will play a crucial role, including (4,5) *Ambient Intelligence,* the seamless delivery of ubiquitous computing, continuous communications, and intelligent user interfaces to consumer and industrial devices; *Grid Computing*, where multiagent system approaches will enable efficient use of the resources of high-performance computing infrastructure in science, engineering, medical, and commercial applications; the *Semantic Web*, where agents are needed both to provide services and to make best use of the resources available, often in cooperation with others; and *Self-* and Autonomic Computing*: To configure and maintain complex computer systems, including IT infrastructure, it is highly required that those systems have self-awareness, self-organization, self-configuration, self-management, self-diagnosis, self correction, and self-repair capabilities. These self-* systems can be viewed as autonomous entities and components with interactions, which provides an application domain for research and development of agent technologies. In addition to these areas agent technologies will also be used in other fields like peer-to-peer computing, computational biology and bioinformatics, web services, and so on.

There are many different views about intelligent agents or multiagent systems. Two principal views are as follows: (1) agents as a paradigm for software engineering; and (2) agents as a tool for understanding human societies (6).

Software engineers have derived a progressively better understanding of the characteristics of complexity in software. It is now widely recognized that *interaction* is probably the most important characteristic of complex software. It is believed that, in the future, computation will be understood chiefly as a process of interaction. Just as we can understand many systems as being composed of essentially passive objects, which have a state and upon which we can perform operations, so we can understand many others as being made up of interacting, semiautonomous agents. This recognition has led to the growth of interest in agents as a new paradigm for software engineering.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

There are far too many variables and unknown quantities in human societies. We can do little about it such as predicting very broad but short-term trends, and even then the process is full of many errors. However, multiagent systems do provide an interesting and novel tool for simulating societies, which may help shed some light on various kinds of social processes.

There are a number of similarities between the object- and agent-oriented views of system development. For example, both emphasize the importance of interactions between entities. However, there are also significant differences between agents and objects (6–8).

- Agents embody a stronger notion of autonomy than objects, and in particular, they decide for themselves whether to perform an action on request from other agents.
- Agents are capable of flexible (reactive, proactive, social) behavior, and the standard object model has nothing to say about such types of behavior.
- A multiagent system is inherently multithreaded, in that each agent is assumed to have at least one thread of control.

Expert systems were the most important artificial intelligence technology of the 1980s. An expert system is one that is capable of solving problems or giving advice in some knowledge-rich domain. The main differences between agents and expert systems are as follows (6):

- Classic expert systems are disembodied—they are not coupled to any environment in which they act, but rather act through a user as a "middleman."
- Expert systems are not generally capable of reactive, proactive behavior.
- Expert systems are not generally equipped with social ability, in the sense of cooperation, coordination, and negotiation.

This article presents a tutorial overview of the field of intelligent agents in brief. Related issues are discussed, which include agent architecture, agent communication languages, agent-oriented software engineering, agent development tools, challenge issues in agent technologies, and so on.

ARCHITECTURES OF INTELLIGENT AGENTS

A wide range of system architecture exists for intelligent agents. This section introduces some representative architectures for intelligent agents, which include the BDI architecture (for individual agents) and open agent architecture (for multiagent systems).

BDI Architecture

The architecture for individual agents can be classified into three classes: deliberative, reactive, and hybrid agent architecture.

Deliberative agents assume an explicit symbolic model of the environment and the capability of logical reasoning as a basis for intelligent actions, and so they maintain the tradition of classic artificial intelligence. The modeling of the environment is normally performed in advance and forms the main component of the agent's knowledge base. Deliberative agents have as a second significant property, in addition to their internal symbolic environment model, their capability to make logical decisions. The agent, as part of the decision-making process, uses the knowledge contained in its model to modify its internal state. This internal state is the mental state and is composed of three components: belief, desire, and intention (BDI).

The procedural reasoning system (PRS) (9) was perhaps the first agent architecture to explicitly embody the BDI paradigm and has proved to be the most durable agent architecture developed to date. The PRS is often referred to as a BDI architecture, which is shown in Fig. 1.

Beliefs contain the fundamental views of an agent with regard to its environment. An agent uses them, in particular, to express its expectations of the possible future states. Desires are derived directly from beliefs. They contain an agent's judgments of future situations. Goals represent that a subset of an agent's desires on whose fulfillment it could act. In contrast to its desire, an agent's goal must be realistic and must not conflict with each other. Intentions are a subset of the goals. If an agent decides to follow a specific goal, this goal becomes an intention. Plans combine an agent's intentions into consistent units. There is a close connection between intentions and plans: Intentions constitute the subplans of an agent's overall plan, and, conversely, the set of all plans reflects the agent's intentions. The BDI model comes from research done in the field of artificial intelligence especially in common sense reasoning and planning over the past 20 years and has proven to be the most robust and flexible model for intelligent agent systems.

Several logical theories of BDI systems have been developed. Closely related to this work on BDI architectures is Shoham's proposal for *agent-oriented programming*, which is a multiagent programming model in which agents are explicitly programmed in terms of mentalistic notions such as belief and desire (10).

The best-known reactive agent architecture is the *subsumption architecture* (11). There are two defining characteristics of the subsumption architecture: (1) An agent's

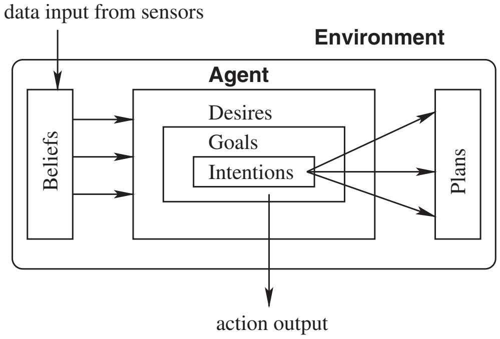

Figure 1. BDI architecture.

decision making is realized through a set of *task-accomplishing behaviors*, and (2) many behaviors can "fire" simultaneously.

For most problems, neither a purely deliberative architecture nor a purely reactive architecture is appropriate. Hybrid architectures are required, which are typically realized as a number of vertical or horizontal software layers. A typical example of hybrid agent architectures is InteRRaP (12).

Open Agent Architecture

Open agent architecture (OAA) developed by the SRI (Stanford Research Institute) is a research framework for constructing multiagent systems (13). This architecture makes it possible for software services to be provided through the cooperative efforts of distributed collections of autonomous agents. Communication and cooperation between agents are brokered by one or more *facilitators*, which are responsible for matching requests, from users and agents, with descriptions of the capabilities of other agents. Thus, it is not generally required that a requester (user or agent) know the identities, locations, or the number of other agents involved in satisfying a request. Facilitators are not viewed as centralized controllers, but rather as *coordinators*, as they draw on knowledge and advice from several different, potentially distributed, sources to guide their delegation choices.

OAA is structured so as to minimize the effort involved in creating new agents and "wrapping" legacy applications, written in various languages and operating on various platforms; to encourage the reuse of existing agents; and to allow for dynamism and flexibility in the makeup of agent communities. Distinct features of OAA as compared with related work include extreme flexibility in using facilitator-based delegation of complex goals, triggers, and data management requests; agent-based provision of multimodal user interfaces; and built-in support for including the user as a privileged member of the agent community.

COMMUNICATION LANGUAGES FOR INTELLIGENT AGENTS

Typically, applications containing multiple agents make use of an agent communication language (ACL); the idea is similar to a human society using a common language such as English. However, it is noted that agent-based applications can be (and have been) developed using traditional third-generation languages like Lisp, C, or Prolog and object-oriented languages such as Java, C++, and Smalltalk. Next, agents working together need to share a certain amount of foundational, "common" knowledge called *ontology* (14), in just the same way that humans do. There are also some current and emerging computing technologies such as client/server model and CORBA that lend themselves to supporting agent-based applications.

The two agent communication languages with broadest uptake are KQML (Knowledge Query and Manipulation Language) (15) and FIPA ACL (16). The most important difference between the two languages is in the collection of performatives they provide.

KQML was developed in the early 1990s as part of the U.S. government's ARPA Knowledge Sharing Effort and is a language and protocol for exchanging information and knowledge, which has been used extensively. KQML was conceived as both a message format and a message-handling protocol to support run-time knowledge sharing among agents. The KQML language can be thought of as consisting of three layers: the *content* layer, the *message* layer, and the *communication* layer. The content layer bears the actual content of message, in the program's own representation language. The communication layer encodes a set of message features that describes the lower level communication parameters, such as the identity of the sender and recipient, and a unique identifier associated with the communication. It is the message layer that is used to encode a message that one application would like to transmit to another. The message layer forms the core of the KQML language and determines the kinds of interactions one can have with a KQML-speaking agent. Each KQML message has a *performative* and a number of *parameters*. Here is an example of a KQML message:

```
(ask-one
   :content (PRICE IBM ?price)
   :receiver stock-server
   :language LPROLOG
   :ontology NYSE-TICKS
)
```

In 1995, the Foundation for Intelligent Physical Agent (FIPA) began its work on developing standards of agent systems. The centerpiece of this initiative was the development of an ACL. This ACL incorporates many aspects of KQML. It defines 20 performatives for defining the intended interpretation of messages, and it does not mandate any specific language for message content. The concrete syntax for FIPA ACL messages closely resembles that of KQML. Here is an example of a FIPA ACL message:

```
(inform
   :sender agent1
   :receiver agent2
   :content (price good2 150)
   :language si
   :ontology hpl-auction
)
```

If two agents are to communicate about certain domain, then it is necessary for them to agree on the *terminology* that they use to describe this domain. For example, in an agent system for financial investment planning, one agent advertises its capability to a middle agent as "pattern watcher in the *stock* market," whereas another agent requests an agent that is a "pattern watcher in the *share* market." In such a situation, problems arise when the middle agent tries to match them. How could the middle agent know the "*stock* market" and the "*share* market" are the same thing? The agents thus need to be able to agree on what terms like *share* or *stock* mean. Thus a specification of a set of terms, an *ontology*, is required. An ontology is a formal definition of a body of knowledge. The most typical type of ontology used in building agents involves a structural component. Essentially a taxonomy of class and subclass relations coupled with definitions of the relationships between these things.

METHODOLOGIES AND DEVELOPMENT TOOLS FOR INTELLIGENT AGENTS

Existing software development techniques (for example, object-oriented analysis and design) are inadequate for analyzing and designing agent systems. There is a fundamental mismatch between the concepts used by other mainstream software engineering paradigms and the agent-oriented perspective. In particular, extant approaches fail to adequately capture an agent's flexible, autonomous problem-solving behavior, the richness of an agent's interactions, and the complexity of an agent system's organizational structure. This section provides an overview of the state of the art in agent-oriented software engineering and a summary of currently available agent development tools.

A *methodology* is a codified set of procedures for some phases of software engineering, such as analysis and design. A system engineering methodology groups the methods and principles used in a particular discipline. A *method* is a systematic way of doing something or, alternatively, the techniques or arrangements of work for a particular subject.

Software Engineering with Agents, Agent-Based Software Engineering, Multiagent Systems Engineering (MaSE), and *Agent-Oriented Software Engineering* (AOSE) are semantically equivalent terms, but *MaSE* refers to a particular methodology and *AOSE* seems to be the most widely used term. In AOSE, there are some preliminary *methodologies* for engineering multiagent systems—these methodologies provide structured but nonmathematical approaches to the analysis and design of agent systems. These can be broadly divided into two groups:

Those that take their inspiration from object-oriented development, and either extending object-oriented methodologies or adapt object-oriented methodologies to the purposes of AOSE. Representatives of this category include the AAII methodology (17) and the Gaia methodology (18,19).

Those that adapt knowledge engineering or other techniques. One representative in this category is the use of *Z* for specifying agent systems (20).

The AAII methodology draws primarily on object-oriented methodologies and enhances them with some agent-based concepts. The methodology is aimed at the construction of a set of models that, when fully elaborated, define an agent system specification. The AAII methodology provides both *internal* and *external* models. The external model presents a system-level view: The main components visible in this model are agents themselves. The external model is thus primarily concerned with agents and the relationships between them. In contrast, the internal model is entirely concerned with the internals of agents: their beliefs, desires, and intentions.

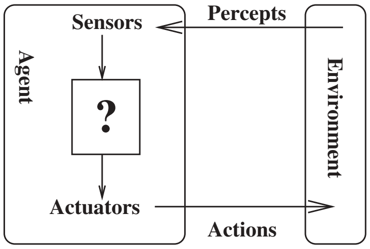

Figure 2. Agents and environments.

The Gaia methodology is intended to allow an analyst to go systematically from a statement of requirements to a design that is sufficiently detailed that it can be implemented directly. In applying Gaia, the analyst moves from abstract to increasingly concrete concepts. Figure 2 shows that agents interact with environments through sensors and actuators, which is adopted from Ref. (21) (page 33). Gaia methodology is well matched with this view of agents. In Gaia, a set of new organizational abstractions that are necessary for designing and constructing systems in complex and open environments are employed. These organizational abstractions, which can be used in the analysis and design phases, include the *environment* in which a multiagent system is situated; the *roles* that have to be played in the agent organization and of their interactions, and the organizational rules and organizational structures. Based on Gaia, the emphasis of the analysis and design is to identify the *environment* that the agent system is situated, the key *roles* in the system and document the various *agent types* that will be used in the system.

In agents in *Z*, a four-tiered hierarchy of the entities that can exist in an agent-based systems is defined. It starts with *entities*, and then *objects* to be entities that have capabilities are defined. *Agents* are then defined to be objects that have goals and are thus in some sense active. Finally, *autonomous agents* are defined to be agents with motivations. The formal definitions of agents and autonomous agents rely on inheriting the properties of lower level components. In the *Z* notation, this is achieved through schema inclusion.

In addition to these representatives, there are also some methodologies for modeling agent systems based on UML notations as well as some formal methods for engineering multiagent systems.

There are dozens of agent construction tools. The tools are categorized as either commercially available products or academic and research projects. The representatives are listed in Table 1.

When building agent systems, certain techniques are required to convert legacy programs into agents. Generally, there are three principal approaches to be taken: implementing a *transducer*, implementing a *wrapper*, and *rewriting* the original programs (22).

Table 1. Agent Construction Tools

Product	Company/ Research Organization	Commercial/ Academic	Language	Description
AgentBuilder	Reticular Systems, Inc.	Commercial	Java	Integrated Agent and Agency Development Environment
Aglets	IBM Japan	Commercial	Java	Mobile Agents

TYPICAL APPLICATIONS OF INTELLIGENT AGENTS

Agent technology is rapidly breaking out of universities and research laboratories, and is used to solve real-world problems in a range of industrial and commercial applications. Some of the key systems are outlined below (7).

- YAMS system. YAMS (Yet Another Manufacturing System) applies the well-known Contract Net Protocol to manufacturing control. YAMS adopts a multiagent approach, where each factory and factory component is represented as an agent. Each agent has a collection of plans, representing its capabilities. The contract net protocol allows tasks to be delegated to individual factories, and from individual factories down to flexible manufacturing systems, and then to individual work cells.
- OASIS Air Traffic Control System. OASIS is a sophisticated agent-realized air traffic control system, which is undergoing field trials at Sydney airport in Australia. In this system, agents are used to represent both aircraft and the various air-traffic control systems in operation. The agent metaphor thus provides a useful and natural way of modeling real-world autonomous components. As an aircraft enters Sydney airspace, an agent is allocated for it, and the agent is instantiated with the information and goals corresponding to the real-world aircraft. OASIS is implemented using the typical BDI architecture.
- Maxims. Maxims is an electronic mail filtering agent that "learns to prioritize, delete, forward, sort, and archive mail messages on behalf of a user." It works by "looking over the shoulder" of a user as he or she works with their e-mail reading program and uses every action the user performs as a lesson. Maxims constantly makes internal predictions about what a user will do with a message. If these predictions turn out to be inaccurate, then Maxims keeps them to itself. But when it finds it is having a useful degree of success in its predictions, it starts to make suggestions to the user about what to do.
- The WARREN financial portfolio management system. WARREN is a multiagent system that integrates information finding and filtering in the context of supporting users to manage their financial portfolios. The system consists of agents that coop eratively self-organize to monitor and track stock quotes, financial news, financial analysts reports, and company earnings reports in order to appraise the portfolio owner of the evolving financial picture. The agents not only answer relevant queries but also continuously monitor available information resources for the occurrence of

interesting events and alert the portfolio manager agent or the user.

To date, the main areas in which agent-based applications have been reported include manufacturing, process control, telecommunication systems, air traffic control, traffic and transportation management, information filtering and gathering, electronic commerce, business process management, entertainment, and medical care. In addition to these existing areas, there are a number of emerging application domains for agent technologies and multiagent systems (4,5). Several of these domains are presented here to demonstrate their wide range and diversity. They indicate the potential impact of agent-related technologies on human life and society. More details can be found in Refs. (4) and (5).

- *Ambient Intelligence* (23). Ambient intelligence represents a vision of the future where we shall be surrounded by electronic environments that are sensitive and responsive to people. Ambient intelligence technologies are expected to combine concepts of ubiquitous computing and intelligent systems putting humans in the centre of techno logical developments. Ambient Intelligence emphasizes greater user-friendliness, more efficient services support, user-empowerment, and support for human interac tions. It builds on three recent key technologies: ubiquitous computing, ubiquitous communication, and intelligent user interfaces; yet it offers perhaps the strongest motivation for, and justification of, agent technologies. The consensus is that auton omy, distribution, adaptation, responsiveness, and so on, are the key characterizing features of ambient intelligent artfacts, and in this sense, they share the same char acteristics as agent.
- *Bioinformatics and Computational Biology* (24). One application of multiagent systems in the biological sciences is for simulation modeling of biological systems, in a manner similar to their use for the simulation of socioeconomic and public policy domains. Another area of application in biology is in bioinformatics. The genomic revolution that has spawned microarrays and high throughout technologies has produced vast amounts of complex biological data that require in tegration and multidimensional analysis. Information-gathering agents can help human researchers in finding appropriate research literature or in conducting auto mated or semiautomated testing of data. Data mining agents can be used to do the integration and multidimensional analysis. A potential longer term application of multiagent systems technologies is the use of agents engaged in a reasoned argument to achieve resolution about ambiguous or conflicting experimental evidence, in a manner similar to the way in which human scientists do currently.
- *Grid Computing* (25). Managing access to computing and data resources is a com plex and time-consuming task. As grid and cluster computing matures, deciding which systems to use, where the data reside for a particular application domain, how to migrate the data to the point of computation (or vice versa), and data rates required to maintain a particular application "behavior" become significant. To support these systems it is important to develop brokering approaches based on intelligent techniques—to support service discovery, performance management, and data selection. Intelligent agents provide a useful means to achieve these objectives. An important and emerging area within grid computing is the role of service ontologies—especially domain-specific ontologies, which may be used to capture particular application needs. Using these ontologies, scientists may be able to share and disseminate their data and software more effectively. This has been recognized as being important, and current efforts toward establishing "semantic grids" is a useful first step in this direction. The agent community on the other hand can find grid environments useful testbeds to deploy agents on a large scale. Often, within the multiagent community, agents are restricted to a few 10 s of agents, and often agents undertake identical tasks. To support grid computing, agents can offer different roles, be organized into regional or national dynamic "groups," and be able to migrate between groups to support load balancing. Therefore agents could play an important role in grid computing, and grid computing can offer useful testbeds for investigating agent services. The grid is not only a low-level infrastructure for supporting computation, but it can also facilitate and enable information and knowledge sharing at the higher semantic levels, to support knowledge integration and dissemination.
- *Electronic Business* (20). The continuing growth of electronic business puts high demands on the underlying technology and infrastructure. Decentralization and flexibility of the information and communication systems are of concern. Agent technology—especially the mobility, autonomy, and intelligence of agents—offers a promising approach in these directions. Even though the notion of "intelligent agent" has been stressed over the last years and many questions like security have remain unanswered, electronic commerce poses new challenges and opportunities for agents. To date agents have been used in the first stages of ecommerce, product and merchant discovery, and brokering. The next step will involve moving into real trading—negotiating deals and making purchases. This stage will involve considerable research and development, including generating new products and services such as market-specific agent shells, payment and contracting methods, risk assessment and coverage, quality and performance certification, security, trust, and individual-ization.

In addition to these domains, agent-oriented perspectives are well suited for constructing hybrid intelligent systems (27). Solving complex problems in real-world contexts, such as financial investment planning or mining large data collections, involves many different subtasks, each of which requires different techniques. To deal with such problems, a great diversity of intelligent techniques are available, including traditional techniques like expert systems approaches and soft computing techniques like fuzzy logic, neural networks, or genetic algorithms. These techniques are complementary approaches to intelligent information processing rather than competing ones, and thus, better results in problem solving are achieved when these techniques are combined in hybrid intelligent systems. Multiagent systems are ideally suited to model the manifold interactions among the many different components of hybrid intelligent systems.

TECHNOLOGICAL CHALLENGES

There are a number of broad technological challenges for research and development over the next decade. These are summarized as follows based on the descriptions in Refs. 4 and 5.

- **Increase quality of agent software to industrial standard**. One of the most fundamental obstacles to large-scale take-up of agent technology is the lack of mature software development methodologies for agent-based systems. Clearly, the basic principles of software and knowledge engineering need to be applied to the development and deployment of multiagent systems, but they also need to be augmented to suit the differing demands of this new paradigm. Technology examples include agent- oriented design methodologies, tools and development environments, and seamless integration with current technologies.
- **Provide effective agreed standards to allow open systems development**. In addition to standard languages and interaction protocols, open agent societies will require the ability to collectively evolve languages and protocols specific to the application domain and to the agents involved. Research in this area will draw on linguistics, social anthropology, biology, the philosophy of language, and information theory. Technology examples contain agent communication language, interaction protocols, and multiagent architectures.
- **Provide semantic infrastructure for open agent communities**. To make information agents widely available in real-world applications, a greater understand ing of how agents, databases, and information systems interact is required. This also demands new Web standards that enable structural and semantic description of information. The creation of common ontologies, thesaurus, or knowledge bases play a central role here.
- **Develop reasoning capabilities for agents in open environments**. The next challenge for agent-based computing is to develop appropriate representations of analogous computational concepts to the norms, legislation, authorities, enforcement, and so on, which can underpin the development and deployment of dynamic electronic institutions. The automation of coalition formation can save time and labor and is more effective at finding better coalitions than humans in complex settings. Related issues include negotiation and argumentation and domain-specific models of reasoning.
- **Develop agent ability to understand user requirements**. At the architecture level, future avenues for learning research include developing distributed models of profile management, as well as more general distributed agent learning techniques rather than just single agent learning in multiagent domains. Developing approaches to personalization that can operate in a standards-based, pervasive computing en vironment presents many interesting research challenges, including how to integrate machine learning techniques (for profile adaptation) with structured XML-based profile representations. Another area deserving of greater activity is that of dis tributed profile management—a task for which the agent-based paradigm should be well suited. The impact of the emerging semantic Web on approaches for wrapper induction and text-mining also requires careful study.
- **Develop agent ability to adapt to changes in environment**. Learning tech nology is crucial for open and scalable multiagent systems, but it is still in early development. Many agent research areas have been looking mainly at nonadaptive technology. However, with increasing maturity of these areas, learning techniques will increasingly move toward the center stage in these areas. Examples of areas where learning will receive more attention in the future are communication, negoti ation, planning and coordination, and information and knowledge management.
- **Trust and reputation management**. Collaboration of any kind, especially in situations in which computers act on behalf of users or organizations, will only succeed if there is trust. To ensure this trust requires a variety of factors to be in place. First, a user must have confidence that an agent or a group of agents that represents them within an open system will act effectively on their behalf. Second, agents must be secure and tamperproof and must not reveal information inappropriately. Finally, if users are to trust the outcome of an open agent system, they must have confidence that agents representing other parties or organizations will behave within certain constraints. Mechanisms to do this include reputation mechanisms; the use of norms (social rules) by all members of an open system; and self- enforcing protocols, which ensure that it is not in the interests of any party to break them; and electronic contracts.
- **Virtual organization formation and management**. Virtual organizations have been identified as one of the key contributions of grid computing, but the conditions under which a new virtual organization should be formed, and the procedures for its formation, operation, and dissolution are still not well defined. In current grid applications, virtual organizations are statically defined by the users of the workflows, which mean that they are incapable of handling dynamic situations and reconfiguring themselves in

an automated manner. This automated formation and ongoing management of virtual organizations in open environments thus constitutes a major research challenge, a key objective of which is to ensure that they are both agile (can adapt to changing circumstances) and resilient (can achieve their aims in a dynamic and uncertain environment).

CONCLUSIONS

This article is mainly focused on the technology view of intelligent agents. Actually, intelligent agents are becoming a computing paradigm. In Ref. 21, Russell and Norvig define artificial intelligence as the study of agents that perceive the environments and take actions. Systems consisting of interacting intelligent agents is evolving a main stream software engineering approach for developing applications in complex domains (19). Intelligent agents and multiagent systems as a computing paradigm are well suited to modeling systems with very high complexity. On the other hand, there are also some challenging issues like complex emergent behavior, self-organized criticality, and phase transition, which are related to multiagent systems. In this respect, autonomy oriented computing (AOC) (28) provides a means of modeling and characterizing complex emergent behaviors in multiagent systems.

As Jennings et al. stated in Ref. 7, the field of intelligent agents is a vibrant and rapidly expanding area of research and development. It represents a melting pot of ideas originating from such areas as distributed computing, object-oriented systems, software engineering, artificial intelligence, economics, sociology, and organizational science. The basic conceptual framework of intelligent agents has become common currency in a range of closely related disciplines and offers a natural and powerful means of analyzing, designing, and implementing a diverse range of software solutions.

Agent-based approaches have been a source of technologies to several research areas, both theoretical and practical. These areas include distributed planning and decision making, automated auction mechanisms, communication languages, coordination mechanisms, matchmaking architectures and algorithms, ontologies and information agents, negotiation, and learning mechanisms. Moreover, agent technologies have drawn from, and contributed to, a diverse range of academic disciplines, in the humanities, the natural sciences, and the social sciences. Agents offer a new and often more appropriate route to the development of complex systems, especially in open and dynamic environments.

Wooldridge (6) is a good introductory text for agent and multiagent systems. For a more comprehensive discussion on these topics, refer to Ref. 8. Ferber (29) is an undergraduate textbook, which focused on multiagent aspects rather than on the theory and practice of individual agents.

For a road map of agent and multiagent system research, refer to Refs. 4, 5, and 7. More resources on intelligent agents can be found in the *Proceedings of International Joint Conference on Autonomous Agents and Multi-Agent Systems, Autonomous Agents and Multi-Agent Systems* (journal), and *AgentLink, the European Network of Excellence for Agent Based Computing* (www.agentlink.org).

In a broader sense, objects and components in today's distributed and concurrent systems are starting to approach the view of agents that was focused here. Active objects or actors in object-oriented community are also becoming closer to the view of agents described in this article (30). In the computer network context, agents are also used to refer to a piece of software such as mail user agents, mail transfer agents, and mail delivery agents, even though they are not as smart as what was described here.

KNOWLEDGE ACQUISITION

Knowledge acquisition is the process by which problem-solving expertise is obtained from some knowledge source, usually a domain expert. This knowledge is then implemented into an expert system program that can provide expert assistance to nonexperts when and where a human expert is not available.

Traditionally knowledge acquisition is accomplished through a series of long and intensive interviews between a knowledge engineer, who is a computer specialist, and a domain expert, who has superior knowledge in the domain of interest. This process is usually referred to as *knowledge elicitation* to distinguish it from the more general knowledge acquisition term.

Experience has shown that knowledge acquisition from experts is the most difficult, time-consuming, and costly part of developing an expert system (1). The difficulty of knowledge acquisition has stimulated research in developing machines that autonomously acquire knowledge without the assistance of humans. Although progress has been made in the area of automated knowledge acquisition, in the foreseeable future, most of the knowledge for practical expert systems will be obtained through the interaction of domain experts and knowledge engineers.

THE KNOWLEDGE ENGINEERING PROCESS

Knowledge acquisition is an activity of a larger process used to develop expert systems, called *knowledge engineering*. The knowledge engineering process consists of several phases, each consisting of several tasks. Although knowledge engineering phases and tasks are usually shown in sequence, in practice they are conducted iteratively. Figure 1 depicts the phases of the knowledge engineering process. The following is a summary of the activities conducted in each phase:

Phase I: Problem assessment. This phase assesses the applicability and feasibility of an expert system solution to a particular problem.

Phase II: Knowledge acquisition. This phase involves the acquisition of knowledge from a domain expert and/or other sources of knowledge. It also involves interpreting, analyzing, and documenting the acquired knowledge.

Phase III: Knowledge representation. This phase involves the selection of a knowledge representation scheme and control strategy. Acquired knowledge is represented using the selected representation.

Phase IV: Knowledge coding. This phase involves coding the knowledge using appropriate expert system development software.

Phase V: Knowledge validation and verification. This phase ensures that the developed system performs at an acceptable level of expertise and that it correctly implements its initial specification.

Phase VI: Maintenance. This is an ongoing phase that corrects system errors and deficiencies. It also updates the system knowledge as the requirements evolve.

An interesting aspect of the iterative nature of the knowledge engineering process is its synergistic effect. Both the system and the development team improve their knowledge about the problem and how best to solve it as the development progresses.

DIFFICULTIES IN KNOWLEDGE ACQUISITION

Experience has shown that knowledge acquisition is a difficult, expensive, and time-consuming process. The major source of difficulty stems from a well-recognized fact in the field of cognitive psychology that eliciting knowledge from humans is an inherently difficult task (2). Humans are usually unaware of their mental processes when solving a problem (3). They may not be able to communicate their knowledge, not because they cannot express it, but because they are unaware of what knowledge they are using in their problem-solving activities (4). Furthermore, humans will provide an explanation of their performance that is different from the way they actually perform their tasks (5).

As most expert system projects rely on elicitation of knowledge between an expert and a knowledge engineer, many of the problems identified by cognitive psychologists are manifested. These problems are as follows:

- Experts may be unaware of knowledge used.
- Experts may be unable to articulate their knowledge.
- Experts may provide irrelevant, incomplete, incorrect, or inconsistent knowledge.

Additional problems that add to the complexity of acquiring knowledge include the following:

- Experts may not be available or may be unwilling to cooperate.
- Lack of well-defined knowledge acquisition methods.
- The complexities of dealing with a large number of participants with different backgrounds, different skills and knowledge sets, and using different terminology.
- The multiplicity of the sources of knowledge required for the system.
- The exponential growth in the complexity and interdependencies of knowledge with the size of the domain.
- The mismatch of the level of abstraction of knowledge between experts and computers.
- Potential interpersonal communication problems between the knowledge engineer and the expert.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

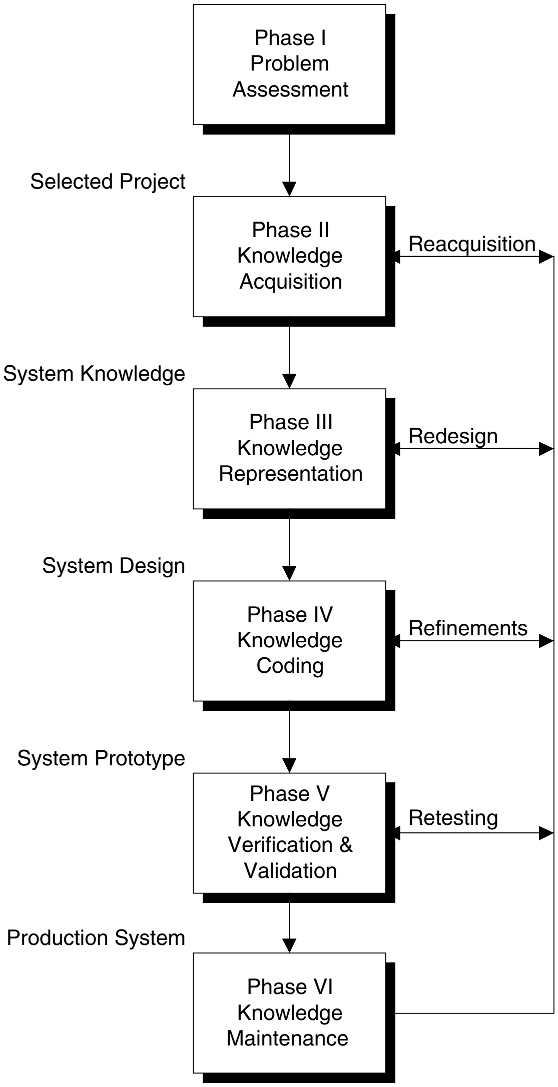

Figure 1. Phases of the knowledge engineering process. Although the phases appear sequential, there is considerable overlap and iteration in their execution.

FUNDAMENTAL CONCEPTS OF KNOWLEDGE

Levels of Knowledge

Knowledge can be broadly classified into two levels: shallow knowledge and deep knowledge.

Shallow knowledge refers to surface-level information that can be used to solve problems in very specific domains. Shallow knowledge is usually empirical and represents knowledge accumulated through the experience of solving past problems. Although shallow knowledge can be easily represented by computers, it is limited in representing and solving problems of a knowledge domain; thus, it is usually insufficient in describing complex situations.

Deep knowledge refers to the fundamental knowledge about a problem represented by its internal structure, fundamental laws, functional relationships, and so on. Deep knowledge can be applied to different tasks and under different situations. Deep knowledge is difficult to represent using computers, as it requires a complete and thorough understanding of the basic elements of knowledge and their complex interactions.

Types of Knowledge

In addition to the above two categories, knowledge can be classified by various types as follows:

Declarative knowledge describes *what* is known about a problem. It is a descriptive representation of knowledge that includes simple statements that are either true or false. The factual statement "The sky is blue" is an example of declarative knowledge. Facts, concepts, and relations are typical examples of declarative knowledge.

Procedural knowledge describes *how* a problem is solved. It provides a step-by-step sequence of instructions on how to solve the problem. For example, "If the temperature falls below 50, turn on the heater." Rules, strategies, and procedures are examples of procedural knowledge.

Heuristic knowledge is a special type of knowledge that describes *rules-of-thumb* used to guide the reasoning process to solve a problem. Heuristic knowledge is acquired through extensive experience. Experts usually compile deep knowledge into simple heuristics to aid in problem solving.

Episodic knowledge is time-stamped knowledge organized as a case or episode. This knowledge can confer the capability to perform protracted tasks or to answer queries about temporal relationships and to use temporal relationships.

Meta-knowledge describes knowledge about knowledge. It is used to select other knowledge and to direct the reasoning on how to best solve a problem.

It is important to identify the type of domain knowledge to be acquired as different types of knowledge are best elicited by different techniques. In many situations, the domain knowledge consists of several types. In these situations, it is usually preferred to employ more than one technique to acquire the knowledge.

Sources of Knowledge

Knowledge may be obtained from a variety of sources. These sources can be divided into two main types: *documented* and *undocumented*. Documented sources include manuals, books, articles, reports, standard procedures, regulations, guidelines, pictures, maps, video, films, and computer databases. Undocumented knowledge largely exists in human minds. Sources of undocumented knowledge include experts, end users, and observed behavior.

PROCESS OF KNOWLEDGE ACQUISITION

The process of knowledge acquisition is a cyclical one. It begins with the collection and recording of knowledge, followed by its interpretation, analysis, and organization.

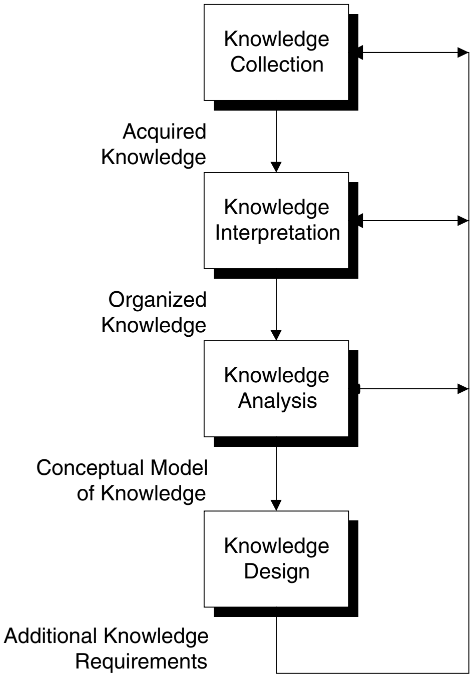

Figure 2. The knowledge acquisition process. The process is cyclic; information obtained from each cycle is used to design new ways to acquire knowledge.

Finally methods are designed for clarifying and collecting additional knowledge based on acquired knowledge. Figure 2 illustrates the knowledge acquisition process.

Knowledge Collection. Knowledge collection is the task of acquiring knowledge from a knowledge source. Usually, this step requires significant interaction between an expert and a knowledge engineer. At the initial stages of knowledge collection, information obtained from the expert represent a broad overview of the domain and the general requirements of the expert system. Later stages of knowledge collection are characterized by their narrow focus, with emphasis on the details of how the expert performs the various tasks. Knowledge acquisition sessions are recorded and transcribed in preparation for interpretation and analysis.

Knowledge Interpretation. This task involves reviewing the collected information and the identification and classification of key pieces of knowledge, such as facts, concepts, objects, rules, problem-solving strategies, and heuristics. In early iterations of the cycle, the knowledge collected will be of a general nature. During later stages, different and deeper problem-solving knowledge will be uncovered.

Knowledge Analysis. This task takes the key pieces of knowledge uncovered during the knowledge interpretation phase and forms theory on the representation of knowledge and problem-solving strategies used. It requires assembling the acquired knowledge into related groups and storing them in the knowledge dictionary. The output of this task is a conceptual model of the domain knowledge that shows the information an expert system will require, the reasoning it will perform, and the sequence of steps it will take in order to accomplish its task. A variety of graphical techniques are typically used to develop the conceptual model. These techniques include flowcharts, cognitive maps, inference networks, decision tables, and decision trees.

Knowledge Design. After the completion of the collection, interpretation, and analysis tasks, some concepts and problem-solving strategies emerge as requiring further investigation and clarification. This task identifies this information and designs an agenda that includes clarifying old issues and discussing new ones with the expert during the following iteration of the acquisition cycle.

Although theoretically the cycle could continue indefinitely, in practice, the process is repeated until the resulting system meets some acceptable performance measures.

PARTICIPANTS IN KNOWLEDGE ACQUISITION

The main participants in knowledge acquisition are the domain expert, the knowledge engineer, and the end user. Each participant plays an important role in knowledge acquisition and must possess certain qualifications to contribute effectively to the knowledge acquisition process.

The Expert

The expert is usually the primary source of knowledge for most expert system projects. The expert's main task is to communicate his/her domain expertise to the knowledge engineer for encoding into an expert system. In addition to possessing extensive knowledge and problem-solving skills in a given domain, an expert should have the following qualifications:

1. Ability to communicate the problem-solving knowledge
2. Willingness and eagerness to participate in the project
3. Ability to work well with others
4. Availability for the duration of the project

The Knowledge Engineer

The main responsibility of a knowledge engineer is to acquire, analyze, interpret, design, and encode the knowledge. Knowledge engineers must have the technical skills for interpreting, analyzing, and coding the collected knowledge. Additionally they should have the following qualifications:

1. Good communications and interpersonal skills
2. Good knowledge elicitation and interviewing skills
3. Good project management skills

The End-user

End users are an important, yet often ignored, additional source of knowledge. They provide a high-level understanding of the problem. They are particularly useful in providing a general perspective and insight early on during the knowledge elicitation process. Some of the qualifications required for end users to support knowledge acquisition include:

1. Availability and willingness to participate in the project
2. Open-minded attitude toward change

METHODS OF KNOWLEDGE ACQUISITION

Knowledge acquisition methods are classified in different ways and appear under different names in different literature. In this article, we follow a classification based on the degree of automation in the acquisition process. The classification divides knowledge acquisition methods into three categories: manual methods, combined manual and automated methods, and automated methods (6). This classification is depicted in Fig. 3.

Manual methods are largely based on some kind of interview between an expert and a knowledge engineer. The knowledge engineer elicits knowledge from the expert during interviewing sessions, refines it with the expert, and then represents it in a knowledge base. The two manual methods commonly used are interviews (structured, unstructured, and questionnaire) and task-based methods (protocol analysis, observation, and case analysis). In some cases, an expert may play the role of a knowledge engineer and self-elicit the knowledge without the help of a knowledge engineer.

Combined manual and automated methods use techniques and tools to support both experts and knowledge engineers in the knowledge acquisition process. Methods intended to support experts provide an environment for constructing the knowledge base with little or no support from a knowledge engineer. Methods intended to support knowledge engineers provide an environment of acquiring and representing knowledge with minimal support from the experts.

Automated methods minimize or even eliminate the roles of both experts and knowledge engineers. They are based on machine learning methods and include learning by induction, neural networks, genetic algorithms, and analogical and case-based reasoning.

It is important to note that the categories of the above classification are not mutually exclusive as some overlap can exist between them.

MANUAL METHODS

Interviews

Interviews are the most common elicitation method used for knowledge acquisition. It involves a two-way dialog between the expert and the knowledge engineer. Information is collected by various means and subsequently transcribed, interpreted, analyzed, and coded. Two types of interviews are used: unstructured and structured. Although many techniques have been proposed for conducting interviews, effective interviewing is still largely an art.

Unstructured Interviews. Unstructured interviews are conducted without prior planning or organization. They

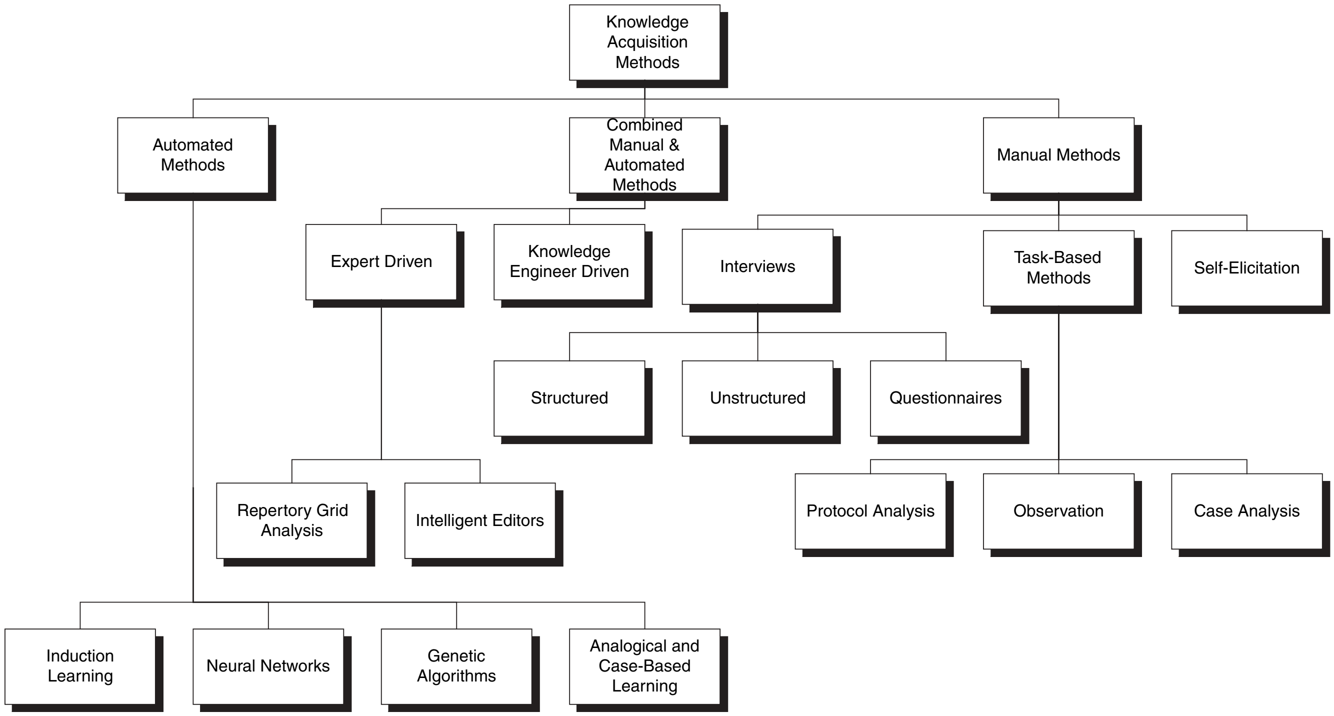

Figure 3. Knowledge acquisition methods. This classification is based on the degree of automation in the acquisition process.

are an informal technique that helps the knowledge engineer gain a general understanding of the problem, its most important attributes, and general problem-solving methods. During unstructured interviews, the knowledge engineer asks some opening questions and lets the expert talk about the problem, its major objects, concepts, and problem-solving strategies. The role of the knowledge engineer is limited to asking clarifying questions or redirecting the interview toward more interesting areas.

Unstructured interviews appear in several variations (6). In the "talkthrough" interview, the expert talks through the steps he follows to solve a specific problem. In the "teachthrough" interview, the expert plays the role of an instructor and explains "what" he does and "why" he does it in order to solve a problem. In the "readthrough" interview, the expert instructs the knowledge engineer on how to read and interpret the documents used for the task.

Unstructured interviews are useful in uncovering the basic structure of the domain, the main attributes of the problem, and the general problem-solving methods used by the expert. They are appropriate during the early stages of knowledge acquisition when the knowledge engineer is exploring the domain.

However, unstructured interviews suffer from several drawbacks (7). First, unstructured interviews lack the organization for the effective transfer of knowledge. Second, due to lack of structure, domain experts find it difficult to express important elements of their knowledge. Third, experts interpret the lack of structure as requiring little or no preparation. Fourth, data collected from an unstructured interview are often unrelated. Fifth, very few knowledge engineers can conduct an effective unstructured interview. Finally, unstructured situations do not facilitate the acquisition of specific information from experts.

Structured Interviews. Structured interviews maintain a focus on one aspect of the problem at a time by eliciting details on that aspect before moving to a different one. This focus is maintained by structuring the interview based on a prior identification of the problem's key issues obtained through earlier unstructured interviews or other sources. The interview structure forces an organized exchange between the expert and the knowledge engineer and reduces the interpretation problems and the distortion caused by the subjectivity of the expert.

Structured interviews require extensive preparation from the part of the knowledge engineer. In addition, conducting and managing the interview properly require attention to several issues. Some of the basic issues relate to items such as setting up the interview, scheduling the session, choosing the interview location, and the conduct of the first interview. Other issues include knowing how to begin and end the interview and how to ask questions in a way that will provide the desired information. Many guidelines exist in the literature on how to conduct effective structured interviews. For example, see the guidelines suggested in McGraw and Harbison-Briggs (7), Prerau (8), and Scott et al. (9).

The main advantage of structured interviews is their focus and the resulting detailed information obtained on a given issue. They are usually easier to manage, and the information collected is easier to analyze and interpret. Structured interviews are particularly useful in identifying the structure of the domain objects and their properties, concept relationships, and general-problem solving strategies.

The main limitation of structured interviews is that concepts unrelated to the interview focus may not be discovered. This limitation will be particularly manifested when the knowledge engineer is not fully aware of the topics' main issues. Additionally, structured interviews provide little insight on procedural knowledge.

Questionnaires. Although questionnaires are not strictly an interviewing method, they are used in knowledge acquisition to complement interviews by asking the expert to clarify already developed topics during advanced stages of knowledge acquisition.

Task-Based Methods

Task-based methods refer to a set of techniques that present the expert with a task and attempt to follow his or her reasoning in solving the problem. Task-based methods can help the knowledge engineer in identifying what information is being used, why it is being used, and how it is being used. The methods that can be grouped under this approach include protocol analysis, observation, and case studies.

Protocol Analysis. In protocol analysis, the expert is asked to perform a real task and to verbalize at the same time his or her thought process while performing the task. Usually a recording is made during this process, using a tape or video recorder, which becomes later a record, or protocol, that traces the behavior of the expert while solving a problem. As with interviews, this recording is transcribed, analyzed, reviewed, and coded by the knowledge engineer.

The main difference between a protocol analysis and an interview is that a protocol analysis is mainly a one-way communication. The knowledge engineer task is limited to selecting a task, preparing the scenario, and presenting it to the expert. During the session, the expert does most of the talking as the knowledge engineer listens and records the process.

The main advantage of protocol analysis is that it provides immediate insight of problem-solving methods, rather than retrospectively after the fact. It is particularly useful for a non-procedural type of knowledge, where the expert applies a great deal of mental and intellectual effort to solve a problem.

However, several cognitive psychologists have argued that asking experts to verbalize their problem-solving knowledge while performing a task creates an unnatural situation that influences task performance (10). In addition, some problems, such as ones that involve perceptual-motor tasks, do not have a natural verbalization. Forcing an expert to "think aloud" in these situations can lead to the collection of misleading and inaccurate information.

Observation. Another useful knowledge acquisition technique is observing the expert in the field while solving a problem. Observation is usually conducted at the place where the expert makes the actual decisions. Experience has shown that the realism of the expert problem-solving approach is greatly influenced by the usual physical environment of the problem.

The main advantage of this approach is that it allows the knowledge engineer to observe the decision making of the expert in a realistic environment. It provides an unbiased and unobtrusive technique for collecting knowledge. It is particularly useful for collecting information on procedural knowledge.

Observations are usually expensive and time consuming. A large amount of information is usually collected from which only a small fraction is useful.

Case Analysis. A case is an actual problem that has been solved together with its solution and the steps taken to solve it. There are two primary ways a case analysis is used for knowledge elicitation: the retrospective and observational case analyses (11). In a *retrospective* case analysis, the expert is asked to review a case and explain in retrospect how it was solved. The expert begins by reviewing the given recommendation and then works backward to identify the problem concepts and knowledge components used to support this recommendation. In an *observational* case analysis, the expert is asked to solve the problem, whereas the knowledge engineer observes the problem-solving approach of the expert.

Several types of cases could be used in conjunction with either the retrospective or observational case analyses. The two common types used by knowledge engineers are the typical case and the unusual case. The *typical* case represents a situation that is well understood and known by the expert. The results of a typical case usually reveal the typical knowledge used by the expert to solve a problem. The *unusual* case represents an unusual or novel situation that requires a deeper level of problem-solving knowledge. Usually typical cases are used initially in the project when a general understanding of the domain and the problem-solving expertise is required. Unusual cases are used later in the project when deeper knowledge is needed to provide greater problem-solving expertise to the system.

A main advantage of the case analysis method is that information is obtained in the context of a realistic situation, thus providing more accurate insight into problem-solving strategies. A case analysis usually reveals more specific problem-solving knowledge than that obtained from interviewing techniques. The retrospective case analysis has the further advantage of not interfering with the problem-solving activity, because retrospection requires the expert to recall from memory the information needed to solve the problem, rather than actually solving the problem.

A major disadvantage of the case analysis method, particularly the retrospective type, is that it may provide incomplete information and few details on the domain under study. Another disadvantage is the expert's bias toward typical situations solved that could produce inconsistent results. Selecting an unusual but solvable case could be challenging and presents yet another difficulty for this approach.

Self-Elicitation. In some cases, the expert may have both the technical interest and the needed training to play the role of a knowledge engineer. In this case the expert may acquire and represent the knowledge directly without the intermediary of a knowledge engineer. This process can be accomplished through self-administered questionnaires or through self-reporting. Self-reporting can take the form of an activity log, knowledge charts, introductory tutorials, or other similar documents that report on the problem-solving activities of the expert.

A main problem with self-elicitation methods is that experts are usually not trained in knowledge engineering methods and techniques. The resulting knowledge tends to have a high degree of bias, ambiguity, new and untested problem-solving strategies, as well as vagueness about the nature of associations among events (11). In addition, experts lose interest rapidly in the process, and consequently, the quality of the acquired knowledge decreases as the reporting progresses. Self-elicitation methods are useful when experts are inaccessible and in the gathering of preliminary knowledge of the domain.

COMBINED MANUAL AND AUTOMATED METHODS

Manual knowledge acquisition methods are usually time consuming, expensive, and even unreliable. Combined manual and automated methods use techniques and tools designed to reduce or eliminate the problems associated with manual methods. They are designed to support both experts and knowledge engineers in the knowledge acquisition process.

Methods to Support the Experts

Repertory Grid Analysis. Repertory grid analysis (RGA) is one of several elicitation techniques that attempt to gain insight into the expert's mental model of the problem domain. It is based on a technique, derived from psychology, called the *classification interview*. When applied to knowledge acquisition, these techniques are usually aided by a computer. RGA is based on Kelly's model of human thinking called Personal Construct Theory (12). According to this theory, people classify and categorize knowledge and perceptions about the world. Based on this classification, they are able to anticipate and act on everyday decisions.

The RGA involves the following steps:

1. Construction of conclusion items. These items are the options that will be recommended by the expert system. For example, an investment portfolio advisor conclusion items might include the following options: 100% investment in savings; a portfolio with 100% stocks (portfolio 1); a portfolio with 60% stocks, 30% bonds, and 10% savings (portfolio 2); and a portfolio with 20% stocks, 40% bonds, and 40% savings (portfolio 3).
2. Construction of traits. These traits are the important attributes that the expert considers in making decisions. For example, in the investment portfolio advisor example, traits might include age, investment

amount, and investment style. Traits are identified by picking three conclusion items and identifying the distinguishing characteristics of each from the two others. Each trait is given values on a bipolar scale (i.e., a pair of opposite values). In the investment portfolio advisor example, the identified traits could have the following values: young/old, small/large, and conservative/aggressive.

3. Rating of conclusion items according to traits. The expert rates each conclusion item on a scale of one to five. Five is given to an item that satisfies the left-hand pole of the trait and one to an item that satisfies the right pole. The answers are recorded in a grid as shown in Table 1.
4. Rule generation. Once the grid is completed, rules are generated that provide decision items given a desired trait importance.

Several knowledge acquisition tools have been developed based on the RGA method. The best known tool of this group is the Expertise Transfer System (ETS) (13). ETS is used to build a knowledge system through several iterative steps: (1) ETS interviews the experts to uncover conclusion items, problem-solving traits, trait structure, trait weights, etc.; (2) information acquired from the expert is built into information bases; (3) information bases are analyzed and built into knowledge bases (rules, frames, or networks); (4) knowledge bases are incrementally refined using test case histories; and (5) knowledge bases are implemented into expert systems. Other representative tools in this category include KRITON (15), and AQUINAS(16).

Intelligent Editors. An intelligent editor allows the domain expert to capture the knowledge directly without the intermediary of a knowledge engineer. The expert conducts a dialog with the editor using a natural language interface that includes a domain-specific vocabulary. Through the intelligent editor, the expert can manipulate the rules of the expert system without knowing the internal structure of these rules.

The editor assists the expert in building, testing, and refining a knowledge base by retrieving rules related to a specific topic and by reviewing and modifying the rules if necessary. The editor also provides an explanation facility. The expert can query the system for conclusions given a set of inputs. If the expert is unhappy with the results, he can have the editor show all the rules used to arrive at that conclusion.

Table 1. A Repertory Grid for an Investment Portfolio Advisor

Attribute	Age	Investment Amount	Investment Style
Trait	Young(5)	Small(1)	Conservative(1)
Opposite	Old(1)	Large(5)	Agressive(5)
Savings	2	1	1
Portfolio 1	4	4	5
Portfolio 2	3	3	3
Portfolio 3	2	2	2

Some editors have the ability to suggest reasonable alternatives and to prompt the expert for clarifications when required. Other editors have the ability to perform syntax and semantic checks on the newly entered knowledge and detect inconsistencies when they occur.

A classic example of intelligent editors is a program called TEIRESIAS that was developed to assist experts in the creation and revision of rules for a specific expert system while working with the EMYCIN shell (1).

Methods to Support the Knowledge Engineer

Several types of tools have been developed to support knowledge acquisition. They include knowledge-base editors, explanation facilities, and semantic checkers.

Knowledge-base editors facilitate the task of capturing the knowledge and entering it into the knowledge base. They provide syntax and semantic checks to minimize errors and ensure validity and consistency. Several types of editors exist. Rule editors simplify the task of defining, modifying, and testing production rules. Graphical editors support the development of structured graphic objects used in developing the knowledge base (17).

Explanation facilities support the knowledge engineer in acquiring and debugging the knowledge base by tracing the steps followed in the reasoning process of the expert to arrive at a conclusion.

Semantic checkers support the construction of, and changes to, knowledge bases. They ensure no errors or inconsistencies exist in the knowledge.

AUTOMATED METHODS

Automated methods refer to the autonomous acquisition of knowledge through the use of *machine learning* approaches. The objective of using machine learning is to reduce the cost and time associated with manual methods, minimize or eliminate the use of experts and knowledge engineers, and improve the quality of acquired knowledge. In this section we will discuss five of these approaches. They include inductive learning, neural networks, genetic algorithms, and case-based reasoning and analogical reasoning.

Inductive Learning

Inductive learning is the process of acquiring generalized knowledge from example cases. This type of learning is accomplished through the process of reasoning from a set of facts to conclude general principles or rules.

Rule induction is a special type of inductive learning in which rules are generated by a computer program from example cases. A rule-induction system is given an example set that contains the problem knowledge together with its outcome. The example set can be obtained from the domain expert or from a database that contains historical records. The rule-induction-system uses an induction algorithm to create rules that match the results given with the example set. The generated rules can then be used to evaluate new cases where the outcome is not known.

Consider the simple example set of Table 2 that is used in approving or disapproving loans for applicants. Applica-

Table 2. Example Dataset from a Loan Application Database Used for Rule Induction

Name	Annual Income	Assets	Age	Loan Decision
Applicant A	High	None	Young	Yes
Applicant B	Medium	Medium	Middle	Yes
Applicant C	Low	High	Young	Yes
Applicant D	Low	None	Young	No

tion for a loan includes information about the applicant's income, assets, and age. These are the decision factors used to approve or disapprove a loan. The data in this table show several example cases, each with its final decision. From this simple example case, a rule-induction system may infer the following rules:

1. If income is high, approve the loan.
2. If income is low and assets are high, approve the loan.
3. If income is medium, assets are medium, and age is middle or higher, approve the loan.

The heart of any induction systems is the induction algorithm, which is used to induce rules from examples. Induction algorithms vary from traditional statistical methods to neural computing models.

A classic and widely used algorithm for inductive learning is ID3 (18). The ID3 algorithm first converts the knowledge matrix into a decision tree. Irrelevant decision factors are eliminated, and relevant factors are organized efficiently.

Rule induction offers many advantages. First, it allows knowledge to be acquired directly from example cases, thus avoiding the problems associated with acquiring knowledge from an expert through a knowledge engineer. Second, induction systems can discover new knowledge from the set of examples that may be unknown to the expert. Third, induction can uncover critical decision factors and eliminate irrelevant ones. In addition, an induction system can uncover contradictory results in the example set and report them to the expert.

Induction systems, however, suffer from several disadvantages. They do not select the decision factors of a problem. An expert is still needed to select the important factors for making a decision. They can generate rules that are difficult to understand. They are only useful for rule-based, classification problems. They may require a very large set of examples to generate useful rules. In some cases, the examples must be sanitized to remove exception cases. Additionally, the computing power required to perform the induction grows exponentially with the number of decision factors.

Neural Networks

Neural networks are a relatively new approach to building intelligent systems. The neural network approach is based on constructing computers with architectures and processing capabilities that attempt to mimic the architecture and processing of the human brain. A neural network is a large network of simple processing elements (PEs) that process information dynamically in response to external inputs. The processing elements are a simplified representation of brain neurons. The basic structure of a neural network consists of three layers: input, intermediate (called the *hidden layer)*, and output. Figure 4 depicts a simple three-layer network.

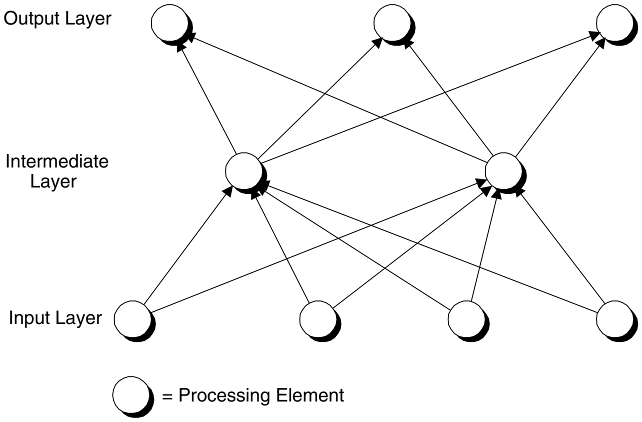

Figure 4. A three-layer neural network architecture. The layers of the network are the input, intermediate (hidden), and output layers.

Each processing element receives inputs, processes the inputs, and generates a single output. Each input corresponds to a decision factor. For example, for a loan approval application, the decision factors may be the income level, assets, or age. The output of the network is the solution to the problem. In the loan approval application, a solution may be simply a "yes" or "no." A neural network, however, uses numerical values only to represent inputs and outputs.

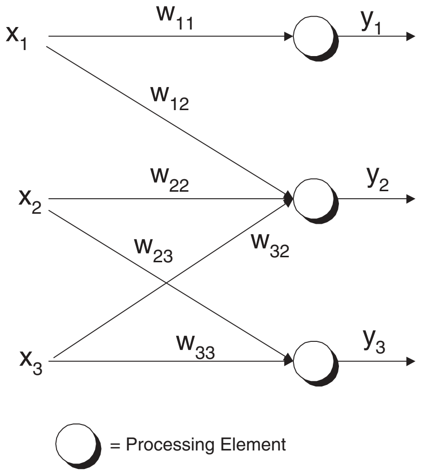
Each input x_i is assigned a *weight* w_i that describes the relative strength of the input. Weights serve to increase or decrease the effects of the corresponding x_i input value. A summation function multiplies each input value x_i by its weight w_i and sums them together for a weighted sum y. As Figure 5 illustrates, for j processing elements, the formula for n input is

$$y_j = \sum_j w_{ij} x_i$$

Based on the value of the summation function, a processing element may or may not produce an output. For example, if the sum is larger than a *threshold value* T, the processing element produces an output y. This value may then be input to other nodes for a final response from the network. If the total input is less than T, no output is produced. In more sophisticated models, the output will depend on a more complex activation function.

Learning in a Neural Network. The knowledge in a neural network is distributed in the form of internode connections and weighted links. These weights must be learned in some way. The learning process can occur in one of two ways: *supervised* and *unsupervised learning*.

In supervised learning, the neural network is repeatedly presented with a set of inputs and a desired output



$$y_1 = x_1w_{11}$$
$$y_2 = x_1w_{12} + x_2w_{22} + x_3w_{32}$$
$$y_3 = x_2w_{23} + x_3w_{33}$$

Figure 5. Summation function for several neurons.

response. The weights are then adjusted until the difference between the actual and the desired response is zero. In one variation of this approach, the difference between the actual output and the desired output is used to calculate new adjusted weights. In another variation, the system simply acknowledges for each input set whether the output is correct. The network adjusts weights in an attempt to achieve correct results. One of the simpler supervised learning algorithms uses the following formula to adjust the weights w_i:

$$w_i(\text{new}) = w_i(\text{old}) + \alpha \times d \times \frac{x_i}{|x_i|^2}$$

where α is a parameter that determines the rate of learning, and d is the difference between actual and desired outputs.

In unsupervised learning, the training set consists of input stimuli only. No desired output response is available to guide the system. The system must find the weights w_{ij} without the knowledge of a desired output response.

Neural networks can automatically acquire knowledge from historical data. In that respect they are similar to rule induction. They do not, however, need an initial set of decision factors or complete and unambiguous sets of data. Neural networks are particularly useful in identifying patterns and relationships that may be subsequently developed into rules for expert systems. Neural networks could also be used to supplement rules derived by other techniques.

Genetic Algorithms

Genetic algorithms refer to a variety of problem-solving techniques that are based on models of natural adaptation and evolution. They are designed the way populations adapt to and evolve in their environments. Members that adapt well are selected for mating and reproduction. The descendants of these members inherit genetic traits from both parents. Members of this second generation that also adapt well are selected for mating and reproduction, and the evolutionary cycle continues. After several generations, members of the resultant population will have adapted optimally or at least very well to the environment.

Genetic algorithms start with a fixed population of data structures that are candidate solutions to specific domain tasks. After requiring these structures to execute the specified tasks several times, the structures are rated for their effectiveness as a domain solution. On the basis of these evaluations, a new generation of data structures is created using specific "genetic operators" such as reproduction, crossover, inversion, and mutation. Poor performing structures are discarded. This process is repeated until the resultant population consists only of the highest performing structures.

Many genetic algorithms use eight-bit strings of binary digits to represent solutions. Genetic algorithms use four primary operations on these strings:

1. *Reproduction* is an operation that produces new generations of improved solutions by selecting parents with higher performance rating.
2. *Crossover* is an operation that randomly selects a bit position in the eight-bit string and concatenates the head of one parent with the tail of the second parent to produce a child. Consider two parents designated *xxxxxxxx* and *yyyyyyyy*, respectively. Suppose the second bit position has been selected as the crossover point (i.e., *xx*: *xxxxxx* and *yy*: *yyyyyy*). After the crossover operation is performed, two children are generated, namely *xxyyyyyy* and *yyxxxxxx*.
3. *Inversion* is a unary operation that is applied to a single string. It selects a bit position at random, and then concatenates the tail of the string to the head of the same string. For example, if the second position was selected for the following string ($x_1x_2 : x_3x_4x_5x_6x_7x_8$), the inverted string would be $x_3x_4x_5x_6x_7x_8x_1x_2$.
4. *Mutation* is an operation ensures that the selection process does not get caught in a local minimum. It selects any bit position in a string at random and changes it.

The power of genetic algorithms lies in that they provide a set of efficient, domain-independent search heuristics for a wide range of applications. With experience, the ability of a genetic algorithm to learn increases, enabling it to accumulate good solutions and reject inferior ones.

Analogical Reasoning and Case-Based Reasoning

Analogical reasoning is the process of adapting solutions used to solve previous problems in solving new problems. It is a very common human reasoning process in which new concepts are learned through previous experience with similar concepts. A past experience is used as a framework for solving the new analogous experience. Analogical learning consists of the following five steps:

1. Recognizing that a new problem or situation is similar to a previously encountered problem or situation.
2. Retrieving cases that solved problems similar to the current problem using the similarity of the new problem to the previous problem as an index for searching the case database.
3. Adapting solutions to retrieved cases to conform with the current problem.
4. Testing the new solutions.
5. Assigning indexes to the new problem and storing it with its solution

Unlike induction learning, which requires a large number of examples to train the system, analogical learning can be accomplished using a single example or case that closely matches the new problem at hand.

KNOWLEDGE ANALYSIS

After knowledge is collected, it must be interpreted and analyzed. First a transcript of the knowledge acquisition session is produced. This transcript is then reviewed and analyzed to identify key pieces of knowledge and their relationships. A variety of graphical techniques are used to provide a perspective of the collected knowledge and its organization (14).

Knowledge Transcription

After the knowledge collection phase, an exact and complete transcript of the knowledge acquisition session is usually made. This transcript is used as a basis for interpreting and analyzing the collected knowledge. Transcription can also be partial. In case of a partial transcription, notes taken during knowledge acquisition session can be used to guide the selection of what should be transcribed.

Each transcript is indexed appropriately with such information as the project title, session date and time, session location, attendees, and the topic of the session. A paragraph index number is assigned to cross-reference the source of knowledge extracted from the transcript with the knowledge documentation. This cross-referencing facilitates the effort of locating the source of knowledge if additional information is needed.

Knowledge Interpretation

Knowledge interpretation begins by reviewing the transcript and identifying the key pieces of knowledge or "chunks" (19). Usually declarative knowledge is easy to identify. Procedural knowledge is harder to recognize, as it can be scattered across the transcript, making it harder to relate. In addition to identifying key pieces of knowledge, an important goal of reviewing the transcript is to identify any issues that need further clarification by the expert.

Several techniques can be used in knowledge interpretation. These include (1) using handwritten notes taken during the knowledge acquisition session in knowledge identification, (2) highlighting of key information in the transcript using word processing software features or a pen, and (3) labeling each piece of knowledge with the type of knowledge it represents.

Knowledge Analysis and Organization

After identifying the different types of knowledge, they need to be analyzed and classified. This effort includes the following steps:

1. Recording each identified piece of knowledge with other related pieces in the *knowledge dictionary*. A knowledge dictionary is a repository that maintains, in alphabetical order, a description of each type of knowledge, for example, objects, rules, problem-solving strategies, and heuristics.
2. Organizing, classifying, and relating the pieces of knowledge collected with similar knowledge stored in the knowledge dictionary. This is a complex iterative step that requires the involvement of the expert to confirm and help refine the structure of knowledge developed.
3. Reviewing the collected knowledge to identify those areas that need further clarification.

Graphical techniques that show how the different pieces of knowledge are related are particularly useful. The next section overviews some of the knowledge representation methods that support both the knowledge engineer and the expert in analyzing knowledge.

KNOWLEDGE REPRESENTATION

Knowledge acquired from experts and other sources must be organized in such a way that it can be implemented and accessed whenever needed to provide problem-solving expertise. Knowledge representation methods can be classified into two broad types: those that support the analysis of the acquired knowledge and the development of a conceptual model of the expert system, and those that support the implementation formalism of the development environment.

The first type of representation, called *intermediate representation*, allows knowledge engineers to focus on organizing, analyzing, and understanding the acquired knowledge without concerning themselves with the representation formalisms of the implementation environment. The intermediate representation is continually refined and updated through additional knowledge acquisition until the knowledge engineers are satisfied they have a sufficiently complete model to guide the implementation design. Intermediate representation methods are usually pictorial and include flowcharts, graphs, semantic networks, scripts, fact tables, decision tables, and decision trees.

The second type of representation, called the *implementation representation*, is used to create an implementation design for the chosen development environment. The conceptual model is mapped directly into the representation model of the development environment without the need to understand the function that the knowledge should serve. Implementation representation often used includes frames or production rules.

Each representation method emphasizes certain aspects of the knowledge represented. The choice of a representation method will depend on how well the representation schemes support the structure of the problem. We consider in this article eight of the most common knowledge representation techniques:

- Logic.
- Production rules.
- Frames.
- Semantic networks.
- Objects–attribute–value triplets.
- Scripts.
- Decision tables.
- Decision trees.

Logic

Logic is the oldest form of knowledge representation. It uses symbols to represent knowledge. Operators are applied to these symbols to produce logical reasoning. Logic is a formal well-grounded approach to knowledge representation and inferencing. There are several types of logic representation techniques. The two approaches used in artificial intelligence and expert system development are *propositional logic* and *predicate calculus*.

Propositional Logic. A proposition is a statement that is either true or false. Symbols, such as letters, are used to represent different propositions. For example, consider propositions A and B used to derive conclusion C:

A	=	Employees work only on weekdays
B	=	Today is Saturday
C	=	Employees are not working today

Propositional logic provides logical operators such as AND, OR, NOT, IMPLIES, and EQUIVALENCE that allows reasoning using various rule structures. Table 3 lists the propositional logic operators and their common symbols.

The AND operator combines two propositions and returns true if both propositions are true. The OR operator combines two propositions and returns true if either one or both propositions are true. The NOT operator is a unary operator that returns false if proposition A is true; otherwise it returns true if proposition A is false. The EQUIVALENCE operator returns true when both propositions have the same truth assignment. The IMPLIES operator indicates that if proposition A is true, then proposition B is also true.

Table 3. Logical Operators and Their Symbols

Operator	Symbol
AND	$\wedge$, & , $\cap$
OR	$\vee$, $\cup$, +
NOT	$\neg$, ~
IMPLIES	$\supset$, $\rightarrow$
EQUIVALANCE	$\equiv$

Table 4. Truth Table for IMPLIES Operator

A	B	A → B
T	T	T
T	F	F
F	T	T
F	F	T

A truth table is used to show all possible combinations of an operator. Table 4 shows the truth table for the IMPLIES operator.

Since propositional logic deals only with the truth of complete statements, its ability to represent real-world knowledge is limited.

Predicate Calculus. Predicate calculus is an extension of propositional logic that provides finer presentation of knowledge. It permits breaking down a statement into the objects about which something is being asserted and the assertion itself. For example, in the statement *color* (*sky*, *blue*), the objects sky and blue are associated through a color relationship.

Predicate calculus allows the use of variables and functions of variables in a statement. It also uses the same operators used in propositional logic in addition to two other symbols, the universal quantifier $\forall$ and the existential quantifier $\exists$, that can be used to define the range or scope of variables in an expression. Inferencing capability in predicate calculus is accomplished through the use of these operators.

As predicate calculus permits breaking statements down into component parts, it allows for a more powerful representation model that is more applicable to practical problems.

Production Rules

Production rules are a popular knowledge representation scheme used for the development of expert systems. Knowledge in production rules is presented as condition-action pairs: IF a *condition* (also called antecedent or premise) is satisfied, THEN an action (or consequence or conclusion) occurs. For example:

IF the sky is clear
THEN it is not going to rain

A rule can have multiple conditions joined with AND operators, OR operators, or a combination of both. The conclusion can contain a single statement or several statements joined with an AND. A certainty factor, usually a value between −1 and 1, can also be associated with a rule to capture the confidence of the expert with the results of the rule (20).

Production rules represent the system's knowledge base. Each rule represents an independent portion of knowledge that can be developed and modified independently of other rules. An inference mechanism uses these rules along with information contained in the working memory to make recommendations. When the IF portion of a rule is satisfied, the rule fires and the statements in the THEN part of the rule are added to the working memory. These statements can trigger other rules to fire. This process continues until the system reaches a conclusion.

Production rules offer many advantages. They have simple syntax, are easy to understand, and are highly modular, and their results are easily inferred and explained. Production rules are, however, not suitable for representing many types of knowledge, particularly descriptive knowledge. They could also be difficult to search, control, and maintain for large complex systems.

Semantic Networks

Semantic networks are graphical depictions of a domain's important objects and their relationships. It consists of nodes and arcs that connect the nodes. The nodes represent the objects and their properties. Objects can represent tangible or intangible items such as concepts or events. The arcs represent the relationships between the objects. Some of the most common arc types are the IS-A and HAS-A type. The IS-A relationship type is used to show class membership; that is, an object belongs to a larger class of objects. The HAS-A relationship type indicates the characteristics of an object.

Figure 6 shows a simple example of a semantic network. In this example, the "Pyramid" node is connected to a property node, indicating that "a pyramid has faces." It is also connected to the "Structure" node via an IS-A link, indicating that "a pyramid is a structure." The "Structure" node is connected to a "Material" node via a MADE OF link, and the "Stone," "Wood," and "Steel" nodes are connected to the "Material" node via an IS-A link.

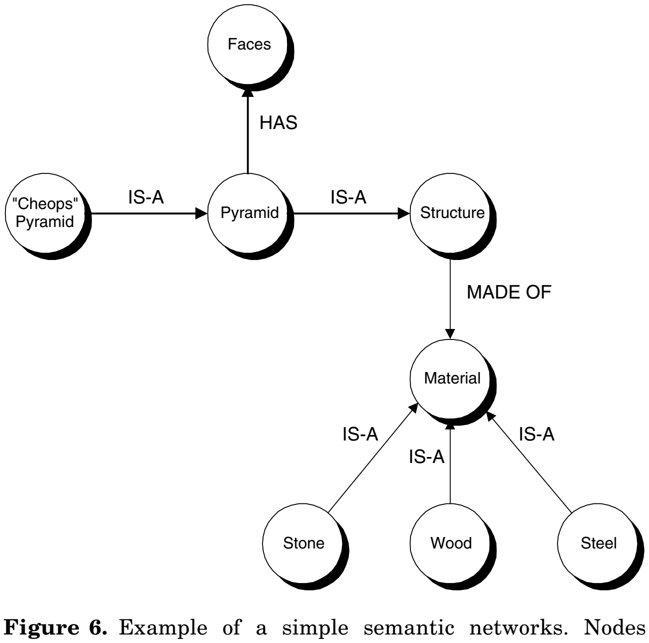


Figure 6. Example of a simple semantic networks. Nodes represent objects, and links represent the relationship between the objects.

A very useful characteristic of semantic networks is the concept of *inheritance*. Inheritance is the mechanism by which nodes connected to other nodes through an IS-A relationship inherit the characteristics of these nodes. A main advantage of inheritance is that it simplifies adding new knowledge to the network. When a new node is added, it inherits a wealth of information throughout the network via the IS-A links. Similarly, when a general node is added (e.g., the "Structure" node), other nodes inherit its properties.

Semantic networks have many advantages as a knowledge representation scheme. They are easy to understand and provide flexibility and economy of effort in adding new objects and relationships. They provide a storage and processing mechanism similar to that of humans, and the inheritance mechanism provides an efficient way of inferencing. Semantic networks also have several limitations. Exceptions offer potential difficulty to the mechanism of inheritance, and because semantic networks do not represent sequence and time, procedural knowledge is difficult to represent.

Frames

A frame is a data structure that includes both declarative and procedural knowledge about a particular object. In that respect, frames are similar to objects used in object-oriented programming. A frame consists of a collection of *slots* that may be of any size and type. Slots have a name and any number of subslots called *facets*. Each facet has a name and any number of values. Figure 7 depicts a simple frame for "Cheops" pyramid.

Facets contain information such as attribute value pairs, default values, conditions for filling a slot, pointers to other related frames, functions, and procedures that are activated under different conditions. The conditions that can activate a procedure are specified in the IF-CHANGED and IF-NEEDED facets. An IF-CHANGED facet contains a procedural attachment, called a *demon*. This procedure is invoked when a value of a slot is changed. An IF-NEEDED facet is used when no slot value is given. It specifies a procedure that is invoked to compute a value for the slot.

For example, the "Cheops" pyramid frame of Figure 7 has attribute value slots (A-KIND-OF, MATERIAL, BASE-LENGTH, HEIGHT), slots that take default values (NO.-OF-FACES and NO.-OF-SATTELITES), and slots

```
("Cheops" Pyramid
              (A-KIND-OF(VALUE pyramid))
              (MATERIAL(VALUE limestone granite))
              (BASE-LENGTH(VALUE 233m))
              (HEIGHT(VALUE 146m))
              (NO.-OF-FACES(DEFAULT fget))
              (ANGLE(VALUE if-needed))
              (BASE-AREA(VALUE if-needed))
              (VOLUME(VALUE if-needed))
              (NO.-OF-SATTELITES(DEFAULT fget))
```

Figure 7. Example of a frame for "Cheops" pyramid. This frame illustrates different types of slots.

with attached IF-NEEDED procedures (ANGLE, BASE-AREA, VOLUME). The value fget in the default values slots is a function call that retrieves a default value from another frame such as the general pyramid frame for which "Cheops" is a KIND-OF. When activated, the fget function recursively looks for default values for the slot from ancestor frames until one is found.

Frames are usually connected together to form a hierarchical structure. This hierarchical arrangement of frames allows inheritance. Each frame inherits the characteristics and behavior of all related frames at higher levels of the hierarchy. For example, the "Cheops" pyramid frame is linked to a general pyramid frame that contains information common to all pyramids. In this case, the "Cheops" pyramid frame inherits all the descriptive and procedural information of the pyramid frame.

Inferencing in frames is based on the premise that previous experiences with objects and events create certain expectations about newly encountered objects and events. First, knowledge about an object or situation is stored in long-term memory as a frame. Then, when a similar object or situation is encountered, an appropriate frame is retrieved from memory and used for reasoning about the new situation.

Frames have many advantages. They are a powerful mechanism for representing knowledge, because both declarative and procedural information are captured. In addition, slots for new attributes and procedures are easy to set up. Frames have, however, a complicated reasoning. As a result, the implementation of their inferencing mechanism is difficult.

Objects–Attribute–Value Triplets

An object, attribute, and value triplet, also known as the *O–A–V triplet*, is another way of representing knowledge. *Objects* can represent physical or abstract items. *Attributes* are properties of the objects, and *values* are specific values that an attribute has at a given time. An attribute can have single or multiple values. These values can be static or dynamic. Figure 8 illustrates a simple O–A–V triplet.

O–A–V triplets can be considered as a variation of either the semantic networks or the frames. They are useful in depicting a relationship between objects, such as inheritance, part-of, and causal relationships.

Scripts

Scripts are frame-like structures used to represent stereotypical situations such as eating in a restaurant, shopping in a supermarket, or visiting a doctor. Similar to a script for a play, the script structure is described in terms of roles, entry conditions, props, tracks, and scenes. *Roles* refer to the people involved in the script. *Entry conditions* describe the conditions that must be satisfied before the events described in the script can occur. *Props* are the items used in the events of the script. *Track* refers to variations that might occur in a particular script. Finally, *scenes* are the sequence of events that take place for the script situation. Figure 9 depicts a typical script. It is adapted from the well-known restaurant example used to show how knowledge is represented in scripts.

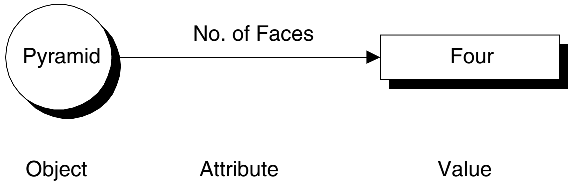

Figure 8. Example of a simple O–A–V triplet.

Script Name	:	Restaurant
Track	:	Fast-food restaurant
Roles	:	Customer
		Server
Props	:	Counter
		Tray
		Food
		Money
		Napkins
		Salt/Pepper/Catsup/Straws
Entry Conditions	:	Customer is hungry
		Customer has money
Scene 1	:	Customer parks car
		Customer enters restaurant
		Customer waits in line at counter
		Customer reads the menu on the wall and makes a decision about what to order
Scene 2	:	Customer gives order to server
		Server fills order by putting food on tray
		Customer pays server
Scene 3	:	Customer gets napkins, straws, salt, etc.
		Customer takes tray to an unoccupied table
		Customer eats food quickly
Scene 4	:	Customer cleans up table
		Customer discards trash
		Customer leaves restaurant
		Customer drives away
Results	:	Customer is no longer hungry
		Customer has less money

Figure 9. Example of a restaurant script.

Similar to frames, reasoning with scripts begins with the creation of a partially filled script that describes the current situation. A known script with similar properties is retrieved from memory using the script name, preconditions, or any other keywords as index values for the search. The slots of the current situation script are then filled with inherited and default values from the retrieved scripts.

Scripts offer many of the advantages of frames, particularly the expressive power. However, similar to frames, they and their inference mechanisms are difficult to implement.

Decision Tables

A decision table is a two-dimensional table that enumerates all possible combinations of attribute values and the conclusions that can be made for each combination of these values. An example of a decision table is shown in Fig. 10. This example gives an expert's recommendations for

Attributes								
Age	Y[1]	Y	Y	Y	O[2]	O	O	O
Investment Amount	S[3]	S	L[4]	L	S	S	L	L
Investment Style	C[5]	A[6]	C	A	C	A	C	A
Conclusions								
Savings	X	X			X	X		
Portfolio 1				X				
Portfolio 2			X					X
Portfolio 3							X	

[1]Y=Young [3]S=Small [5]C=Conservative
[2]O=Old [4]L=Large [6]A=Aggressive

Figure 10. Example of a decision table for an investment portfolio advisor.

investment decisions based on age, amount of investment, and investment style.

Decision tables are suitable for a small number of decision attributes, each with a small number of possible values. If the number of attributes or possible values is large, the decision table becomes quite complex. Decision tables are suitable as an intermediate representation for documenting and analyzing knowledge. It is not possible to make inferences directly from the tables, except through rule induction.

Decision Trees

Decision trees are a graphical representation of a problem domain search space. A decision tree is composed of nodes and branches. Initial and intermediate nodes represent decision attributes, and leaf nodes represent conclusions. A path from the root node to a leaf node corresponds to a decision path that might be encountered in the problem domain. Figure 11 shows the decision tree version of the problem presented as a decision table in Fig. 10.

Decision trees are useful not only to show the problem-solving steps, but also the order in which input data are requested and the reasoning steps the expert system should take in order to reach a conclusion. Decision trees are more natural for experts to understand and use than formal methods such as rules of frames. They are particularly useful to represent the knowledge of identification systems (diagnostics, troubleshooting, classification, etc.).

VALIDATION AND VERIFICATION OF KNOWLEDGE

An important activity of knowledge acquisition is the testing and evaluation of the quality and correctness of the acquired knowledge and its implementation. This activity can be separated into two components: validation and verification (21).

Validation refers to determining whether the "right" system was built, i.e., whether the system does what it was meant to do at an acceptable level of accuracy. Validating the knowledge involves confirming the acquired knowledge is sufficient to perform the task at a sufficient level of expertise.

Verification refers to determining whether the system was built "right," i.e., whether the system correctly implements its specifications. Verifying a system means that the program accurately implements the acquired knowledge as acquired and documented.

Validation and verification of knowledge are highly interrelated. Errors in the knowledge implementation are often discovered during validation when the acquired knowledge is checked to see whether it performs the desired task at a sufficient level of expertise.

Validation and Verification as Part of Knowledge Acquisition

Since expert systems are developed iteratively, they inherently include repeated validation and verification testing as part of the development process. Each time a version of the

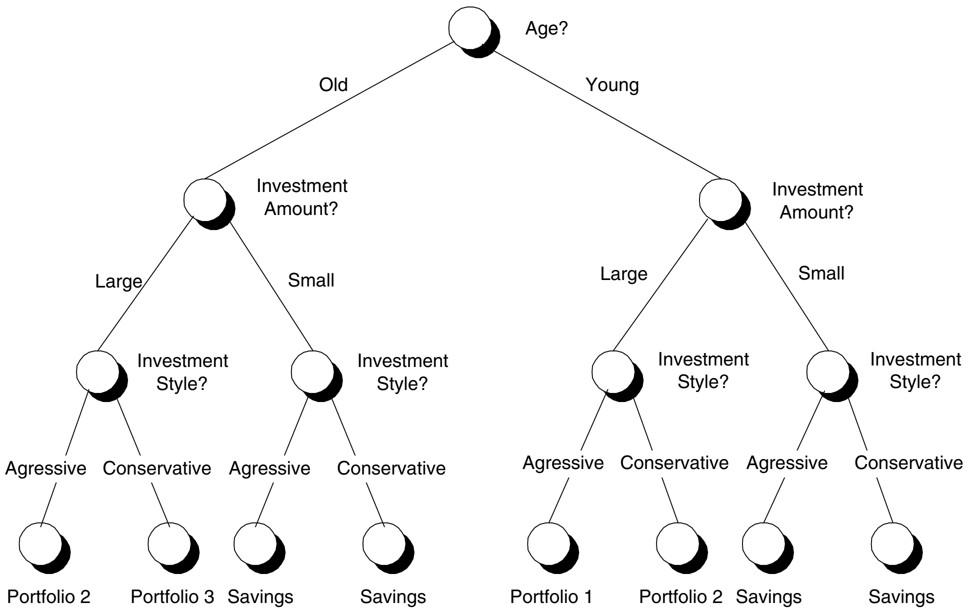

Figure 11. Example of a decision tree for the investment portfolio advisor of Fig. 10.

expert system program is run to test the knowledge, the correctness of the program is checked as well. Thus, in addition to finding deficiencies in the acquired knowledge, the knowledge acquisition cycle detects and corrects programming errors. Validation and verification during knowledge acquisition can occur before implementation has begun using manual simulation or after initial implementation by testing the evolving prototype.

Validation Using Manual Simulation. Early in the expert system development project and before implementation has begun, knowledge acquisition follows a basic development cycle: (1) eliciting knowledge; (2) interpreting, analyzing, and organizing acquired knowledge; and (3) testing knowledge. In this approach, a test case is analyzed by the expert and manually using hand simulation of the acquired knowledge. The results of the expert's analysis are compared with those of the hand simulation. If the results differ, the appropriate area of knowledge is revised and corrected. This process is repeated until no discrepancies occur between the expert's analysis and the results of the simulation of the acquired knowledge.

Validation Using Evolving Prototype. When enough knowledge is acquired to allow a prototype implementation, the knowledge acquisition process follows a modified cycle consisting of the following steps: (1) eliciting knowledge; (2) interpreting, analyzing, and organizing acquired knowledge; (3) implementing knowledge; and (4) testing knowledge. During the testing phase, a test case is presented to the expert and run using the evolving prototype. The results of the expert's analysis are compared against the results of the prototype. If the results differ, the portion of the knowledge that produced the discrepancy is identified and is manually simulated to see whether it agrees with the expert's analysis. If manual simulation produces results that agree with the expert, then an implementation error is likely the source of the discrepancy. If manual simulation does not agree with the expert's analysis, acquired knowledge is revised, modified, or expanded until it comes into agreement with the expert analysis. This process is repeated throughout the knowledge acquisition phase.

Validation testing during expert system development could be conducted by the domain expert or by a group of consulting experts. Using multiple experts has the advantage of removing potential biases of single experts, and will generally reveal and correct more errors in the expert system's knowledge and implementation. It also provides the nontechnical benefit of adding credibility to the validation effort.

On the other hand, multiple experts might disagree and provide contradicting opinions. In that case, one of several approaches can be used to integrate the expert's opinions (22). These techniques include selecting the majority decision; blending different lines of reasoning through consensus methods, such as Delphi; applying analytical models used in multiple-criteria decision making; selecting a specific line of reasoning based on the situation; and using blackboard systems that maximize the independence among knowledge sources by appropriately dividing the problem domain.

Validation of the Developed Expert System

In some domains, the correctness of the expert system recommendation can be trivially determined without the need for comparison against the human expert's judgment. In other domains, the correctness of the results needs to be confirmed by experts who will generally agree on the quality of the system's recommendations.

Validation of the developed system is accomplished by comparing the developed system's operational results against the judgment of the expert. A variation of this approach is to run a number of test cases on the developed system and compare the system's recommendations against the results obtained by the human experts.

If feasible, it is highly recommended to evaluate the performance of the expert system in the field under actual operating conditions. This approach provides the most realistic validation of the system in addition to, if tests are successful, convincing potential users of the value of the system.

As in the case of validating an expert system during development, validating a developed expert system can be accomplished using a single expert or multiple experts. These are usually the same experts that performed validation testing during the expert system development.

Verification of the Expert System Program

Verification ensures that the program accurately implements the acquired knowledge. The knowledge acquisition process by its nature uncovers errors not only in the knowledge but in the implementation as well. Implementation errors are often identified during validation when the knowledge of the system is checked for correctness.

In addition to ensuring that the coded knowledge reflects the documented knowledge accurately, verification requires checking the expert system program for internal errors in the knowledge base and the control logic that provides the inferencing mechanism. For example, a rule-based system should not have redundant, conflicting, inconsistent, superfluous, subsumed, or circular rules. In frame-based systems, there should not be any slot with illegal values, inheritance conflicts that are unresolved, circular inheritance paths, and so on. Most rule-and frame-based systems provide capabilities for checking many of these potential problems. Other testing methods should be employed for potential problems not checked automatically. Software systems with better testing and error detection capability enhance the verification phase of the system. Verifying the control logic that performs inferencing can be minimized if the project is using a standard, commercial off-the-shelf tool.

KNOWLEDGE-BASED COMPUTATION

INTRODUCTION

The field of artificial intelligence (AI) studies the computational requirements for performing tasks such as perception, reasoning, and learning (1). Knowledge appears to play a key role in achieving high-level performance on many human tasks, as people draw on background knowledge and pick strategies to apply that knowledge. The *knowledge-based computation* approach to AI studies how to develop intelligent systems that exploit explicitly represented knowledge, and it sees knowledge as the crucial determiner of system performance.

AI theories depend on specifying processes, domain content, and representations for that content. Research in knowledge-based computation addresses questions such as how knowledge should be represented in computational systems for particular tasks, which knowledge must be captured for a particular task and task domain, how knowledge should be organized and accessed, and how knowledge can be applied to the task itself. Applications of knowledge-based computation have been fielded in a wide range of areas, demonstrating the practical value of knowledge-based approaches.

The phrase "knowledge-based systems" is often used to describe rule-based expert systems, which replicate expert performance with the "narrow but deep" knowledge required for high-level performance in focused domains. These systems provided early and visible successes, and they continue to have great impact. However, knowledge-based computation also includes additional knowledge-based methods, such as model-based reasoning, which exploits models of structure and behavior, and case-based reasoning, which exploits stored records of specific problem-solving episodes. The tasks amenable to knowledge-based techniques can go beyond problem solving to include areas such as story understanding, planning, diagnosis, explanation, and learning.

Knowledge-based methods contrast with conventional programming, in which knowledge about the task domain is often implicit in the design of the program and its specific mechanisms, rather than reflected in an explicit form accessible to system manipulation. They also contrast with AI approaches in which knowledge is not explicitly represented, such as neural network models that capture knowledge in a distributed form. Using explicit representations can facilitate the addition of specific new pieces of knowledge, can aid in explaining system behavior, and can facilitate examination of the systems' knowledge state. Examination of the system's knowledge state can be useful for outside observers, increasing their confidence in the system by enabling them to understand or confirm the system's decisions. It may also be useful for the system to examine its own knowledge and to perform metareasoning—reasoning about its own reasoning process—to guide or refine its own internal processes.

This article begins by summarizing some central hypotheses proposed as theoretical foundations for knowledge-based computing. Next, because a crucial question for knowledge-based computation is how knowledge should be represented, it discusses principles for knowledge representation and illustrates some ways those principles are realized. It then describes a sampling of major currents of knowledge-based computing, highlighting their issues, strengths, and challenges.

FUNDAMENTAL PRINCIPLES

Groundwork for knowledge-based computation was laid by research in the symbolic computation paradigm articulated by Newell and Simon in the early days of AI. Their Physical Symbol Systems hypothesis proposed that "a physical symbol system has the necessary and sufficient means for general intelligent action" ((2): 116). They describe physical symbol systems as machines existing within a larger world of objects, which "[produce] through time an evolving collection of symbol structures," whose symbols relate to objects that they *designate:* Given the symbol, the system can either affect the object, or can behave in ways that depend on the object. Physical symbol systems can *interpret* expressions, executing the process an expression designates.

Given the Physical Symbol Systems hypothesis, a key question is how such systems accomplish intelligent action. Newell and Simon's Heuristic Search Hypothesis proposes that they do so by search: "generating and progressively modifying structures until [they produce] a solution structure" ((2): 120).

As the field of AI addressed new tasks, it became clear that general reasoning methods have wide applicability, but that their success is crucially bound to the specific knowledge that they apply, which gave rise to the view that "knowledge is power," articulated by Lenat and Feigenbaum (3). On this view, a small set of general-purpose reasoning methods is sufficient for achieving high-level performance in a wide range of domains—provided the reasoning system has the right knowledge. The *knowledge principle* states:

> A system exhibits intelligent understanding and action at a high level of competence primarily because of the *specific* knowledge that it can bring to bear: the concepts, facts, representations, methods, models, metaphors, and heuristics about its domain of endeavor (3).

Lenat and Feigenbaum proposed that a first important part of problem solving is formulating a representation of the problem. As knowledge is then added to the system, it first reaches the Competence Threshold, and then—through the addition of more rarely used knowledge—the Total Expert Threshold, at which point the system's knowledge is sufficient to handle rare problems.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

KNOWLEDGE REPRESENTATION

Principles for Knowledge Representation Schemes

For programs to manipulate and exploit knowledge, their knowledge must be represented in a suitable form within the computer. Consequently, the development of knowledge-based systems is inextricably tied to the development of the knowledge representations they will use. Davis et al. (4) propose five roles for knowledge representations:

1. *A surrogate:* Given a representation scheme, a system may explore effects of actions by manipulating the representations rather than the objects themselves.
2. *A set of ontological commitments:* The representation scheme determines which concepts and relationships can exist for the system, determining which features of the system's domain will be preserved, abstracted, or ignored.
3. *A fragmentary theory of intelligent reasoning:* The representation scheme is associated to a theory of reasoning with that scheme.
4. *A medium for efficient computation:* The representation scheme must support the types of reasoning required for its intended uses.
5. *A medium of human expression:* The scheme must support expression of the desired information and must support human encoding and understanding of represented knowledge.

Selection of the right knowledge representation scheme can play a crucial role in the success of knowledge-based systems and the types of questions that they can address. For example, qualitative models use coarse-grained representations to enable commonsense reasoning (5).

Logic and Knowledge Representation

The field of logic studies formal languages, truth conditions, and rules for deriving conclusions (see *Formal Logic*). The use of logic to represent knowledge long predates AI, and with the advent of AI, logic was applied to AI knowledge representation to provide a formal structure for knowledge and reasoning, addressing the questions of what form a representation should take and what inferences are sanctioned.

The language of first-order logic includes predicates denoting propositions, logic operators such as $\wedge$ (and), $\neg$ (not), and $\Rightarrow$ (implies) (note that $\vee$ (or) can be derived from $\wedge$ and $\neg$), functions, variables, and quantifiers $\exists$ (there exists) and $\forall$ (for all) to form expressions. Values for the variables are selected from an agreed on universe of discourse. For example, an assertion that all animals covered with hair are mammals could be expressed as:

$$\forall x((animal(x) \wedge has\,Hair(x)) \Rightarrow mammal(x))$$

given the predicates *mammal, animal*, and *hasHair*.

Inference rules license the formation of conclusions. For example, *modus ponens* asserts that given two propositions P and Q, and given the rule $(P \Rightarrow Q)$ (which represents "P implies Q"), then if P is known to be true, Q is true as well. In many real-world situations, general rules have exceptions; in a medical domain, symptom *X* might suggest disease *Y*—unless symptom *Z* has been observed as well. This process motivates research on how to enable default reasoning in a logical framework.

A long-standing current of knowledge representation research focuses on the problem of formalizing common sense knowledge. This challenge was highlighted in 1959 by McCarthy (6), and has been addressed in efforts such as Hayes' ontology for liquids (7). For a fuller discussion of the logic-based perspective on knowledge representation and reasoning, see Brachman and Levesque (8). Formalization of common sense knowledge is examined by Davis (9) and plays a key role in the Cyc project (10), which aims to accumulate a knowledge base spanning human consensus knowledge.

Semantic Networks

Semantic networks (11) represent knowledge as a network of labeled nodes and arcs, facilitating graphical visualization of knowledge for human inspection as well as providing an indexing structure for retrieval of particular types of knowledge for automated reasoning. Semantic networks can capture classification knowledge, with nodes representing categories and arcs representing subcategory relations in a hierarchical structure from the most generic categories to specific instances. An illustration is a zoological taxonomy (e.g., a mammal is an animal is a living thing). Specific graphical notations may be used to represent aspects of first-order logic (12). A simple example of a semantic network fragment, involving statements about tigers, mammals, and carnivores, is shown in Fig. 1.

Semantic networks may also be used for computation. For example, networks may pass messages in the form of tokens or markers from node to node, for tasks such as identifying relationships or managing expectations during parsing or language understanding, (13). Sowa's conceptual graphs (14) illustrate the use of semantic networks to model the semantics of natural language. A conceptual graph represents a proposition as a set of labeled nodes and unlabeled arcs. In the graphical form, rectangles represent concepts and ovals represent conceptual relations; extensions support the use of boxes for nesting conceptual graphs, to encode complex natural language propositions to represent statements about propositions. For example, "Jim believes that tigers are mammals" includes both the proposition that tigers are mammals and the proposition that Jim believes the former proposition.

Conceptual Dependency Theory: Primitives of Meaning

Developing a knowledge representation scheme requires selecting the basic units of meaning. Schank's Conceptual Dependency (CD) Theory (15) provides a concrete example of how the requirements for a knowledge representation are reflected in the primitives chosen to represent actions

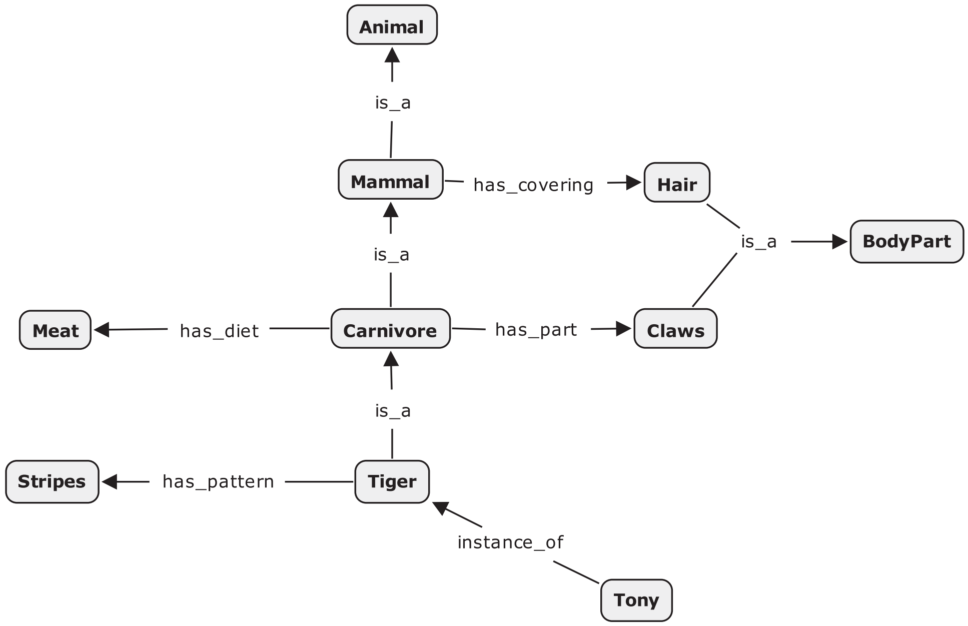

Figure 1. A sample semantic network about mammals.

for a particular domain. CD theory is both a theory of the requirements for designing sets of primitives and an example of the application of the proposed theory to develop a specific set of primitives.

CD theory aims to represent everyday actions to support the task of story understanding—establishing the coherence of stories by filling in their causal connections. CD theory distills everyday actions into a small set of 12 "primitive acts," listed in Table 1. PTRANS stands for Physical TRANSfer (of location), and underlies verbs such as "to go," "to walk," "to run," "to drive," "to fly," and so on. PROPEL describes the act of causing a force to be applied to an object in a specified direction, and underlies verbs such as "push," "throw," and "shoot." ATRANS describes transfer of possession, underlying verbs such as "buy," "sell," and "lend." MTRANS describes mental transfers (of information), underlying verbs such as "read," "listen," and "hear;" MBUILD describes formation of conclusions. ATTEND describes focusing a sense organ on a stimulus (as in "listen" or "look"); SPEAK describes production of sounds; INGEST, taking something into the body (as in "eat," "breathe," and "inject"); EXPEL, expelling from the body; MOVE, moving a body part; and GRASP, grasping an object. The names of the primitives are selected both to suggest their meaning to humans and to avoid ambiguities of natural language. A final primitive, DO, is used to represent unspecified actions.

The CD acts can depend on other acts in two ways, by causality (one causes another, enables another, motivates another, and so on) or by instrumentality. For example, walking somewhere can be represented as a PTRANS to that location, with the instrumental action of MOVEing the feet. Taking in textual information by reading visually is represented by MTRANS with an instrumental ATTEND of the eyes, whereas the representation for reading braille includes an ATTEND of the hand.

Each primitive is associated with a structure of "slots" to fill to describe an act, providing expectations. CD allowed a highly limited set of slots, including the ACTOR of the act, the OBJECT of the act, the direction (FROM and TO) and the INSTRUMENTAL ACTION by which the act was performed. Each primitive could be associated with inferences (e.g., that at the end of a PTRANS, the OBJECT of the PTRANS was at the location specified by the TO slot).

The structure of CD provides expectations that were used to guide conceptual parsing of natural language text, representation, and inferencing within a line of story understanding systems (16). The small number of primitives facilitated connecting events by inference chaining, by limiting the set of inference procedures needed.

Frames, Frame Systems, and Scripts

Knowledge representation schemes may also collect information into larger units. Minsky's theory *of frames*, based on the premise that units of knowledge should be large and structured, proposed the use of large-scale structures for representing stereotyped situations, such as being in a living room or at a child's birthday party. Frames can be seen as networks of nodes and connections, linking together associated information such as expectations, responses to expectation failures, and viewpoints. The slots of frames are associated with default information, recommending standard inferences and enabling a frame system to draw defeasible conclusions about information that may not be confirmable deductively. For example, birthday parties often include the presentation of gifts, but the assumption that gifts were given may not hold in a particular case. Numerous frame systems have been developed to support knowledge storage, retrieval, and inference, providing general tools that may be used to manage the knowledge for task-specific systems.

Table 1. The Conceptual Dependency Theory Primitive Actions

PROPEL	MBUILD	INGEST	GRASP
ATRANS	ATTEND	EXPEL	DO

Schank and Abelson's Script theory (17) illustrates the use of large-scale knowledge structures for story understanding. During story understanding, many inferences could be generated in principle; which ones are actually appropriate is context-dependent. For example, it is reasonable to infer that a person who wants food will ask for it, when at a restaurant—but not when that person is looking into a refrigerator at home. Scripts facilitate context-specific inferences by packaging the standard events that occur in particular contexts, such as restaurant dining.

Script theory was based on a theory of stereotyped knowledge structures, which were hypothesized to be built up by people through repeated experience. Scripts capture expectations, inferences, and knowledge that apply to common situations. For example, the restaurant script includes the following standard events, with standard roles of *restaurant*, *diner, food*, and *waiter*, which are filled in for each specific episode:

Diner enters the *restaurant*.
Diner sits at a table.
Diner orders *food* from *waiter*.
Waiter brings *food*.
Diner eats *food*.
Diner pays for *food*.
Diner leaves the *restaurant*.

Script-based expectations can aid disambiguation during story understanding. For example, when the restaurant script is active and "Mary asked for a hamburger" is processed, "Mary" refers to the *diner* and "hamburger" provides the role-filler for *food*. When "She paid for it" is encountered later, the script provides the expectation that "she" is Mary and "it" is the hamburger. In addition, scripts are useful for guiding summarization of text. Routine events, provided by the script, can be assumed; only the role-fillers provide new information and need to be reported in a summary.

Later research on Memory Organization Packages (MOPs) (18) developed hierarchical episodic memory models with shared structure, enabling cross-contextual learning by permitting a component to be refined in one context and reapplied in another. For example, something learned about payment in the context of a restaurant (e.g., that some restaurants refuse to accept credit cards to pay small amounts), would also be available in other MOPs which share the PAY scene, such as MOPs for grocery stores or service stations.

RULE-BASED REASONING

Rule-based systems use knowledge encoded in the form of rules to draw conclusions from chains of rule applications. Rule-based reasoning has been studied both as a cognitive model and as an AI method, and it was central to the explosive growth of industrial expert systems applications in the 1970s and 1980s.

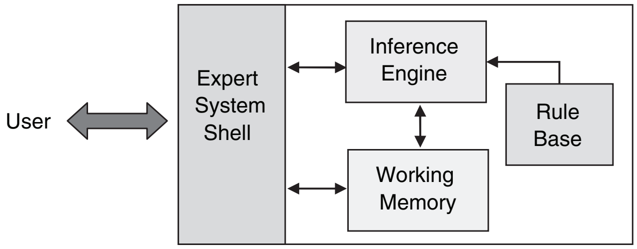

Figure 2. Production system architecture.

Production Systems

Production systems contain three components, an inference engine, a rule base, and a working memory, as illustrated in Fig. 2. Prior to problem solving, the working memory is initialized with a set of facts, which are updated during processing by deleting existing facts and adding new conclusions, or by adding information provided externally (e.g., by sensors or from querying the user).

Production systems apply their knowledge through the execution of production rules. Each production rule has two parts, a conditional part and an action part (see *Production Rules)*. At each processing step, the inference engine identifies rules whose conditional parts match the facts in working memory, to execute or "fire" the rules by performing their associated actions. This approach to flexible control differs from the prespecification of a solution path, and from the mixture of knowledge and control, commonly found in programs written in traditional programming languages.

An early focus of research in production systems was to model human problem-solving processes, as explored by Newell and Simon in the 1970s (19). Production systems continue to be studied as cognitive models. Soar, a cognitive architecture that represents knowledge in the form of productions (20), has been used in successive versions by a large body of researchers since the 1980s. As the goal of the Soar project is to support all capabilities required for a general intelligent agent, the Soar project also investigates capabilities such as interruptibility and the integration of learning and problem solving.

Rule-Based Expert Systems

A classic example of a rule-based expert system is MYCIN, a system for medical diagnosis (21). MYCIN is a goal-driven abduction system that aims to capture physicians' expert knowledge and to model reasoning with missing or incomplete information.

MYCIN's task domain is the diagnosis of infectious blood diseases including meningitis and bacteremia, which require rapid treatment. Although laboratory tests could be used to identify the organism causing blood disease, when MYCIN was developed, complete testing took 24–48 hours or more, too long for timely treatment. The time-critical nature of the task led doctors to acquire substantial expertise in the domain, making it especially interesting for studying diagnostic reasoning.

To capture expert knowledge, MYCIN uses production rules associated with certainty factors. Each rule represents a conclusion that an expert would draw given some evidence, and the certainty factor associated with each rule captures how strongly the evidence supports the rule's conclusion. For example, one MYCIN production rule states that "IF the infection is primary-bacteremia, and the site of the culture is one of the sterile sites, and the suspected portal of entry is the gastrointestinal tract, THEN there is suggestive evidence (0.7) that infection is bacterioid." The rules were acquired in interviews with doctors, conducted by knowledge engineers who elicited the rules and encoded them in a machine-readable form. MYCIN's initial rule base contained 450 production rules. In an evaluation of the system, MYCIN's performance on randomly selected case histories of meningitis was measured against that of members of Stanford Medical School, with MYCIN's performance comparable with—and in some cases better than—the humans' performance (22).

To enable MYCIN's inference engine to apply to other tasks, it was made into a stand-alone system, EMYCIN (for "empty MYCIN"). More generally, rule-based system *shells* became widely available, enabling developers of rule-based systems to focus only on domain knowledge. The success of such systems in many domains provided support for the knowledge principle.

Control Strategies for Rule Execution

Rule-based systems may guide rule execution either with a data-driven *forward chaining* strategy or with a goal-driven *backward chaining* strategy.

Forward Chaining. In a forward chaining system, the inference engine checks the conditional part of a rule against the facts stored in working memory to fire rules whose antecedents are matched. If multiple rules match, additional strategies determine which one to fire. For example, rules can be associated with salience values specifying their priorities compared with a default, and the most salient rule triggered. Other strategies include favoring rules matching recently generated facts (to help to focus on a single line of reasoning), favoring rules that have fired less recently (to help avoid loops), or favoring more specific rules (to exploit knowledge relevant to the specific situation), or using special-purpose reasoning based on metarules. Execution may stop when predefined conditions are met (e.g., when the system generates a desired conclusion), or may continue indefinitely, (e.g., if the production system is generating actions to control a robot's behavior).

Table 2 illustrates production rules and forward chaining with a sample rule base written in the syntax of JESS (Java Expert System Shell) (23). The sample rule base identifies mammals based on their characteristics of having body hair or producing milk. Given the initial facts shown in (B), the inference engine matches both the rules in the rule base in (A) but executes the rule *Hair→Mammal* before *Milk→Mammal* due to the higher salience value of the first rule. The second rule is consistent with the first rule and when both are executed, the modified working memory shown in (C) contains an additional fact about the animal being a mammal.

Table 2. Sample JESS Rule Base for Classifying Mammals, Initial Working Memory, and Working Memory After Rule Application

(A) Rule Base

```
(defrule Hair->Mammal
   (declare (salience 100))
   (attribute (type hasHair) (value “yes”)) ⇒
   (assert (animal (type mammal) (value “yes”))))

(defrule Milk->Mammal
   (declare (salience 50))
   (attribute (type producesMilk) (value “yes”)) ⇒
   (assert (animal (type mammal) (value “yes”))))

(defrule Ruminant+Mammal->Ungulate
   (attribute (type isRuminant) (value “yes”))
   (animal (type mammal) (value “yes”)) ⇒
   (assert (animal (type ungulate) (value “yes”))))
```

(B) Initial Working Memory

```
(attribute (type hasHair) (value “yes”))
   (attribute (type producesMilk) (value “yes”))
```

(C) Modified Working Memory

```
(attribute (type hasHair) (value “yes”))
   (attribute (type producesMilk) (value “yes”))
   (animal (type mammal) (value “yes”))
```

Rule-based system shells require efficient strategies to determine which rules to fire to handle large-scale rule sets. The Rete algorithm (24), used in a modified version by JESS, provides a method for determining which rules to fire without having to check every rule against working memory in each step. Rete builds a network of nodes in which each node, except for leaf and root nodes, corresponds to a pattern in the conditional statement of the rule. Paths from the root to a leaf node correspond to the conditional statement of a rule. Nodes store the facts that satisfy their pattern. As new facts are asserted or modified, the nodes in the network are annotated with the facts. As the algorithm annotates nodes with facts, it checks whether rules linked to the annotated nodes need to be fired due to changes in the conditional nodes. A rule can be fired if the nodes in its conditional part are satisfied. Figure 3 illustrates the network for the rule base of part *A* of Table 2, with the node values resulting from processing the facts of part *B*.

Backward Chaining. Forward chaining systems start from known information and generate possible conclusions. In backward chaining systems, such as MYCIN, chaining is focused by a hypothesized goal condition, which the system

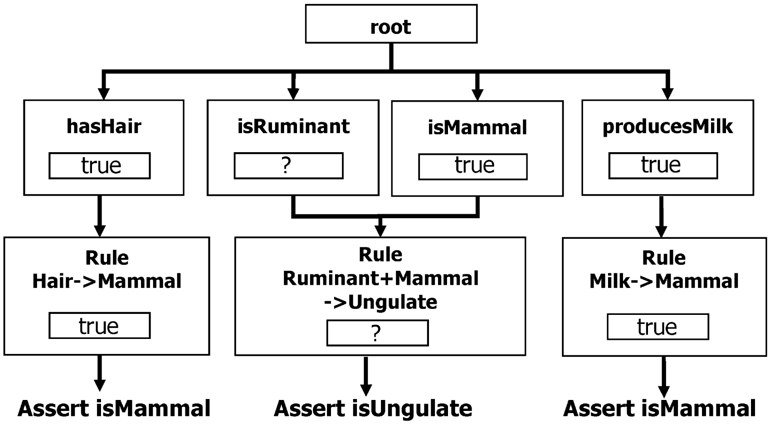

Figure 3. The Rete node network for three sample rules.

attempts to establish by pursuing a chain of rules chosen to confirm that hypothesis. For the MYCIN task, the goal is a possible diagnosis: a candidate infecting organism. As described previously, the system identifies rules and inquires about facts in support of the selected goal.

In backward chaining, the system starts from the goal, selects rules from which the goal could be concluded, and determines whether the facts in working memory are sufficient to trigger the selected rules. If not, it takes the antecedents of the selected rules as new goals to establish, forming a chain of rules and, if necessary, eventually asking the user for information that it cannot establish. Different strategies may control the order in which alternatives are pursued.

As an example of the chaining process, if the goal is to determine whether a particular animal is a mammal, the first rule in Table 2 suggests checking whether the animal has hair. In some contexts (such as medical systems, for which test results may be available), the system may also ask users questions to verify or reject the selected hypothesis. At any given time, the system may be considering multiple chains backward from a hypothesized goal, each of which containing a sequence of rules that, when triggered, leads to the selected goal. If the systems cannot construct any chain that fires, the hypothesized goal is rejected.

For example, in the rule base in Table 3, to determine whether an animal under consideration is a tiger, the system first attempts to establish whether the animal has black stripes, a tawny color, and is a mammal, and a carnivore. If this information is not available internally, it may ask the observer to provide the necessary information to trigger the Tiger rule. If any of the required information is missing (e.g., the user knows that the animal has the right color, is a mammal, and has black stripes, but not whether it is a carnivore), either of the rules to determine whether an animal is a carnivore may be tried to find the missing information.

When a rule-based system asks questions, how those questions are managed is important to user acceptance of the system. Consistent with the general practices of human physicians, MYCIN first asks general background questions about the patient before focusing on specific questions related to the hypothesized goal in the diagnosis of the disease and, as facts are needed, tries to gather related information at the same time to increase coherence of the interaction and improve user confidence.

Managing Uncertainty and Vagueness

In practice, it may be difficult to assign appropriate certainty factors. One approach to address this problem is to use machine learning to refine certainty factors. For example, the RAPTURE system (25) maps the rules in a rule base to a neural network architecture and then uses a modified version of the backpropagation learning algorithm (see *Artificial Neural Networks*) to revise the certainty factors associated with the rules. This system has been successfully applied to revise the MYCIN rule base. An alternative approach to handling uncertainty is to use methods based on probability, as described in the probabilistic graphical models section.

Table 3. JESS Rule Base for Classifying a Tiger

```
defrule Mammal+Carnivore+Tawny+Stripes->Tiger
  (animal (type mammal) (value “yes”))
  (attribute (type carnivore) (value “yes”))
  (attribute (type tawnyColor) (value “yes”))
  (attribute (type blackStripes) (value “yes”))⇒
  (assert (animal (type tiger) (value “yes”))))

(defrule Mammal+EatsMeat->Carnivore
(animal (type mammal) (value “yes”))
  (attribute (type eatsMeat) (value “yes”))⇒
  (assert (animal (type carnivore) (value yes”))))

(defrule Mammal+PointedTeeth+
Claws+ForwardEyes->Carnivore
  (animal (type mammal) (value “yes”))
  (attribute (type pointedTeeth) (value “yes”))
  (attribute (type claws) (value “yes”))
  (attribute (type fowardPointingEyes) (value “yes”))⇒
  (assert (attribute (type carnivore) (value “yes”)))
```

In some domains, such as control and pattern recognition, production systems commonly use fuzzy logic (26) to deal with imprecise measurements. In fuzzy rules, the conditional and action part are described with fuzzy sets, functions that specify a membership value between 0 and 1 for each element of the set. For example, a fuzzy rule whose antecedent checked whether a patient has a high temperature might use a fuzzy set to describe a range of temperature values, and their corresponding membership values would determine the extent to which a particular temperature value is considered "high" (see *Fuzzy Logic and Theory*). The consequent of the rule could generate a fuzzy set that is converted to a crisp value through a process called "defuzzification." Fuzzy rules enable vague knowledge to be expressed in a language that is natural to the experts.

Applications and Applications Issues

Rule-based expert systems have been applied to an extensive range of problem-solving tasks such as diagnosis, interpretation, planning, scheduling, and system configuration. Specific examples include expert systems for configuring computer systems and to perform audit risk analysis, to identify debit card fraud. Rule-based systems are also embedded within other systems to support decision making (e.g., to enforce software agent policies in open network environments) (see *Expert Systems*).

One of the social and economic motivations for expert systems is to make expertise, which is normally expensive and available in limited supply, more widely available. For example, medical expert systems could increase the accessibility of medical knowledge. However, larger issues can impede the transition from research system to technology. A case in point is MYCIN, which for ethical and legal reasons was never deployed, despite its successful evaluations. For knowledge-based systems, both the inference engine and the knowledge must be verified (see *Knowledge Verification*). In addition, as described later in this article, knowledge acquisition may be a difficult problem.

BLACKBOARD SYSTEMS

Blackboard systems coordinate independent processes for cooperative problem solving. Blackboard systems reflect the metaphor of experts working around a shared blackboard accessible to all, and each one able to consult, add, or remove the entries. In blackboard systems, the shared *blackboard* is hierarchically organized, representing information at different levels of abstraction. A set of independent programs, called *knowledge sources*, each reflect different capabilities or perspectives on the overall task, and individually monitor and update the blackboard during processing, incrementally taking advantage of results generated by the ongoing processing of other knowledge sources. For example, the HEARSAY-II system uses a blackboard system architecture to process continuous speech input, with knowledge sources performing functions such as extracting acoustic parameters, classifying acoustic segments, recognizing words, parsing phrases, and making predictions (27). Whenever the blackboard changes (e.g., with an addition), each knowledge source determines whether the change is relevant to its knowledge. Those knowledge sources that are relevant become eligible to be run by a scheduler, which controls knowledge source execution.

PROBABILISTIC GRAPHICAL MODELS

In a purely deductive reasoning framework, each rule describes a set of antecedents from which a conclusion must necessarily follow. However, deterministic rules may not be sufficient to characterize the connections in a domain. For example, rules for drawing medical conclusions must reflect the possibility of false positives. In complex real-world domains, rules cannot exhaustively include all potentially relevant factors, resulting on uncertainty in whether the conclusions of a rule will hold for any given instance. For effective reasoning, it is desirable to summarize the level of uncertainty and take it into account when drawing conclusions, which may be done by applying approaches such as probability theory (see *Probability and Statistics)* or alternative methods such as Dempster–Schafer theory, which distinguishes between belief and plausibility (28).

Probabilistic graphical models apply probability theory to knowledge-based systems, using a graph structure to represent information about dependence and independence. For example, Bayesian Networks are directed acyclic graphs in which nodes represent random variables and links represent the variables' dependence relationships. By implicitly encoding independence assumptions in the network structure, Bayesian Networks provide a concise representation.

For Bayesian Networks, knowledge capture involves developing the domain model encoded in the network, first qualitatively, reflecting relevance through the choice of connections, and then quantitatively, in terms of conditional probabilities. The inference problem becomes the problem of how to compute each node's belief, given current evidence; approximation techniques have been developed to enable rapid computations. See Charniak (29) for an overview and Pearl (30) for an extensive discussion. Dynamic Probabilistic Networks can be used to model dynamic systems, and stochastic simulation algorithms can be used to rapidly approximate the results of these networks. See *Bayesian Belief Networks* and *Hidden Markov Models* for related information.

MODEL-BASED REASONING

Device models provide another useful form of knowledge for diagnosis and troubleshooting. Model-based reasoning (MBR) exploits models of the structure and behavior of devices—characterizations of internal function, rather than simply descriptions of associations between observed antecedents and conclusions—to support a process of prediction and observation (31). The model-based troubleshooting process starts from observations of a device, such as measurements of inputs and outputs, a model of device structure, such as components and their connections, and descriptions of each component's behavior. To diagnose component failures, the approach generates hypotheses about the components causing the problem and tests hypotheses against device behavior to find suitable candidates. It then discriminates between the hypotheses consistent with the symptoms, by methods such as probing, selecting new points to measure within the device. Additional knowledge may be brought to bear in this process, for example, to select the probes expected to be most informative based both on their discriminating power and on known failure probabilities.

CASE-BASED REASONING

Case-based reasoning (CBR) focuses on reasoning from specific experiences, rather than from general rules or models. A case-based reasoner addresses new situations by retrieving prior cases and adapting their lessons to fit new circumstances. Case-based reasoning can be seen as combining a number of processes (32):

$$\text{Case-based reasoning} = \text{retrieval} + \text{analogy} + \text{adaptation} + \text{learning}$$

Early investigations of CBR were inspired by studies of human cognition, such as on the role and organization of episodic memory in understanding and the role of cases in human reasoning (see Ref. (33) for a survey of case-based reasoning viewed as a cognitive model). As humans solve problems, they may be reminded of similar problems in the past, suggesting starting points for new problems or warning of possible pitfalls to avoid. For example, a doctor responding to an adverse reaction to medication might be reminded of a specific similar emergency and how it was addressed, providing useful guidance that would not be contained in general rules (e.g., that adrenaline kits in a particular emergency room are kept on the top shelf). Motivations for applying CBR include that CBR can facilitate knowledge capture from experts, by enabling direct storage of their "war stories," rather than generation of rules, and systems may be fielded with a small set of "seed cases" to be augmented by the system's own experiences. Likewise, CBR systems can reuse reasoning effort, can adapt and apply prior solutions even when the reasons for their successes are poorly understood, and can justify their answers in terms of real examples rather than generalizations, which users may find harder to accept (32,34).

A fundamental difference between rule-based and case-based reasoning is that rule-based systems model problem solving as a process of *generate and test*, whereas case-based systems rely on *retrieve and adapt* (35). Reuse may be possible even when the underlying causal factors are unknown (e.g., when adapting an externally provided solution). For example, a novice cook may be able to adapt a vanilla cake recipe to chocolate, by adding cocoa power, without understanding why the basic recipe produces its results.

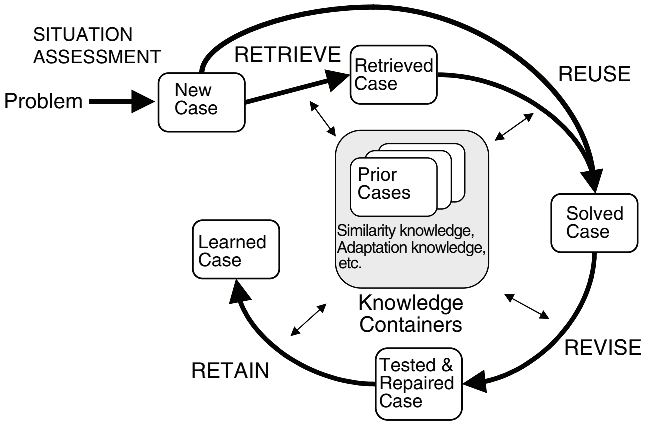

Figure 4. The case-based reasoning cycle (adapted with changes from Ref. 36).

The CBR Cycle and Knowledge Sources

A case-based reasoning system's processing can be seen as a cycle, beginning with retrieval of a case to address a new problem, and ending with a new case placed in memory for future use, as illustrated in Fig. 4. Given a problem description, situation assessment generates a problem description used as an index to retrieve a relevant prior case. The system attempts to reuse the solution of the prior case, revising it as needed for differences. The case is then retained in memory for future use, possibly after filtering for the expected benefit of retaining it.

As suggested by Fig. 4, CBR systems rely on multiple knowledge sources, the CBR "knowledge containers" (37), which include the cases themselves, knowledge implicit in the choices of representational vocabulary, similarity criteria, indexing knowledge to guide retrieval, and case adaptation information. These knowledge containers overlap, in the sense that, for example, an extensive case library may cover enough problems that the availability of cases compensates for limited adaptation knowledge; rich adaptation knowledge may enable successful performance with few cases. The ability to select where to place system knowledge facilitates the development of CBR systems by enabling system developers to provide knowledge in whichever container is most practical for a given task.

Methods and Issues in CBR

CBR systems often perform "nearest-neighbor" retrieval, selecting cases that minimize the distance between the current problem and the retrieved problem, based on a distance function considering the distance for each attribute. If problems are described by vectors of numeric or symbolic feature values, with the new problem situation $Q = q_1, q_2, \ldots, q_n$ and a previously solved problem $P = p_1, p_2, \ldots, p_n$, and $W = w_1, w_2, \ldots, w_n$ is a vector of non-negative weights reflecting feature importance, then the distance function is often defined by:

$$distance(Q,P) = (\Sigma_i w_i \times \text{difference}(q_i, p_i)^2)^{\frac{1}{2}}$$

for a given difference function. One simple approach is to define difference $(q_i, p_i) = |q_i - p_i|$ for numerical features, and 1 for identical symbolic feature values, 0 otherwise. However, more complex distance functions may be chosen to make difference values more directly comparable and to reflect other aspects of the task domain.

For classification or regression tasks, the risk of error due to noise may be mitigated by retrieving the top k cases and combining their solutions (e.g., by taking their majority vote to assign a categorical value, or by averaging their solution values for a numerical one).

For large case bases, cases may be organized into discrimination trees for retrieval efficiency. In case-based problem solving, cases may be indexed by the goals and constraints they satisfy, with indices varying from abstract, domain-independent features to highly concrete features. For example, the CHEF planning system, which plans in the domain of cooking, uses features ranging from "a plan step side-effect disabled a required condition for a concurrent step" to "the dish uses chicken" (38)). Retrieval based on concrete indices helps to retrieve cases with specific matches, facilitating reapplication; indexing based on abstract indices aids in cross-contextual retrievals, enabling cases to be applied to novel situations. Indexing vocabularies have been developed for a number of domains.

Case adaptation knowledge is often rule-based, but other knowledge-based methods, such as model-based reasoning have also been applied. As it may be difficult to generate needed knowledge in poorly understood domains—where CBR may be a method of choice—case adaptation remains a central challenge to CBR. Some research has addressed this fact by applying case-based methods to the adaptation process. Extensive index reformulation or case adaptation may be necessary to apply a prior lesson to a novel situation in a different domain, potentially resulting in a creative reasoning process (e.g., Refs. 39 and 40).

Case-based reasoning is widely used in help desk applications, which guide case selection through a conversational process with the user, focusing on retrieval support rather than case adaptation (41). The FormTool system, developed for plastics color matching, illustrates a high-impact application that includes case adaptation (42). As the number of long-term applications of CBR increased, how to control case-base growth while maintaining system competence was recognized as an important area (43), and interest grew in how to maintain CBR systems' knowledge (see Ref. 44 for an analysis and survey of CBR system maintenance). An extensive discussion of research on core CBR issues and methods is available in Ref. 45.

EXPLANATION IN KNOWLEDGE-BASED SYSTEMS

The explicit representation of knowledge makes reasoning processes amenable to explanation. This explanation process may be aimed for the system's own internal use or for the benefit of an external user.

Internal Explanation

Understanding programs that form connections by inference chaining can be seen as performing a basic form of explanation, generating causal connections to account for why events in a story are coherent. Script-based understanding systems also use their knowledge to explain, but by fitting new information into existing knowledge structures: an event (e.g., handing money to someone) is explained if it is expected by an active script (e.g., as the payment in the restaurant script).

Script-based models explain routine events, but cannot explain novel events. However, the attempt to apply scripts can still be useful for focusing the explanation effort, because the parts of a story that are useful to explain are the expectation failures or anomalies. For example, what to explain about a death would be quite different if the anomalous aspect were that it was premature (in which case the focus might be the cause) or if it were the advanced age of the deceased (in which case the focus might be explaining the secrets of the longevity of the deceased). The SWALE system (39) illustrates multiple roles of knowledge in internal explanation with a case-based approach drawing on knowledge sources including MOPs, explanation cases, an indexing vocabulary for anomalies, and a collection of explanation requirements called explanation purposes.

SWALE's explanation cases, which are adapted to explain new events, can be seen as providing flexible schemas to handle novel events. An alternative approach for generating new schemas is to perform explanation-based learning, in which a domain theory is used to explain the relevance of particular features, enabling correct generalizations from a single example (46).

Explanation for an External User

Expert systems research recognized early on the importance of explaining system behavior to users to increase their acceptance and confidence in system decisions (e.g., Ref. 21). A basic approach to the explanation process in a chaining system is to display the rule chain leading to a system decision. However, this detailed trace may be difficult for users to follow, and it may not include all information end users need. To address this problem, reconstructive explanation (47) treats the explanation process itself as a problem-solving task, reorganizing and augmenting explanations as needed.

One of the benefits of case-based reasoning is that the cases used to generate solutions can also provide compelling support to users, as shown by Ref. 48. However, the use of cases is not a panacea; additional reasoning may be needed to select the most effective cases to use for explanation, and additional explanation may be required to account for why the presented case was selected or how it was adapted (see Ref. 49 for a sampling of this work).

KNOWLEDGE ACQUISITION ISSUES

A classic problem for knowledge-based systems is how to secure the needed knowledge. Experts often have difficulties expressing their knowledge in a rule-based form, requiring the rule capture process to be mediated by knowledge engineers, who interview experts, represent, and refine the needed knowledge in a labor-intensive process, resulting in the “knowledge acquisition bottleneck” (50) (see *knowledge acquisition*).

Despite methodologies developed to facilitate knowledge capture, the process remains laborious. For example, a project that captured the knowledge in a chemistry textbook resulted in impressive system capabilities (at the level expected for college-level advanced placement examinations), but at an estimated knowledge acquisition cost of $10,000 per page (51). Research is under way on methods for supporting knowledge acquisition from humans, aiding them in identifying and resolving differences in their conceptualizations of a domain, and knowledge engineering, as well as on automatically extracting knowledge from sources such as the World Wide Web. User-centered knowledge acquisition methodologies may help to eliminate the need for knowledge engineers as mediators between the system and domain expert, enabling domain experts to enter their knowledge directly into a knowledge base. Machine learning methods may be useful for rule generation and refinement (see *Machine Learning)*.

Expert systems are normally designed with narrow and deep knowledge of a specific domain, which can cause brittleness, as systems are incapable of gracefully handling situations outside their narrow domain. The Cyc project (10) aims to address this and other problems by encoding an immense knowledge base of carefully crafted representations of common sense knowledge. Another endeavor, Open Mind Commonsense, takes a different tack, capturing informal knowledge entered by volunteers. Although this knowledge is less suited to machine reasoning, it has been used to develop advisory applications in domains for which it can provide a payoff and for which failure is noncritical (52).

THE SEMANTIC WEB

The World Wide Web now contains vast amounts of information on a large variety of topics. Although machines provide, display, and even produce the content of web pages dynamically, the information on the pages is designed primarily for human use. Despite promising work on automatically extracting such information (53), the problem remains challenging.

One cause of the difficulty of machine processing for web pages is that most web pages lack metadata tags describing their content. The Semantic Web (54) is a vision of a future World Wide Web that provides information to make Web content meaningful for machines as well as people. Semantic Web applications exploit web pages tagged with metadata defining the meaning of their content to enable knowledge-based methods to improve existing services such as Web search (e.g., by improving retrieval quality and enabling search systems to return answers, rather than pages). They also enable new services, such as software agents that use the metadata to find, compare, and respond to information from many sources, for tasks such as automating situation awareness aids or facilitating supply chain integration. A sampling of such applications is provided by Ref. 55.

The Semantic Web defines rules, concepts, and statements to annotate web pages with labels that define the semantics of the information on the pages allowing machines to make inferences about its content. The vocabulary used to define such labels is based on *ontologies*, which capture a “specification of a shared conceptualization of a domain” (56).

New languages, building on Web technologies such as XML (eXtensible Markup Language) and RDF (Resource Description Format) have emerged for the Semantic Web and have been adopted by the World Wide-Web Consortium (W3C) as standardized Semantic Web languages. A prominent example is the Web Ontology Language (OWL)(57), used for building ontologies that can be published on the Web and used to annotate Web content or make inferences about a subject. OWL builds on previous work on ontology languages including the DARPA Markup Language (DAML) and DAML+OIL (DAML Ontology Inference Layer). It covers and extends the language constructs and representational features offered by these languages to provide a language that can meet the requirements for representing knowledge in the Semantic Web. Both DAML and DAML-OIL also build on RDF and RDF Schema (RDFS).

RDF is an assertion language intended to express propositions about resources on the Web. In general, a resource is considered anything that can be assigned a Uniform Resource Identifier (URI). RDF expresses propositions as triples: a subject, a predicate, and an object. Each element can be a resource with a unique URI, whereas an object can also be a literal, which is a typed or untyped text string. Resources may be divided into groups called classes and members of a class are known as instances of the class. RDF Schema is a semantic extension of RDF that provides basic constructs for defining classes and properties and relationships between classes such as a class being a subclass of another class. DAML and DAML+OIL support constructs to define more complex relationships such as cardinality restrictions on properties.

OWL is a recent extension of existing ontology languages, providing a rich set of language features to enable efficient representation of ontologies. The language is specifically engineered for the Web, supporting features that make it easy to publish ontologies or to reuse existing ontologies on the Web, to annotate Web content, or to make inferences. OWL has three different sublanguages with a different level of expressiveness to serve the needs of the Semantic Web community. OWL Lite supports defining classification hierarchies and simple constraints. OWL DL (DL refers to description logic) is more expressive than OWL Lite, adding additional language constructs from OWL while retaining computational completeness (all conclusions are guaranteed to be computable) and decidability (all computations will finish in finite time). OWL Full is the complete OWL language providing maximum expressiveness without computational guarantees. Table 4 illustrates a fragment from an OWL ontology on food. The ontology includes a base class ConsumableThing, a class NonConsumableThing that is complementary to ConsumableThing, a class EdibleThing that is a ConsumableThing,

Table 4. Excerpt From an Ontology on Food, [Adapted from Ref. 58].

  </owl:Class>
```

and a class PotableLiquid that is also a ConsumableThing but different from EdibleThing.

The promise of the Semantic Web and the creation of standard Semantic Web languages have prompted considerable interest in developing inference systems and tools to build and merge ontologies and to mark up web pages to provide meaning to the content. For example, Protégé (59) is an open-source framework, developed at Stanford University, for building editing tools that support the creation, visualization, and manipulation of ontologies in various representation formats; Protégé-OWL is a version for editing OWL ontologies. Other frameworks such as KAON (Karlsruhe ontology management infrastructure) (60) assist users in the creation, storage, and management of ontologies and support scalable and efficient reasoning with ontologies.

The Semantic Web of the future is likely to provide a set of standardized ontologies, enabling users to rapidly build their own ontologies by using existing and agreed on definitions of concepts. However, when new ontologies need to be constructed or existing ontologies modified, it will be crucial to aid users in finding the right parts of those ontologies. Consequently, research has focused on building tools to support retrieval and reuse of ontologies. For example, Swoogle (61) is a search engine for Semantic Web documents (online documents written in a Semantic Web language) that facilitates search within the documents based on keywords, focusing on matching class and property definitions in the Semantic Web documents. Hendler proposes that the Semantic Web is a step toward the large-scale knowledge source needed to realize the full potential of the knowledge principle (62).

HYBRID SYSTEMS

Each knowledge-based computation paradigm provides particular strengths. Consequently, many knowledge-based systems take a hybrid approach, combining multiple strategies. To provide a few illustrations combining case-based reasoning with other approaches, rule-based reasoning has been combined with CBR in domains such as legal reasoning, with cases and rules being jointly applied for legal arguments, and for generating pronunciations, with cases handling exceptions. Model-based reasoning has been combined with CBR for predicting forage consumption for rangeland management, with CBR generating an initial solution from a stored case, for refinement based on a model. These and other integrations are surveyed in Ref. 63. Hybrid methods may also be used internally, for one method to support the internal processing of another, for example, with constraint-based reasoning used to support case adaptation in CBR.

Hybrid approaches may also extend to combinations of knowledge-based and nonknowledge-based methods. For example, neural networks may be combined with knowledge-based approaches for each to make some classes of decisions, or symbolic knowledge may be inserted into neural networks to enable its refinement using neural network methods, for later extraction as refined symbolic knowledge (64). Such methods may simplify the development of intelligent systems and facilitate the application of knowledge-based systems technologies.

CONCLUSION

Knowledge-based computation spans many AI approaches. Each exploits explicit knowledge, but the forms of knowledge and mechanisms to manipulate them vary widely, for example, from formal to informal, from associations to models, from rules to cases, and from deductive to abductive inference. Knowledge-based computation has already been applied spanning a wide range of task areas, and the requirements of hard real-world problems have prompted calls to increase the emphasis on knowledge in areas such as AI planning, for which the use of knowledge can have considerable effect (65).

Despite these successes, a continuing challenge since the early days of knowledge-based computation has been how to obtain the needed knowledge. New knowledge capture methods, large-scale knowledge sources, and the advent of the Semantic Web promise to have significant impact on both research and applications in the next generation of knowledge-based computation systems.

ACKNOWLEDGMENT

We would like to thank George Luger for very helpful comments on a draft of this article.

K

KNOWLEDGE MANAGEMENT APPLICATION

Information and communication technologies (ICT) that support the handling of knowledge in organizations have been discussed for a long time. From the 1950s to the 1980s, systems that apply artificial intelligence (AI) technologies had a powerful impact on the conceptualization of knowledge, not only in the discipline computer science, but also in fields such as management science, organization science, or psychology. However, many business organizations that attempt to implement these technologies were frustrated by their comparably high complexity and the difficulties of applying them to business challenges. Thus, AI technologies survived only in specific application fields. In the 1990s, after a period of high attention to the increase of efficiency, organizations were faced with the transformation of the economy into a knowledge economy and its challenges to increase significantly the speed of innovation and to improve the way organizations handle (distributed) knowledge. For those countries that do not have (anymore) the possibility to exploit some form of natural resources, it is knowledge that creates wealth. Organizations strive to increase productivity of *knowledge work*. Knowledge work is creative work, it solves ill-structured problems in complex domains with high variety and many exceptions, and thus it requires a high level of skills and expertise from employees. The challenge is to design, implement, and maintain an organizational and ICT environment conducive for this type of work. The importance of knowledge work can be underlined by a recent study that showed that most jobs created in the United States between 1990 and 2000 in fact are jobs in the knowledge work sector (1).

Concepts of knowledge management (KM) have been suggested to meet this challenge, starting with the highly innovative work by authors such as in Refs. (2–5), just to name a few. Many authors from a variety of disciplines created, applied, and reflected several approaches, concepts, methods, tools, and strategies for KM. These innovations have led to several terms that are used differently, approaches that are incommensurable, and a lack of applicability in a business context. More recently, however, several instruments have emerged as state-of-the-art of KM practice. Examples are competence management, community management, or semantic content management.

Backed by tremendous interest in KM in the academic field and in business practice, vendors of information and communication systems as well as researchers in the field of computer science and management information systems showed prototypes, tools, and systems to support KM called *knowledge management systems* (KMSs). The term KMS has been a strong metaphor for the development of a new breed of ICT systems. In this view, KMSs combine, integrate, and extend several heterogeneous ICT. Examples are AI technologies, communication systems, content and document management systems, group support systems, Intranet technologies, learning environments, search engines, visualization technologies, and workflow management systems. Given the complexity of these technologies, it seems obvious that the development of KMS is a complex undertaking. Recently, many vendors have insisted that their products have "knowledge management technology inside." More recently, however, it seems that many technologies provided by the avant-garde systems have been woven into the enterprise infrastructure implemented in many organizations. Whereas enterprise resource planning systems target the informational representation of business transactions, enterprise knowledge infrastructures create an ICT environment for knowledge work throughout the organization.

The aim of this article is to give an overview of the manifold recent developments in the field of KM in general and with respect to KMS in particular. To achieve this goal, first KM approaches are analyzed systematically as the conceptual basis of ICT applications built to foster the implementation of KM initiatives in businesses and in organizations. The next sections review the ICT roots of KMS, define the term, and obtain a set of characteristics that differentiates KMS from its roots. The article then outlines an ideal architecture before it discusses classes of KMS and summarizes some empirical findings on the state-of-practice. The last section gives an outlook on future trends and concludes the article.

KNOWLEDGE MANAGEMENT

The field of KM has drawn insights, ideas, theories, metaphors, and approaches from diverse disciplines. The roots of the term can be traced back to the late 1960s and early 1970s in the Anglo-American literature. However, it took almost another 20 years until the term appeared again in the mid-1980s in the context as it is still used today (e.g., Refs. 4 and 5). The underlying concepts have been around for some time. Many fields and disciplines exist that deal with the handling of knowledge, intelligence, innovation, change, learning, or memory in organizations. Various approaches have played a role in the development of the theories of organizational learning, organizational memory, and, ultimately, of KM. These theories can be divided into several categories: a psychologic and sociologic line of development (e.g., organizational psychology and sociology), the sociology of knowledge with concepts such as social networks and foundations for approaches in organizational learning, a business line of development (e.g., human resource management, organization science, strategic management) with the knowledge-based view of business strategy and intellectual asset management, and an ICT line of development (e.g., systems theory AI, or management information systems).

In addition to this interdisciplinary perspective on KM, another popular conceptualization compares it with data management and information (resource) management. The

perspective on KM in these approaches can be characterized as primarily technology oriented. Many authors who went to the trouble of making a clear distinction between data, information, and knowledge within the IS discipline seem to agree on some form of hierarchical relationship. Each higher level is based on or extends the preceding level. This conceptualization is used to postulate different demands for management (i.e. goals, approach, organizational roles, methods, instruments) and different resulting systems (e.g., database systems, data warehouses, information and communication systems, and knowledge management systems) on each of these levels. After a period with no special attention to data, in the 1970s and the beginning of the 1980s, the focus was on data management (see Fig. 1). First, the main goal was to technically integrate previously isolated data storage units. Step two consists of semantic or conceptual data integration, data modeling, and data handling. Step three creates a separate organizational responsibility for data management composed of both technical and conceptual tasks. On step four, information was understood as a production factor that had to be managed like other production factors (e.g., capital, labor). Thus, the scope of information management was much broader compared with data management. The most important aspects were (1) the extension from the management of syntactic and semantic to pragmatic aspects of information, (2) the understanding of information as an instrument for preparing decisions and actions, (3) information logistics, (4) the contingency approach to information, i.e., the different interpretation of data in different situations, and (5) the perspective-based approach to information, i.e., different groups of users might interpret the same data differently.

Whereas organizations have realized substantial benefits from data and information management, knowledge has proven to be difficult to manage. Knowledge work and knowledge-intensive business processes have been difficult to reengineer (7). An organization's ability to learn or to handle knowledge assets, processes, or services have been considered new key success factors. It has required new organizational design alternatives, implemented with the help of KM instruments, and also new information and communication systems to support the smooth flow of knowledge, which consequently has been called KMS. Already existing tasks on lower steps have been once again extended. With the advent of advanced database and network technologies, as well as with the availability of sophisticated AI technologies for purposes such as text mining, user profiling, behavior analysis, pattern analysis, and semantic text analysis, KM extended the focus of information management to handle new information and communication technologies as well as to enrich application development with intelligent technologies.

Knowledge management is defined as (1) the management function responsible for regular (2) selection, implementation and evaluation of knowledge strategies (3) that aim at creating an environment to support work with knowledge (4) internal and external to the organization (5) to improve organizational performance. The implementation of knowledge strategies comproes all (6) knowledge management instruments (7) suitable to improve the organization-wide level of competencies, education, and ability to learn.

In item (1), the term "management" is used here in a functional sense (managerial functions approach) to describe the processes and functions (such as planning, organization, leadership, and control) in organizations as opposed to the institutional sense (managerial roles approach) that describes the persons or groups that are responsible for management tasks and roles. In item (2), the systematic interventions into an organization's knowledge base have to be tied to business strategy. Knowledge strategies guide the implementation of a KM initiative and tie it to business strategy. According to traditional strategic management, a strategic gap is the difference between what an organization should do to compete and what it is doing currently. Strategies try to close this gap by aligning what an organization can do considering its strengths and weaknesses with what it must do to act on opportunities and threats. A knowledge strategy addresses knowledge gaps—differences between what an organization must know to execute its strategy and what it actually knows (8). In item (3), KM creates an organizational and technological infrastructure to improve knowledge work. In item (4), knowledge processes are not restricted to the organization's boundaries, but involve cooperation with partners, suppliers, and customers. Examples for knowledge processes are submission of knowledge elements to a knowledge base, discovery of applicable knowledge, acquisition of knowledge external to an organization, or moderating a community of practice, interest, or purpose. In item (5), KM aims primarily to improve organizational effectiveness. However, creating, maintaining, or distributing intellectual capital results in a higher valuation of an organization.

In item (6), depending on the perspective on KM, objects of the implementation of knowledge strategies can be objectified knowledge resources, (documented knowledge, people, organizational or social structures, knowledge-related information, and communication technologies). These resources are targeted by KM instruments such as collections of organizational, human resources, and ICT measures that are aligned, clearly defined, and can be deployed purposefully to achieve knowledge-related goals. In addition, ICT measures are independent of a particular knowledge domain (examples include expert advice, personal knowledge routines, idea and proposal management, competence management, technology-enhanced learning, good/best practice management, case debriefings, lessons learned, or semantic content management). In item (7), KM is not exclusively about individual learning. Collective learning is of differing types [single loop, double loop, deutero learning (9)], occurs on various levels of the organization (e.g., work group, project, community or network, organization, network of organizations, business ecosystem), and occurs in various phases (e.g., identification or creation, diffusion, integration, application, or feedback). KM aims to improve the organizational competence base as well as the ability to learn. No areas focus explicitly on the contents [i.e., the actual subjects, topics or knowledge area(s)] around which a KM initiative builds a supportive environment. The reason for this is that the definition of KM should support all kinds of knowledge areas.

Two groups of KM approaches exist: human-and technology-oriented. Basically, these approaches reflect their origin, either in a human/process-oriented organizational learning, organization science background, or in a technological/structural MIS or computer science/AI background. They even have found their way into KM strategy, where a technical codification strategy is distinguished from a human-oriented personalization strategy (10). It is agreed that more holistic KM conceptualizations exist that encompass both directions. These approaches can be distinguished with respect to the main focus area of KM they concentrate on (12). KM measures and tools are bundled as KM instruments to provide specific KM services for one of four KM focus areas identified by Wiig (11), as follows: people, intellectual capital, enterprise effectiveness, and information technology/management. The approaches also differ in their conceptualizations of knowledge. Table 1 shows perspective, focus area, and definitions of knowledge as well as characterization of strategy, organizational design, KM instruments and systems that together make up a KM initiative bound tightly to one central KM approach.

A technology-oriented codification strategy focuses on externalized knowledge that is separable from people and can be documented, retained, and reused in other application areas or organizational units. Corresponding KM instruments focus heavily on information and communication technologies with an economic model that develops reusable knowledge assets and standardization of procedures even in knowledge-intensive areas. A human-oriented personalization strategy focuses on knowledge that is inseparable from people and aims to create an environment in which people can work together efficiently. Corresponding KM instruments develop networks of people so that tacit knowledge can be shared. As the focus is on people, a pivotal goal is to reduce time-to-proficiency when a knowledge worker takes on a new role. A process-oriented, on-demand strategy bridges the gap between these two roles by designing services systematically for knowledge-intensive business processes and for knowledge processes. Complex knowledge management services are composed of basic services offered by heterogeneous systems such as document, content, workflow management, communication, collaboration, and personal information management systems. Viewing KM instruments from a service perspective bound to processes eases the integration into a general business framework.

An implementation of ICT to support a strategically relevant KM initiative must not only select a KM approach, strategy, organizational design, and combination of KM tools and systems, but also must integrate KM instruments with the supporting technology. KM instruments and systems are discussed in the following sections.

ROOTS OF KNOWLEDGE MANAGEMENT SYSTEMS

A review of the literature on ICT to support KM reveals several common terms, such as knowledge warehouse, KM software, suite, (support) system, technology, as well as learning management platform, portal, suite, system, or organizational memory (information) system (12,13). In addition to these terms that suggest a comprehensive platform in support of KM, many authors provide more or less extensive lists of individual tools or technologies that can be used to support KM initiatives as a whole or for certain processes, life cycle phases, or tasks thereof (14–17). The latter can be described as roots of KMS that are combined and integrated to build KMS.

Figure 2 uses the metaphor of a magnetic field produced by a coil to show the technological roots and the influences that impact the design and the implementation of KMS.

Table 1. Comparison of approaches to knowledge management

Dimensions	Technology-oriented	Human-oriented	Process-oriented
(1) Approach			
Perspective	engineering, congnitive	cultivation, community	business, customer-orientation, socio-technical
Focus area	IT: maximize capture, transformation, storage, retrieval and development of knowledge	people: maximize effectiveness of people-centric learning organization	intellectual asset & enterprise effectiveness: maximize building and value reallocation of knowledge assets, maximize operational effectiveness
Knowledge	documented, separable from people	exclusively in the heads of people	asset, skill, competence, embedded in social networks and (knowledge) processes
(2) Strategy			
Knowledge Strategy	codification; reuse documented knowledge	personalization; foster handling of knowledge of persons/in groups	on-demand; situation-oriented design of knowledge processes for business processes
Goals	improve documentation and retention of knowledge, acquire external knowledge, turn implicit into explicit knowledge	improve communication, train newly recruited, improve knowledge sharing, improve personnel development	improve visibility of knowledge, improve access to and use of tacit and explicit knowledge, improve innovation, change culture
(3) Organization			
Roles	author, knowledge (base) administrator, knowledge broker	expert, mentor, network chair, community manager, moderator	knowledge partner and stakeholder, boundary spanner, coordinator for KM, subject matter specialist, owner and manager of knowledge processes
Tasks	storing, semantic release and distribution, refinement, deletion/archiving of knowledge,acquisition of external knowledge	establish, foster, and moderate communities; document competences and expertise; organize knowledge sharing events	identify knowledge stances; design knowledge maps, profiles, portals and processes; personalize organizational knowledge base; implement learning paths
Culture	technocratic	socio-cultural	socio-technical, management
(4) KM instruments and systems			
Instruments	semantic document and content management, instruments for discovery, publication, collaboration, learning and adaptation	competence, idea, and proposal management; personal knowledge routines; expert advice; communities; knowledge networks, self-managed ad-hoc learning	management of patents and licenses, KM scorecards, case debriefings, lessons learned, good/best practices, knowledge process reengineering, technology-enhanced learning
Contents	knowledge about organization, processes, products; internal studies, patents, online journals	employee yellow pages, skills directories, ideas, proposals, knowledge about business partners	cases, lessons learned, good/best practices, learning objects, profiles, valuations, comments, feedback to knowledge elements
Architecture	integrative KMS	interactive KMS	KMS bridging the gap
Type	infrastructure for documented knowledge	infrastructure for communication, management of competences	process-oriented system offering composed services for knowledge and business processes
Functions	publication, classification, formalizing, organization, search, presentation, visualization of knowledge	asynchronous and synchronous communication, collaboration and cooperation, community support	profiling, personalization, contextualization, recommendation, technology-enhanced learning, navigation from knowledge elements to people and processes
Tools/systems	semantic document and contentmanagement system, Wiki, knowledge portal	skill management system, computer-mediated communication, social software	process warehouse, integrated case-based reasoning, lessons learned, learning object and good/best practice repository

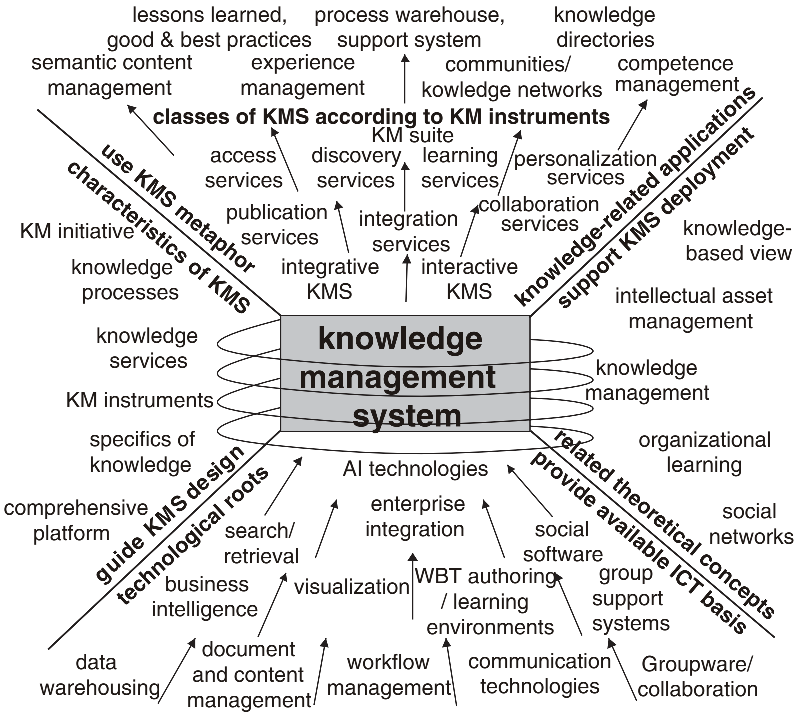

Figure 2. Technologic roots and influences of knowledge management systems.

The term KMS plays the role of the coil, the magnetic center. Theoretical approaches that support the deployment of KMS are shown to the right of the magnetic center (see section on "Knowledge management"). The main characteristics of KMS stress the differences to their ICT predecessors (see section "Toward a definition of KMS") and are shown on the left side. Together, both influences provide the energy to integrate, (re-)interpret, (re-)arrange, and (re-) combine ICT technologies that are the roots of KMS into a set of KMS-specific services (see section on "Architecture") that in turn are integrated into application systems, tools, and platforms with a clear focus on the support of KM concepts and instruments. Finally, KM instruments represent the classes of KMS in a narrow sense (see section on "Classification").

In the following sections, the most important ICT will be reviewed that forms the technologic roots of KMS. Comprehensive KMS combine and integrate the functionality of several of these predecessors.

Data Warehousing

A data warehouse is a subject-oriented, integrated, nonvolatile, time-variant collection of data in support of management decision processes (18). It is assumed implicitly that a data warehouse is separated physically from operational systems. External databases are the sources from where data are loaded regularly into the data warehouse. Data are organized by how users refer to them. Inconsistencies are removed and data are cleaned to remove errors and misinterpretations, are converted (e.g., concerning measures, currencies, and sometimes summarized and denormalized) before they are integrated into the data warehouse. Data in the data warehouse usually are optimized for analysis with business intelligence tools (e.g., star and snowflake data model, multidimensional databases).

Document and Content Management

The term *document management* denotes the automated control of electronic documents, both individual and compound documents, throughout their entire lifecycle within an organization (i.e., creation, storage, organization, transmission, retrieval, manipulation, update, and eventual disposition of documents). Document management systems provide functions to support all tasks related to the management of electronic documents, such as to capture, structure, distribute, retrieve, output, access, edit, and archive documents over their entire lifecycle. Web content management systems are applied to handle efficiently all electronic resources required to design, run, and maintain a website and to support all tasks related to authoring, acquiring, reviewing, transforming, storing, publishing, and delivering contents in Web formats. They are used to manage the entire web publishing process; to offer mechanisms for releasing new contents; to support HTML generation with the help of templates, standard input, and output screens; and to separate content and layout that provides a standardized look and feel of the web pages. As a consequence, participants who are not familiar with HTML can publish web content that fits into an organization's corporate (web) identity.

Workflow Management

A workflow is the operative, technologic counterpart of a business process and consists of activities related to one another that are triggered by external events and are carried out by persons using resources such as documents, application software, and data. A workflow management system “defines, creates and manages the execution of workflows through the use of software, running on one or more workflow engines, which is able to interpret the process definition, interact with workflow participants and, where required, invoke the use of IT tools and applications” (19). Most workflow management systems primarily support well-structured organizational processes. More recently, some systems also support flexible workflows and so-called ad-hoc workflows. An ad-hoc workflow is a sequence of tasks that cannot be standardized, but they must be designed spontaneously by participants. Workflow functionality can be used in knowledge management to support processes such as the publication or the distribution of knowledge elements. Several KMS contain flexible functions for workflow management, such as Open Text Livelink.

Communication Technologies

Communication systems are electronic systems that support asynchronous and synchronous communication between individuals, such as point-to-point communication systems, collectives, and multipoint communication systems. Examples of synchronous communication systems include teleconferencing systems such as text conferencing (chat), instant messaging, audio, and video conferencing systems. Examples of asynchronous communication systems include email, listserver, and newsgroups.

Groupware/Collaboration

Groupware is a category of software to support workgroups and teams. Usually, groupware is classified according to a matrix of group interaction with the two dimensions time and place: same time versus different time as well as same place versus different place. Groupware tools can be classified even more into (1) communication systems such as email, audio/video systems, and chat systems; (2) information sharing systems such as message boards, tele-consultation systems, co-browser; (3) cooperation systems such as co-authoring, shared CAD, whiteboard, word processor, spreadsheet, and group decision support systems; (4) coordination systems such as group calendar, shared planning, notification systems; and (5) social encounter systems such as media spaces and virtual reality. A Groupware platform provides general support for collecting, organizing, and sharing information within (distributed) collectives of people, such as work groups and project teams over corporate networks as well as the Internet. Examples for Groupware platforms are Lotus Notes, Microsoft Exchange, and BSCW (which is available freely over the Internet). Groove, which was developed by Groove Networks (now Microsoft) is a recent example for a Groupware platform that uses the peer-to-peer metaphor instead of the client-server paradigm.

Business Intelligence

Business intelligence denotes the analytic process that transforms fragmented, organizational, and competitive data into goal-oriented “knowledge” about competencies, positions, actions, and goals of internal and external actors and processes. The analytic process requires an integrated data basis usually provided by a data warehouse. Examples of technologies that support this process are decision support system technologies; multidimensional analysis; online analytical processing; data mining, text mining, and web mining technologies; balanced scorecard; business simulation techniques; and also artificial intelligence technologies, such as case-based reasoning and issue management.

Visualization

Visualization is used in a multitude of tools and systems. Most visualization systems are based on graph theory. In addition to two-dimensional graphs that represent elements and relationships, several tools also provide three-dimensional visualization techniques. Examples are tools for data, function, organization, process or object-oriented modeling, or tools that provide mapping techniques that have a long tradition in psychology, sociology, and pedagogy, such as mind mapping.

Web-Based Training (WBT) Authoring and Learning Environments

Learning environments are application systems that offer specified learning content to the learner in an interactive way, and thus they support the teaching and/or learning process. Computer-based training has its historical roots in programmed instruction or learning in the late 1950s, which was based on the concept of operant conditioning developed by Skinner. Psychologic and pedagogic, as well as technologic advancements have led to a wide variety of systems and learning environments that reflect the diversity of learning. Examples are drill and practice systems, (intelligent) tutoring systems, active assistance systems, micro-worlds, simulation systems, experimental game systems, hypertext-/hypermedia learning systems, as well as WBT, multimedia learning environments, teleteaching, distance learning, tele-tutoring, and computer-supported collaborative learning. Recently, these diverse concepts have found their way into integrated learning (content) management systems that overlap with KMS.

Group Support Systems (GSSs)

GSSs, also called group decision support systems, are interactive systems that combine communication, computer, and decision technologies to support the formulation and the solution of unstructured problems in group meetings. GSSs integrate technologies to support communication in groups, structure of processes by which groups interact (e.g., agenda setting, facilitation), and information processing (e.g., aggregating, evaluating, or structuring information). They can be classified according to the level of support in (1) removing communication barriers, (2) decision modeling and group decision techniques, and (3) expert advice to select and to arrange rules in a meeting that lead to machine-induced group communication patterns (20).

Search

A search engine is a program that can be used to find resources (e.g., documents or images) either in an organization's Intranet or in the WWW. Search engines apply programs that trace permanently the Web or an Intranet for new web pages, so-called spiders or robots. A newfound web page is scanned for keywords that are stored together with the URL of the web page in the search engine's database. At the time when a user submits a search term to the search engine, only this database is searched and intelligent algorithms are applied to retrieve those web pages that fit most to what the user has searched for. So-called meta- or multi-search engines forward search strings including boolean operators to various search services, collect and filter the results for redundancies, and present them accordingly. Both search engines and meta-search engines can be distinguished even more with respect to the search domain that they support, such as organization-internal and/or organization-external systems.

Enterprise Integration

This bundle of technologies aims to provide the basis for interactions between a variety of data and document sources and between application components and systems. Integration in information processing can be classified according to the object into data, function, and program integration. Enterprise integration is an integration infrastructure, sometimes called middleware, that covers these classes and provides a basis for fully automated, organization-wide integration, or even integration between organizations. Typical standard technologies for data integration are based on XML, XML Schema, and XSLT that offer a metalanguage for annotation, description of the structure, and transformation of semi-structured data. Because of the importance of users as participants accessing KMS, integration of user data sometimes is discussed separately, called identity management. The semantic web stack, particularly RDF, RDF Schema, and OWL, provide the basis for semantic integration as required in KMS. With respect to function integration, the web service stack offers a standard way for describing and discovering public interfaces of software systems. With respect to process integration, many initiatives exist for standardizing XML-based languages to describe workflows that in turn invoke Web services, such as the Business Process Execution Language (21).

Social Software

Social software is a recent concept, a subset of computer-mediated communication that covers software and is used to create and to maintain social networks or virtual communities. Typically, this category of software allows easy-to-use mechanisms to create and to maintain online profiles (social identity), build relationships and reputation (social capital), stay aware of a network's activities (social presence), comment on and recommend to others (social feedback), interact with others (social interaction), organize physical meetings (social planning), and share content (social spaces) on the Internet. Social software focuses on supporting individuals who enter networks or communities voluntarily and therefore supports informal gatherings rather than formal organizational groupings in teams or workgroups, which typically are focused by Groupware, project management, and collaboration software. Because of this informal, self-directed nature of joining networks, it could be described as employing a peer-to-peer, bottom-up metaphor rather than a server-based, top-down metaphor (22). It has the potential of building larger and more effective networks. Examples for software that can be used with this goal in mind are easy-to-use content management systems such as text, audio and video Blogs, Wikis, fora, real-time communication (e.g., instant messaging or chat), and software platforms for rich interactions between its members that build on the friend-of-a-friend metaphor, such as the FOAF project, MSN Groups, Tribe.Net, Meetup.com or, with a business connotation, LinkedIn or Xing. Currently, many organizations adopt these technologies and attempt to profit from them. Social software seems to be particularly promising to fill in the gap of the less supported personalization and collaboration portion of organizational KMS. However, it remains to be seen whether and how the additional challenges in business or organizational settings, particularly with respect to power distribution, incentive systems, data privacy and concerns about knowledge risks, can be overcome.

AI Technologies

Many specific technologies are discussed as supporting KM. Most technologies have their roots in the field of AI. Results from AI research play a crucial role in the development of KMS and provide intelligent functions for KM. Examples for AI-based tools for KM are as follows:

- *Experience and know-how data base systems* are ordered collections of application solutions, such as specialized data base systems that store experiences, lessons learned, best practices, as well as technical solutions. Experience data bases rely technologically on conventional information retrieval and document management technology, augmented with business process models and ontologies about the application domain as well as additional meta data categories for describing knowledge documents. The term experience data base aims more at management, organizational, and technical experiences, such as customer relations, business processes, projects, whereas the term know-how database aims more at technical problems and solutions.
- *Case-based reasoning systems* provide an approach to solve problems with the help of known solutions for similar problems that has its roots in AI research. The approach is composed of four steps: (1) retrieve cases from the system's case base which are similar to the problem presented by the user, (2) reuse solved cases, (3) revise the selected case and confirm the solution, and (4) retain the learned case if it is an interesting extension of the case base.
- *Recommender systems* extend systems that support information retrieval and give recommendations

based on techniques such as test of context correspondence, frequency analysis, and agent technologies. Some authors also use the term *collaborative filtering* to denote the social process of recommending. The systems collect and aggregate recommendations of a multitude of people and make good matches between the recommenders and those who seek recommendations. To accomplish this task, recommender systems have to model the users' characteristics, interests, and/or behavior. This action is called user modeling, profiling, or personalization. Profiles are a requirement for the application of many intelligent technologies, especially intelligent software agents. Systems that use content-based filtering recommend items similar to those a given user has liked in the past.

- *Intelligent software agents* are autonomous units of software that execute actions for a user. Intelligent software agents use their intelligence to perform parts of their tasks autonomously and to interact with their environment in a useful manner. Thus, software agents differ from more traditional software programs with respect to their autonomy, ability to communicate and cooperate, mobility, reactive and proactive behavior, reasoning, and adaptive behavior; some agents even might show human characteristics. Roots of agent technology can be traced back to (1) approaches of distributed AI where agents deconstruct tasks into sub-tasks, distribute them, and combine their results and (2) developments in the area of networks and communication systems. Intelligent or semi-intelligent agents can be classified according to their main area of application into information, cooperation, and transaction agents and are applied in a multitude of settings. Prominent examples for agents can be found in electronic market processes. In KM, agents can be used to scan emails, newsgroups, and chats; to group and update automatically user-specific messages and information items in the Internet (newswatchers); to analyze and classify documents; to search, integrate, evaluate, and visualize information from a multitude of sources; to handle information subscriptions intelligently; to identify and network experts; to visualize knowledge networks; and to recommend participants, experts, communities; and documents.

TOWARD A DEFINITION OF KNOWLEDGE MANAGEMENT SYSTEMS

During the last couple of years, the term KMS has gained acceptance in the literature and on the market, but the term is often used ambiguously for specific KM tools, for KM platforms, or for a combination of tools that are applied with KM in mind. Investigations about the notion of KMS often remain on the abstract level of what a KMS is used for, such as "a class of information systems applied to managing organizational knowledge" (13). Consequently, the term KMS is used here, since numerous similar conceptualizations exist that complement the functionality and the architectures of KMS. The following list summarizes the most important characteristics of KMS as found in the literature (see Fig. 2, left-hand side).

Specifics of Knowledge

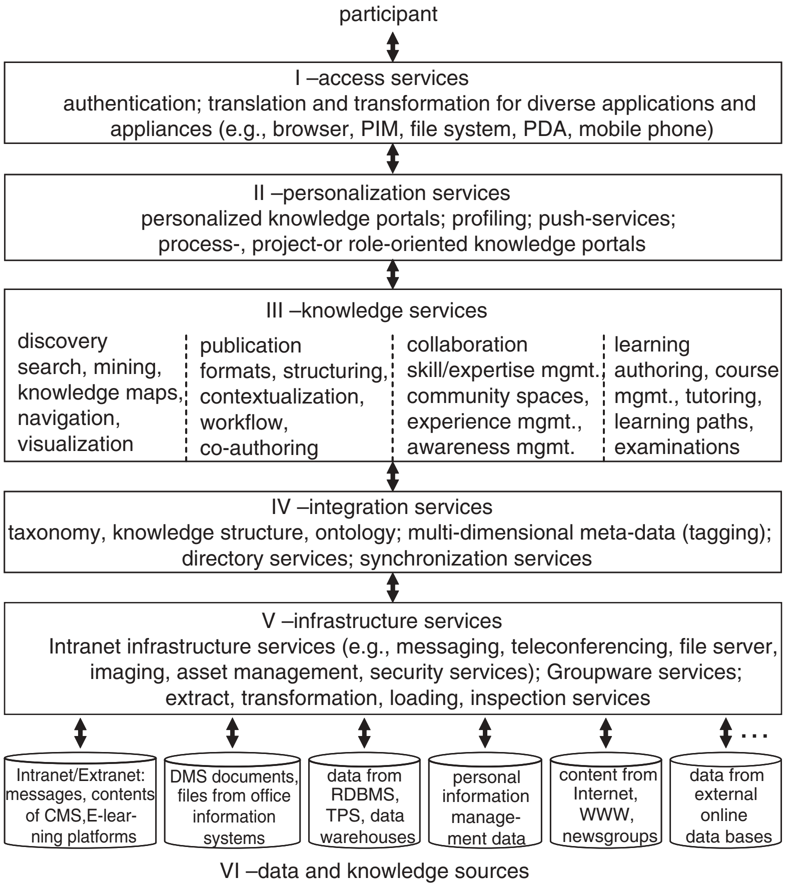
KMSs are applied to manage knowledge that is described as "personalized information [...] related to facts, procedures, concepts, interpretations, ideas, observations, and judgments" (13). From the perspective of KMSs, knowledge is information that is organized meaningfully, accumulated, and embedded in a context of creation and application. KMSs leverage primarily codified knowledge and also aid communication or inference used to interpret situations and to generate activities, behavior, and solutions. KMS help to assimilate contextualized information, provide access to sources of knowledge and, with the help of shared context, increase the breadth of knowledge sharing between persons rather than storing knowledge itself (13). The internal context of knowledge describes the circumstances of its creation. The external context relates to retrieval and application of knowledge. Contextualization is a key characteristic of KMS that provides a semantic link between explicit, codified knowledge and the persons that hold or seek knowledge in certain subject areas. Therefore, users play the roles of active, involved participants in the knowledge network fostered by KMSs.

KM Initiative

The primary goal of KMS is to bring knowledge from the past to bear on present activities, which results in increased levels of organizational effectiveness (12). Thus, KMSs are the technologic part of a KM initiative that also comprises person-oriented and organizational instruments targeted at improving productivity of knowledge work (23). KM initiatives can be classified into technology-, human-, and process-oriented initiatives (see section on "Knowledge management"). The type of initiative determines the type of KMS for its support. In effect, KMSs aid knowledge work by supporting employees' awareness, networking, exploration, and exploitation of knowledge assets.

Knowledge Processes

KMSs are developed to support and to enhance knowledge-intensive tasks, processes, or projects of knowledge creation, organization, storage, retrieval, transfer, refinement and packaging, (re-)use, revision and feedback (also called the knowledge life cycle) to support knowledge work ultimately (2). In this view, KMSs provide a seamless pipeline for the flow of knowledge through a refinement process (24). Although the focus used to be on explicit knowledge with most KMSs being built on some form of content or document management system, with the advent of sophisticated collaboration technologies and so-called social software, KMSs increasingly target both explicit and implicit knowledge by helping to network people and to share and refine implicit knowledge.



participant
I –access services
authentication; translation and transformation for diverse applications and appliances (e.g., browser, PIM, file system, PDA, mobile phone)
II –personalization services
personalized knowledge portals; profiling; push-services; process-, project-or role-oriented knowledge portals
III –knowledge services
discovery search, mining, knowledge maps, navigation, visualization
publication formats, structuring, contextualization, workflow, co-authoring
collaboration skill/expertise mgmt. community spaces, experience mgmt., awareness mgmt.
learning authoring, course mgmt., tutoring, learning paths, examinations
IV –integration services
taxonomy, knowledge structure, ontology; multi-dimensional meta-data (tagging); directory services; synchronization services
V –infrastructure services
Intranet infrastructure services (e.g., messaging, teleconferencing, file server, imaging, asset management, security services); Groupware services; extract, transformation, loading, inspection services
...
Intranet/Extranet: messages, contents of CMS,E-learning platforms
DMS documents, files from office information systems
data from RDBMS, TPS, data warehouses
personal information management data
content from Internet, WWW, newsgroups
data from external online data bases
VI –data and knowledge sources

Figure 3. Architecture of knowledge management system.

Comprehensive Platform

Whereas the foci on individual initiatives, processes, and participants can be seen as a goal-, application-, and user-centric approach, an IT-centric approach provides a base system to capture and to distribute knowledge (25). This platform is then used throughout the organization. In this case, a KMS is not an application system targeted at a single KM initiative, but it is a platform that can be used either as-is to support knowledge processes or as the integrating base system and repository on which KM application systems are built. In this case, *comprehensive* indicates that the platform offers functionality for user administration, messaging, conferencing, and sharing of documented knowledge, such as publication, search, retrieval, and presentation.

Knowledge Services

KMSs are ICT platforms on which several integrated services are built. The processes that have to be supported give a first indication of the types of services that are needed. Examples are rather basic services (collaboration, workflow management, document and content management, visualization, search and retrieval) or more advanced services (personalization, text analysis, clustering, and categorization) to increase the relevance of retrieved and pushed information, advanced graphical techniques for navigation, awareness services, shared workspaces, (distributed) learning services, as well as integration of and reasoning about various (document) sources on the basis of a shared ontology (15).

KM Instruments

KMSs are applied in many application areas and support KM instruments specifically, such as capture, creation, and sharing of good or best practices; implementation of experience management systems; creation of corporate knowledge directories, taxonomies, or ontologies; competency management; collaborative filtering and handling of interests used to connect people; creation and fostering of communities or knowledge networks; and facilitation of knowledge process reengineering (13,26,27). Thus, KMSs offer a targeted combination and integration of knowledge services that together foster one or more KM instrument(s).

Consequently, a KMS is defined as a comprehensive ICT platform for collaboration and knowledge sharing with advanced knowledge services built on top that are contextualized, integrated on the basis of a shared ontology, and personalized for participants networked in communities. KMSs foster the implementation of KM instruments to support knowledge processes targeted at increasing organizational effectiveness.

Actual implementations of ICT systems certainly fulfill the characteristics of an ideal KMS only to a certain degree. Thus, a continuum between traditional IS and advanced KMSs might be imagined with minimal requirements that provide some orientation (28).

ARCHITECTURE

Many KMS solutions that are implemented in organizations and offered on the market are client/server solutions. Figure 3 shows an ideal layered architecture for KMS that represents an amalgamation of theory-driven, market-oriented, and several vendor-specific architectures (24,29) such as Open Text Livelink, http://www.opentext.com/. A thorough analysis of these architectures and the process of amalgamation can be found in Ref. 23. The ideal architecture is oriented toward the metaphor of a central KM server that integrates all knowledge shared in an organization and offers a variety of services to the participant or to upward layers.

Data and knowledge sources include organization-internal and organization-external sources as well as sources of structured and semi-structured information and knowledge.

Infrastructure services provide basic functionality for synchronous and asynchronous communication, sharing of data and documents, as well as management of electronic assets. Extract, transformation, and loading tools provide access to data and knowledge sources. Inspection services (viewer) are required for heterogeneous data and for document formats.

Integration services help to organize and link knowledge elements meaningfully from a variety of sources by means of an ontology. They are used to analyze the semantics of the organizational knowledge base and to manage meta data about knowledge elements and users. Synchronization services export and (re-)integrate a portion of the knowledge workspace for work offline.

Knowledge services provide intelligent functions for discovery, such as search, retrieval, and presentation of knowledge elements and experts; for publication, such as structuring, contextualization, and release of knowledge elements; for collaboration, such as the joint creation, sharing, and application of knowledge; and for learning, such as authoring tools and tools for managing courses, tutoring, learning paths, and examinations; as well as for reflecting on learning and knowledge processes established in the organization.

Personalization services provide a more effective access to the large amounts of knowledge elements. Subject matter specialists or managers of knowledge processes can organize a portion of the contents and services for specific roles or can develop role-oriented push services. The services can be personalized with the help of (automated) interest profiles, personal category nets, and personalizable portals.

Access services transform contents and communication to and from KMS to fit heterogeneous applications and appliances. KMS have to be protected against eavesdropping and unauthorized use by tools for authentication and for authorization.

Summing up, many functions exist to provide knowledge-related services that have been combined into a KMS architecture. However, this architecture can be seen as ideal in the sense that almost all actual tools and systems offered on the market or implemented in organizations only offer a certain portion of these services. The next section organizes the abundant number of tools and systems that are discussed as being helpful for KM.

CLASSIFICATION

The field is still immature in the sense that no classes of systems exist that the literature has agreed on. Several proposals for classifications of systems exist which lack mostly completeness and also exclusiveness in the sense that one system fits into one and only one category. A comprehensive overview of classifications of technologies, tools, and systems that support KM can be found in Ref. 23. The classifications in the literature fall into two categories. Market-oriented classifications try to cover either technologies, tools, and systems that support KM (wide view) potentially or they cover the functionality of KMSs (narrow view). Theoretical classifications are based on existing models that describe types of knowledge (abstract view) or KM processes or tasks, respectively (concrete view) that could be supported potentially by ICT in general or KMSs in particular. Taken together, KM tools and systems fall into one of the following four categories:

- *Technological roots* This group is composed of more traditional ICT that can be used to support KM initiatives. The most important roots have been described above.
- *Platforms* Corporate Intranet infrastructures, enterprise document and content management systems, or Groupware platforms can be designed “with KM in mind.” These platforms turn infrastructures into comprehensive, integrated KMS solutions. A modern, integrated Intranet platform can be considered as a KM platform in the sense of a kind of “starter solution” for knowledge sharing. This KM platform comprises at least the levels Intranet infrastructure including extract, transformation, and loading, as well as access and security in the KMS architecture presented above. Integrated KMS solutions combine a large set of technologies for knowledge sharing into a common platform.
- *Specialized tools* Some KM tools have roots in the AI field and perform specific functions necessary for KM.

Others are necessary to integrate several of these functions or several of the more traditional ICT. These tools are heterogeneous with each tool targeting a specific challenge within individual steps of knowledge processes or along the knowledge lifecycle.

- *KMS in a narrow sense* These systems provide functionality that goes well beyond the functions in roots, platforms, and specialized tools in that they represent the ICT part of a KM instrument. In an empirical study, large organizations have been surveyed for their KMS implementations (23). Based on the findings of this empirical study together with the findings reported in the literature (13), KMSs (in a narrow sense) can be classified according to the KM instruments they support.

In the next sections, KMSs in a narrow sense are described in detail for exemplary KM instruments (30).

Knowledge Directories

Different types of knowledge maps are suggested for all categories of KM instruments. A central goal is to create corporate knowledge directories that visualize existing knowledge in organizations and support a more efficient access to and handling of knowledge. The main objects of mapping are experts, project teams, networks, white papers or articles, patents, lessons learned, meeting protocols, or generally document stores. Knowledge source maps visualize the location of knowledge, either people (sometimes also called knowledge carrier maps, or information systems) and their relation to knowledge domains or topics. Knowledge asset maps visualize the amount and the complexity of knowledge that a person or a system holds. Knowledge development and application maps are combinations of process models and knowledge carrier maps. Knowledge development maps visualize processes or learning paths that can or must be performed by individuals or teams to acquire certain skills. Knowledge application maps describe what process steps have to be performed in what situation at what step in a business process, such as who should be contacted for a second opinion. Knowledge structure maps show the types of relationships between knowledge domains or topics. The formal definition of knowledge structures results in ontologies and is an important instrument for the integration of diverse knowledge sources.

Competence Management

Competencies held by individuals in organizations are analyzed, visualized, evaluated, improved, and applied systematically. Competence management composes expertise locators, yellow and blue pages, as well as skill management systems, which are also called people-finder systems. Skill management makes skill profiles accessible, and it defines learning paths for employees that have to be updated together with skill profiles. A central skill ontology has to be defined that provides context for all existing, required, and wanted skills in the organization. Training measures have to be offered. Skill management systems often not only contain information about skills, their holders, and their skill levels, but also contain information about job positions, projects, and training measures in which employees learned, used, and improved their skills. Yellow and blue pages are directories of organization-internal and -external experts, respectively. Profiles of the experts together with contact details are listed according to several knowledge domains for which they might be approached. Information about employees' skill levels and degrees of expertise can be used to connect people; to staff projects; to find training and education measures for training into, on, along, near, off, and out of the job (31); to filter; and to personalize KMS contents and functions.

Experience Management

These systems ease documentation, sharing, and application of personal experiences in organizations and have to be integrated into the daily work practices of employees to be accepted. Several approaches exist that support capturing of experiences, such as information mapping, learning histories, or micro-articles. The systematic management of personal experiences enables a company to solve recurring problems more effectively. However, some barriers exist that prevent the documentation of experiences or the reuse of already documented experiences. Foremost, time required for documenting experiences is a critical factor because it imposes additional efforts on employees. Simultaneously, sufficient context of the experience has to be provided. ICT solutions help to ease the effort of documenting experiences, to detect context automatically, and to apply rights management to the knowledge assets.

Communities/Knowledge Networks

Community management targets the creation and the fostering of communities or knowledge networks. Communities differ from knowledge networks with respect to who initiated their foundation. Communities are founded by like-minded people (bottom-up) and can at most be fostered by the organization. Knowledge networks are established and legitimated by management (top-down). However, organizational and ICT measures to foster communities are the same as those used to support knowledge networks. Communities per definition cannot be controlled or induced externally. But organizations can provide employees with time and space to share thoughts; to establish IT tools, such as social software, community builder, and home spaces that support exchange of thoughts; to create new roles like community managers that help to keep discussions going; and to look for important topics that should gain management attention.

Process Warehouses and Support Systems

Knowledge process reengineering (KPR) aims to redesign business processes from a knowledge perspective. The term references the field of business process reengineering (BPR) that aims at fundamental (process innovation) or evolutionary (process redesign) changes of business processes in organizations to increase organizational effectiveness. In addition to traditional BPR instruments, knowledge-intensive business processes are improved partially by KPR. The focus is on designing knowledge processes that connect business processes, defining cooperation scenarios, improving communication patterns between employees, and "soft" skills, or on designing an organizational culture supportive of knowledge sharing (2). Business processes are modeled with the help of modeling techniques. The models are stored in model bases. The model base can be expanded so that it handles not only knowledge about the process, but also knowledge created and applied in the process. This process is termed process warehouse, and it can be used as a foundation for systematic KPR. Examples for contents in process warehouses are exceptional cases, case-based experiences, reasons for decisions, checklists, hints, frequently asked questions and answers, potential cooperation partners, or suggestions for improvements.

Lessons Learned, Good and Best Practices

Lessons learned are the essence of experiences made jointly and documented systematically by members of the organization in projects or learning experiments. In a process of self-reflection, for example at the end of a project milestone, also called after-action review or project debriefing, project members review jointly and document critical experiences made in this project. ICT supports coding, linking, storing, and sharing lessons learned. Templates support structured documentation of experiences and help the team to include important context information. Lessons learned target project experiences and their reasons but ideally make no statement about how processes should be adapted considering these experiences. The sharing of good or best practices is an approach to capture, create, and share experiences in a process-oriented form as procedures or workflows that have proven to be valuable or effective within one organizational unit and may be applied in other organizational units. As managers might argue about what exactly is "best" practice, several organizations use different levels of best practice, such as a good (unproven) idea, good practice, local best practice, company best practice, industry best practice. Permanent best practice teams provide guidelines and support identification, transfer, implementation, evaluation, and improvement of practices.

Semantic Content Management

"Semantic" is used here to indicate that content is embedded in context, and it is well described with the help of meta data that assigns meaning and structure to the content. These descriptions are machine-interpretable and can be used for inferencing. Semantic content management extends document management and enterprise content management. Certainly, the instrument is related tightly to an IT solution, but rules must exist that guide definition and use of semantics, monitor external knowledge sources for interesting content that should be integrated, develop an appropriate content structure, as well as publish semantically enriched documents in the system. Semantic content management also allows for "smart" searching and collaborative filtering, and it can be integrated with competence management to handle interests used to connect people with the help of the joint analysis of semantic content and skills.

KMS can also be distinguished according to the main organizational level on which they focus. The list contains a wider set of KM-related tools and systems, as KMSs in a narrow sense span the three levels, which are described as follows:

1. *Enterprise KMS* Includes enterprise-wide broadcasting systems, knowledge repositories, enterprise knowledge portals, directory services, meta-search systems, knowledge push systems with information subscriptions, community support, knowledge visualization systems, knowledge work process support, learning management systems, social network services and intelligent agents that support organizational information processing.
2. *Group and community KMS* Includes community builders and workspaces; Wikis; theme, project, or community Blogs; ad-hoc workflow management systems; multipoint communication systems, such as listserver, newsgroups, group video conferencing, and collaboration systems; and intelligent agents that support information processing in groups.
3. *Personal KMS* Includes personal search systems, such as desktop search, user profiling, search filters, knowledge discovery and mapping; point-to-point communication systems, such as email, point-to-point video conferencing, or instant messaging; personal Blogs; and intelligent agents that support personal knowledge management for knowledge search, sharing, integration, or visualization.

KMSs available on the market fall into at least one of these categories. A classification of KMS can only be considered as preliminary because of the considerable dynamics of the market for KMS. At this stage, the analysis of KMS is a challenge.

STATE-OF-PRACTICE

In the following list, the state of practice of KMS is summarized in the form of theses that describe activities that concern KMSs in German-speaking countries as investigated in an empirical study (23):

1. Almost all large organizations have an Intranet and/or Groupware platform in place that offers a solid foundation for KMSs. These platforms, together with a multitude of extensions and add-on tools, provide good, basic KM functionality, which includes the easy sharing of documents and access to company information.
2. Large organizations have already implemented KM-specific functions. Many implemented functions are

not used intensively, in some cases because of technical problems, but mostly because they require substantial organizational changes and significant administrative effort.

3. Most organizations rely on organization-specific developments and combinations of tools and systems rather than on standard KMS solutions. The market for KMS solutions is confusing and dynamic, and integration with existing systems is often difficult. Organizations might also fear the loss of strategic advantages if they exchange their home-grown KMS solutions for standard software.
4. Explicit, documented knowledge is emphasized strongly. This finding is not surprising because in many cases, large amounts of documents have existed already in electronic form and an improved handling of documents and the redesign of corresponding business processes can improve quickly organizational effectiveness. A trend toward collaboration and learning functions exists, because technical requirements for media-rich electronic communication can now be met at reasonable costs.
5. Comprehensive KMS are highly complex ICT systems because of (1) the technical complexity of advanced knowledge services and of large volumes of data, documents, messages, links, as well as contextualization and personalization data, (2) the organizational complexity of a solution that affects business and knowledge processes throughout the organization; and (3) the human complexity because of the substantial change in habits, roles, and responsibilities that is required as KMS have to be integrated into daily practices of knowledge work.
6. In many organizations, a multitude of partial systems are developed without a common framework to integrate them. Some organizations also build enterprise knowledge portals that at least integrate access to ICT systems relevant for the KM initiative. Only recently, comprehensive and integrated KMS offer functionality integrated within one system.

CONCLUSION

KM is a lively and dynamic field that composes technology-, human-, and process-oriented approaches. A KM initiative is one characteristic that distinguishes KMSs from more traditional systems that represent the roots of KMS. The most important services offered by KMS in the sense of comprehensive platforms can be systematized with the help of an architecture. In a narrow sense, KMSs can be classified with the help of the KM instruments they support. The field of KM has changed considerably during the last 20 years. Particularly, since KM has come back after some years of declining interest after the dot-com bubble burst, several new or extended facets have developed. Some are described briefly in the following list as potential trends for the future of KM:

Business. Whereas during the initial development of the field the focus was mostly on the knowledge side of KM, now the field concentrates increasingly on management with increasing activities to measure the outcome of KM, business models, and the integration of knowledge processes into the business process landscape of organizations. KM instruments, particularly those that are supported by information and communication technologies, are reframed and recombined as services.

Collaboration. Generally, a shift in perspective of KMS vendors has occurred, as well as organizations that apply those systems from a focus on documents that contain knowledge to relationships between resources and people, a combination and integration of functions for handling internal and external context, locating experts, competency management, and so on. Advanced services that support collaboration in teams and communities, link knowledge providers and seekers as well as e-learning functionality, have been integrated into many KMSs. To be successful, such KMSs should also consider diversity of knowledge workers, which is another megatrend that will likely have its impact on KM.

Mobility. KMSs are still developed with the knowledge worker at the desktop in mind. However, mobile devices will have sophisticated knowledge tools for the knowledge worker no matter where he or she might be. Also, substantial research and development activities exist surrounding the "Internet of things," i.e., the ubiquitous availability of computing power embedded into artifacts.

Knowledge Ecosystem. The success of easy-to-use content management systems and social software on the Internet increases the proportion of active contributors of all Internet users greatly. Because of network effects, the user bases show tremendous growth rates, and phenomena develop that are sometimes described as collective intelligence. Breaking the boundaries of the organization and having customers, suppliers, or the entire business ecosystem that surround an organization contribute to its knowledge base might be a viable option for many businesses and organizations. Thus, KMS would be extended from an organizational knowledge base, an organizational memory, toward a knowledge ecosystem that is enhanced by more than just the organization's members.

Safety. Most KM instruments aim to increase transparency, sharing, and reusing of knowledge. However, an important new strand in the field aims at prioritizing knowledge assets and balancing chances and risks of easing access to valuable and competitively superior knowledge. A systematic management of knowledge risks identifies, assesses, governs, and evaluates knowledge risks with respect to knowledge-intensive business processes.

These trends might continue as many organizations strive to profit from the promised benefits of comprehensive ICT platforms for increasing productivity of knowledge work and, consequently, organizational effectiveness, and for fostering an organizational environment conducive to attract and to retain creative knowledge workers.

MACHINE LEARNING

DEFINITION AND STATE

Learning, as defined in Webster's dictionary, is the act to gain knowledge or skill or a behavioral tendency by study, instruction, or experience. As such, learning has found its place in diverse fields ranging from philosophy to psychology and pedagogy. This definition of learning is broad and mostly refers to human or animal learning. Machine learning, on the other hand, is more specific about its domain of coverage and has been defined by several authors in the fields of computer science and engineering. For example,

> A computer program is said to learn from experience E with respect to some class of tasks T and performance measure P, if its performance at tasks in T, as measured by P, improves with experience E.(1)
>
> ... the system can acquire new knowledge from external sources, or the system can modify itself to exploit its current knowledge more effectively.(2)
>
> The goal of machine learning is to build computer systems that can adapt and learn from their experience.(3)
>
> Machine learning is programming computers to optimize a performance criterion using example data or past experience. We have a model defined up to some parameters, and learning is the execution of a computer program to optimize the parameters of the model using the training data or past experience. The model may be predictive to make predictions in the future, or descriptive to gain knowledge from data, or both.(4)

Thus, machine learning is about programming a computer to improve a performance measure through experience in performing certain tasks. For this purpose, a computer program is used that adapts to its environment by gaining knowledge through experience. In this setting, we also assume that the adaptability is positive, namely a performance measure exists to assess the fitness of the program in the environment and this measure should improve as more examples are given to the program to learn. The requirement of an improving performance measure differentiates machine learning from learning in psychology where behavioral change, not necessarily improving some performance measure, can be considered a form of learning.

Machine learning has a history of about 50 years. From the early day of game-playing computers to the modern practice of data mining, machine learning has developed into a multidisciplinary field in academia. Currently, advanced degrees (master and Ph.D. level) are being offered in this field (Carnegie Mellon University), a central repository of benchmark data has been established (5), and annual conferences and meetings in this area are conducted continually for academic researchers and industrial practitioners. Also, several academic journals are devoted to the communication of ideas and practices in machine learning.

THE LEARNING PROCESS

To achieve the goal of machine learning, we need to consider several things in the process of machine learning.

Reasoning

Learning can sometimes be achieved by simply memorizing patterns. A human learns by memorizing several key points in a field. For a computer program, memory is implemented by using efficient data structures and good database systems. For most cases, memory cannot store all patterns in a learning process; thus, proper reasoning is needed. Two types of reasoning exist: deductive and inductive. A deductive reasoning works with rules and facts to deduce more facts, and an inductive reasoning distills useful hypotheses from a bundle of data by using data summarization. Most current machine learning algorithms involve inductive reasoning. Different memory structures and reasoning procedures may result in different combinations of knowledge representations, features, and algorithms.

Model of Knowledge

The objective of machine learning is to produce a model of knowledge. Such a model can be expressed in two forms: a black-box form and a white-box form. The former focuses on the utility of relationships between inputs and outputs regardless of how such relationships are organized and expressed; and the latter emphasizes the representation of relationships between inputs and outputs in a readable and understandable manner. Selecting suitable representation of models for a task often requires domain knowledge in the area where machine learning is applied to improve a performance measure. Machine learning has been used to perform tasks of classification (e.g., written character recognition), prediction (e.g., credit risk prediction), and problem solving (e.g., robot control). Different tasks require different means to represent the models of knowledge efficiently. For example, robot control may be implemented easily if the knowledge model is expressed in terms of rules, and written character recognition may achieve a higher performance level when the model is represented with neural nets. Knowledge representation depends on not only the nature of a task, but also on current technologies in algorithms design. In addition to the rules and neural nets representation, other popular forms of knowledge representation include frames, maps, and decision trees.

Feature Representation

If knowledge refers to insights to be learned from experience, then features stand for the ways to represent experience. Just like knowledge, features depend heavily on the task and experience. What kinds of features are to be collected? Do we and can we collect them at our will? How are they represented, and how do we avoid noise in the collected features? Many ways exist to represent features.

For example, tuples from a relational database and predicates from logical programming are popular forms for feature representation. Several techniques in statistics can be used to detect outliers and hence improve the quality of collected data. Research is are being conducted to deal with the issues related to features.

Learning Algorithms

As machine learning is about gaining knowledge from experience, a learning algorithm that generates a satisfactory model of knowledge plays an important role. This role is usually accomplished by searching through the space of all possible models. Frequently, this space of models is so large that an exhaustive search is impossible; therefore, a heuristic search processes must be considered. Some algorithms may simply use a greedy search procedure (e.g., inductive decision tree) or a mathematical optimization by taking advantage of the nature of a problem (e.g., a quadratic optimization procedure in kernel-based algorithms). Besides search procedures, the presentation order of experience may also affect the final result significantly. Learning algorithms can be categorized from different perspectives and will be discussed later.

General Procedure of Machine Learning

Starting with the task of a machine learning job, we need to decide what kinds of memory and reasoning are needed to fulfill the task. Based on this analysis, we can choose the best combination of knowledge representation, features, and algorithms to achieve higher performance measure when more experiences are available. A generic processing procedure of machine learning can be illustrated like the one shown in Fig. 1.

In this process, three phases exist, i.e., the training phase, the testing phase, and the validation phase. First, data describing the domain problems to be processed are collected and represented in proper formats. Depending on the types of domain problems, data can be labeled or unlabeled by users. According to some selection criteria, these data are divided into three, usually disjointed, subsets, called training data, testing data, and validation data, respectively. In the training phase, training data are fed into learning algorithms to produce models of knowledge for the domain problem. The correctness of the produced models is evaluated against the testing data with respect to specific error functions. At this moment, parameters of a model are tuned accordingly for improving the quality of learning. Such a produce-and-modify process iterates for several times until the quality criteria are satisfactory. Finally, one or more models may be obtained. Then, the validation phase is invoked to test the validity of the models learned, and the best model will survive for applications. As the model is learned based on subsets of the domain problem, it can be considered a partial model of the underlying domain problem. If the validation results are not satisfactory, the learning process goes on again by selecting new training data or by modifying the learning algorithm. Otherwise, the learning algorithm is effective and the model is accepted. Afterward, the final model learned from this process is taken for practical applications.

Note that, depending on the design concepts of the learning algorithms and application problems, some learning systems invoke all three phases and some do not. The learning process can be performed in a batch style or in an incremental style. In a batch mode, all training data are fed into the learning algorithm and the testing data are used for verifying after the model is produced and are modified according to all training data. Conversely, an incremental learning process produces a model for application based on some training data and updates the model when new training patterns are encountered. Additionally, the selection of data for training, testing, and validation is critical and should be considered seriously to learn an effective and complete model for the final applications.

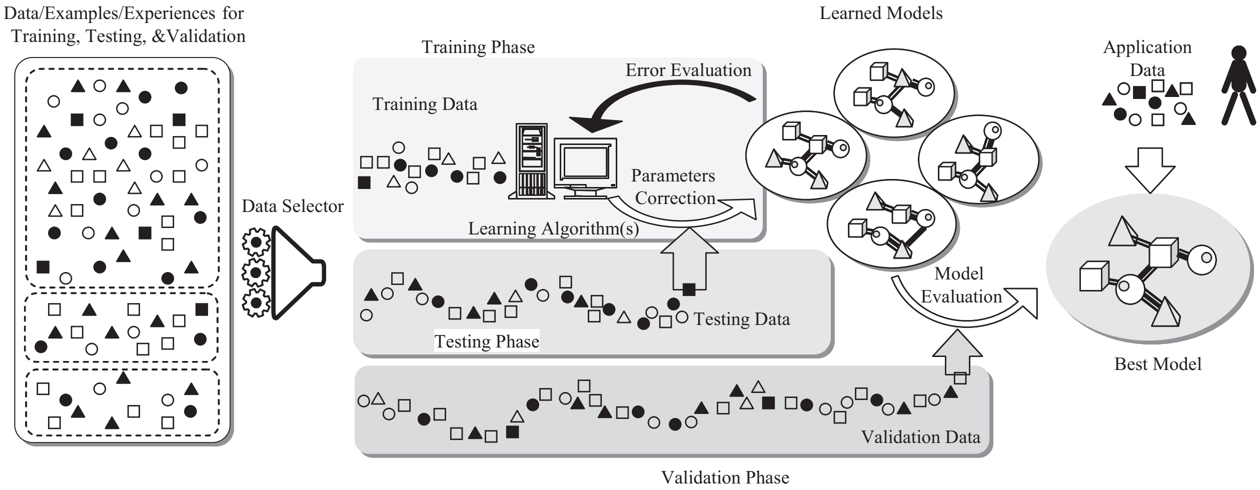

Figure 1. A generic flow of machine learning.

LEARNING METHODS

Many studies in machine learning are devoted to algorithm designs. Computing methods in machine learning can be categorized from different perspectives. For example, they can be classified into supervised, unsupervised, and reinforcement leaning depending on the existence of a *teacher* in the learning environment. Based on the feature representations, some symbolic and numeric algorithms take advantage of different representations of features. There are lazy and rigor algorithms. A typical example of a lazy learner is the nearest neighbor learning algorithm that does not have a separate training phase. Most algorithms belong to the category of rigor algorithms, in which a model must be learned first before it can be used. Also, algorithm independent procedures are used to combine different learners. These procedures include bagging and boosting meta-learners. Below, we discuss the most commonly used algorithms in this field.

Supervised Learning

Supervised learning is a machine learning technique that handles training data labeled with the desired output to guide the progression of learning. The output can be a discrete value (called classification) or a continuous value (called regression). In the case of classification learning, all output classes have a well-defined meaning to users of this type of learning. For example, the output can be a benign or malignant tumor in a medical examination. The input variables should be important factors that affect the output. The goal of supervised learning is to learn a model that predicts an output given a new input case. The model can be assessed based on different performance measures such as accuracy, precision, and recall rates. The representative algorithms of supervised learning include artificial neural networks (ANNs), support vector machines (SVMs) (6), and inductive decision tree (ID3).

Pattern recognition is the most common application of supervised learning techniques, which has been applied widely to image or speech recognition. For example, in digital, handwritten character recognition, digitalized handwritten characters are labeled by their real characters and are collected as patterns of training data. Learning algorithms of classification such as ANN and SVM are employed to produce classification models for the given training data. A performance measurement can be based on the accuracy of successful identification of characters. Until the classification model is rebuilt, application data of new handwritten characters are classified by the learned model. The most similar class label with the lowest error is the recognized character for the new input data.

Unsupervised Learning

Unsupervised learning is different from supervised learning in that no teacher is involved in the learning process. In other words, no desired output exists for reference. The goal of the learner is to attempt to find the regularities or patterns in the input data. Two classic examples of unsupervised learning are clustering and dimensionality reduction. Clustering partitions a set of data points into clusters of data so that intracluster homogeneity is high and intercluster homogeneity is low. For many applications, clustering outputs can be used to extract key concepts from the data set, and the extracted concepts become meaningful labels used in a supervised learning. The judgment of a clustering result can be very subjective in some applications. Lately, objective clustering validation indices have been developed to handle certain types of input data. The self-organizing map (SOM) and expectation-maximization (EM) are two well-known unsupervised learning algorithms.

Unsupervised learning of customer segmentation is useful for business applications. Transactional and demographic data of customers are used to find clusters of customers with similar consumption behavior. Special promotions can be designed for each cluster of customers to boost the sales of products or services. Learning algorithms such as support vector clustering (SVC) and SOM can be used for this purpose. Similar ideas have been used in text mining to find meaningful concepts from texts expressed in natural languages or Web mining to find browsing patterns of users.

Reinforcement Learning

Reinforcement learning (RL) is an approach to machine intelligence that combines the fields of dynamic programming and supervised learning to yield powerful machine learning systems. In RL, the learner (a decision-making agent) is simply given a goal to achieve and then it learns how to achieve that goal by performing enough trial-and-error interactions with its environment. Three fundamental parts camprise a RL model: (1) a discrete set of environment states, (2) a discrete set of agent actions, and (3) a set of scalar reinforcement signals. On the other hand, two main strategies are used for solving RL problems. The first strategy is to search in the space of behaviors to find one that performs well in the environment. The second strategy is to use statistical techniques and dynamic programming methods to estimate the utility of taking actions in states of the world (7). The Q-learning method and temporal difference approach are two popular and widely used reinforcement learning algorithms.

Game playing, such as chess or poker, is one of the promising application areas of reinforcement learning. A game-playing system normally faces a huge search space. Traditional approaches tackle this NP-complete problem by using parallel or distributed algorithms with problem partitioning. Using reinforcement learning-based methods, tactics or strategies for winning the games are learned from interactions with human players or other programs. Patterns learned in this case are game-playing sequences that win the games.

Genetic Programming

Genetic programming (GP) is an automated method to generate a working computer program for solving hard optimization problems (8). GP provides a general paradigm to solve problems ranging from formula seeking (symbolic regression) to automated circuit designs. Like its sibling algorithm, the genetic algorithm (GA), GP is based on Darwinian evolutionary theory to search heuristically in a large solution space to find a near-optimal solution. Unlike GA, GP can use more flxible data structures to represent a chromosome. A typical chromosome in GP is a computer program like $v_1 + \mathrm{sin}(\mathrm{iif}(v_2 > 0, 1, 0))$ that usually is represented as a parsing tree. Leaf nodes in the tree include problem-dependent variables and random constants, which together are called the terminal set of a GP. On the other hand, internal nodes formed by problem-dependent operators constitute the function set of a GP.

Like other evolutionary algorithms, the fitness to the problem of each parsing tree must be assessed, and this usually is done with the setup of a test environment. Based on fitness values, evolutionary operators (selection, crossover, and mutation) are applied repeatedly to a population of parsing trees until a preset stopping criterion has been met. The final solution is then extracted from the last generation of individuals.

Instance-Based Learning

The most basic instance-based method is the k-nearest neighbor (k-*NN*) algorithm. The procedure of k-NN runs as follows: Given a new instance, the distance between the instance and all samples in the training set is calculated. The distance used in practically all nearest-neighbor classifiers is the Euclidean distance. With the distance calculated, the samples are ranked according to the distance. Then the k samples that are nearest to the new instance are used to assign a classification label or a regression value to the case. As no separate phase of model learning exists, k-*NN* is considered a lazy type of learning algorithm. Two issues related to this algorithm are choosing the number of neighbors (k) and the quick determination of nearest neighbors. The former issue usually is solved by a trial-and-error type of approach, whereas the latter issue is solved by using well-designed data structures.

Bagging

Bootstrap aggregating (or bagging) is a meta-algorithm that can be used to improve the performance of classification and regression models (9). Bagging has its roots in statistics, in which bootstrap technology is used to sample training data with a replacement. Initially, a base supervised learning algorithm is called B such as a decision tree or a neural net, and a training set T of size n. We generate m data sets $T_1, \ldots, T_m$, each with the size n by sampling with a replacement from T. That is, for each data set T_j, a training example is sampled from T with uniform distribution and is returned to the population for next sampling. This procedure is repeated until n examples have been collected for T_j. Then, the algorithm B is applied to T_j to get a prediction model B_j. If the prediction output is a class label, a simple majority vote from outputs of B_j's is used to determine the final class label. On the other hand, if the output is a regression value, then the average of outputs from B_j's is taken to be the output for the bagging predictor.

Bagging has the advantage of increased prediction accuracy and reduced instability of base models. By aggregating different versions of a base model, sensitivity with respect to training data in certain supervised learning algorithms can be reduced. For example, it is known that the output from a decision tree is very sensitive to the training set. If a bagging predictor is constructed using decision tree as the base learner, accuracy can be improved substantially.

Boosting

Boosting is another meta-algorithm that ensembles base learners to perform supervised learning (10). Similar to bagging, boosting trains different versions of a base learner by using different samplings from the original training set. Unlike bagging, each sampling of the training set in boosting does have its own probability distribution for choosing the data. Although training of a bagging predictor is parallel in nature because bootstrap samplings of training sets can be conducted simultaneously, boosting is sequential because the distribution function for sampling data is determined in a sequential order.

The most popular boosting algorithm is called AdaBoost (Adaptive Boosting). Freund and Schapire (10) have indicated that AdaBoost can boost a weak learning algorithm—one that performs slightly better than random guessing—into a strong learning algorithm, which can generate a predictor with arbitrarily low error rate provided that sufficient data are available.

OTHER CONSIDERATIONS

Connections with Other Fields

As a multidisciplinary field, machine learning is related closely to and has gained many great ideas from other scientific fields. These fields include computer science, artificial intelligence, cognitive science, and statistics, among others. The discussion below is based on the historical development of machine learning and the close relationships among the fields.

- *Computer Science*: Because machine learning is about an adaptive computer program, it benefits from advancements and shares many problems in computer science. An algorithmic breakthrough in computer science may advance machine learning to the next level of achievement. Likewise, tractability and complexity theory in computer science constrains the development of machine learning as well. However, differences still exist between these two fields. As computer science emphasizes correct programming, machine learning requires writing programs that can learn.
- *Artificial Intelligence*: Originated as a subfield of artificial intelligence (AI), machine learning has a close tie to AI. History shows that AI has many other subfields such as planning, pattern recognition, natural language processing, and expert systems that may or may not be related closely to machine learning. Traditionally, AI offers more domain-specific solutions via machines, whereas machine learning provides more general-purpose algorithms that can be used in many different settings. Heuristic search algorithms in AI have advanced the capability of machine learning in finding appropriate models, and development and per-

fection of machine learning algorithms have made AI more practical in daily applications.

- *Cognitive Science*: Machine learning has been applied successfully to areas that are hard to explain but can be performed easily by human beings. These areas of applications frequently involve human cognition or perception. For example, it is easy for a person to recognize written characters or spoken words, but it is hard to explain the cognition process and code a program directly to perform such tasks. Today, optical character recognition and speech recognition software based on machine learning algorithms that adapt to different writing styles or speaking accents has provided the best performance in these areas of applications. Machine learning may gain additional improvement by using discovery in cognitive science, and cognitive science may understand human or animal cognition process better by using results from machine learning. For example, reinforcement learning can be used to explain the dopaminergic neuron activity in a brain (11).
- *Statistics*: Much of machine learning work uses inductive reasoning to draw a reasonably good model from a set of data. Statistics has long been known for its ability to summarize results from experimental data. Thus, machine learning and statistics share many principles of data summarization. Learning algorithms such as classification and regression tree (CART) and clustering have their roots in statistics. On the other hand, machine learning has helped statistics to advance its capability in handling a large amount of data by using computers.

Caveat

When we employ machine learning to solve scientific or engineering problems, limitations and constraints associated with it should be well considered. For example, the output attribute predicated by the ID3 must be discrete valued, and the attributes tested in the decision nodes of a tree must also be discrete valued (1). Some delicate phenomena worthy of additional consideration are listed in the following.

- *Concept drift*: A difficult problem with machine learning in many real-world applications is that the target concepts are not stable but may shift from time to time. For example, today's companies collect a large amount of data like sales figures and customers' preferences to find patterns of customer behavior and to predict future sales. As the customer behavior tends to change over time, the model built on old data is inconsistent with the new data and must be updated accordingly. This problem generally is known as concept drift (12).
- *Overfitting*: Given a model space $\boldsymbol{H}$, a model $h \in \boldsymbol{H}$ is said to overfit the training data if some alternative model $h' \in \boldsymbol{H}$, exists such that h has a smaller error than h' over the training examples, but h' has a smaller error than h over the entire distribution of instances (1). Empirical error-(i.e., error based on the training data)-based learning algorithms such as decision trees or neural networks often have this type of unwanted behaviors and must be treated carefully. Structural error-based learning algorithms such as support vector machines consider structural complexity in addition to the empirical error when judging the goodness of a model, and they usually can reduce the overfitting effect.
- *Occam's razor principle*: Occam's razor is a logical principle attributed to the Fourteenth century logician and Franciscan friar, William of Occam (or Ockham). The principle states that "Entities should not be multiplied unnecessarily." In other words, the principle states that simpler explanations are more plausible and any unnecessary complexity should be shaved off (4). Sometimes, this principle is also called the "principle of parsimony" or "principle of economy." This principle can be used to help avoid the overfitting phenomenon.
- *The minimum description length principle* recommends choosing the model that minimizes the description length of the model plus the description length of the data given the model. Bayes's theorem and basic results from information theory can be used to provide a rationale for this principle (1).
- *Wolpert and Macready*(13) proposed "no free lunch theorems." They show that all algorithms that search for an extremum of a cost function perform exactly the same, when averaged over all possible cost functions. In particular, if algorithm $\boldsymbol{A}$ outperforms algorithm $\boldsymbol{B}$ on some cost functions, then loosely speaking, as many other functions where $\boldsymbol{B}$ outperforms $\boldsymbol{A}$ must exist exactly.
- *The ugly duckling* theorem demonstrates that no such thing as a class of similar objects exists in the world, insofar as all predicates (of the same dimension) have the same importance (14). In the absence of assumptions on features, any two patterns are "equally similar" regardless of the patterns involved. The implication for machine learning is that no canonical set of features exists for any given classification task. Good feature representations of patterns must be problem dependent.
- *The famous Garbage-In–Garbage-Out rule* can be found in many practices of machine learning. Because machine learning is a compound process of selecting data, generating and adjusting models of knowledge, testing the validity of the model, and so on, each stage in the process may produce defective outputs to the next stage. This result could be from imperfect data collected or the limitations of learning algorithms adopted. Users need to pay attentions to each stage when working with machine learning to gain the best performance.

Future Outlook

The techniques of machine learning have been applied successfully to various areas of applications. However, with the growth of versatile data and extensive demands, research on machine learning also becomes a never-ending story. Below are several issues worthy of additional study.

- *Problem representation and data selection*: Feature collection and representation can play a central role in a machine learning job. For the past few decades, efforts on machine learning have focused mainly on effective and efficient learning algorithms and have assumed that data for training or testing are well prepared. However, with the growth of the Internet, data to be processed have become versatile and voluminous, probably containing lots of noises, redundancies, or errors and being represented unstructuredly. Also, data are not static any more; they may be observed in a snap shot and be described by features that are changing with time. These features make the preparation of data for learning algorithms more difficult in practical applications. Methods of proper representation of the underlying problems, selection of the most significant data subset for complete learning, being tolerable or robust of noises, or errors for scalable applications are issues that need to be addressed.
- *More adaptive and robust learning algorithms*: Most current learning algorithms are static in model learning and utilization. Retraining usually is necessary when a lot of new data not learned in the training phase are encountered. Future learning algorithms are expected to be robust and adaptive no matter how dynamically the data are fed and must even be able to change the learning structures and strategies used in the algorithm when necessary. Some of today's learning algorithms like GP can only fulfill these requirements partially.
- *Hybrid learning algorithms*: Each learning algorithm has its pros and cons. Hybridizing two or more heterogeneous learning algorithms that can produce complementary results is a trend in practical applications. Two strategies are used most often. The first one is to make the learning process an n-tier process in which each stage employs one learning algorithm. The second one is to integrate different learning algorithms in a task, for example, GA-based adjustment of ANN structures.
- *Semisupervised learning*: During the last few years, semisupervised learning (SSL) has received increasing attention in the machine learning research community. The basic idea behind it is to learn not only from the labeled training data but also to exploit the structural information in additionally available unlabeled data; that is, SSL combines labeled and unlabeled data during training to improve performance. SSL has been applied successfully to both classification and clustering problems.
- *Measurement criteria*: The success of learning algorithms is measured by performance measurements. Most measurement criteria are defined objectively, and their applicability and usefulness are case dependent. Defining measurement criteria to reflect truly insights of learning algorithms and models of knowledge for the applications is a fundamental yet important issue.
- *Non-monotonic issues*: As mentioned most learning algorithms assume that input data are well prepared and that training data are true. It is possible that data originally considered true are proved to be inadequate by new evidences. When models need to be revised because of the arrival of new data, non-monotonic reasoning and non-monotonic truth maintenance that are important and hard issues in AI must be handled properly.

NEURAL CONTROLLERS

INTRODUCTION

Modern control systems have steadily evolved into complex devices that are characterized by their increased nonlinearity, flexibility, intelligence, and enhanced capability to handle uncertainty. Conventional control techniques such as robust control and adaptive control, which largely rely on a well-formulated model of the plant to be controlled, fail to address these issues in situations where a precise analytical model of the plant may be difficult to obtain due to nonlinearity, uncertainty, or complexity. These and similar issues have led to a desire for development of better control techniques that are intelligent, adaptive, self-learning, and capable of handling highly uncertain, nonlinear, and complex systems whose dynamics may be time-delayed, ill-defined, or simply unavailable. Moreover, the solutions of such issues have also contributed to the development of new concepts such as autonomous control with a need for sensor fusion, decision making, planning, and learning. The objective for meeting new challenges in the field of control has led to a reappraisal of existing conventional control techniques. Neural networks (1–3), because of their ability to model nonlinearity and uncertainty and their nondependence on mathematical model of plant, and their learning ability, have been a natural choice as controllers and system identifiers for the practitioners in the controls community. Figure 1 shows a typical scheme in which neural network controller and neural network plant model can be used. In this figure, two neural networks are illustrated. One neural network produces control action to drive the plant, and the other one is the model of the plant. The figure also shows the feedback scheme, which is used to train the networks online, making them adaptive to changes in plant behavior.

A neural network (NN) (4–6) is an information-processing paradigm inspired by the manner in which the heavily interconnected, parallel structure of the human brain processes information. The human brain is the most complex computing device in nature. An NN is a computer model that attempts to match the functionality of the brain in a very fundamental manner. The key feature of the NN paradigm is the novel structure, which is composed of a large number of highly interconnected processing elements (called neurons) that are coupled together with weighted connections (analogous to synapses). The information, which is represented as a bundle of signals, is passed between neurons via connection links that get multiplied by connection weights and get transformed with the help of activation functions at each neuron. In other words, NNs are collections of mathematical models (representing mathematical operations in layered fashion) that emulate some of the observed properties of biological nervous systems and draw on the analogies of adaptive biological learning. Similar to biological systems, learning in neural networks typically occurs via training or exposure to an accurate set of input/output data where the training algorithm iteratively adjusts the connection weights. These connection weights store the knowledge necessary to solve specific problems.

NNs have been implemented in several architecture. A typical multilayer feed-forward NN is shown in Fig. 2. The figure shows the inputs and the two layers (one hidden layer and one output layer) of neurons. In general, several hidden layers may exist in an NN. Each input node is connected to all neurons (nodes) in the next layer (hidden layer), and each node in the hidden layer is connected to all neurons in the output layer. Each of these connections has a weight associated with it, and a bias is associated with each node. Each node also applies an activation function to the sum total of its input. Another kind of network is a recurrent network, which contains feedback elements from the output, with time delay. This type of network is very effective for recognizing not only spatial patterns but also temporal patterns. The Hopfield network (7,8) and the Elman network (9) are examples of this kind of network. Another type of network, called the radial basis function network (RBFN) (10,11), was introduced as an alternative to the feed-forward network for approximating continuous functions. The RBFN has a feed-forward structure consisting of a single hidden layer of locally tuned units that are fully interconnected to an output layer. All hidden units simultaneously receive the n-dimensional real-valued input vector x. The hidden unit outputs are not calculated using the weighted sum/sigmoidal activation mechanism. Rather, each hidden unit output is obtained by calculating the “closeness” of the input x to an n-dimensional parameter vector associated with the hidden unit.

Currently, NNs are being applied to several complex real-world problems. They are very efficient and robust at recognizing and classifying patterns, and they possess the ability to make effective decisions in the presence of imprecise input data. They offer ideal solutions to a range of problems such as speech, character, and signal recognition, as well as functional approximation and prediction, and system modeling where the dynamical processes are not well formulated or are extremely complex. The primary advantage of NNs lies in their robustness against uncertainty in the input data and in their capability of learning. They are often effective for solving complex problems that do not have an analytical solution or for which an analytical solution is too difficult to be found.

NEURAL CONTROLLER AND LEARNING

A control system is said to have learning capabilities if the system acquires any information pertaining to the environment, which is unknown in the system’s internal model of the environment and uses that information for updating the model for future estimation, classification, identification, or control such that overall performance of the system

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

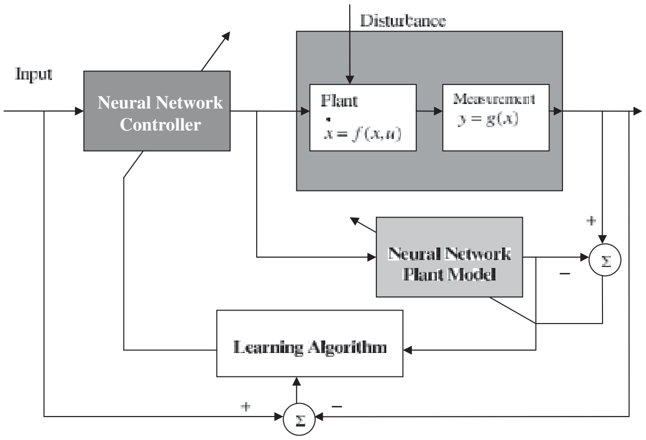

Figure 1. A typical neural network control scheme.

is improved. If this process of learning is carried out while the control system is in operation, the system is said to possess adaptive learning capabilities. An adaptive learning control system has the ability to use information it gained in the past to improve its performance in the future. For the control system to be completely autonomous, it should be able to handle any uncertainty that might arise in the plant and in the environment. In addition, it should be able to operate in a large range of operating conditions, and it should be able to adjust itself to any change in dynamics of the plant. In conventional control techniques, learning occurs by tuning the parameters of the controller (e.g., by tuning proportional gain (K_p), integral gain (K_i), and derivative gain (K_d) of the PID controller by means of the Zeigler–Nichols method). In the NN, learning occurs by adjusting the weights of the connection between neurons.

The field of neural networks had its beginning in the 1940s, with the pioneering work of McCulloch and Pitts (12) on the model of elementary computational neuron. The next major development occurred with the introduction of the *Hebbian Learning Rule* (13) in 1949, which reads as follows: "*When one cell repeatedly assists in firing another, the axon of the first cell develops synaptic knob (or enlarges them if they already exist) in contact with the soma of the second cell*." In other words, during a learning process in the brain, repeated activation by one neuron (cell) to another increases the conductance of synapse between the two neurons. This learning concept was used by Rosenblatt (14) to develop the first artificial neuron (or *perceptron*, as he called it) with the capability to learn. Widrow and Hoff (15) in 1960, developed a model of a neuron called ADALINE (ADAptive LInear NEuron), which could learn quickly and accurately, based on a powerful learning rule called the *Widrow–Hoff Learning Rule*. This learning rule first introduced the concept of supervised learning using a "teacher" that guides the learning process based on a least-mean-square (LMS) algorithm. In 1962, Rosenblatt (16) introduced the *perceptron learning rule* and proved that a perceptron could be trained to learn whatever it represents. However, in 1969, the research in the field of NNs received a major setback when Minsky and Papert, in their book *Perceptrons*(17), proved that single-layer networks, which were in use then, were limited in their abilities to process data and were theoretically incapable of solving many problems, including the *Exclusive-OR* logical function. These findings and similar ones led to a stagnation in research on NNs for almost two decades until 1986, when Rumelhart et al., (18) introduced an error backpropagation algorithm to train multilayer NNs and overcame the limitations of the single-layer networks. This development triggered off a renewed interest in NNs, and since then, there has been a flurry of research activities in this field leading to a well-developed science that has found applications in several areas, such as the controls, space, manufacturing, medical sciences, and process industries.

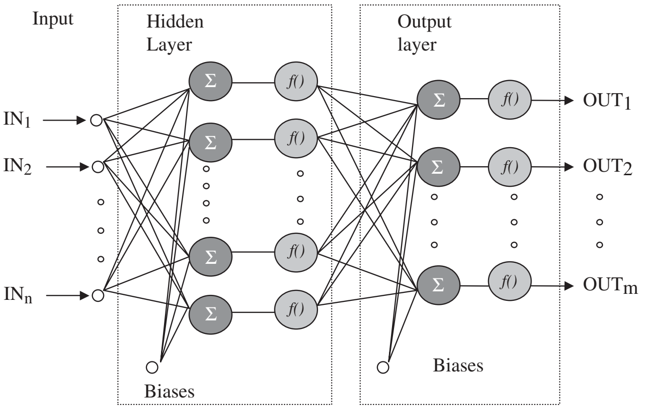

Figure 2. A multilayer feed-forward neural network.

Learning is the most important part of NNs, and intense research has been carried out in devising efficient learning algorithms (19). The three most popular learning algorithms are as follows: the supervised, the unsupervised, and the reinforced learning methods. The supervised learning attempts to reduce the error between the actual and the desired outputs and needs a training dataset comprised of inputs and desired outputs. The objective to minimize the error, along with the presented input–output data, act as a teacher. Backpropagation, based on the gradient descent method, is one of the most popular methods that falls under this category. Unsupervised learning does not involve a teacher guiding the learning process. The data presented to learn the network in this case do not include the input–output pairs. Instead, the parameters of the network (the connection weights and biases) are adjusted based on clustering techniques such as the self-organizing Kohonen's map (20) or competitive learning techniques (21) upon presentation of input patterns. Reinforcement learning is similar to the reward and punishment method in psychological learning. The reinforcement learning technique (22) is based on maximizing the reward or reinforcement signal as a consequence of action taken by the controller. Reward or reinforcement signal is obtained by means of a utility function that calculates a sum of future rewards, which represents correctness of action in some form. This kind of learning technique has received increased interest because of its adaptive feature and the autonomous manner in which the system learns while interacting with the environment.

NEURAL NETWORK APPROXIMATION AND IDENTIFICATION: A CONTROLS PERSPECTIVE

Three-layered NNs (i.e., one input layer, one output layer, and one hidden layer), with the hidden layer having sufficient nodes and a sigmoid transfer function, and a linear transfer function in the input and output layer are considered to be universal approximators (23,24). They can approximate functions to an arbitrary accuracy. This ability of NNs to approximate large classes of nonlinear functions accurately makes them a popular candidate for use in obtaining a dynamic model of a nonlinear plant. The process of obtaining a model of the plant that can approximate the plant response (output) under stimuli (input) is called identification and is an important part of control. The NN, being an excellent function approximator, can identify complex nonlinear governing equations of plant dynamics. By making the weights of the connections and biases of neurons adjustable, the NN can be extremely adaptive to changes in system and environment parameters. Such NN models can aid in the development of an efficient controller. Figure 3 shows the scheme demonstrating how an NN can be made to learn (via supervised learning) to emulate an unknown function or plant dynamics.

The nonlinear dynamics of a plant can be described by the following pair of difference equations expressed in discrete time:

$$\begin{aligned} x(k+1) &= f(x(k), u(k)) \\ y(k) &= h(x(k)) \end{aligned} \tag{1}$$

where *x(k)* is the state of the system at time step k, *y(k)* is the output vector that can be measured, *u(k)* is the applied input, and f and h are nonlinear operational functions. Some issues that arise in neural modeling of dynamical systems (such as uniformity of the approximation and whether the model would be able to capture the underlying (continuous time) differential equation) have been dealt with by Zbikowski and Dzielinski (25). The usual analytical way to model and control a plant governed by Equation (1) has been to perform linearization about an operating point to obtain equations of the form:

$$\begin{aligned} x(k+1) &= Ax(k) + Bu(k) \\ y(k) &= Cx(k) \end{aligned} \tag{2}$$

Learning / Parameter Identification

Figure 3. Neural network for identification/function approximation.

The system represented by the above set of equations is controllable and observable in the neighborhood of specified operating point. Under some assumptions (26), it can be shown via an implicit function algorithm and inverse mapping theorem (27) that the nonlinear system can be controlled using nonlinear controllers in the neighborhood of the operating point. Extensive computer simulations have further shown that the range within which the system can be controlled is substantially larger than the neighborhood within which the linear model is valid.

The real problem of identification arises when the functions f and h are unknown. In that case, it becomes necessary to estimate those functions from input–output data. Two neural networks N_1 and N_2, with sufficient number of nodes, are used for approximating those functions. If the state variables *x(k)* is accessible, then both networks N_1 and N_2 can be easily trained because input and output data are available. However, if state variables are not accessible, then the error between the plant output and the NN output $(y(k) - \hat{y}(k))$ can be used to train the network via static and dynamic backpropagation (28). The past values of input and output can also be fed as input to the NN via tapped delay line (TDL) to assist in better identification of the plant. These NN models can be used further in arriving at the linearized feedback control of the plant.

The system identification model, which is obtained from the NN, can also be used to predict the plant outputs and controlled variables over a specified time horizon. This information can be extremely useful to optimize the controller to minimize the tracking error. The multistep predictions of output variables (29) via NNs can be made by either using multiple network outputs or recursively using a single network output.

The use of feed-forward networks, recurrent networks, and RBFNs for approximation and identification tasks has been studied extensively, and it has been shown that these networks can approximate arbitrary functions from one finite-dimensional space to another with desired accuracy. It is also true that the same properties are shared by polynomials, trigonometric series, splines, and orthogonal functions. Several research studies have revealed that NNs are more robust to uncertainties and noise, more fault-tolerant, easily implementable on hardware, and enjoy numerous other practical advantages over conventional methods.

NEURAL NETWORKS AS CONTROLLERS

The universal approximation capabilities of multilayer neural networks have made them a very popular choice for identifying nonlinear processes and implementing nonlinear controllers. Several ways (30) exist in which NNs can be made to implement a controller. For example, an NN can be made to mimic a human expert. In this approach, the expert human knowledge, intuition, and experience about the system and appropriate control actions for an ill-defined system are captured in the form of NN mapping (31). The resultant NN emulates the expert and may even perform better than the expert because of its property of ignoring the mistake outliers while being trained. Here, the discretized perception of information and decision of control action by the human operator expert is replaced by continuous interpolations of the network. Similarly, an NN can emulate a well-designed nonlinear controller. This emulation is particularly helpful when a given controller requires a large amount of computational or tuning effort for each process condition. The NN, in this case, approximates the nonlinear controller and the control action eliminates the extra computations and tuning needs. Several applications have been reported in literature where NNs have been used to emulate the controller. Typical examples include multimodel optimal control (32), time optimal control (33), and one-step inverse control (34). In another approach, the NN is trained based on open-loop input/output data to identify an inverse model of the plant. The controller then uses the desired output values to calculate the appropriate control action (input) and is also implementable in the feedback model (35). However, this method faces a problem when no unique inverse model of the plant exists or when the mapping is inadequate for the dynamic plant.

An extensive research effort has been undertaken in the field of controls based on NNs (36–39), and several different architectures (40), using NNs for identification and control of nonlinear systems, have been proposed. This section will provide a brief overview of some popular architectures.

Internal Model Control

A schematic of the structure of the neural internal model control (NIMC) is shown in Fig. 4. Two NNs are included in the control architecture. The first NN, which acts as controller, is generally trained to represent the inverse model of the plant. The second network is the NN model of the plant. The error between the output of the NN plant model and the output of the plant is used as a feedback signal. The NN plant model and the NN controller can be trained offline, and then it can be made to improve over time by letting it learn online. Internal model control (IMC) using conventional methods has been used in the process industry for a long time. As the control strategy is based on a model of the plant, its performance is greatly dependent on the accuracy of the plant model. IMC based on conventional methods tends to perform poorly in the presence of large modeling uncertainty or external disturbances. However, the use of NNs in IMC with online training of the networks has shown significant improvement (41) in system performance.

Model Predictive Control

The model predictive control (MPC) scheme minimizes the future output deviation from the set point, while taking into account the control action needed to achieve the prescribed objective. Neural MPC, based on the receding horizon control (RHC) technique (42), uses an NN plant model to estimate/predict future plant responses to potential control signals over a specified time horizon. An algorithm then computes control actions that optimizes the performance or minimizes the objective function:

$$J(N_1,N_2,N_u) = \sum_{j=N_1}^{N_2}\{y_r(t+j) - y_m(t+j)\}^2 + \rho\sum_{j=1}^{N_u}\{u(t+j-1) - u'(t+j-2)\}^2 \tag{3}$$

where N_1 and N_2 define the minimum and maximum output prediction horizons and N_u is the control horizon. The variable u' is the tentative control signal, y_r is the desired response, and y_m is the network model response. The parameter ρ determines the contribution that the sum of the squares of the control increments has on the performance index. The predictive controllers penalize the excessive control action by providing nonzero ρ. The prediction horizons specify the range of future predicted outputs to be considered, and the control horizon specifies the number of control moves required to reach the desired goal. An MPC architecture based on NN is shown in Fig. 5. As shown in the figure, the NN plant model provides predictive estimates of the states of the plant to the controller, which computes the control action based on the optimization of the objective function given by Equation (3). Predictive control based on conventional methods has proven to be very successful for linear systems. However, for nonlinear systems, the unavailability of accurate models limits the use of MPC. The NNs, with their ability to model nonlinearities in the system accurately, eliminate this problem, and their use in MPC has resulted in robust controllers in a variety of practical situations where the nature of the nonlinearity of the system is not known. However, controllers based on the MPC technique are computationally intensive because of the technique's requirement of carrying out the multistep optimization process. An NN can be made to learn the

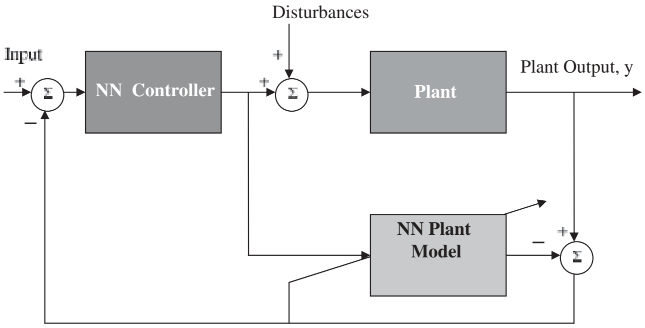

Figure 4. Neural internal model control.

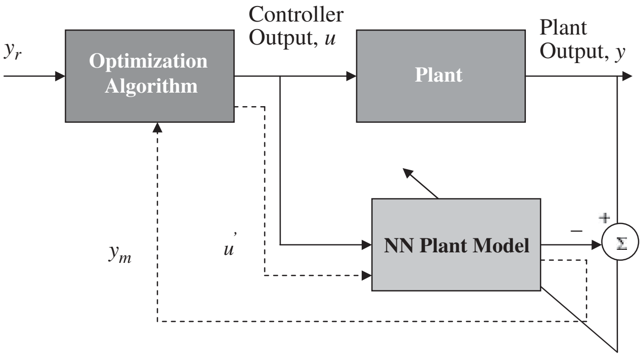

Figure 5. Neural model predictive control.

optimization process and can replace the optimization function after the network has been trained satisfactorily.

Feedback Linearization Control

Feedback linearization control (FLC) aims to transform nonlinear system dynamics into linear dynamics by eliminating nonlinearities. The nonlinear autoregressive moving average (NARMA) model (43) under certain conditions, provides an exact input–output representation of a nonlinear system. One popular NARMA model for identifying nonlinear systems is the NARMA-L2 (44) model. This model can be represented by the following equation:

$$\hat{y}(k+d) = f[y(k), y(k-1), \ldots, y(k-n+1), u(k), u(k-1), \ldots, u(k-m+1)] + g[y(k), y(k-1), \ldots, y(k-n+1), u(k), u(k-1), \ldots, u(k-m+1)]u(k+1) \tag{4}$$

where $d \geq 2$. This equation relates the past n plant outputs and past m plant inputs (and one-step future input) to estimate the d-step future output. This estimate of future output can be made to track the desired reference output $y_r(k+d)$. The controller can be defined as

$$u(k+1) = \frac{y_r(k+d) - f[y(k), y(k-1), \ldots, y(k-n+1), u(k), u(k-1), \ldots, u(k-m+1)]}{g[y(k), y(k-1), \ldots, y(k-n+1), u(k), u(k-1), \ldots, u(k-m+1)]} \tag{5}$$

which can be realized for $d \geq 2$. Hence, the control scheme begins first with the identification of the plant with the help of an NN. The past plant inputs and past plant outputs can be fed to the NN model via TDLs, and the network can be trained offline and then made to be adaptive to all online data. Figure 6 shows the architecture of neural adaptive feedback linearization control based on the NARMA-L2 model. As shown in the figure, the controller consists of two NN models of the nonlinear functions f and g. The controller receives the past inputs via the TDLs, and implements the logic of Equation (5). The NN models of the functions f and g receive feedback from the plant and get trained online.

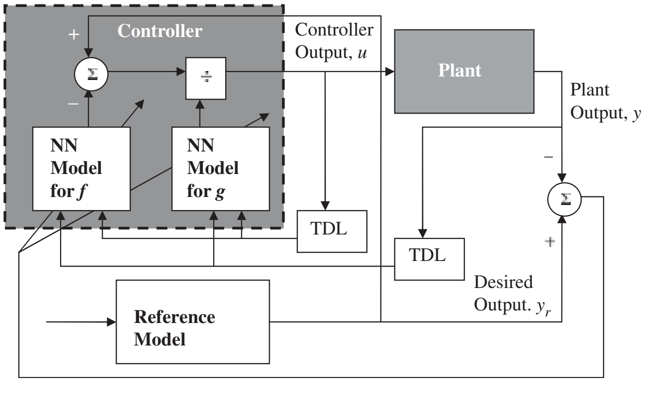

Figure 6. Neural feedback linearization control.

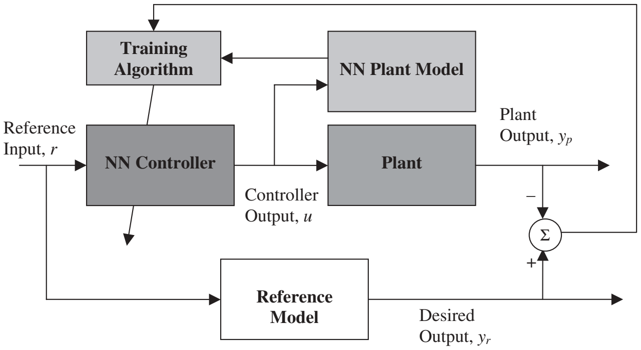

Figure 7. Neural model reference control.

Neural Model Reference Control

The neural model reference control (45) (NMRC), as shown in Fig. 7, uses two NNs: a controller network and a network for plant model. The controller is trained to make the plant respond to minimize the error between the plant output and the output from reference model, which represents the desired closed-loop dynamics of the plant. This goal is achieved by adjusting the parameters of the controller via the training mechanism that minimizes the error between the reference model and the system. The plant model of the network can be obtained offline or adjusted online (if the parameters of the plant are expected to vary) based on input/output data. This model network is then used to predict the controller changes on plant output, which facilitates the adaptive training of the controller.

NEURO-FUZZY CONTROLLERS

Fuzzy set theory (46,47) was specifically designed to mathematically represent uncertainty and vagueness and to provide formalized tools for dealing with the imprecision that is intrinsic to many real-world problems. Designing a fuzzy inference system requires describing human knowledge/experience linguistically. The inference system captures these traits in the form of fuzzy sets, fuzzy logic operation, and fuzzy rules. The ability of fuzzy logic to deal with uncertainty and noise, and its simple understandable linguistic structure, has motivated researchers to use it for controlling complex systems for which precise analytical models may not be available. However, the design of a fuzzy logic controller suffers from certain problems regarding the selection of membership function characteristics (e.g., type and number of membership functions and their shape and range and choosing appropriate fuzzy rules. Developing a rule base is the most time-consuming part of designing a fuzzy logic controller. Thus, a need exists for developing efficient methods to tune membership functions, i.e., to obtain their optimal shapes, range, and number.

Both NN and fuzzy logic (48–52) are model-free estimators and share the common ability to deal with uncertainties and noise. Both of them encode the information in a parallel and distributed architecture in a numerical framework. Hence, it is possible to convert a fuzzy logic architecture to an NN and vice versa. This capability makes it possible to combine the advantages of both NNs and fuzzy logic. A network obtained in this manner could use excellent training algorithms that NNs have at their disposal to obtain the parameters that would not have been possible in a fuzzy logic architecture alone. Moreover, the network obtained this way would have the transparency of a rule-based fuzzy system, because this network would have fuzzy logic capabilities to interpret its actions in terms of linguistic variables. This fusion of two powerful control mechanisms has led to the research and development of neuro-fuzzy controllers (where fuzzy controllers are formulated using the learning capabilities of NNs) and fuzzy neural systems (where fuzzy techniques are applied to speed up the learning or fuzzification of NN is carried out to process fuzzy inputs).

Several algorithms have been developed that address the problem of learning fuzzy rules and tuning the membership functions in an NN architecture. The adaptive-network-based fuzzy inference system (ANFIS) developed by Jang (53) is one of the pioneering works in this field. ANFIS is a fuzzy inference system developed within the framework of an adaptive network (which is a superset of all kinds of feed-forward NNs with supervised learning capabilities). The learning rule proposed for this method is basically a hybrid of the gradient descent method and the least-squares technique, which are implementable both offline (batch learning) and online (pattern learning). This approach, based on the gradient descent method, implements a Sugeno-like fuzzy system, which uses differentiable functions. Subsequent to the development of the ANFIS approach, several methods were proposed for learning rules and for obtaining an optimal set of rules. For example, Mascioli et al. (54) proposed to merge the min–max and ANFIS models to obtain a neuro-fuzzy network and to determine the optimal set of fuzzy rules. Lin and Lee (55) proposed an NN based fuzzy logic control system (NN-FLCS), which learns the structure and parameter of the network to develop fuzzy logic rules and finds the optimal input–output membership functions. A few other neuro-fuzzy approaches developed in recent years include GenFIS (56), NEFGEN (57), FDIMLP (58), and NEFCON (59).

NEURAL CONTROL APPLICATIONS

Since their development, controllers based on an NN have found application in several fields (60), including robotics and automated manufacturing, machining (61), uncertain systems (62,63), aerospace, communication systems, consumer appliances, electric power systems, process engineering, micro-electromechanical systems (MEMS), and power electronics and motion control. NNs have played an important role in machine intelligence by integrating sensors, actuators, software, and computers to make machines capable of acquiring information efficiently and by responding safely and rapidly to both deterministic and unexpected events. Intelligent machines (64) play a potentially important role in a variety of areas, such as manufacturing, the service industry, space explorations, defense, and nonmilitary operations. NNs, along with other soft computing algorithms such as fuzzy logic and genetic algorithm, have been used widely in several intelligent machines and have been a popular choice for machine learning. Typical examples of intelligent machines that have been developed using the NNs include consumer appliances such as washing machines (65), expert systems for medical diagnosis (66,67), and intelligent system (68) for agriculture in Japan.

NNs with their unique ability for pattern recognition in data, classification, and nonlinear functional mapping have been successfully used in areas of knowledge management and data mining with applications in economics, finance, accounting, and marketing. NNs have proved to be theoretically sound alternatives to traditional statistical approaches, and many applications (69–71) in business management and finance have been reported. NN-based modeling and prediction tools have been used in forecasting (72,73), credit card fraud detection (74), credit evaluation (75), bankruptcy prediction (76), state revenue forecasting (77), and prediction of regularities in foreign exchange rates (78). In the areas of marketing and business management, NNs have been used in mining useful information and generating knowledge (79) from a large pool of data that can suitably support marketing decisions and customer relationship management. The following description is of two specific fields with case studies where neural controllers have been successfully used.

Robotics

The field of robotics has provided tough challenges for the controls community because of inherent system nonlinearity, presence of backlash and nonlinear friction, existence of uncertainty from neglected dynamics, and difficulty to obtain precise analytical models of the system. In view of these reasons, NNs have been a favorite choice for identification and control (80,81) of robotic systems. Since the late 1980s, in the field of robotics, NN controllers have been found useful in applications such as manipulator control (82), path planning (83), contact control and grasping (84), multiple robot coordination (85,86), and mobile robot autonomous navigation (87). A case study showing the use of NNs in robot manipulator position control (88) is described as follow.

The dynamics of a rigid n-link robot manipulator can be expressed in Lagrange's form:

$$\tau = M(q)\ddot{q} + V_m(q,\dot{q})\dot{q} + G(q) + F(\dot{q}) + \tau_d \tag{6}$$

where $q(t) \in R^n$ is the vector containing joint angles, $M(q)$ is the inertia matrix, $V_m(q,\dot{q})$ is the matrix containing Coriolis and centrifugal forces, $G(q)$ is the vector containing terms from gravity, $F(\dot{q})$ is the friction, τ_d is the bounded unknown disturbances, and $\tau(t)$ is the vector of input joint torques. The robot is required to follow a desired trajectory $q_d(t) \in R^n$. The tracking error is given by

$$e(t) = q_d(t) - q(t) \tag{7}$$

and the filtered tracking error is defined by

$$r = \dot{e} + \Lambda e \tag{8}$$

where Λ is a positive semi-definite design parameter matrix. Using Equations (6), (7), and (8), the robot dynamics can be written as

$$M\dot{r} = -V_m r + f + \tau_d \tag{9}$$

where *f* is a nonlinear function containing robot parameters (such as link masses, lengths, and inertia), joint friction coefficients, and payload information, and is given by

$$f(x) = M(q)(\ddot{q}_d + \Lambda\dot{e}) + V_m(q,\dot{q})(\dot{q}_d + \Lambda e) + G(q) + F(\dot{q}) \tag{10}$$

The vector x is defined as $x = \left[e^T e^{\dot{T}} q_d^T q_d^{\dot{T}} q_d^{\ddot{T}}\right]$. The control law is given by

$$\tau = \hat{f} + K_v r - v \tag{11}$$

where $\hat{f}$ is the estimate of function $f(x)$ and K_v is the gain matrix. The signal $v(t)$ is the robustifying signal responsible for compensation of unaccounted disturbances. Figure 8 shows the controller structure, which makes use of the NN in the inner loop to approximate function $\hat{f}$. Several ways (89) exist to tune NN parameters and signal $v(t)$, and control gain K_v. The NN controller, designed using this approach, guarantees the tracking error to be bounded by

$$|r| \le \frac{\varepsilon_{NN} + b_d + kC}{K_{v_{\min}}} \tag{12}$$

where ε_{NN} is the NN functional reconstruction error bound, b_d is the robot disturbance term bound, and C represents other constant terms. The denominator $K_{v_{\min}}$ is the smallest PD gain. By choosing a larger PD gain, it is possible to limit the tracking error to an arbitrarily small value. As the NN weights and biases are bounded, it can be shown that the control input τ is also bounded. Moreover, the tuning algorithms guarantee that the closed-loop control system has a strict passivity property that makes it robust to unmodeled uncertainties and disturbances.

Industrial Applications

NNs have been used extensively in industrial environments. In particular NNs have found applications in the aerospace industry (90), automated manufacturing (91), electric power systems (92), steel industry (93), and process industry (94).

Figure 9. Schematic representation of the HDCL control system.

Lu and Markward (95) have developed an NN-based control system for coating weight control for a hot dip coating line (HDCL), which has been successfully implemented at the Burns Harbor Division of Betlehem Steel Co., Chesterton, IN. The major goals of the control system are to minimize the error between the desired and the actual coating weight, and to minimize the coating weight transition time that determines the sheet transitional footage. The control system, as shown in Fig. 9, consists of two multilayered feed-forward NNs and a neural adaptive controller. These NNs perform coating weight real-time prediction, feed-forward control (FFC), and adaptive feedback control (FBC). Traditionally, these strategies are performed by relevant analytical algorithms and identification models based on the first principles. The NN prediction model takes air pressure P, line speed S, and air knife gap D as inputs and outputs the coating weight CW. The dynamics of the coating process can be represented by the following equation in the Z-domain:

$$CW(z) = G_p F_p(z)P(z) + G_s F_s(z)S(z) + G_d F_d(z)D(z) + \varepsilon(z) \tag{13}$$

where G_p, G_s, and G_d are process gains from P, S, and D, respectively. F_p, F_s, and F_d are Z-transfer functions from inputs P, S, and D to the coating weight, respectively, and ε is the process noise. The measurement equation representing the average coating weight can be written as

$$CW_M(t) = CW(t-\tau) + \omega(t) \tag{14}$$

where τ is the time delay from the pot coating weight to the gauge sensor and ω is the measurement noise.

The neural prediction model is first trained offline via supervised backpropagation, and then the weights are updated in an online training environment. The neural network FFC is an open-loop control scheme that takes S, D, and the desired coating weight R_{cw} to output the FFC component of the air pressure. The training is performed to minimize the desired and predicted coating weights. This network, which is similar to the prediction model, is trained both offline and then online. The NN adaptive FBC, is a self-tuning controller with online learning capabilities that makes use of the adaptive backpropagation learning algorithm.

The NN-based control system designed above has been tested and successfully implemented at the Burns Harbors steel plant. A comparative study of the neural controller with the control system based on the traditional regression model used earlier shows that the NN-based control system (i) provided better prediction results, (ii) had better servo-tracking and robust behavior, (iii) indicated reduced error between target coating weight and actual coating weight (over 69% improvement in average mean), and (iv) showed substantial improvement in "coating weight transitional footage" (9.9% average mean improvement), which indicates how fast the coating weight can reach its new target. The control system could provide a quick response to reach a new target and was robust enough to compensate for the disturbance of line speed.

FUTURE TRENDS

For neural network controllers to be acceptable as a preferred control strategy in industries, the area of neurocontrol needs to establish a sound theoretical foundation. Development of NN-based controllers typically focuses more on algorithms and less on stability issues. Moreover, the black-box nature of the NN leads to industrial apprehensions by control system manufacturers regarding robustness and functioning of the controller. NN-based control, which is a recently developed field, has to compete with fully established and extensively researched conventional control techniques such as PI, PID, optimal, and robust control. Hence, for NNs to gain a wider application in industry, research addressing the significant issues of stability and rigorous analysis needs to be pursued.

NNs provide a perfect platform where numerous learning algorithms can be implemented very easily. This learning capability of NNs can be used to develop goal-driven fully autonomous systems that learn from scratch (as well as from previous examples, experiences, and human knowledge whenever available) with interaction with the environment. Moreover, research needs to be done extensively to fuse other methodologies of intelligent control such as fuzzy logic, expert system, and genetic algorithm to obtain a hybrid system that has the advantages of all component strategies and weaknesses of none. Such hybrid systems would derive their strength from the learning capabilities of biological nerve cells; capabilities of human reasoning, intuition, and experience; and capacity of biological evolutionary mechanisms.

A truly intelligent system needs to acquire all the information about the environment in which it operates. Sensors, which are used in maintaining and updating an intelligent machine's internal description of an external world, enable a system to interact with its environment by providing diverse, redundant, complementary, and timely information. Multiple sensor fusion, which is a systematic method to combine data from a variety of sensory sources, is increasingly becoming an area of active research. NNs, with their learning ability and capacity to approximate functions and recognize patterns, can play an important role in sensor fusion.

SUMMARY

NN-based controllers have recently gained much popularity because of their ability to handle ill-defined, uncertain, and nonlinear problems; their dexterity to learn and adapt to changing situations; and their potential to approximate any function to an arbitrary degree of accuracy. Much research has been carried out in the last two decades on using NNs for controlling complex nonlinear systems, and several architectures have been proposed to use the unique capabilities of NNs to identify and control such systems. Subsequently, neural controllers have found applications in several fields such as the aerospace, communication systems, automated manufacturing, robotics, medical diagnosis systems, electric power systems, and process industries. Research is underway to combine the abilities of the NN with other soft computing methodologies such as fuzzy logic and evolutionary computing to obtain a hybrid intelligent system that derives its strength from human brain-like learning abilities of the NN, intuitive and reasoning capacity of fuzzy logic, and power of biological evolution demonstrated by genetic algorithms. Such hybrid systems would process multiple sensory information to learn and adapt to independently survive and achieve their objectives in an unknown and unstructured environment.

NEURAL NETWORK ARCHITECTURES

INTRODUCTION

From the architectural and computational standpoints, a neural network consists of a collection of simple, nonlinear processing components (neurons) that are combined together via a collection of adjustable numeric connections. The development of a neural network is realized through learning. Selecting an appropriate network's structure (followed by an efficient learning method) becomes essential to its overall performance. In this article, we offer a comprehensive discussion on the architectures of neural networks. We discuss a variety of neurons and topologies encountered in the area and link the properties of the networks and their functionality with the architecture of the constructs. The article follows a bottom-up direction and reflects on historical developments of neurocomputing. We start with the commonly encountered model of the neuron (being regarded as a weighted sum of inputs followed by some nonlinear transformation) and present the main topologies of the networks. Next, we elaborate on more functionally advanced neurons and show how their functionality is exploited in the resulting structures of the networks and their increased heterogeneity (which is reflective of the use of a variety of neurons in their architectures). Throughout the article, a standard notation will be adhered to. Vectors will be denoted by boldface letters. The distance is denoted by $||\cdot||$.

COMPUTATIONAL MODEL OF NEURONS

A commonly encountered model of an artificial neuron (neuron, for short) (1–3) is realized in a form of an n-input single-output nonlinear mapping, see Fig. 1, described as follows:

$$y = f\left(\sum_{i=1}^{n} w_i x_i\right) \tag{1}$$

where $x_1, x_2, \ldots, x_n$ are the inputs of the neuron, whereas w_1, $w_2, \ldots, w_n$ are the associated with the corresponding inputs connections (weights). The nonlinear nondecreasing mapping "f" brings an important component of nonlinear processing to the functionality of the neuron. Positive values of the weights correspond to excitatory synapses of the neuron, whereas negative weights model inhibitory synapses. The adjustable character of the connections makes the neuron (and the entire neural network) highly elastic and facilitates all parametric learning faculties (which in essence are concerned with the adjustments of the values of the connections). Commonly, the neuron is equipped with a bias term w_0 that comes with the constant input equal to 1. Taking it into consideration, Equation (1) is modified and reads as

$$y = f\left(\sum_{i=1}^{n} w_i x_i + w_0\right)$$

Geometrically, the bias means that the hyperplane

$$\sum_{i=1}^{n} w_i x_i$$

is translated with respect to the origin. With the acceptance of the vector notation, $\mathbf{x} = [x_1\ x_2\ \ldots\ x_n\ 1]^T$ and $\mathbf{w} = [w_1\ w_2\ \ldots\ w_n\ w_0]^T$, the output of the neuron is expressed as $y = f(\mathbf{w}^T\mathbf{x})$

The nonlinear activation function (f) may be realized in different ways. Some commonly encountered examples include the following:

1. Threshold function $f(u) = \begin{cases} 1 \text{ if } u \geq 0 \\ 0 \text{ if } u < 0 \end{cases}$
2. Piecewise linear function $f(u) = \begin{cases} 1 \text{ if } u \geq 1/2 \\ u \text{ if} -1/2 < u < 1/2 \\ 0 \text{ if } u \leq -1/2 \end{cases}$
3. Sigmoid function $f(u) = \dfrac{1}{1 + \exp(-\lambda u)}$ with $\lambda(>0)$ being a positive slope of the function
4. Hyperbolic tangent function $f(u) = \tanh(u)$

In addition to the neuron governed by Equation (1), in the literature we also encounter so-called product neurons where the overall aggregation of the inputs is realized by taking the product of the weighted inputs,

$$y = \prod_{i=1}^{n} x_i^{w_i} \tag{2}$$

As before, w_i serves as a connection of the neuron whose values can be adjusted.

ARCHITECTURES OF NEURAL NETWORKS

Neurons are simple processing units. The processing capabilities of neural networks stem from the use of many neurons being organized in a certain topology (structure). Individual neurons are connected and realize a certain flow of computing. The most commonly present architecture of neural networks consists of neurons organized in a series of interconnected layers (3–5). Depending on the flow of processing, in the general taxonomy of the architectures of neural networks we distinguish between the two important categories, that is feedforward networks and recurrent (feedback) networks. In feedforward neural networks, the neurons are arranged in a series of layers, and a flow of processing is linear: It starts from the inputs of the network, and the results of processing are carried through consecutive layers finally showing at the output layer. An example of a single layer network is illustrated in Fig. 2, whereas Fig. 3 shows a three-layer network. In general, we may envision multilayer topologies, say, an L-layer neural network. In all cases, the structures are regular, and the connectivity occurs between the neurons positioned in successive layers.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

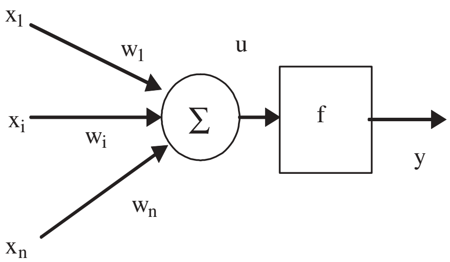

Figure 1. A topology of a neuron; note a two-phase processing of linear aggregation of the its inputs followed by nonlinear mapping (f).

In feedforward networks, input signals (inputs) are processed by the units of the first layer whose outputs becomes inputs for the next layer, and so on, for the rest of the network. Typically, the neurons of each layer have as their inputs the outputs that come from the preceding layer only. Feedforward neural networks produce static nonlinear input-output mappings. The form of the nonlinear mapping realized in this way depends on the number of layers, the size of the layers, and the form of the individual neurons. Intermediate layers between input nodes and output layer are referred to as hidden layers (the name comes from the fact that the neurons present there are not exposed directly to the input signals). We say that the neural network is fully connected if every node in each layer is connected to every other node in the consecutive forward layer. If this does not occur, then we refer to this network as partially connected. Some clarifying note is worth making here. In the terminology used in the literature, the input layer that distributes the inputs to the neurons located at the next layer (however does not realize any computing) is either included in the count of the number of layers or not. In this sense, if we count the layer that distributes the inputs, the network in Fig. 2 consists of 2 layers; likewise following this naming the network in Fig. 3 comes with 3 layers.

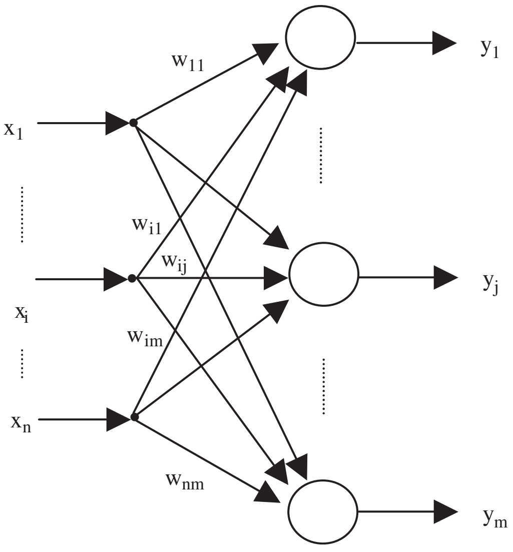

Figure 2. Single-layer feedforward neural network.

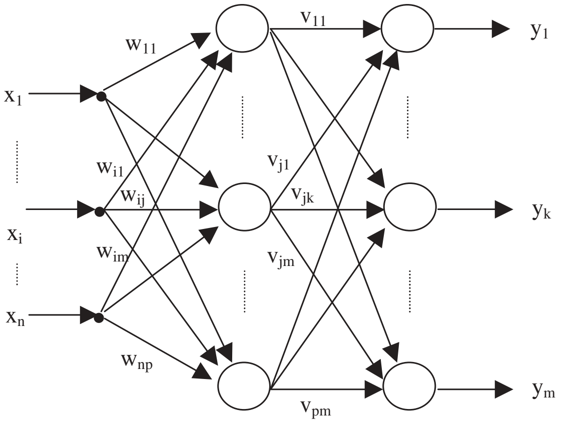

Figure 3. Two-layer feedforward neural network.

Recurrent neural networks (6–8) distinguish themselves from feedforward networks by admitting feedback loops, see Fig. 4. These networks may or may not have hidden layers. Feedback can be of *local* nature if only self-feedback loops exist, namely, if the outputs of neurons are fed back to its own input. Feedback loops of a *global* nature form if the loop engages different neurons located either in the same layer or in different layers. Recurrent neural networks can exhibit full or partial feedback, which depends on how the feedback loops have been structured.

In contrast to feedforward neural networks, neural networks with feedback are of interest when modeling a nonlinear dynamic input-output behavior. The feedback component is crucial to the realization of the dynamic nature of the phenomena.

NEURAL NETWORKS AS UNIVERSAL APPROXIMATORS

Neural networks implicitly encode in its structure a function that maps inputs on outputs. The character of functions that can be represented in this manner depends on the structure of the network. Currently, no definite result indicates which types of networks describe corresponding

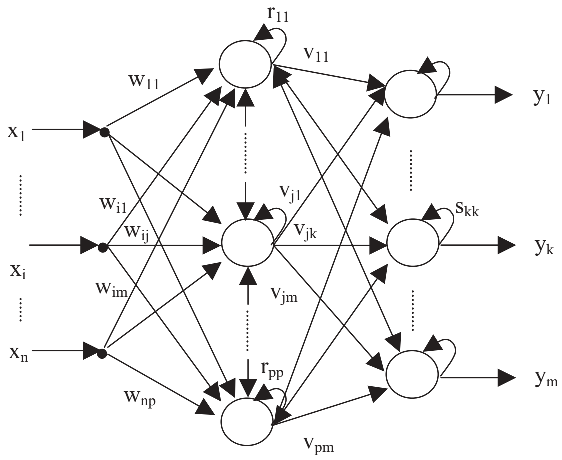

Figure 4. Recurrent neural network.

classes of functions. However, some general findings have been cited. The representation capabilities of neural networks are expressed in the form of a so-called theorem of universal approximation. This theorem states that a feedforward network with a single hidden layer (where the neurons in this layer are equipped with sigmoid type of transfer function) and an output layer composed of linear neurons (viz. with linear transfer functions) is a universal approximator (9–16). In other words, a neural network of such topology can approximate any given bounded continuous function $\mathbf{R}^n \rightarrow \mathbf{R}$ to any arbitrarily *small* approximation error.

In more detail, one formulation of the universal approximation capabilities of neural networks can be articulated as follows.

Given any continuous function "f" defined in the m-dimensional unit hypercube and any positive $\varepsilon > 0$, an integer "n" and real constants a_i, b_i, and w_{ij} exist such that the function

$$F(\mathbf{x}) = \sum_{i=1}^{n} \alpha_i \varphi\left(\sum_{j=1}^{m} w_{ij} x_j + b_i\right) \tag{3}$$

realizes an ε-approximation of "f" meaning that

$$|F(\mathbf{x}) - f(\mathbf{x})| < \varepsilon \tag{4}$$

for any $\mathbf{x}$ in this hypercube. φ is a nonconstant, bounded, and monotonically increasing function (we note that the sigmoid function satisfies such requirements).

The theorem of universal approximation of neural networks has to be put in a certain context. It is definitely an important and fundamental finding because it assures us about the representation capabilities of neural networks (viz. if the function satisfies the continuity assumption, we are confident that a neural network approximates it to any desired accuracy). This finding comes in the form of a typical existence theorem because it does not offer any constructive clue on how such a neural network could be constructed. For an interesting discussion of linkages between theoretical results and resulting algorithms refer to the literature (16).

So far, we have presented the most generic version of the neuron and discussed the underlying architectures of the network whose capabilities emerge through a collective processing realized by the neurons. Several generalizations of neurons augment their processing capabilities.

FUNCTIONAL NEURONS

Functional neurons are generic processing units in which we encounter some functional relationships $f_i(x_i, \mathbf{a}_i)$ instead of numeric values of the connections as schematically portrayed in Fig. 5.

The functional links f_i are equipped with some adjustable parameters $\mathbf{a}_i$ whose values can be modified (learned) during the learning process. Note that if we consider $f_i(x_i, \mathbf{a}_i)$ as constants, say a_i, then this construct collapses to the generic neurons discussed so far.

Polynomial neurons constitute an interesting class of functional neurons where f_i is a certain polynomial of the input variable. Typically, the order of this polynomial is kept low, say polynomials of the second order, that is, $f_i(x_i, \mathbf{a}_i) = a_{i0} + a_{i1}x_i + a_{i2}x_i^2$ This type of polynomial neurons yields polynomial neural networks, cf. Refs. 17–19. One can think of a few first harmonic terms that could be included in the functional link, say the terms such as $\sin(\omega x_{i1})$, $\sin(\omega x_{i2})$,... and so on. It is worth noting that the processing capabilities of this type of neuron are higher than the generic neurons, and these neurons exhibit nonlinear characteristics because of the processing realized at the level of each connection.

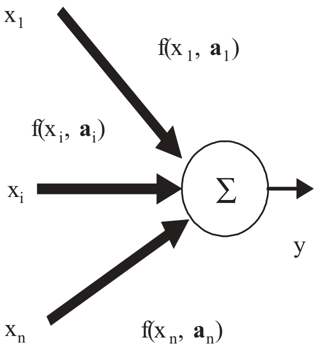

Figure 5. A schematic illustration of functional neuron.

LOGIC NEURONS

Neural networks are highly distributed topologies. The individual neurons do not exhibit any underlying interpretation. The category of fuzzy neurons (or fuzzy logic neurons) addresses these burning issues of a lack of transparency of neural networks. Our objective is to build a network with the aid of conceptually simple and logically appealing nodes (neurons) that complete generic *and* and *or* logic operations. By equipping the neurons with a set of connections, we furnish them with the badly required adaptive properties; the values of the connections could be adjusted easily by implementing some standard learning schemes available in neurocomputing.

Main Categories of Fuzzy Neurons

The logic aspect of transparent neurocomputing requires that the processing elements be endowed with the clearly delineated logic structure. We discuss several types of aggregative and referential neurons. Each neuron comes with a clearly defined semantics of its underlying logic expression and is equipped with significant parametric flexibility necessary to facilitate substantial learning abilities.

Aggregative Neurons. Formally, these neurons realize a logic mapping from $[0,1]^n$ to $[0,1]$. Two main classes of the processing units exist in this category (20–25).

The OR neuron realizes an *and* logic aggregation of inputs $\mathbf{x} = [x_1\, x_2 \ldots x_n]$ with the corresponding connections (weights) $\mathbf{w} = [w_1\ w_2 \ldots\ w_n]$ and then summarizes the partial results in an *or*-wise manner (hence the name of the neuron). In virtue of the logic flavor of processing, the values of the inputs **x** and connections **w** are confined to the unit hypercube $[0,1]^n$. The concise notation captures the logic character of computing, that is $y = \mathrm{OR}(\mathbf{x}; \mathbf{w})$, whereas the realization of the logic operations yields the expression as follows: (commonly referring to it as an s-t combination or s-t aggregation)

$$y = \underset{i=1}{\overset{n}{\mathbf{S}}}(x_i \, t w_i) \tag{5}$$

Bearing in mind the interpretation of the logic connectives (t-norms, t, and t-conorms, s), the OR neuron realizes the following logic expression being viewed as an underlying logic description of the processing of the input signals:

$$(x_1 \, \textit{and} \, w_1) \, \textit{or} \, (x_2 \, \textit{and} \, w_2) \textit{or} \ldots \textit{or} (x_n \, \textit{and} \, w_n) \tag{6}$$

Apparently, the inputs are logically "weighted" by the values of the connections before producing the final result. In other words, we can treat "y" as a truth value of the above statement where the truth values of the inputs are affected by the corresponding weights. Noticeably, lower values of w_i discount the impact of the corresponding inputs; higher values of the connections (especially those being positioned close to 1) do not affect the original truth values of the inputs that result in the logic formula. In limit, if all connections w_i, $i = 1, 2, \ldots, n$ are set to 1, then the neuron produces a plain *or*-combination of the inputs, $y = x_1$ *or* x_2 *or* ... *or* x_n. The values of the connections set to zero eliminate the corresponding inputs. Computationally, the OR neuron exhibits nonlinear characteristics (that is inherently implied by the use of the t- and t-conorms that are evidently nonlinear mappings). The plots of the characteristics of the OR neuron shown in Fig. 6 shows this effect (note that the characteristics are affected by the use of some triangular norms). The connections of the neuron contribute to its adaptive character; the changes in their values form the crux of the parametric learning.

The neurons in the AND neuron category, which are denoted by $y = \mathrm{AND}(\mathbf{x}; \mathbf{w})$ with **x** and **w** being defined as in case of the OR neuron, are governed by the expression

$$y = \underset{i=1}{\overset{n}{\mathrm{T}}}(x_i s w_i) \tag{7}$$

Here, the *or* and *and* connectives are used in a reversed order: First the inputs are combined with the use of the t-conorm, and the partial results produced in this way are aggregated *and*-wise. Higher values of the connections reduce impact of the corresponding inputs. In limit, $w_i = 1$ eliminates the relevance of x_i. With all w_i set to 0, the output of the AND neuron is just an *and* aggregation of the inputs

$$y = x_1 \, \textit{and} \, x_2 \, \textit{and} \ldots \textit{and} \, x_n \tag{8}$$

The characteristics of the AND neuron are shown in Fig. 7; note the influence of the connections and the specific realization of the triangular norms on the mapping completed by the neuron.

Let us conclude that the neurons are highly nonlinear processing units whose nonlinear mapping depends on the specific realizations of the logic connectives. They also come with potential plasticity whose usage becomes critical when learning the networks including such neurons.

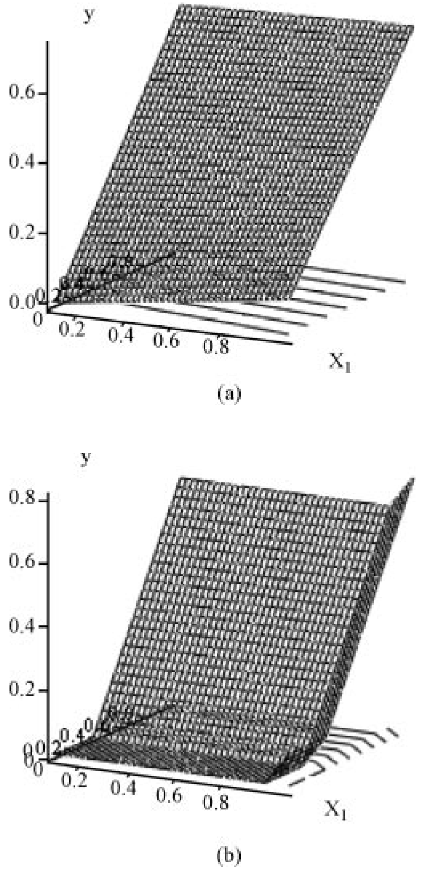

Figure 6. Characteristics of the OR neuron for selected pairs of t- and t-conorms. In all cases, the corresponding connections are set to 0.1 and 0.7 with intent to visualize their effect on the input-output characteristics of the neuron: (a) product and probabilistic sum, (b) Lukasiewicz *and* and *or* connectives.

The architecture of the logic neurons could be augmented by discussing a way in which bias could be introduced and how we can handle the inhibitory nature of some inputs.

Incorporation of the Bias Term (Bias) in the Fuzzy Logic Neurons. In analogy to the standard constructs of a generic neuron as presented above, we could also consider a bias term, denoted by $w_0 \in [0, 1]$, which enters the processing formula of the fuzzy neuron in the following manner:

for the OR neuron

$$y = \underset{i=1}{\overset{n}{\mathbf{S}}}(x_i t w_i) s w_0 \tag{9}$$

for the AND neuron

$$y = \underset{i=1}{\overset{n}{\mathbf{T}}}(x_i s w_i) t w_0 \tag{10}$$

We can offer some useful interpretation of the bias by treating it as some nonzero initial truth value associated

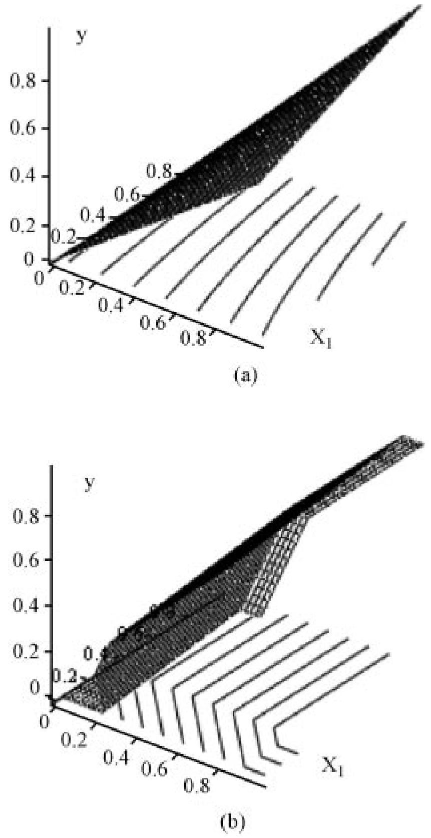

Figure 7. Characteristics of AND neurons for selected pairs of t- and t-conorms. In all cases, the connections are set to 0.l and 0.7 with intent to visualize their effect on the characteristics of the neuron: (a) product and probabilistic sum, (b) Lukasiewicz logic connectives.

with the logic expression of the neuron. For the OR neuron, it means that the output does not reach values lower than the assumed threshold. For the AND neuron equipped with some bias, we conclude that its output cannot exceed the value assumed by the bias. The question whether the bias is essential in the construct of the logic neurons cannot be fully answered in advance. Instead, we may include it into the structure of the neuron and carry out learning. Once its value has been obtained, the relevance of the bias can be established, considering the specific value it has been produced during the learning. It may be that the optimized value of the bias is close to zero for the OR neuron or close to one in the case of the AND neuron, which indicates that it could be eliminated without exhibiting any substantial impact on the performance of the neuron.

Dealing with Inhibitory Character of Input Information. Because of the monotonicity of the t-norms and t-conorms, the computing realized by the neurons exhibits an excitatory character. This finding means that higher values of the inputs (x_i) contribute to the increase in the values of the output of the neuron. The inhibitory nature of computing realized by "standard" neurons by using negative values of the connections or the inputs is not available here as the truth values (membership grades) in fuzzy sets are confined to the unit interval. The inhibitory nature of processing can be accomplished by considering the complement of the original input, that is $1\text{-}x_i$. Hence, when the values of x_i increase, the associated values of the complement decrease; subsequently in this configuration, we could effectively treat such an input as having an inhibitory nature.

Referential (reference) Neurons. The essence of referential computing deals with processing logic predicates. The two-argument (or generally multivariable) predicates such as *similar*, *included in*, and *dominates*(21), are essential components of any logic description of a system. In general, the truth value of the predicate is a degree of satisfaction of the expression P(x, a) where "a" is a certain reference value (reference point). Depending on the meaning of the predicate (P), the expression P(x, a) reads as "x is similar to a," "x is included in a," "x dominates a," and so on. In case of many variables, the compound predicate comes in the form $P(x_1, x_2, \ldots, x_n, a_1, a_2, \ldots, a_n)$ or more concisely $P(\mathbf{x}; \mathbf{a})$ where **x** and **a** are vectors in the *n*-dimensional unit hypercube. We envision the following realization of $P(\mathbf{x}; \mathbf{a})$

$$P(\mathbf{x}; \mathbf{a}) = P(x_1, a_1)\, \mathit{and}\, P(x_2, a_2)\, \mathit{and}\, \ldots \mathit{and}\, P(x_n, a_n) \quad (11)$$

which means that the satisfaction of the multivariable predicate relies on the satisfaction realized for each variable separately. As the variables could come with different level of relevance as to the overall satisfaction of the predicates, we represent this effect by some weights (connections) $w_1, w_2, \ldots, w_n$, so that Equation (11) can be expressed in the following form

$$\begin{aligned} P(\mathbf{x}; \mathbf{a}, \mathbf{w}) = {} & [P(x_1, a_1) \mathit{or}\, w_1]\, \mathit{and}\, [P(x_2, a_2)\ \mathit{or}\, w_2]\, \mathit{and} \ \ldots \\ & \mathit{and}\, [P(x_n, a_n)\, \mathit{or}\, w_n] \end{aligned} \quad (12)$$

Taking another look at the above expression and using a notation $z_i = P(x_i, a_i)$, it corresponds to a certain AND neuron $y = \text{AND}(\mathbf{z}; \mathbf{w})$ with the vector of inputs **z** being the result of the referential computations done for the logic predicate. Then, the general notation to be used reads as $\text{REF}(\mathbf{x}; \mathbf{w}, \mathbf{a})$. In the notation below, we explicitly articulate the role of the connections

$$y = \mathop{\mathbf{T}}_{i=1}^{n} (\text{REF}(x_i, a_i) s w_i) \quad (13)$$

In essence, as visualized in Fig. 8, we may conclude that the reference neuron is a realized as a two-stage construct where first we determine the truth values of the predicate (with **a** being treated as a reference point) and then treat these results as the inputs to the AND neuron.

So far, we have used the general term of predicate-based computing not confining ourselves to any specific nature of the predicate itself. Among several available possibilities of such predicates, we discuss the three of them, which tend to occupy an important place in logic processing. Those examples are inclusion, dominance, and match (similarity) predicates. As the names stipulate, the predicates return truth values of satisfaction of the relationship of inclusion, dominance, and similarity of a certain argument "x" with respect to the given reference "a." The essence of all these

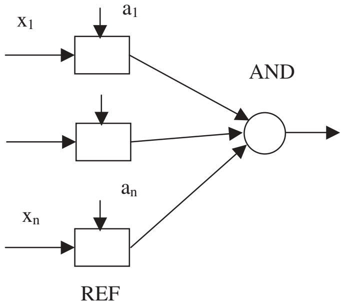

Figure 8. A schematic view of computing realized by a reference neuron and involving two processing phases (referential computing and aggregation).

calculations is in the determination of the given truth values, which is done in the carefully developed logic framework so that the operations retain their semantics and interpretability. What makes our discussion coherent is the fact that the proposed operations originate from triangular norms. The inclusion operation, denoted by ⊂, as discussed earlier, is modeled by an implication ⇒ that is induced by a certain left continuous t-norm (26)

$$a \Rightarrow b = \sup\{c \in [0,1] | atc \leq b\}, a, b \in [0,1] \tag{14}$$

For instance, for the product the inclusion takes on the form $a \Rightarrow b = \min(1, b/a)$. The intuitive form of this predicate is self-evident: The statement "x is included in a" and modeled as INCL(x, a) = x ⇒ a comes with the truth value equal to 1 if x is less or equal to a (which in other words means that x is included in a) and produces lower truth values once x starts exceeding the truth values of "a." Higher values of "x" (those above the values of the reference point "a") start generating lower truth values of the predicate. The dominance predicate acts in a dual manner when compared with the predicate of inclusion. It returns 1 once "x" dominates "a" (so that its values exceeds "a") and values below 1 for x lower than the given threshold. The formal model can be realized as DOM(x, a) = a ⇒ x. With regard to the reference neuron, the notation is equivalent to the one being used in the previous case, that is DOM(**x**; **w**, **a**) with the same meaning of **a** and **w**.

The similarity (match) operation is an aggregate of these two, SIM(x,a) = INCL(x,a) t DOM(x,a), which is appealing from the intuitive standpoint: We say that x is similar to a if x is included in a *and* x dominates a. Noticeably, if x = a the predicate returns 1; if x moves apart from "a," then the truth value of the predicate becomes reduced. The resulting similarity neuron is denoted by SIM(**x**; **w**, **a**) and reads as follows:

$$y = \underset{i=1}{\overset{n}{\mathbf{T}}}(\mathrm{SIM}(x_i, a_i) s w_i) \tag{15}$$

It is worth noting that by moving the reference point to the origin or the **1**-vertex of the unit hypercube (with all its coordinates being set up to 1), the referential neuron starts to resemble the aggregative neuron. In particular, we have

- for $\mathbf{a} = \mathbf{1} = [1\,1\,1\ldots 1]$ the inclusion neuron reduces to the AND neuron
- for $\mathbf{a} = \mathbf{0} = [0\,0\,0\ldots 0]$ the dominance neuron reduces to the AND neuron

One can draw a loose analogy between some types of the referential neurons and the two categories of processing units encountered in neurocomputing. The analogy is based on the *local* versus *global* character of processing realized therein. Perceptrons come with the global character of processing. Radial basis functions realize a local character of processing as focused on receptive fields. In the same vein, the inclusion and dominance neurons are after the global nature of processing, whereas the similarity neuron carries more confined and local processing.

An interesting taxonomy of referential neurons is observed. We distinguish between two main categories of these processing elements. The first group is formed by homogeneous neurons viz. those in which encounter the same type of logic predicate (P) used in the underlying processing. Refer also to Equation (11). As shown above, the underlying logic expression reads as follows:

$$y = (P(x_1, r_1), w_1) \text{ and} (P(x_2, r_2), w_2) \text{ and} \ldots \text{and} (P(x_n, r_n), w_n) \tag{16}$$

where r_i and w_i are the point of reference and the corresponding weight associated with the *i*th variable. Thus, all inputs are processed making use of the same predicate, which could be inclusion, dominance, tolerance, similarity, and so on.

In the second group of referential neurons, we admit a higher level of diversity by allowing different predicates P_i associated with the individual inputs. The general logic expression comes in the following format:

$$y = (P_1(x_1, r_1), w_1) \text{ and} (P_2(x_2, r_2), w_2) \text{ and} \ldots \text{and} (P_n(x_n, r_n), w_n) \tag{17}$$

Referential computing is reflective of processing logic constraints conveyed by logic predicates when dealing with existing domain knowledge and encapsulating it in the structural format of the network or its part.

For instance, we can represent existing constraints for the variables $x_1, x_2, \ldots, x_n$, which are spelled out as

$$x_1 \text{ should not exceed } g_1 \text{ and } x_2 \text{ should not exceed } g_2 \text{ and} \ldots$$
$$x_n \text{ should not exceed } g_n \tag{18}$$

In the form of a single inclusion neuron, Fig. 9(a) demonstrates where the weights are used to calibrate the relevance (importance) of the corresponding constraint. Note that both x_i and g_i standing in the above compound predicate assume values in the unit interval. One might capture a variety of constraints

$$x_1 \text{ should not exceed } g_1 \text{ and } x_2 \text{ should be similar to } g_2 \text{ and} \ldots$$
$$x_n \text{ should dominate } g_n \tag{19}$$

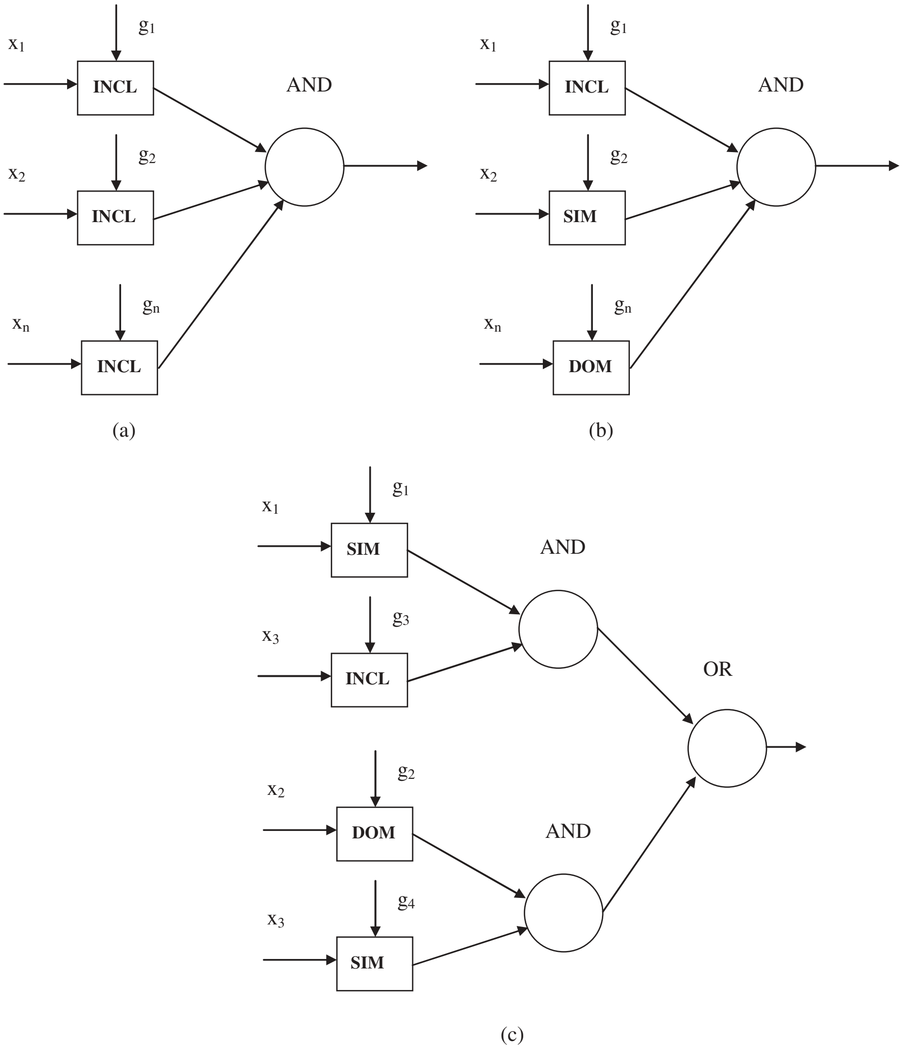

Figure 9. Examples of logic expressions that involve predicates and their realization in the form of logic neurons and architectures of logic-oriented networks.

By considering various predicates; see Fig. 9(b). Interestingly, one could consider a variety of logic constraints of different dimensionality, that is, each referential neuron might have different number of inputs depending on the nature of locally identified constraints. For instance, given three inputs x_1, x_2, and x_3, we have

$$\begin{array}{l}x_1 \text{ should be similar to } g_1 \text{ and } x_3 \text{ should not exceed } g_3 \\ \text{or} \\ x_2 \text{ should dominate } g_2 \text{ and } x_3 \text{ should be similar to } g_4\end{array} \tag{20}$$

This logic description translates into the logic network illustrated in Fig. 9(c).

One could stress that in several architectures of neuro-fuzzy systems, the capabilities of neural networks are combined with the technology of fuzzy sets, cf. Refs. 26 and 27.

GRANULAR NEURONS

A certain interesting generalization of the generic topology of the neuron comes with a realization of its connections as some information granules. Instead of a single numeric value of the connection discussed so far, we admit that it can be represented as some information granule, in particular some interval or a fuzzy set. As the name suggests, by the granular neuron we mean a neuron with granular connection. More precisely, we consider the transformation of many numeric inputs $u_1, u_2, \ldots, u_c$ (confined to the unit interval) of the form

$$Y = N(u_1, u_2, \ldots, u_c, W_1, W_2, \ldots, W_c) = \sum_{\oplus}(W_i \otimes u_i) \tag{21}$$

with W_1, W_2, ... W_c denoting granular weights (connections), see Fig. 10. The symbols of generalized (granular) addition and multiplication (that is $\oplus$, $\otimes$) are used here to emphasize a granular character of the arguments being used in this aggregation. When dealing with interval-valued connections, $W_i = [w_{i-}, w_{i+}]$, the operations of their multiplication by some positive real input u_i produce the results in the form of the following interval

$$W_i \otimes u_i = [w_{i-}u_i, w_{i+}u_i] \tag{22}$$

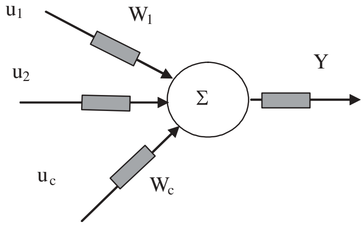

Figure 10. Computational model of a granular neuron; note a granular character of the connections and the resulting output Y.

When adding such intervals being produced at the level of each input of the neuron, we arrive at the expression

$$Y = \left[\sum_{i=1}^{n} w_{i-}u_i, \sum_{i=1}^{n} w_{i+}u_i\right] \tag{23}$$

For the connections represented as fuzzy sets, the result of their multiplication by a positive scalar u_i is realized through the use of the extension principle

$$(W_i \otimes u_i)(y) = \sup_{w:y=wu_i}[W_i(w)] = W_i(y/u_i) \tag{24}$$

Next, the extension principle is used to complete additions of fuzzy numbers, which are the partial results of this processing. Denote by Z_i the fuzzy number $Z_i = W_i \otimes u_i$. We obtain

$$Y = Z_1 \oplus Z_2 \oplus \ldots \oplus Z_n \tag{25}$$

that is

$$Y(y) = \sup\{\min(Z_1(y_1), Z_2(y_2), \ldots, Z_n(y_n))\}$$

$$\text{s.t. } y = y_1 + y_2 + \ldots + y_n \tag{26}$$

Depending on a specific realization, these connections can be formalized as intervals, fuzzy sets, shadowed sets, rough sets, and so on. One could note that despite potential diversity of the formalisms of granular connections, the output is always a granular construct, Fig. 10.

The granular neuron exhibits several interesting properties that generalize the characteristics of (numeric) neurons. Adding a nonlinearity component (g) to the linear aggregation does not change the essence of computing; in case of monotonically increasing relationship (g(Y)), we end up with a transformation of the original output interval or fuzzy set (in this case we have to follow the calculations using the well-known extension principle).

RADIAL BASIS FUNCTION NEURAL NETWORKS

Radial basis function (RBF) neural networks (NNs), are examples of feedforward neural structures that combine a weighted collection of receptive fields defined in the input space for function approximation and classification. The RBFs known as receptive fields are constructs that help the network to focus on individual regions of the multidimensional input space. In the sequel, the activation levels of the RBFs implied by some input x are aggregated by a single linear neuron located in the output layer of the network. The general structure of the network is visualized in Fig. 11.

From the functional standpoint, the activation levels of the receptive fields (RBFs), $z_j = R(\mathbf{x})$ are combined in a linear form as

$$y = \sum_{i=1}^{c} w_j z_j$$

where w_j is the *j*th connection of the neuron. RBFs can assume different forms. Commonly, they are treated as Gaussian receptive fields where $R(\mathbf{x}) = \exp(-||\mathbf{x}-\mathbf{v}_j||^2/\sigma_j^2)$ where $\mathbf{v}_j$ denotes a center of the field, and σ_j describes a spread of the *j*th RBF. As it becomes visible from all these examples of the RBFs, they come with a great deal of flexibility. In particular, they are distributed in the input space by selecting their modal values (centers of the receptive fields) and choosing the spread values. This substantial level of flexibility is of interest when learning the network. Instead of defining a certain class of the receptive fields, there is an alternative way of their formation that directly links to experimental data and exploits the techniques of fuzzy clustering. Let us recall that in fuzzy clustering, data are organized in groups in such a way that we allow data to share nonzero membership grades between several clusters. The commonly used method of Fuzzy C-Means (26) leads to the development of the prototypes of the clusters. The prototypes serve as modal values of the receptive fields, whereas the membership functions are described in the following form:

$$R_i(\mathbf{x}) = \frac{1}{\sum_{j=1}^{c}\left(\frac{||\mathbf{x}-\mathbf{v}_i||}{||\mathbf{x}-\mathbf{v}_j||}\right)^{2/(m-1)}} \tag{27}$$

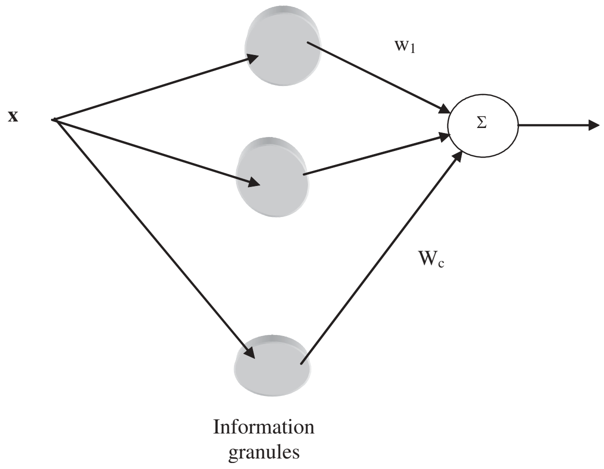

Figure 11. A generic topology of RBF neural network.

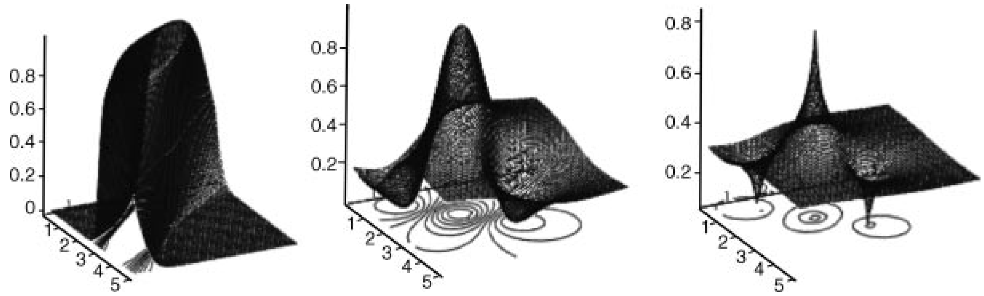

Figure 12. Examples of receptive fields formed by the FCM algorithm: (a) m = 1.2, (b) m = 2.0, (c) m = 3.0.

Where $m > 1$ is a so-called fuzzification coefficient. Interestingly, the location of the fields (as well as their spreads—which do not explicitly show in the above) has been determined on a basis of the available learning data. In this sense, these receptive fields are immediately reflective of the experimental evidence available for training purposes. It is worth stressing that the geometry of the receptive fields obtained in this manner is affected by the values of the fuzzification coefficient. Some illustrative examples are shown in Fig. 12.

The optimal value of "m" can be determined through data clustering. Note that even the neuron in the output layer realizes a linear processing; overall the network is highly nonlinear and the source of nonlinearity is associated with the highly nonlinear character of the RBFs.

We can envision a certain generalization of RBF NNs in which the linear neuron is replaced by a functional neuron or a granular neuron. The topologies of such neural networks fall under the category of neurofuzzy systems that combine some features of neural networks and fuzzy sets.

For the functional neuron, the resulting network can be interpreted as a collection of "if-then" rules

$$\text{- if } x \text{ is } R_i \text{ then } y \text{ is } f_i(\mathbf{x}, \mathbf{a}_i),\ i = 1, 2, \ldots, c \tag{28}$$

where R_i is the *i*th receptive field that serves as some information granule, say some fuzzy set.

In case of the granular neuron, the collection of rules reads as follows

$$\text{- if } x \text{ is } R_i \text{ then } Y \text{ is } W_i,\ \ i = 1, 2, \ldots, c \tag{29}$$

where W_i is the granular connection of the neuron; note that the output is an information granule as well.

The concept of receptive fields is highly appealing. As a matter of fact, in the layer of receptive fields, one could consider using wavelets, local expert networks as discussed in Ref. 28, or kernels (29).

ARCHITECTURES OF LOGIC NETWORKS

The logic neurons (aggregative and referential) can serve as building blocks of more comprehensive and functionally appealing architectures. The diversity of the topologies one can construct with the aid of the proposed neurons is surprisingly high. This architectural multiplicity is important from the application point of view as we can fully reflect the nature of the problem in a flexible manner. It is essential to capture the problem in a logic format and then to set up the logic skeleton also known as the conceptual blueprint—by forming it and finally refining it parametrically through a thorough optimization of the connections. Throughout the entire development process, we are positioned comfortably by monitoring the optimization of the network as well as interpreting its meaning.

The typical logic network that is at the center of logic processing originates from the two-valued logic and comes in the form of the famous Shannon theorem of decomposition of Boolean functions. Let us recall that any Boolean function $\{0,1\}^n \rightarrow \{0,1\}$ can be represented as a logic sum of its corresponding miniterms or a logic product of maxterms. By a minterm of "n" logic variables $x_1, x_2, \ldots, x_n$, we mean a logic product that involves all these variables either in direct or complemented form. Having "n" variables, we end up with 2^n minterms starting from the one that involves all complemented variables and ending up at the logic product with all direct variables. Likewise, by a maxterm we mean a logic sum of all variables or their complements. Now in virtue of the decomposition theorem, we note that the first representation scheme involves a two-layer network, in which the first layer consists of AND gates whose outputs are combined in a single OR gate. The converse topology occurs for the second decomposition mode: A single layer of OR gates is followed by a single AND gate aggregating *or*-wise all partial results.

The proposed network (referred here as a logic processor) generalizes this concept as shown in Fig. 13. The OR-AND mode of the logic processor comes with the two types of aggregative neurons being swapped between the layers. Here, the first (hidden) layer is composed of the OR neuron and is followed by the output realized by means of the AND neuron.

The logic neurons generalize digital gates. The design of the network (viz. any fuzzy function) is realized through learning. If we confine ourselves to {0,1} values, then the network's learning becomes an alternative to a standard digital design, especially a minimization of logic functions. The logic processor translates into a compound logic statement (we skip the connections of the neurons to underline the underlying logic content of the statement)

$$\text{- if } (\text{input}_l\ and \ldots\ and\ \text{input}_j)\ or (\text{input}_d\ and\ \ldots and\ \text{input}_f)$$
$$\text{then}\ output$$

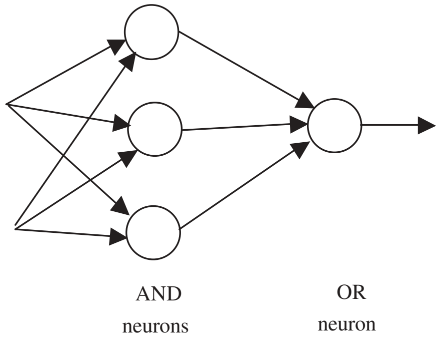

Figure 13. A topology of the logic processor in its AND-OR mode.

The logic processor's topology (and underlying interpretation) is standard. Two LPs can vary in terms of the number of AND neurons as well as their connections, but the format of the resulting logic expression is uniform (as a sum of generalized minterms).

As an illustrative example, let us consider a simple fuzzy neural network in which the hidden layer includes two AND neurons whose outputs are combined through a single OR neuron located in the output layer. The connections of the first AND neuron are equal to 0.3 and 0.7. For the second AND neuron, we have the values of the connections equal to 0.8 and 0.2. The connections of the OR neuron are equal to 0.5 and 0.7, respectively. The input-output characteristics of the network are illustrated in Fig. 14; to demonstrate the flexibility of the architecture, we included several combinations of the connections as well as used alternative realizations of the triangular norms and conorms.

The resulting networks exhibit a significant diversity in terms of the resulting nonlinear dependencies. More importantly, we note that by choosing certain logic connectives (triangular norms) and adjusting the values of the connections, we could substantially affect the behavior (input-output characteristics) of the corresponding network. This plasticity becomes an important feature that plays a paramount role in the overall learning process.

CONCLUDING COMMENTS

We have covered main issues of architectural developments of neural networks and stressed their importance for the resulting quality of the resulting networks. A significant diversity of neurons is available, which come with different levels of computational sophistication and characteristics that could be taken advantage of when dealing with the problem at hand. Although a "standard" neuron is still dominant in neurocomputing, we witness interesting trends of expanding its functionalities, which manifests in granular, functional or logic-oriented neurons.

In the development of the architectures of neural networks and selecting specific neurons, one can take into account some general guidelines:

1. The static or dynamic nature of the problem at hand: This aspect determines whether we should consider networks with feedback or whether a standard feedforward neural network is suitable.
2. The size of the network is expressed in terms of the number of the neurons as well as an layout of the network itself (which links to the number of its layers). Large networks could lead to low values of the approximation error on the training data and could eventually reduce it to values close to zero. The performance of the network might suffer from that when it comes to generalization capabilities of the network (assessed on a basis of the testing data). The learning time also could be excessively long.
3. The choice of the individual neurons. More advanced neurons may lead to a more compact network (as the underlying functionality of the processing elements is more extended). They may, however, require more advanced learning mechanisms whose complexity and a level of sophistication could be high. The choice associates with the available optimization tools.
4. When choosing the architecture of the network, one has to have in mind what learning mechanisms will be considered afterward so that we could take full advantage of the functionality of the existing architecture. In particular, a decision has to be made with regard to supervised-unsupervised learning as well as structural or parametric optimization of the network.
5. If the interpretability of the network is a desired feature, then the use of neurons whose semantics is clear is advisable.

Despite current advances in the learning theory (1,2,6), the applications of neural networks still require careful experimentation and a prudent use of engineering judgment to make their design effective. The development of the networks is an iterative process and requires successive architectural refinements.

PATTERN RECOGNITION

Pattern recognition (PR) concerns the description or classification (recognition) of measurements. PR capability is often a prerequisite for intelligent behavior. PR is not one technique, but rather a broad body of often loosely related knowledge and techniques. PR may be characterized as an *information reduction, information mapping*, or *information labeling* process. Historically, the two major approaches to pattern recognition are statistical (or decision theoretic), hereafter denoted StatPR, and syntactic (or structural), hereafter denoted SyntPR. The technology of artificial neural networks has provided another alternative, neural pattern recognition, hereafter denoted NeurPR. NeurPR is especially well suited for "black box" implementation of PR algorithms. As no single technology is always the optimal solution for a given PR problem, all three are often considered in the quest for a solution.

The structure of a generic PR system is shown in Fig. 1 (1). Notice that it consists of a sensor or set of sensors, a feature extraction mechanism (algorithm), and a classification or description algorithm (depending on the approach). In addition, usually some data that has already been classified or described is assumed available in order to train the system (the so-called "training set").

PATTERNS AND FEATURES

PR, naturally, is based on *patterns*. A pattern can be as basic as a set of measurements or observations, perhaps represented in vector notation. *Features* are any extracted measurement used. Examples of low-level features are signal intensities. Features may be symbolic, numeric, or both. An example of a symbolic feature is color; an example of a numerical feature is weight (measured in pounds). Features may also result from applying a *feature extraction algorithm or operator* to the input data. Additionally, features may be higher-level entities, for example, geometric descriptors of either an image region or a three-dimensional (3-D) object appearing in the image. For example, in *image analysis* applications (2), aspect ratio and Euler number are higher-level geometric features extracted from image regions. Recently, there has been a renewal of interest in employing biometric features based on face, voice, fingerprint, or eye measurements.

Significant computational effort may be required in feature extraction and the extracted features may contain errors or "noise." Features may be represented by continuous, discrete, or discrete-binary variables. *Binary features* may be used to represent the presence or absence of a particular attribute. The inter-related problems of *feature selection* and *feature extraction* must be addressed at the outset of any PR system design.

Statistical PR is explored in depth in numerous books. Good sources include Refs. 1, 3–10.

The Feature Vector and Feature Space

Feature vectors are typically used in StatPR and NeurPR. It is often useful to develop a geometrical viewpoint of features in these cases. Features are arranged in a d-dimensional *feature vector*, denoted $\underline{x}$, which yields a multidimensional *feature space*. If each feature is an unconstrained real number, the feature space is R^d. In other cases, for example, those involving artificial neural networks, it is convenient to restrict feature space to a subspace of R^d. Specifically, if individual neuron outputs and network inputs are restricted to the range [0, 1], for a d-dimensional feature vector, the feature space is a unit volume hypercube in R^d.

Classification of feature vectors may be accomplished by partitioning feature space into regions for each class. Large feature vector dimensionality often occurs unless the data is preprocessed. For example, in *image processing* applications, it is impractical to directly use all the pixel intensities in an image as a feature vector because a 512 × 512-pixel image yields a 262,144 × 1 feature vector.

Feature vectors are somewhat inadequate or at least cumbersome when it is necessary to represent relations between pattern components. Often, classification, recognition, or description of a pattern is desired that is invariant to some (known) pattern changes or deviation from the "ideal" case. These deviations may be because of a variety of causes, including "noise."

In many cases, a set of patterns *from the same class* may exhibit wide variations from a single exemplar of the class. For example, humans are able to recognize (that is, classify) printed or handwritten characters with widely varying font sizes and orientations. Although the exact mechanism that facilitates this capability is unknown, it appears that the matching strongly involves structural analysis of each character.

Feature Vector Overlap. As feature vectors obtained from exemplars of two different classes may overlap in feature space, classification errors occur. An example of this overlap is shown in Fig. 2.

Example of Feature Extraction. Consider the design of a system to identify two types of machine parts. One part, which is denoted a "shim," is typically dark and has no surface intensity variation or "texture." Another part, denoted a "machine bolt," is predominantly bright and has considerable surface intensity variation. For illustration, only texture and brightness are used as features, thus yielding a 2-D *feature space* and *feature vector*. We also assume these features are extracted from suitable measurements. Other possible features, such as shape, weight, and so on, may be used. The problem, as formulated, is challenging because these features are only *typical* of each part type. There exist cases of shims that are bright and textured and bolts that are dark and have little texture, although they are *atypical*, that is, they donot occur often.

Description

Figure 1. Generic PR system elements (Adapted from Ref. 1).

More importantly, when features overlap, perfect classification is not possible. Therefore, classification error, characterized via the probability *P(error)*, indicates the likelihood an incorrect classification or decision. In this example, element $x_i, i = 1, 2$ is *a feature*, where x_1 is measured or computed brightness and x_2 is measured or computed texture. Furthermore, w_i is a *class*, or a "state of nature," where w_1 is taken to be shim and w_2 is bolt. Feature vector overlap may occur in this example. If the underlying class is w_1 (shims), we expect typical measurements of x_1 and x_2 (brightness and texture, respectively) to be small, whereas if the object under observation is from class w_2 (bolts), we expect the values of x_1 and x_2 to be, on the average, large (or at least larger than those of w_1). Of particular importance is the region where values of the features overlap. In this area, errors in classification are likely. A more general cost or risk measure may be associated with a classification strategy.

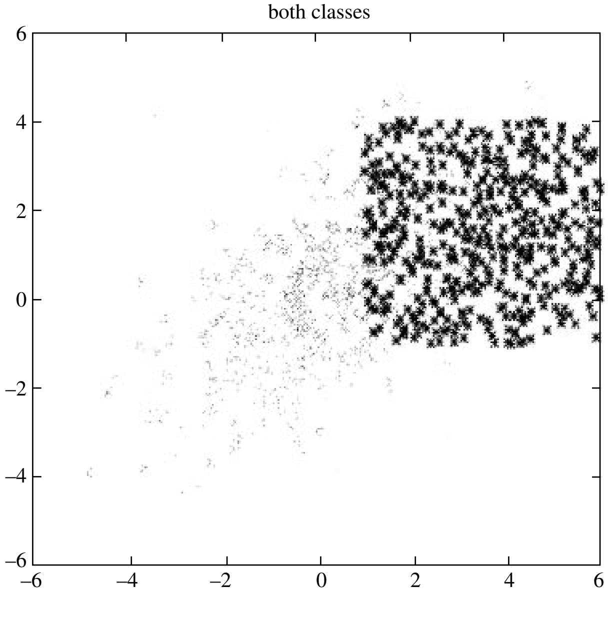

Figure 2. Example of feature vector overlap, leading to classification error.

Pattern Classification

Classification is the assignment of input data into one or more of *c* prespecified classes based on extraction of significant features or attributes and the processing or analysis of these attributes. It is common to resort to probabilistic or grammatical models in classification.

Recognition is the ability to classify. Often, we formulate PR problems with a $c + 1^{st}$ class, corresponding to the "unclassifiable," "donot know," or "cannot decide" class.

Description is an alternative to classification in which a structural description of the input pattern is desired. It is common to resort to linguistic or structural models in description. A *pattern class* is a set of patterns (hopefully sharing some common attributes) known to originate from the same source. The key in many PR applications is to identify suitable attributes (e.g., features) and form a good measure of similarity and an associated matching process.

Preprocessing is the filtering or transforming of the raw input data to aid computational feasibility and feature extraction and minimize noise.

Noise is a concept originating in communications theory. In PR, the concept is generalized to represent a number of nonideal circumstances.

Pattern Matching

Much of StatPR, SyntPR, and NeurPR is based on the concept of *pattern similarity*. For example, if a pattern, *x*, is very similar to other patterns known to belong to class w_1, we would intuitively tend to classify *x* as belonging in w_1. *Quantifying similarity* by developing suitable *similarity measures* is often quite difficult. Universally applicable similarity measures that enable good classification are both desirable and elusive.

Measures of similarity (or dissimilarity) using feature vectors are commonly used. Distance is one measure of vector similarity. The Euclidean distance between vectors $\underline{x}$ and $\underline{y}$ is given by

$$d(\underline{x},\underline{y}) = \|\underline{x}-\underline{y}\| = \sqrt{(\underline{x}-\underline{y})^T(\underline{x}-\underline{y})} = +\sqrt{\sum_{i=1}^{d}(x_i-y_i)^2}$$

A related and more general metric is

$$d_p(\underline{x},\underline{y}) = \left(\sum_{i=1}^{d} |x_i - y_i|^p\right)^{\frac{1}{p}}$$

Commonly, weighted distance measures are used. An example is

$$d_w^2(\underline{x},\underline{y}) = (\underline{x} - \underline{y})^T R(\underline{x} - \underline{y}) = \|\underline{x} - \underline{y}\|_R^2$$

which implements on a *weighted inner product* or weighted R-norm. The matrix R is often required to be positive definite and symmetric. When $\underline{x}$ and $\underline{y}$ are binary, measures such as the Hamming distance are useful.

Training

A set of "typical" patterns, in which typical attributes or the class or structure of each is known, forms a database. This database is called the *training set* and denoted H. In a general sense, the training set provides significant information on how to associate input data with output decisions (i.e., classifications or structural descriptions). Training is often associated (or loosely equated) with learning. The training set is used to enable the system to "learn" relevant information, such as statistical parameters, natural groupings, key features, or underlying structure. In SyntPR, training samples are used to learn or infer grammars.

Supervised and Unsupervised Classification

Training uses representative (and usually labeled) samples of types of patterns to be encountered in the actual application. The training set is denoted H or H_i, in which the subscript denotes a training set for a specific pattern class. In some cases, the training set for class w_i contains examples of patterns in w_i (positive exemplars) as well as examples of patterns not in w_i (negative exemplars).

In this context, *supervised* learning or training assumes a labeled (with respect to pattern class) set, whereas in *unsupervised* learning, the elements of H do not have class labels and the system must determine "natural" partitions of the sample data.

For example, consider the application of PR to *image segmentation* (i.e., the classification of image pixels into groupings that represent some higher entity or information in the images). Unfortunately, it is rare to have either a statistical model to aid in this grouping or a training set. Therefore, so-called *unsupervised learning* techniques are often applied.

Two unsupervised learning approaches that embody more general measures of feature vector similarity and do not require H are known as *hierarchical clustering* and *partitional clustering*. A set of feature vectors is sequentially partitioned (or merged) on the basis of dissimilarity (or similarity). Thus, given only a similarity measure, we either aggregate feature vectors into a single class or sequentially subdivide feature vector partitions. A neural network-based example of unsupervised learning is the Kohonen SOFM.

STATISTICAL PATTERN RECOGNITION (StatPR)

Statistical Analysis

StatPR is used to develop statistically based *decision or classification strategies*, which form *classifiers* and attempts to integrate all available problem information, such as measurements and a priori probabilities. Decision rules may be formulated in several inter-related ways. A measure of expected classification error or "risk" may be formulated, and a decision rule is then developed that minimizes this measure. The Bayesian approach involves converting an a priori class probability $P(w_i)$ into a measurement-conditioned ("a posteriori') probability $P(w_i|\underline{x})$, which leads to a partitioning of R^d, and may be implemented via *discriminant functions*.

Bayes Decision Theory

In the Bayesian approach, the extracted features $\underline{x}$ are modeled as a realization of a (continuous) random vector $\underline{X}$. The case of discrete r.v.s is treated similarly, but with probabilities, as opposed to density functions for characterization of $\underline{x}$. Suppose the class-conditioned probability density functions for feature vector $\underline{x}$ (i.e., $p(\underline{x}|w_i)$ where $i = 1, c$) are available, which may be the result of training or learning. Assume that something is known about the a priori (i.e., before measurement) likelihood of the occurrence of class w_1 or w_2, specifically assume the a priori probabilities $P(w_i), i = 1, c$ are known. For example, in the shim-bolt example above, if we know that on a given day we inspect four times as many shims as bolts, then $P(w_1) = 0.8$ and $P(w_2) = 0.2$. In the absence of this information, an often reasonable assumption is that $P(w_i) = \frac{1}{c}$ (i.e., the a priori probabilities of the states of nature are equal).

Using Bayes Theorem. Bayes theorem is used to enable a solution to the classification problem that uses available feature and training data. The a priori estimate of the probability of a certain class is converted to the a posteriori, or *measurement conditioned*, probability of a state of nature via:

$$p(w_i|\underline{x}) = \frac{[p(\underline{x}|w_i)P(w_i)]}{p(\underline{x})}$$

where

$$p(\underline{x}) = \sum_i p(\underline{x}|w_i)$$

An intuitive classification strategy is that a given realization or sample vector $\underline{x}$ is classified by choosing the state of nature w_i for which $P(w_i|\underline{x})$ is largest. Notice the quantity $p(\underline{x})$ is common to all class-conditional probabilities; therefore, it represents a scaling factor that may be eliminated. Thus, in our shim-bolt example, the decision or classification algorithm is

$$choose \begin{cases} w_1 & \text{if } p(\underline{x}|w_1)P(w_1) > p(\underline{x}|w_2)P(w_2) \\ w_2 & \text{if } p(\underline{x}|w_2)P(w_2) > p(\underline{x}|w_1)P(w_1) \end{cases}$$

Note also that any monotonically nondecreasing function of $P(w_i|\underline{x})$ may be used for this test (see discriminant functions, below). The significance of this approach is that both a priori information ($P(w_i)$) and measurement-related information ($p(\underline{x}|w_i)$) are *combined* in the decision procedure. If $P(w_1) \neq P(w_2)$, for example, this information may be explicitly incorporated in the decision process.

Decision Regions and Discriminant Functions

A *classifier* partitions feature space into class-labeled *decision regions*. In order to use decision regions for a possible and unique class assignment, these regions must cover R^d and be disjoint (nonoverlapping). An exception to the last constraint is the notion of *fuzzy sets*. The border of each decision region is a *decision boundary*. With this viewpoint, classification of feature vector $\underline{x}$ becomes quite simple: We determine the decision region (in R^d) into which $\underline{x}$ falls and assign $\underline{x}$ to this class. Although the classification strategy is straightforward, the determination of decision regions is a challenge. It is sometimes convenient, yet not always necessary (or possible), to visualize decision regions and boundaries. Moreover, computational and geometric aspects of certain decision boundaries (e.g., linear classifiers that generate hyperplanar decision boundaries) are noteworthy.

A number of classifiers are based on *discriminant functions*. In the c-class case, discriminant functions, denoted $g_i(\underline{x}), i = 1, 2, \ldots c$, are used to partition R^d using the *decision rule:* Assign $\underline{x}$ to class w_m (region R_m), where $g_m(\underline{x}) > g_i(\underline{x}) \, \forall i = 1, 2, \ldots c$ and $i \neq m$. The case in which $g_k(\underline{x}) = g_l(\underline{x})$ defines a *decision boundary*.

Linear Separability (1,2). If a linear decision boundary (hyperplanar decision boundary) exists that correctly classifies all the training samples in H for a $c = 2$ class problem, the samples are said to be linearly separable. This hyperplane, denoted H_{ij}, is defined by parameters $\underline{w}$ and w_o in a linear constraint of the form

$$g(\underline{x}) = \underline{w}^T \underline{x} - w_o = 0 \tag{1}$$

$g(\underline{x})$ separates R^d into positive and negative regions R_p and R_n, where

$$g(\underline{x}) = \underline{w}^T \underline{x} - w_o = \begin{cases} > 0 & \text{if} \quad \underline{x} \in R_p \\ 0 & \text{if} \quad \underline{x} \in H_{ij} \\ < 0 & \text{if} \quad \underline{x} \in R_n \end{cases} \tag{2}$$

Problems that are not linearly separable are sometimes referred to as *nonlinearly separable* or *topologically complex*.

From a PR viewpoint, the computational advantages (both in implementation and training) and ease of visualization of linear classifiers account for their popularity. Seminal works include Refs. 11–13.

Using the Bayesian approach, one choice of discriminant function is $g_i(\underline{x}) = P(w_i|\underline{x})$. In the case of equal a priori probabilities and class-conditioned Gaussian density functions, Equation (2) shows that the decision boundaries are hyperplanes.

Training in StatPR. One of the problems not addressed in the previous section is determination of the parameters for the class-conditioned probability density functions. A labeled set of *training samples* (i.e., sets of labeled feature vectors with known class) are often used. This training set is denoted H. In the case of Gaussian pdf models, it is only necessary to estimate $\underline{\mu}_i$ and $\sum_i$ for each class. Large-dimension feature vectors, and consequently density functions, lead to situations in which this approach is impractical. For example, in an *image processing* application, if we use the gray-level measurements directly as features, an image with 100 × 100 pixel spatial resolution yields a 1000 × 1 feature vector, and requires estimation of a 1000 × 1000 covariance matrix. This application is seldom practical.

Nearest Neighbor Classification

An alternative, which is related to the minimum distance classification approach, is the use of a nonparametric technique known as *nearest neighbor classification*. We illustrate the concept of a 1-nearest neighbor classification rule (1-NNR) first. Given a feature vector $\underline{x}$, we determine the vector in H which is closest (in terms of some distance measure) to $\underline{x}$, and denote this vector $\underline{x}\prime$. $\underline{x}$ is classified by assigning it to the class corresponding to $\underline{x}\prime$. A variation is the k-NNR, where the k samples in H that are nearest to $\underline{x}$ are determined, and the class of $\underline{x}$ is based on some measure of the labels of these samples (e.g., a voting scheme may be employed). This approach, although conceptually and computationally straightforward, may be shown to have a greater error rate than the minimum distance classifier. However, the concept of classification based on nearness, or similarity, of features is significant (see Pattern Matching).

General Decision Rules. We formulate a *loss function, cost function*, or *risk function*, denoted λ_{ij}, as the cost or risk of choosing class w_i when class w_j is the true class. For example, in the $c = 2$ (w_1 or w_2) case, there are four values of λ_{ij} (i.e., λ_{11}, λ_{12}, λ_{21}, λ_{22}). λ_{11} and λ_{22} are the costs (or perhaps "rewards" for a correct decision), whereas λ_{12} and λ_{21} are the costs of a classification error. It is desirable to measure or estimate overall classification risk. To measure this risk, the decision rule, cost functions, and the observations $\underline{x}$ are used. A *decision or classification* to choose class w_i is denoted α_i. A *decision rule* is a mapping of the observed feature vector $\underline{x}$ into an α_i through a decision rule $\alpha(\underline{x})$

$$\alpha(\underline{x}) \rightarrow \{\alpha_1, \alpha_2 \ldots \alpha_c\}$$

As

$$P(\alpha_i \cap w_j) = P(\alpha_i|w_j)P(w_j)$$

an overall risk measure for the $c = 2$ case is

$$\begin{aligned} R = {} & \lambda_{11}P(\alpha_1|w_1)P(w_1) + \lambda_{21}P(\alpha_2|w_1)P(w_1) \\ & + \lambda_{12}P(\alpha_1|w_2)P(w_2) + \lambda_{22}P(\alpha_2|w_2)P(w_2) \end{aligned}$$

Of course, the $P(\alpha_i|w_j)$ terms depend on the chosen mapping $\alpha(\underline{x}) \to \alpha_i$, which in turn depends on $\underline{x}$. Thus, a measure of *conditional risk* associated with a $c = 2$ class decision rule is

$$R(\alpha(\underline{x}) \to \alpha_1) = R(\alpha_1|\underline{x}) = \lambda_{11}P(w_1|\underline{x}) + \lambda_{12}P(w_2|\underline{x})$$

for α_1 and

$$R(\alpha(\underline{x}) \to \alpha_2) = R(\alpha_2|\underline{x}) = \lambda_{21}P(w_1|\underline{x}) + \lambda_{22}P(w_2|\underline{x})$$

for α_2. For a c-class decision problem, the expected risk is given by an application of the total probability theorem

$$R(\alpha(\underline{x})) = \int R(\alpha(\underline{x})|\underline{x})p(\underline{x})\underline{d}x$$

Minimizing the conditional risk, $R(\alpha(\underline{x})|\underline{x})$ thus minimizes the expected risk. The lower bound on $R(\alpha(\underline{x}))$ is often referred to as the *Bayes risk*. In order to minimize $R(\alpha(\underline{x}))$ for $c = 2$, because only two choices or classifications (α_1 or α_2) are possible, the decision rule is formulated as

$$R(\alpha_1|\underline{x}) \quad \underset{\alpha_1}{\overset{\alpha_2}{\gtrless}} \quad R(\alpha_2|\underline{x})$$

which may be expanded into

$$\lambda_{11}P(w_1|\underline{x}) + \lambda_{12}P(w_2|\underline{x}) \quad \underset{\alpha_1}{\overset{\alpha_2}{\gtrless}} \quad \lambda_{21}P(w_1|\underline{x}) + \lambda_{22}P(w_2|\underline{x})$$

or

$$(\lambda_{11} - \lambda_{21})p(\underline{x}|w_1)P(w_1) \quad \underset{\alpha_1}{\overset{\alpha_2}{\gtrless}} \quad (\lambda_{22} - \lambda_{12})p(\underline{x}|w_2)P(w_2)$$

When $\lambda_{11} = \lambda_{22} = 0$ (there is no “cost” or “risk” in a correct classification) and $(\lambda_{11} - \lambda_{21}) < 0$, the above may be rewritten as

$$\frac{p(\underline{x}|w_1)}{p(\underline{x}|w_2)} \quad \underset{\alpha_2}{\overset{\alpha_1}{\gtrless}} \quad \frac{(\lambda_{22} - \lambda_{12})P(w_2)}{(\lambda_{11} - \lambda_{21})P(w_1)}$$

This form yields a classifier based on a *likelihood ratio test* (LRT).

For c classes, with the loss function

$$\lambda_{ij} = \begin{cases} 0 & i = j \\ 1 & i \neq j \end{cases}$$

all errors are *equally costly*. The conditional risk of decision α_i is

$$\begin{aligned} R(\alpha(\underline{x}) \to \alpha_i) &= \sum_{j=1}^{c} \lambda_{ij}P(w_j|\underline{x}) \\ &= \sum_{j \neq i} P(w_j|\underline{x}) = 1 - P(w_i|\underline{x}) \end{aligned}$$

To minimize the conditional risk, the decision rule is therefore to choose the α_i that maximizes $P(w_i|\underline{x})$ (i.e., the w_i for which $P(w_i|\underline{x})$ is largest, which is intuitively appealing. As $P(w_i|\underline{x})$ is the a posteriori probability, this results in the *maximum a posteriori probability* (MAP) classifier, which may be formulated as

$$P(w_i|\underline{x}) \overset{\alpha_i}{>} P(w_j|\underline{x}) \ \ \forall_j \neq i$$

As before, Bayes rule is used to reformulate these tests in terms of class-conditioned density functions and a priori probabilities.

For general formulations of risk (through λ_{ij}), the resulting decision rule is

$$R(\alpha_i|\underline{x}) \overset{\alpha_i}{<} R(\alpha_j|\underline{x}) \ \ \forall_i \neq j$$

Clustering

In some cases, a training set, H, is not available for a PR problem. Instead, an unlabeled set of *typical* features, denoted H_u, is available (see *unsupervised learning*). For each sample, $\underline{x} \in H_u$, the class origin or label is unknown. Desirable attributes of H_u are that the cardinality of H_u is large, all classes are represented in H_u, and subsets of H_u may be formed into natural groupings or “clusters”. Each cluster most likely (or hopefully) corresponds to an underlying pattern class.

Clustering is a popular approach in unsupervised learning (14). Clustering applications in *image analysis*, for example, include Refs. 15 and 16. Iterative algorithms involving cluster splitting and merging in *image analysis* are shown in Ref. 2.

Unsupervised learning approaches attempt to develop a representation for the given sample data, after which a classifier is designed. In this context, clustering may be conceptualized as “how do I build my fences?” Thus, in unsupervised learning, the objective is to *define the classes*. A number of intuitive and practical approaches exist to this problem. For example, a self-consistent procedure is

1. Convert a set of unlabeled samples H_u into a *tentative* training set H_T.
2. Using H_T, apply a supervised training procedure and develop corresponding discriminant functions/decision regions.
3. Use the results of 2 on H_u (i.e., reclassify H_u). If the results are consistent with H_T, stop, otherwise go to 1 and revise H_T.

This approach “clusters” data by observing similarity. There exist neural networks with this feature (see *Self Organizing Feature Maps*). In many PR applications involving unsupervised learning, features naturally fall into natural, easily observed groups. In others, the grouping is unclear and very sensitive to the measure of similarity used. The c-means algorithm [Equation (2)] and it’s derivatives are one of the most popular approaches.

The *c*-means Algorithm.

1. Choose the number of classes, c.
2. Choose class means or exemplars, denoted $\underline{\hat{\mu}}_i, \underline{\hat{\mu}}_2, \cdots \underline{\hat{\mu}}_c$.
3. Classify each of the unlabeled samples $\underline{x}_k$ in H_u.
4. Recompute the estimates for $\underline{\hat{\mu}}_i$ using the results of 3.
5. If the $\underline{\hat{\mu}}_i$ are consistent, stop, otherwise go to step 1, 2, or 3.

Notice the essence of this approach is to achieve a self-consistent partitioning of the data. Choice of initial parameters (c and $\underline{\hat{\mu}}_i(o)$) is a challenging issue, which has spawned an area of study concerning *cluster validity*.

An Example of the c-means Algorithm. Figure 3 shows examples of the c-means algorithm for the $c = 2$ class case on a set of unlabeled data (1). The trajectory of the $\underline{\hat{\mu}}_i$ as a function of iteration is shown.

Iterative and Hierarchical Clustering. Clustering may be achieved through a number of alternative strategies, including iterative and hierarchical approaches. Hierarchical strategies may further be subdivided into agglomerative (merging of clusters) or devisive (splitting of clusters). Hierarchical strategies have the property that not all partitions of the data are considered. However, when the number of samples is large, hierarchical clustering may be inappropriate. In an agglomerative procedure, two samples, once in the same class, remain in the same class throughout subsequent cluster merging, which may lead to resulting data partitions being suboptimal.

Clustering Criterion Functions. Developing appropriate similarity measures $d(\underline{x}_i, \underline{x}_j)$ is paramount in clustering. For a given partition of H_u, denoted P, a measure of the "goodness" of the overall clustering is given by *clustering criterion function*, $J(P)$. If

$$J(P_1) < J(P_2)$$

P_1 is a better partition than P_2. Once a suitable $J(P)$ is defined, the objective is to find P_m such that

$$J(P_m) = \overset{min}{P}\,(J(P))$$

in a computationally efficient manner, which is a problem in discrete optimization. One of the more popular clustering metrics is the *sum of squared error (SSE) criterion*. Given n_i samples in H_i, with sample mean $\underline{m}_i$, where

$$\underline{m}_i = \frac{1}{n_i} \sum_{\underline{x}_j \in H_i} \underline{x}_j$$

the SSE criterion, J_{SSE} is defined as

$$J_{SSE}(P) = \sum_{i=1}^{c} \sum_{\underline{x}_j \in H_i} \|\underline{x} - \underline{m}_i\|^2$$

J_{SSE} thus indicates the total "variance" for a given partition. For example, cluster-swapping approaches are a variant on the c-means iterative algorithm that implements a "good" cluster reorganization strategy, where "good" means

$$J_{SSE}(P_{k+1}) \leq J_{SSE}(P_k)$$

For illustration, our reorganization strategy is restricted to the movement of a single vector $\underline{x}_j$ from H_i to H_j, denoted $H \xrightarrow{\underline{x}_j} H_j$. The revised clusters in P_{k+1} are denoted H_i

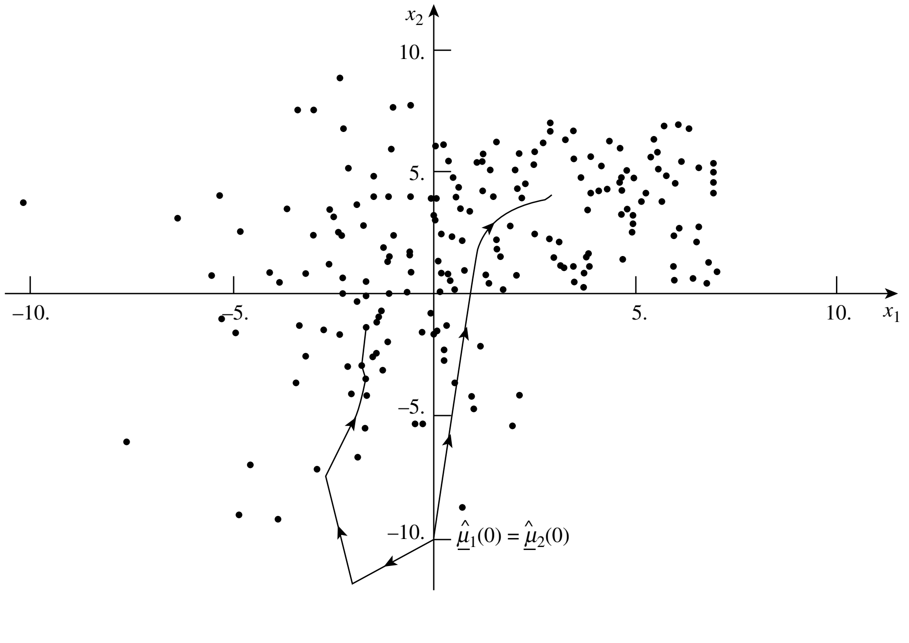

Figure 3. Example of the trajectories of the class means in the c-means algorithm (Adapted from Ref. 1).

and H_j. It is possible to show $H_i \overset{x_k}{\to} H_j$ decreases $J_{SSE}(P_k)$ if

$$\left(\frac{n_j}{n_j+1}\right)\|\underline{x}_j-\underline{m}_j\|^2<\left(\frac{n_i}{n_i-1}\right)\|\underline{x}_j-\underline{m}_i\|^2$$

Hierarchical Clustering. Consider a hierarchical clustering procedure in which clusters are merged so as to produce the smallest increase in the SSE at each step. The *ith* cluster or partition, denoted H_i, contains n_i samples with sample mean $\underline{m}_i$. The smallest increase results from merging the pair of clusters for which the measure M_{ij}, where

$$M_{ij}=\frac{n_i n_j}{n_i+n_j}\|\underline{m}_i-\underline{m}_j\|^2$$

is minimum. Recall

$$J_e=\sum_{j=1}^{c}\sum_{\underline{x}\in H_i}\|\underline{x}-\underline{m}_i\|^2$$

(i.e., J_e measures the total squared error incurred in representing the n samples $\underline{x}_1,\ldots\underline{x}_n$ by c cluster means $\underline{m}_1\ldots\underline{m}_c$).

The *change* in the SSE after merging clusters i and j is

$$\Delta J_e=-\left(\sum_{\underline{x}\in H_i}\|\underline{x}-\underline{m}_i\|^2+\sum_{\underline{x}\in H_j}\|\underline{x}-\underline{m}_j\|^2\right)+\sum_{\underline{x}\in H_i or H_j}\|\underline{x}-\underline{m}_{ij}\|^2$$

where

$$\underline{m}_i=\frac{1}{n_i}\sum_{\underline{x}\in H_i}\underline{x}\quad \underline{m}_j=\frac{1}{n_j}\sum_{\underline{x}\in H_j}\underline{x}$$

and

$$\underline{m}_{ij}=\frac{1}{n_i+n_j}\sum_{\underline{x}\in H_i\, or\, H_j}\underline{x}$$

The objective is to merge clusters so that ΔJ_e is minimum. It is possible to show

$$\Delta J_e=\frac{n_i n_j}{(n_i+n_j)}\|\underline{m}_j-\underline{m}_i\|^2=\frac{n_i n_j}{(n_i+n_j)}\|\underline{m}_i-\underline{m}_j\|^2$$

and therefore use this measure in choosing clusters to merge.

The popularity of clustering has spawned a sizable and varied library of clustering algorithms and software (17), one of the most popular being the *ISODATA algorithm* (10–18).

SYNTACTIC (STRUCTURAL) PATTERN RECOGNITION

Many times the significant information in a pattern is not merely in the presence or absence, or the numerical values, of a set of features. Instead, the interrelationships or interconnections of features yield important *structural* information, which facilitates structural description or classification, which is the basis of syntactic (or structural) PR. Figure 4 shows the general strategy (1).

In using SyntPR approaches, it is necessary to quantify and extract structural information and determine the structural similarity of patterns. One syntactic approach is to relate the structure of patterns with the syntax of a formally defined language in order to capitalize on the vast body of knowledge related to pattern (sentence) generation and analysis (parsing). Syntactic PR approaches are presented in Refs. 1, 19–23. A unified view of StatPR and SyntPR is shown in Ref. 24. An extended example of the use of SyntPR in an *image interpretation* application is shown in Ref. 25.

Typically, SyntPR approaches formulate hierarchical descriptions of complex patterns built up from simpler subpatterns. At the lowest level, *primitive elements* or "building blocks" are extracted from the input data. One distinguishing characteristic of SyntPR involves the choice of primitives. *Primitives must be subpatterns or building blocks, whereas features (in StatPR) are any measurements*.

Syntactic structure quantification is shown using two approaches: formal grammars and relational descriptions (attributed graphs). These tools allow structurally quantitative pattern representation, which facilitate recognition, classification, or description. A class of procedures for *syntactic recognition*, including *parsing* (for formal grammars) and *relational graph matching* (for attributed relational graphs) are then developed. Although it is not mandatory, many SyntPR techniques are based on generation and analysis of complex patterns by a hierarchical decomposition into simpler patterns.

Formal Grammars and Syntactic Recognition by Parsing

The syntax rules of formal grammars may be used to generate patterns (possibly from other patterns) with constrained structural relations. A grammar may therefore serve to model a class-specific pattern-generating source that generates all the patterns with a class-specific

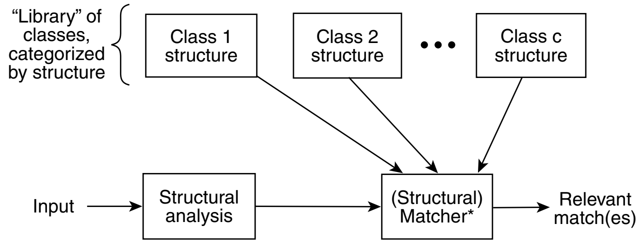

Figure 4. Generic syntactic (or structural) PR system (Adapted from Ref. 1).

structure. Furthermore, it is desirable to have each class-specific grammar derivable from a set of sample patterns (i.e., training must be considered, which raises the issue of *grammatical inference*.

Useful introductions to formal grammars are available in Refs. 26 and 27. References 19, 21–23 are devoted entirely to SyntPR.

Grammars. A *grammar* consists of the following four entities:

1. A set of terminal or primitive symbols (primitives), denoted V_T (or, alternately, $\sum$). In many applications, the choice of the terminal set or primitives is difficult and has a large component of "art" as opposed to "science."
2. A set of *nonterminal symbols, or variables*, which are used as intermediate quantities in the generation of an outcome consisting solely of terminal symbols. This set is denoted as V_N (or, alternately, *N*).
3. A set of *productions, or production rules or rewriting rules* that allow the previous substitutions. It is this set of productions, coupled with the terminal symbols, which principally gives the grammar its "structure." The set of productions is denoted *P*.
4. A starting (or root) symbol, denoted S. $S \in V_N$.

Note that V_T and V_N are disjoint sets (i.e., $V_T \cap V_N = \phi$).

Thus, using the above definitions, we formally denote a grammar G as the four-tuple:

$$G = (V_T, V_N, P, S)$$

Constraining Productions. Given V_T and V_N, the productions *P* may be viewed as constraints on how class-specific patterns may be described. Different types of grammars place restrictions on these mappings. For example, it is reasonable to constrain elements of *P* to the form

$$A \rightarrow B$$

where

$$A \in (V_N \cup V_T)^+ - V_T^+$$

and

$$B \in (V_N \cup V_T)^*$$

Thus, *A* must consist of at least one member of V_N, (i.e., a nonterminal), and *B* is allowed to consist of any arrangement of terminals and nonterminals. This example is a partial characterization of *phrase structure grammar*.

Grammar Application Modes. A grammar may be used in one of two modes: *Generative:* The grammar is used to create a string of terminal symbols using P; a *sentence* in the language of the grammar is thus generated.

Analytic: Given a sentence (possibly in the language of the grammar), together with specification of G, one seeks to determine if the sentence was generated by G and, if so, the structure (usually characterized as the sequence of productions used) of the sentence.

The following formal notation is used. Symbols beginning with a capital letter (e.g., S_1 or S) are elements of V_N. Symbols beginning with a lowercase letter (e.g., a or b) are elements of V_T. n denotes the length of string s, for example,

$$n = |s|$$

Greek letters (e.g., α and β) represent (possibly empty) strings, typically comprised of terminals or nonterminals.

Constraints on the production or rewrite rules, *P*, in string grammar G are explored by considering the "general" production form

$$\alpha_1 \rightarrow \beta_2$$

which means string α_1 "is replaced by" string β_2. In general, α_1 and β_2 may contain terminals or nonterminals.

In a context-free grammar, the production restrictions are

$$\alpha_1 = S_1 \in V_N$$

that is, α_1 *must be a single nonterminal* for every production in *P*, and

$$|S_1| \leq |\beta_2|$$

An alternate characterization of a T_2 grammar is that every production must be of the form

$$S_1 \rightarrow \beta_2$$

where $\beta_2 \in (V_N \cup V_T)^* - \{\epsilon\}$. Note the restriction in the above productions to the replacement of S_1 by string β_2 *independently of the context in which* S_1*appears*.

Context-free grammars can generate a string of terminals or nonterminals in a single production. Moreover, because productions of the form $A \rightarrow \alpha A \beta$ are allowed, context-free grammars are *self-embedding*.

Context-free grammars are important because they are the most descriptively versatile grammars for which effective (and efficient) parsers are available. The production restrictions increase in going from context-sensitive to context-free grammars.

Finite-state or regular grammars are extremely popular. The production restrictions in a finite-state or regular grammar are those of a context-free grammar, plus the additional restriction that *at most one nonterminal symbol is allowed on each side of the production*. for example,

$$\alpha_1 = S_1 \in V_N$$
$$|S_1| \leq |\beta_2|$$

and productions are restricted to

$$A_1 \rightarrow a$$

or

$$A_1 \rightarrow aA_2$$

Finite-state grammars have many well-known characteristics that explain their popularity, including simple graphical representations and known tests for equivalence. Finite-state grammars are useful when analysis (parsing) is to be accomplished with finite-state machines (26).

Other Grammar Types Used for SyntPR. Grammars other than string grammars exist and are usually distinguished by their terminals and nonterminals (as opposed to constraints on P), which are useful in 2-D and higher-dimensional pattern representation applications in that the structure of the productions involving terminals and nonterminals is greater than one dimensional. Higher-dimensional grammars also facilitate relational descriptions. Productions in higher-dimensional grammars are usually more complex, because rewriting rules embody operations more complex than simple 1-D string rewriting. For example, in 2-D cases, standard "attachment points" are defined. Two of the more popular are *tree grammars* and *web grammars*(19). Not surprisingly, there is little correlation between the dimension of the *grammar* used for pattern generation and the dimensionality of the pattern space. For example, a 1-D grammar may be used for 2-D or 3-D patterns.

Example of Grammatical Pattern Description for Chromosome Classification. Figure 5, excerpted from Ref. 28, shows the conversion of a chromosome outline to a string in a formal grammar, where the primitives and productions are given. Using the primitives and productions of grammar, G_M, given in part (a), the string $x =$ *cbbbabbbbdbbbbabbbcbbbabbbbdbbbbabbb* may be produced to describe the sample chromosome outline shown in part (b).

Parsing

Chomsky Normal Form (CNF). A CFG is in Chomsky Normal Form (CNF) if each element of P is in one of the following forms:

$$\begin{aligned} A &\rightarrow BC \ \ where \ A, B, C \in V_N \\ A &\rightarrow a \ \ where \ \in V_N, a \in V_T \end{aligned}$$

The Cocke–Younger–Kasami (CYK) Parsing Algorithm. The CYK algorithm is a parsing approach that will parse string x ina number of steps proportional to $|x|^3$. The CYK algorithm requires the CFG be in Chomsky Normal Form (CNF). With this restriction, the derivation of any string involves a series of binary decisions. First, the CYK table is formed. Given string $x = x_1, x_2 \ldots x_n$, where $x_i \in V_T$, $|x| = n$, and a grammar G, we form a triangular table with entries t_{ij} indexed by i and$j$ where $1 \leq i \leq n$ and $1 \leq j \leq (n - i + 1)$. The origin is at $i = j = 1$, and entry t_{11} is the lower left-hand entry in the table. t_{1n} is the uppermost entry in the table. This structure is shown in Fig. 6.

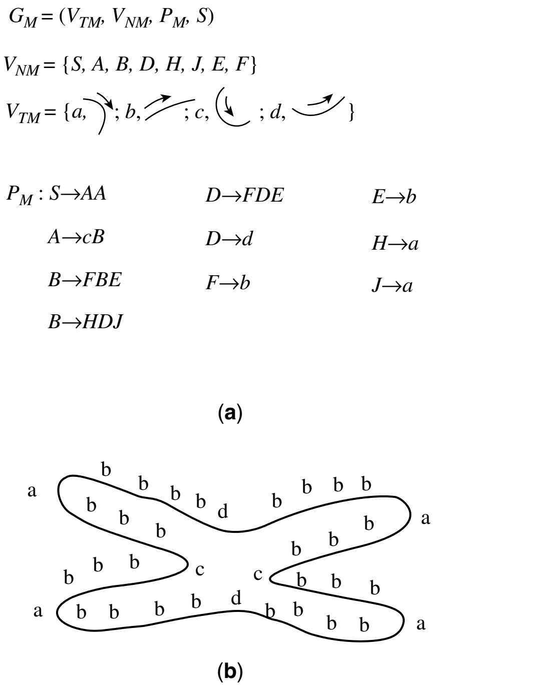

Figure 5. Conversion of a chromosome outline to a string in a formal grammar (excerpted from Ref. 28). (a) Primitives and productions in L(G). (b) Sample chromosome outline yielding string $x =$ *cbbbabbbbdbbbbabbbcbbbabbbbdbbbbabbb*.

To build the CYK table, a few simple rules are used. Starting from location (1,1), *if a substring ofx, beginning withx$_i$, and of lengthjcan be derived from a nonterminal, this nonterminal is placed into cell* (i,j). If cell $(1,n)$ contains S, the table contains a valid derivation of x in $L(G)$. It is convenient to list the x_i, starting with $i = 1$, under the bottom row of the table.
