It is a mistake to think that the choice uncertainty principle is limited to hardware. Suppose that your software contains a critical section guarded by semaphores. Your proof that the locks choose only one process at a time to enter the critical section implicitly assumes that only one CPU at a time can gain access to the memory location holding the lock value. If that is not so, then occasionally your critical section will fail no matter how careful your proofs. Every level of abstraction at which we prove freedom from synchronization errors always relies on a lower level at which arbitration is solved. But arbitration can never be solved absolutely.

Therefore, software's assumption that variables denoting alternatives are well defined and unchanging when we look at them is not always valid. The choice uncertainty principle warns us of this possibility and helps to manage it.

COMPUTATIONAL COMPLEXITY THEORY

Complexity theory is the part of theoretical computer science that attempts to prove that certain transformations from input to output are impossible to compute using a reasonable amount of resources. Theorem 1 below illustrates the type of "impossibility" proof that can sometimes be obtained (1); it talks about the problem of determining whether a logic formula in a certain formalism (abbreviated WS1S) is true.

Theorem 1. *Any circuit of* AND, OR, *and* NOT *gates that takes as input a WS1S formula of 610 symbols and outputs a bit that says whether the formula is true must have at least* 10^{125}*gates.*

This is a very compelling argument that no such circuit will ever be built; if the gates were each as small as a proton, such a circuit would fill a sphere having a diameter of 40 billion light years! Many people conjecture that somewhat similar intractability statements hold for the problem of factoring 1000-bit integers; many public-key cryptosystems are based on just such assumptions.

It is important to point out that Theorem 1 is specific to a particular circuit technology; to prove that there is no efficient way to compute a function, it is necessary to be specific about *what* is performing the computation. Theorem 1 is a compelling proof of intractability precisely because every deterministic computer that can be purchased today can be simulated efficiently by a circuit constructed with AND, OR, and NOT gates. The inclusion of the word "deterministic" in the preceding paragraph is significant; some computers are constructed with access to devices that are presumed to provide a source of random bits. Probabilistic circuits (which are allowed to have some small chance of producing an incorrect output) might be a more powerful model of computing. Indeed, the intractability result for this class of circuits (1) is slightly weaker:

Theorem 2. *Any probabilistic circuit of* AND, OR, *and* NOT *gates that takes as input a WS1S formula of 614 symbols and outputs a bit that says whether the formula is true (with error probability at most 1/3) must have at least* 10^{125}*gates.*

The underlying question of the appropriate *model of computation* to use is central to the question of how relevant the theorems of computational complexity theory are. Both deterministic and probabilistic circuits are examples of "classical" models of computing. In recent years, a more powerful model of computing that exploits certain aspects of the theory of quantum mechanics has captured the attention of the research communities in computer science and physics. It seems likely that some modification of theorems 1 and 2 holds even for quantum circuits. For the factorization problem, however, the situation is different. Although many people conjecture that classical (deterministic or probabilistic) circuits that compute the factors of 1000-bit numbers must be huge, it is known that small quantum circuits can compute factors (2). It remains unknown whether it will ever be possible to build quantum circuits, or to simulate the computation of such circuits efficiently. Thus, complexity theory based on classical computational models continues to be relevant.

The three most widely studied general-purpose "realistic" models of computation today are deterministic, probabilistic, and quantum computers. There is also interest in *restricted* models of computing, such as *algebraic circuits* or *comparison-based* algorithms. Comparison-based models arise in the study of sorting algorithms. A comparison-based sorting algorithm is one that sorts n items and is not allowed to manipulate the representations of those items, other than being able to test whether one is greater than another. Comparison-based sorting algorithms require time $\Omega(n \log n)$, whereas faster algorithms are sometimes possible if they are allowed to access the bits of the individual items. Algebraic circuits operate under similar restrictions; they cannot access the individual bits of the representations of the numbers that are provided as input, but instead they can only operate on those numbers via operations such as $+$, $\times$, and $\div$. Interestingly, there is also a great deal of interest in "unrealistic" models of computation, such as nondeterministic machines. Before we explain why unrealistic models of computation are of interest, let us see the general structure of an intractability proof.

DIAGONALIZATION AND REDUCIBILITY

Any intractability proof has to confront a basic question: How can one prove that there is *not* a clever algorithm for a certain problem? Here is the basic strategy that is used to prove theorems 1 and 2. There are three steps.

Step 1 involves showing that there is program A that uses roughly 2^n bits of memory on inputs of size n such that, for every input length n, the function that A computes on inputs of length n requires circuits *as large as are required by any function on n bits*. The algorithm A is presented by a "diagonalization" argument (so-called because of similarity to Cantor's "diagonal" argument from set theory). The same argument carries through essentially unchanged for probabilistic and quantum circuits. The problem computed by A is hard to compute, but this by itself is not very interesting, because it is probably not a problem that anyone would ever *want* to compute.

Step 2 involves showing that there is an efficiently computable function f that transforms any input instance x for A into a WS1S formula ϕ(i.e., $f(x) = \phi$) with the property that A outputs "1" on input x if and only if the formula ϕ is true. If there were a small circuit deciding whether a formula is true, then there would be a small circuit for the problem computed by A. As, by step 1, there is

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

no such small circuit for A, it follows that there is no small circuit deciding whether a formula is true.

Step 3 involves a detailed analysis of the first two steps, in order to obtain the concrete numbers that appear in Theorem 1.

Let us focus on step 2. The function f is called a *reduction*. Any function g such that x is in B if and only if $g(x)$ is in C is said to *reduce* B to C. (This sort of reduction makes sense when the computational problems B and C are problems that require a "yes or no" answer; thus, they can be viewed as *sets*, where x is in B if B outputs "yes" on input x. Any computational problem can be viewed as a set this way. For example, computing a function h can be viewed as the set $\{(x, i)$: the ith bit of $f(x)$ is $1\}$.)

Efficient reducibility provides a remarkably effective tool for classifying the computational complexity of a great many problems of practical importance. The amazing thing about the proof of step 2 (and this is typical of many theorems in complexity theory) is that it makes *no use at all* of the algorithm A, other than the fact that A uses at most 2^n memory locations. *Every* problem that uses at most this amount of memory is efficiently reducible to the problem of deciding whether a formula is true. This provides motivation for a closer look at the notion of efficient reducibility.

EFFICIENT COMPUTATION, POLYNOMIAL TIME

Many notions of efficient reducibility are studied in computational complexity theory, but without question the most important one is polynomial-time reducibility. The following considerations explain why this notion of reducibility arises.

Let us consider the informal notion of "easy" functions (functions that are easy to compute). Here are some conditions that one might want to satisfy, if one were trying to make this notion precise:

- If f and g are easy, then the composition $f \circ g$ is also easy.
- If f is computable in time n^2 on inputs of length n, then f is easy.

These conditions might seem harmless, but taken together, they imply that some "easy" functions take time n^{100} to compute. (This is because there is an "easy" function f that takes input of length n and produces output of length n^2. Composing this function with itself takes time n^4, etc.) At one level, it is clearly absurd to call a function "easy" if it requires time n^{100} to compute. However, this is precisely what we do in complexity theory! When our goal is to show that certain problems require *superpolynomial* running times, it is safe to consider a preprocessing step requiring time n^{100} as a "negligible factor".

A polynomial-time reduction f is simply a function that is computed by some program that runs in time bounded by $p(n)$ on inputs of length n, for some polynomial p. (That is, for some constant k, the running time of the program computing f is at most $n^k + k$ on inputs of length n.) Note that we have not been specific about the programming language in which the program is written. Traditionally, this is made precise by saying that f is computed by a *Turing machine* in the given time bound, but exactly the same class of polynomial-time reductions results, if we use any other reasonable programming language, with the usual notion of running time. This is a side-benefit of our overly generous definition of what it means to be "easy" to compute.

If f is a polynomial-time reduction of A to B, we denote this $A \leq_m^p B$. Note that this suggests an ordering, where B is "larger" (i.e., "harder to compute") than A. Any efficient algorithm for B yields an efficient algorithm for A; if A is hard to compute, then B must also be hard to compute. If $A \leq_m^p B$ and $B \leq_m^p A$, this is denoted $A \equiv_m^p B$.

One thing that makes complexity theory useful is that naturally-arising computational problems tend to clump together into a shockingly small number of equivalence classes of the $\equiv_m^p$ relation. Many thousands of problems have been analyzed, and most of these fall into about a dozen equivalence classes, with perhaps another dozen classes picking up some other notably interesting groups of problems.

Many of these equivalence classes correspond to interesting time and space bounds. To explain this connection, first we need to talk about *complexity classes*.

COMPLEXITY CLASSES AND COMPLETE SETS

A *complexity class* is a set of problems that can be computed within certain resource bounds on some model of computation. For instance, P is the class of problems computable by programs that run in time at most $n^k + k$ for some constant k; "P" stands for "polynomial time." Another important complexity class is EXP: the set of problems computed by programs that run for time at most 2^{n^k+k} on inputs of length n. P and EXP are both defined in terms of time complexity. It is also interesting to bound the amount of memory used by programs; the classes PSPACE and EXPSPACE consist of the problems computed by programs whose space requirements are polynomial and exponential in the input size, respectively.

An important relationship exists between EXP and the game of checkers; this example is suitable to introduce the concepts of "hardness" and "completeness."

Checkers is played on an 8-by-8 grid. When the rules are adapted for play on a 10-by-10 grid, the game is known as "draughts" (which can also be played on boards of other sizes). Starting from any game position, there is an *optimal strategy*. The task of finding an optimal strategy is a natural computational problem. $N \times N$-*Checkers* is the function that takes as input a description of a $N \times N$ draughts board with locations of the pieces, and returns as output the move that a given player should make, using the optimal strategy. It is known that there is a program computing the optimal strategy for $N \times N$-*Checkers* that runs in time exponential in N^2; thus, $N \times N$-*Checkers* $\in$ EXP.

More interestingly, it is known that for every problem $A \in \mathrm{EXP}$, $A \leq_m^p N \times N$-*Checkers*. We say that $A \leq_m^p N\times$ N-*Checkers* is *hard* for EXP (3).

More generally, if $\mathcal{C}$ is any class of problems, and B is a problem such that $A \leq_m^p B$ for every $B \in \mathcal{C}$, then we say that B is hard for $\mathcal{C}$. If B is hard for $\mathcal{C}$ and $B \in \mathcal{C}$, then we say that B is *complete* for $\mathcal{C}$. Thus, in particular, $N \times N$-*Checkers* is complete for EXP. This means that the complexity of $N \times N$-*Checkers* is well understood, in the sense that the fastest program for this problem cannot be too much faster than the currently known program. Here is why: We know (via a diagonalization argument) that there is some problem A in EXP that cannot be computed by any program that runs in time asymptotically less than 2^n. As $N \times N$-*Checkers* is complete for EXP, we know there is a reduction from A to $N \times N$-*Checkers* computable in time n^k for some k, and thus $N \times N$-*Checkers* requires running time that is asymptotically at least $2^{n^{1/k}}$.

It is significant to note that this yields only an *asymptotic* lower bound on the time complexity of $N \times N$-*Checkers*. That is, it says that the running time of any program for this problem must be very slow *on large enough inputs*, but (in contrast to Theorem 1) it says *nothing* about whether this problem is difficult for a given fixed input size. For instance, it is still unknown whether there could be a handheld device that computes optimal strategies for 100 × 100-Checkers (although this seems very unlikely). To mimic the proof of Theorem 1, it would be necessary to show that there is a problem in EXP that requires large circuits. Such problems are known to exist in EXPSPACE; whether such problems exist in EXP is one of the major open questions in computational complexity theory.

The complete sets for EXP (such as $N \times N$-*Checkers*) constitute one of the important $\equiv_m^p$-equivalence classes; many other problems are complete for PSPACE and EXPSPACE (and of course every nontrivial problem that can be solved in polynomial time is complete for P under $\leq_m^p$ reductions). However, this accounts for only a few of the several $\equiv_m^p$-equivalence classes that arise when considering important computational problems. To understand these other computational problems, it turns out to be useful to consider *unrealistic* models of computation.

UNREALISTIC MODELS: NONDETERMINISTIC MACHINES AND THE CLASS NP

Nondeterministic machines *appear* to be a completely unrealistic model of computation; if one could *prove* this to be the case, one would have solved one of the most important open questions in theoretical computer science (and even in all of mathematics).

A *nondeterministic Turing machine* can be viewed as a program with a special "guess" subroutine; each time this subroutine is called, it returns a random bit, zero or one. Thus far, it sounds like an ordinary program with a random bit generator, which does not sound so unrealistic. The unrealistic aspect comes with the way that we define how the machine produces its output. We say that a nondeterministic machine *accepts* its input (i.e., it outputs one) if there is some sequence of bits that the "guess" routine could return that causes the machine to output one; otherwise it is said to *reject* its input. If we view the "guess" bits as independent coin tosses, then the machine rejects its input if and only if the probability of outputting one is zero; otherwise it accepts. If a nondeterministic machine runs for t steps, the machine can flip t coins, and thus, a nondeterministic machine can do the computational equivalent of finding a needle in a haystack: If there is even one sequence r of length t (out of 2^t possibilities) such that sequence r leads the machine to output one on input x, then the nondeterministic machine will accept x, and it does it in time t, rather than being charged time 2^t for looking at all possibilities.

A classic example that illustrates the power of nondeterministic machines is the Travelling Salesman Problem. The input consists of a labeled graph, with nodes (cities) and edges (listing the distances between each pair of cities), along with a bound B. The question to be solved is as follows: *Does there exist a cycle visiting all of the cities, having length at most B?* A nondeterministic machine can solve this quickly, by using several calls to the "guess" subroutine to obtain a sequence of bits r that can be interpreted as a list of cities, and then outputting one if r visits all of the cities, and the edges used sum up to at most B.

Nondeterministic machines can also be used to factor numbers; given an n-bit number x, along with two other numbers a and b with $a < b$, a nondeterministic machine can accept whether there is a factor of x that lies between a and b.

Of course, this nondeterministic program is of no use at all in trying to factor numbers or to solve the Traveling Salesman Problem on realistic computers. In fact, it is hard to imagine that there will ever be an efficient way to simulate a nondeterministic machine on computers that one could actually build. This is *precisely* why this model is so useful in complexity theory; the following paragraph explains why.

The class NP is the class of problems that can be solved by *nondeterministic* machines running in time at most $n^k + k$ on inputs of size n, for some constant k; NP stands for Nondeterministic Polynomial time. The Traveling Salesman Problem is one of many hundreds of very important computational problems (arising in many seemingly unrelated fields) that are *complete* for NP. Although it is more than a quarter-century old, the volume by Garey and Johnson (4) remains a useful catalog of NP-complete problems. The NP-complete problems constitute the most important $\equiv_m^p$-equivalence class whose complexity is unresolved. If any one of the NP-complete problems lies in P, then P = NP. As explained above, it seems much more likely that P is *not* equal to NP, which implies that any program solving any NP-complete problem has a worst-case running time greater than $n^{100{,}000}$ on all large inputs of length n.

Of course, even if P is not equal to NP, we would still have the same situation that we face with $N \times N$-*Checkers*, in that we would not be able to conclude that instances of some fixed size (say n = 1,000) are hard to compute. For that, we would seem to need the stronger assumption that there are problems in NP that require very large circuits; in fact, this is widely conjectured to be true.

Although it is conjectured that deterministic machines require exponential time to simulate nondeterministic machines, it is worth noting that the situation is very different when memory bounds are considered instead. A classic theorem of complexity theory states that a nondeterministic machine using space $s(n)$ can be simulated by a deterministic machine in space $s(n)^2$. Thus, if we define NPSPACE and NEXPSPACE by analogy to PSPACE and EXPSPACE using nondeterministic machines, we obtain the equalities PSPACE = NPSPACE and EXPSPACE = NEXPSPACE.

We thus have the following six complexity classes:

$$\mathrm{P} \subseteq \mathrm{NP} \subseteq \mathrm{PSPACE} \subseteq \mathrm{EXP} \subseteq \mathrm{NEXP} \subseteq \mathrm{EXPSPACE}$$

Diagonalization arguments tell us that $\mathrm{P} \neq \mathrm{EXP}$, $\mathrm{NP} \neq \mathrm{NEXP}$, and $\mathrm{PSPACE} \neq \mathrm{EXPSPACE}$. All other relationships are unknown. For instance, it is unknown whether P = PSPACE, and it is also unknown whether PSPACE = NEXP (although at most one of these two equalities can hold). Many in the community conjecture that all of these classes are distinct, and that no significant improvement on any of these inclusions can be proved. (That is, many people conjecture that there are problems in NP that require exponential time on deterministic machines, that there are problems in PSPACE that require exponential time on nondeterministic machines, that there are problems in EXP that require exponential space, etc.) These conjectures have remained unproven since they were first posed in the 1970s.

A THEORY TO EXPLAIN OBSERVED DIFFERENCES IN COMPLEXITY

It is traditional to draw a distinction between mathematics and empirical sciences such as physics. In mathematics, one starts with a set of assumptions and derives (with certainty) the consequences of the assumptions. In contrast, in a discipline such as physics one starts with external reality and formulates theories to try to explain (and make predictions about) that reality.

For some decades now, the field of computational complexity theory has dwelt in the uncomfortable region between mathematics and the empirical sciences. Complexity theory is a mathematical discipline; progress is measured by the strength of the theorems that are proved. However, despite rapid and exciting progress on many fronts, the fundamental question of whether P is equal to NP remains unsolved.

Until that milestone is reached, complexity theory can still offer to the rest of the computing community some of the benefits of an empirical science, in the following sense. All of our observations thus far indicate that certain problems (such as the Traveling Salesman Problem) are intractible. Furthermore, we can observe that with surprisingly few exceptions, natural and interesting computational problems can usually be shown to be complete for one of a handful of well-studied complexity classes. Even though we cannot currently *prove* that some of these complexity classes are distinct, the fact that these complexity classes correspond to natural or unnatural models of computation gives us an intuitively appealing explanation for *why* these classes appear to be distinct. That is, complexity theory gives us a vocabulary and a set of plausible conjectures that helps explain our observations about the differing computational difficulty of various problems.

NP AND PROVABILITY

There are important connections between NP and mathematical logic. One equivalent way of defining NP is to say that a set A is in NP if and only if there are short *proofs* of membership in A. For example, consider the Traveling Salesman Problem. If there is a short cycle that visits all cities, then there is a short *proof* of this fact: Simply present the cycle and compute its length. Contrast this with the task of trying to prove that there is *not* a short cycle that visits all cities. For certain graphs this is possible, but nobody has found a general approach that is significantly better than simply listing all (exponentially many) possible cycles, and showing that all of them are too long. That is, for NP-complete problems A, it seems to be the case that the complement of A (denoted co-A) is not in NP.

The complexity class coNP is defined to be the set of all complements of problems in NP; $\mathrm{coNP} = \{\mathrm{co} - A : A \in \mathrm{NP}\}$. This highlights what appears to be a fundamental difference between deterministic and nondeterministic computation. On a deterministic machine, a set and its complement always have similar complexity. On nondeterministic machines, this does not appear to be true (although if one could prove this, one would have a proof that P is different from NP).

To discuss the connections among NP, coNP, and logic in more detail, we need to give some definitions related to propositional logic. A propositional logic formula consists of variables (which can take on the values True and False), along with the connectives And, Or, and Not. A formula is said to be *satisfiable* if there is some assignment of truth values to the variables that causes it to evaluate to True; it is said to be a *tautology* if *every* assignment of truth values to the variables causes it to evaluate to True. SAT is the set of all satisfiable formulas; TAUT is the set of all tautologies. Note that the formula ϕ is in SAT if and only if "Notϕ" is not in TAUT.

SAT is complete for NP; TAUT is complete for coNP. [This famous theorem is sometimes known as "Cook's Theorem" (5) or the "Cook-Levin Theorem" (6).]

Logicians are interested in the question of how to *prove* that a formula is a tautology. Many proof systems have been developed; they are known by such names as *resolution*, *Frege systems*, and *Gentzen calculus*. For some of these systems, such as resolution, it is known that certain tautologies of n symbols require proofs of length nearly 2^n(7). For Frege systems and proofs in the Gentzen calculus, it is widely suspected that similar bounds hold, although this remains unknown. Most logicians suspect that for *any* reasonable proof system, some short tautologies will require very long proofs. This is equivalent to the conjecture that NP and coNP are different classes; if every tautology had a short proof, then a nondeterministic machine could "guess" the proof and accept if the proof is correct. As TAUT is complete for coNP, this would imply that NP = coNP.

The P versus NP question also has a natural interpretation in terms of logic. Two tasks that occupy mathematicians are as follows:

1. Finding proofs of theorems.
2. Reading proofs that other people have found.

Most mathematicians find the second task to be considerably simpler than the first one. This can be posed as a computational problem. Let us say that a mathematician wants to prove a theorem ϕ and wants the proof to be at most 40 pages long. A nondeterministic machine can take as input ϕ followed by 40 blank pages, and "guess" a proof, accepting if it finds a legal proof. If P = NP, the mathematician can thus determine fairly quickly whether there is a short proof. A slight modification of this idea allows the mathematician to efficiently *construct* the proof (again, assuming that P = NP). That is, the conjecture that P is different than NP is consistent with our intuition that finding proofs is more difficult than verifying that a given proof is correct.

In the 1990s researchers in complexity theory discovered a very surprising (and counterintuitive) fact about logical proofs. Any proof of a logic statement can be *encoded* in such a way that it can be verified by picking a few bits at random and checking that these bits are sufficiently consistent. More precisely, let us say that you want to be 99.9% sure that the proof is correct. Then there is some constant k and a procedure such that, no matter how long the proof is, the procedure flips $O(\log n)$ coins and picks k bits of the encoding of the proof, and then does some computation, with the property that, if the proof is correct, the procedure accepts with probability one, and if the proof is incorrect, then the procedure detects that there is a flaw with probability at least 0.999. This process is known as a *probabilistically checkable proof*. Probabilistically checkable proofs have been very useful in proving that, for many optimization algorithms, it is NP-complete not only to find an optimal solution, but even to get a very rough approximation to the optimal solution.

Some problems in NP are widely believed to be intractable to compute, but are not believed to be NP-complete. Factoring provides a good example. The problem of computing the prime factorization of a number can be formulated in several ways; perhaps the most natural way is as the set FACTOR = {(x, i, b): the ith bit of the encoding of the prime factorization of x is b}. By making use of the fact that primality testing lies in P (8), set FACTOR is easily seen to lie in NP ∩ coNP. Thus, FACTOR cannot be NP-complete unless NP = coNP.

OTHER COMPLEXITY CLASSES: COUNTING, PROBABILISTIC, AND QUANTUM COMPUTATION

Several other computational problems appear to be intermediate in complexity between NP and PSPACE that are related to the problem of *counting* how many accepting paths a nondeterministic machine has. The class #P is the class of functions f for which there is an NP machine M with the property that, for each string x, $f(x)$ is the number of guess sequences r that cause M to accept input x. #P is a class of *functions*, instead of being a class of *sets* like all other complexity classes that we have discussed. #P is equivalent in complexity to the class PP (probabilistic polynomial time) defined as follows. A set A is in PP if there is an NP machine M such that, for each string x, x is in A if and only if more than half of the guess sequences cause M to accept x. If we view the guess sequences as flips of a fair coin, this means that x is in A if and only the probability that M accepts x is greater than one half. It is not hard to see that both NP and coNP are subsets of PP; thus this is not a very "practical" notion of probabilistic computation.

In practice, when people use probabilistic algorithms, they want to receive the correct answer with *high* probability. The complexity class that captures this notion is called BPP (bounded-error probabilistic polynomial time). Some problems in BPP are not known to lie in P; a good example of such a problem takes two algebraic circuits as input and determines whether they compute the same function.

Early in this article, we mentioned quantum computation. The class of problems that can be solved in polynomial time with low error probability using quantum machines is called BQP (bounded-error quantum polynomial time). FACTOR (the problem of finding the prime factorization of a number) lies in BQP (2). The following inclusions are known:

$$\mathrm{P} \subseteq \mathrm{BPP} \subseteq \mathrm{BQP} \subseteq \mathrm{PP} \subseteq \mathrm{PSPACE}$$
$$\mathrm{P} \subseteq \mathrm{NP} \subseteq \mathrm{PP}$$

No relationship is known between NP and BQP or between NP and BPP. Many people conjecture that neither NP nor BQP is contained in the other.

In contrast, many people now conjecture that BPP = P, because it has been proved that if there is any problem computable in time 2^n that requires circuits of nearly exponential size, then there is an efficient deterministic simulation of any BPP algorithm, which implies that P = BPP (9). This theorem is one of the most important in a field that has come to be known as *derandomization*, which studies how to simulate probabilistic algorithms deterministically.

INSIDE P

Polynomial-time reducibility is a very useful tool for clarifying the complexity of seemingly intractible problems, but it is of no use at all in trying to draw distinctions among problems in P. It turns out that some very useful distinctions can be made; to investigate them, we need more refined tools.

Logspace reducibility is one of the most widely used notions of reducibility for investigating the structure of P; a logspace reduction f is a polynomial-time reduction with the additional property that there is a Turing machine computing f that has (1) a read-only input tape, (2) a write-only output tape, and (3) the only other data structure it can use is a read/write worktape, where it uses only $O(\log n)$ locations on this tape on inputs of length n. If A is logspace-reducible to B, then we denote this by $A \leq_m^{log} B$. Imposing this very stringent memory restriction seems to place severe limitations on polynomial-time computation; many people conjecture that many functions computable in polynomial time are not logspace-computable. However, it is also true that the full power of polynomial time is not exploited in most proofs of NP-completeness. For essentially all natural problems that have been shown to be complete for the classes NP, PP, PSPACE, EXP, and so on using polynomial-time reducibility, it is known that they are also complete under logspace reducibility. That is, for large classes, logspace reducibility is essentially as useful as polynomial-time reducibility, but logspace reducibility offers the advantage that it can be used to find distinctions among problems in P.

Logspace-bounded Turing machines give rise to some natural complexity classes inside P: If the characteristic function of a set A is a logspace reduction as defined in the preceding paragraph, then A lies in the complexity class L. The analogous class, defined in terms of nondeterministic machines, is known as NL. The class #P also has a logspace analog, known as #L. These classes are of interest primarily because of their complete sets. Some important complete problems for L are the problem of determining whether two trees are isomorphic, testing whether a graph can be embedded in the plane, and the problem of determining whether an undirected graph is connected (10). Determining whether a *directed* graph is connected is a standard complete problem for NL, as is the problem of computing the length of the shortest path between two vertices in a graph. The complexity class #L characterizes the complexity of computing the determinant of an integer matrix as well as several other problems in linear algebra.

There are also many important complete problems for P under logspace reducibility, such as the problem of evaluating a Boolean circuit, linear programming, and certain network flow computations. In fact, there is a catalog of P-complete problems (11) that is nearly as impressive as the list of NP-complete problems (4). Although many P-complete problems have very efficient algorithms in terms of time complexity, there is a sense in which they seem to be resistent to extremely fast parallel algorithms. This is easiest to explain in terms of circuit complexity. The *size* of a Boolean circuit can be measured in terms of either the number of gates or the number of wires that connect the gates. Another important measure is the *depth* of the circuit: the length of the longest path from an input gate to the output gate. The problems in L, NL, and #L all have circuits of polynomial size and very small depth ($O(\log^2 n)$). In contrast, all polynomial-size circuits for P-complete problems seem to require a depth of at least $n^{1/k}$.

Even a very "small" complexity class such as L has an interesting structure inside it that can be investigated using a more restricted notion of reducibility than $\leq_m^{log}$ that is defined in terms of very restricted circuits. Further information about these small complexity classes can be found in the textbook by Vollmer (12).

We have the inclusions $\mathrm{L} \subseteq \mathrm{NL} \subseteq \mathrm{P} \subseteq \mathrm{NP} \subseteq \mathrm{PP} \subseteq \mathrm{PSPACE}$. Diagonalization shows that $\mathrm{NL} \neq \mathrm{PSPACE}$, but no other separations are known. In particular, it remains unknown whether the "large" complexity class PP actually coincides with the "small" class L.

TIME-SPACE TRADEOFFS

Logspace reducibility (and in general the notion of Turing machines that have very limited memory resources) allows the investigation of another aspect of complexity: the tradeoff between time and space. Take, for example, the problem of determining whether an undirected graph is connected. This problem can be solved using logarithmic space (10), but currently all "space-efficient" algorithms that are known for this problem are so slow that they will never be used in practice, particularly because this problem can be solved in linear time (using linear space) using a standard depth-first-search algorithm. However, there is no strong reason to believe that no fast small-space algorithm for graph connectivity *exists* (although there have been some investigations of this problem, using "restricted" models of computation, of the type that were discussed at the start of this article).

Some interesting time-space tradeoffs have been proved for the NP-complete problem SAT. Recall that it is still unknown whether SAT lies in the complexity class L. Also, although it is conjectured that SAT is not solvable in time n^k for any k, it remains unknown whether SAT is solvable in time $O(n)$. However, it *is* known that if SAT *is* solvable in linear time, then any such algorithm must use much more than logarithmic space. In fact, any algorithm that solves SAT in time $n^{1.7}$ must use memory $n^{1/k}$ for some k(13,14).

CONCLUSION

Computational complexity theory has been very successful in providing a framework that allows us to understand why several computational problems have resisted all efforts to find efficient algorithms. In some instances, it has been possible to prove very strong intractibility theorems, and in many other cases, a widely believed set of conjectures explains why certain problems appear to be hard to compute. The field is evolving rapidly; several developments discussed here are only a few years old. Yet the central questions (such as the infamous P vs. NP question) remain out of reach today.

By necessity, a brief article such as this can touch on only a small segment of a large field such as computational complexity theory. The reader is urged to consult the texts listed below, for a more comprehensive treatment of the area.

C

COMPUTATIONAL NUMBER THEORY

In the contemporary study of mathematics, number theory stands out as a peculiar branch, for many reasons. Most development of mathematical thought is concerned with the identification of certain structures and relations in these structures. For example, the study of algebra is concerned with different types of operators on objects, such as the addition and multiplication of numbers, the permutation of objects, or the transformation of geometric objects—and the study of algebra is concerned with the classification of the many such types of operators.

Similarly, the study of analysis is concerned with the properties of operators that satisfy conditions of continuity.

Number theory, however, is the study of the properties of those few systems that arise naturally, beginning with the natural numbers (which we shall usually denote $\mathbb{N}$), progressing to the integers ($\mathbb{Z}$), the rationals ($\mathbb{Q}$), the reals ($\mathbb{R}$), and the complex numbers ($\mathbb{C}$). Rather than identifying very general principles, number theory is concerned with very specific questions about these few systems.

For that reason, for many centuries, mathematicians thought of number theory as the purest form of inquiry. After all, it was not inspired by physics or astronomy or chemistry or other "applied" aspects of the physical universe. Consequently, mathematicians could indulge in number theoretic pursuits while being concerned only with the mathematics itself.

But number theory is a field with great paradoxes. This purest of mathematical disciplines, as we will see below, has served as the source for arguably the most important set of applications of mathematics in many years!

Another curious aspect of number theory is that it is possible for a very beginning student of the subject to pose questions that can baffle the greatest minds. One example is the following: It is an interesting observation that there are many triples of natural numbers (in fact, an infinite number) that satisfy the equation $x^2 + y^2 = z^2$. For example, $3^2 + 4^2 = 5^2$, $5^2 + 12^2 = 13^2$, $7^2 + 24^2 = 25^2$, and so on.

However, one might easily be led to the question, can we find (nonzero) natural numbers x, y, and z such that $x^3 + y^3 = z^3$? Or, indeed, such that $x^n + y^n = z^n$, for any natural number $n > 2$ and nonzero integers x, y and z?

The answer to this simple question was announced by the famous mathematician, Pierre Auguste de Fermat, in his last written work in 1637. Unfortunately, Fermat did not provide a proof but only wrote the announcement in the margins of his writing. Subsequently, this simply stated problem became known as "Fermat's Last Theorem," and the answer eluded the mathematics community for 356 years, until 1993, when it was finally solved by Andrew Wiles (1).

The full proof runs to over 1000 pages of text (no, it will not be reproduced here) and involves mathematical techniques drawn from a wide variety of disciplines within mathematics. It is thought to be highly unlikely that Fermat, despite his brilliance, could have understood the true complexity of his "Last Theorem." (Lest the reader leave for want of the answer, what Wiles proved is that there are no possible nonzero x, y, z, and $n > 2$ that satisfy the equation.)

Other questions that arise immediately in number theory are even more problematic than Fermat's Last Theorem. For example, a major concern in number theory is the study of prime numbers—those natural numbers that are evenly divisible only by themselves and 1. For example, 2, 3, 5, 7, 11, and 13 are prime numbers, whereas 9, 15, and any even number except 2 are not (1, by convention, is not considered a prime).

One can easily observe that small even numbers can be described as the sum of two primes: $2 + 2 = 4$, $3 + 3 = 6$, $3 + 5 = 8$, $3 + 7 = 5 + 5 = 10$, $5 + 7 = 12$; $7 + 7 = 14$, and so on. One could ask, can all even numbers be expressed as the sum of two primes? Unfortunately, no one knows the answer to this question. It is known as the *Goldbach Conjecture,* and fame and fortune (well, fame, anyway) await the person who successfully answers the question (2).

In this article, we will attempt to describe some principal areas of interest in number theory and then to indicate what current research has shown to be an extraordinary application of this purest form of mathematics to several very current and very important applications.

Although this will in no way encompass all of the areas of development in number theory, we will introduce:

Divisibility: At the heart of number theory is the study of the multiplicative structure of the integers under multiplication. What numbers divide (i.e., are factors of) other numbers? What are all the factors of a given number? Which numbers are prime?

Multiplicative functions: In analyzing the structure of numbers and their factors, one is led to the consideration of functions that are *multiplicative*: In other words, a function is multiplicative if $f(a \times b) = f(a) \times f(b)$ for all a and b.

Congruence: Two integers a and b are said to be congruent modulo n (where n is also an integer), and written $a \equiv b \pmod{n}$, if their difference is a multiple of n; alternatively, that a and b yield the same remainder when divided (integer division) by n. The study of the integers under congruence yields many interesting properties and is fundamental to number theory. The modular systems so developed are called modulo n arithmetic and are denoted either $\mathbb{Z}/n\mathbb{Z}$or$\mathbb{Z}_n$.

Residues: In $\mathbb{Z}_n$ systems, solutions of equations (technically, *congruences*) of the form $x^2 \equiv a \pmod{n}$ are often studied. In this instance, if there is a solution for x, a is called a quadratic residue of n. Otherwise, it is called a quadratic nonresidue of n.

Prime numbers: The prime numbers, with their special property that they have no positive divisors other than themselves and 1, have been of continuing interest to number theorists. In this section, we will see, among other things, an estimate of how many prime numbers there are less than some fixed number n.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Diophantine equations: The term *Diophantine equation* is used to apply to a family of algebraic equations in a number system such as $\mathbb{Z}$ or $\mathbb{Q}$. A good deal of research in this subject has been directed at polynomial equations with integer or rational coefficients, the most famous of which being the class of equations $x^n + y^n = z^n$, the subject of Fermat's Last Theorem.

Elliptic curves: A final area of discussion in number theory will be the theory of elliptic curves. Although generally beyond the scope of this article, this theory has been so important in contemporary number theory that some discussion of the topic is in order. An elliptic curve represents the set of points in some appropriate number system that are the solutions to an equation of the form $y^2 = \mathrm{A}x^3 + \mathrm{B}x^2 + \mathrm{C}x + \mathrm{D}$ when A, B, C, D $\in \mathbb{Z}$.

Applications: The final section of this article will address several important applications in business, economics, engineering, and computing of number theory. It is remarkable that this, the purest form of mathematics, has found such important applications, often of theory that is hundreds of years old, to very current problems in the aforementioned fields!

It should perhaps be noted here that many of the results indicated below are given without proof. Indeed, because of space limitations, proofs will only be given when they are especially instructive. Several references will be given later in which proofs of all of the results cited can be found.

DIVISIBILITY

Many questions arising in number theory have as their basis the study of the divisibility of the integers. An integer n is divisible by k if another integer m exists such that $k \times m = n$. We sometimes indicate divisibility of n by k by writing $k|n$ or $k|n$ if n is not divisible by k.

A fundamental result is the division algorithm. Given m, $n \in \mathrm{Z}$, with $n > 0$, unique integers c and d exist such that $m = c \times n + d$ and $0 \leq d < n$.

Equally as fundamental is the Euclidean algorithm.

Theorem 1. Let $m, n \in \mathbb{Z}$, both $m, n \neq 0$. A unique integer c exists satisfying $c > 0, c|m, c|n$; and if $d|m$ and $d|n$, then $d|c$.

Proof. Consider $\{d | d = am + bn, \forall\ a, b \in \mathbb{Z}\}$. Let c^* be the smallest natural number in this set. Then c^* satisfies the given conditions.

Clearly $c^* > 0. c^*|a$, because by the division algorithm, s and t there exist such that $a = cs + t$ with $0 \leq t < u$. Thus, $a = c^*s + t = ams + bns + t$; thus, $a(1{-}ms) + b(-ns) = t$. As $t < c^*$, this implies that $t = 0$, and thus $a = c^*s$ or $c^* \mid a$. Similarly $c^* \mid b$. c^* is unique because, if c' also meets the conditions, then $c^* \mid c$' and c' $\mid c^*$, so c' $= c^*$.

The greatest common divisor of two integers m and n is the largest positive integer [denoted GCD(m,n)] such that GCD(m,n) $\mid m$ and GCD (m,n) $\mid n$.

Theorem 2 (Greatest Common Divisor). The equation $am + bn = r$ has integer solutions $a, b \Leftrightarrow \mathrm{GCD}(m, n)|r$.

Proof. Let $r \neq 0$. It is not possible that GCD(m,n) $\mid r$ because GCD(m,n) $\mid m$ and GCD(m,n) $\mid n$; thus, GCD(m,n) $\mid (am + bn) = r$. By Theorem 1, this means that there exist a', b' such that $a'm + b'n = \mathrm{GCD}(m,n)$.

Thus, $a'' = ra'/\mathrm{GCD}(m,n), b'' = rb'/\mathrm{GCD}(m,n)$ represent an integer solution to $a''m + b''n = r$.

A related concept to the GCD is the least common multiple (LCM). It can be defined as the smallest positive integer that a and b both divide. It is also worth noting that $\mathrm{GCD}(m,n) \times \mathrm{LCM}(m,n) = m \times n$.

Primes

A positive integer $p > 1$ is called prime if it is divisible only by itself and 1. An integer greater than 1 and not prime is called composite. Two numbers m and n with the property that GCD(m,n) = 1 are said to be relatively prime (or sometimes coprime).

Here are two subtle results.

Theorem 3. Every integer greater than 1 is a prime or a product of primes.

Proof. Suppose otherwise. Let n be the least integer that is neither; thus, n is composite. Thus $n = ab$ and a,$b < n$. Thus, a and b are either primes or products of primes, and thus so is their product, n.

Theorem 4. There are infinitely many primes.

Proof (Euclid). If not, let $p_1, \ldots, p_n$ be a list of all the primes, ordered from smallest to largest. Then consider $q = (p_1 p_2 \ldots p_n) + 1$. By the previous statement,

$$q = p'_1 p'_2 \ldots p'_k \tag{1}$$

p'_1 must be one of the $p_1, \ldots, p_n$, say p_j (as these were all the primes), but $p_j \,|\, q$, because it has a remainder of 1. This contradiction proves the theorem.

Theorem 5 (Unique Factorization). Every positive integer has a unique factorization into a product of primes.

Proof. Let

$$\begin{aligned} a &= p_1^{\alpha_1} \ldots p_k^{\alpha_k} = P \\ &= q_1^{\beta_1} \ldots q_m^{\beta_m} = Q \end{aligned} \tag{2}$$

For each p_i, $p_i \mid Q \Rightarrow p_i \mid q_s^{\beta_s}$ for some s, $1 \leq s \leq m$.

Since p_i and q_s are both primes, $p_i = q_s$. Thus, $k = m$ and $Q = p_1^{\beta_1} \ldots p_k^{\beta_k}$. We only need to show that the α_i and β_i are equal. Divide both decompositions P and Q by $p_i^{\alpha_i}$. If $\alpha_i \neq \beta_i$, on the one hand, one decomposition $a/p_i^{\alpha_i}$ will contain p_i, and the other will not. This contradiction proves the theorem.

What has occupied many number theorists was a quest for a formula that would generate all of the infinitely many prime numbers.

For example, Marin Mersenne (1644) examined numbers of the form $M_p = 2^p - 1$, where p is a prime (3). He discovered that some of these numbers were, in fact, primes. Generally, the numbes he studied are known as Mersenne numbers, and those that are prime are called Mersenne primes. For example, $M_2 = 2^2 - 1 = 3$ is prime; as are $M_3 = 2^3 - 1 = 7$; $M_5 = 2^5 - 1 = 31$; $M_7 = 2^7 - 1 = 127$. Alas, $M_{11} = 2^{11} - 1 = 2047 = 23 \times 89$ is not. Any natural number ≥ 2 ending in an even digit 0, 2, 4, 6, 8 is divisible by 2. Any number ≥ 5 ending in 5 is divisible by 5. There are also convenient tests for divisibility by 3 and 9—if the sum of the digits of a number is divisible by 3 or 9, then so is the number; and by 11—if the sum of the digits in the even decimal places of a number, minus the sum of the digits in the odd decimal places, is divisible by 11, then so is the number.

Several other Mersenne numbers have also been determined to be prime. At the current writing, the list includes 42 numbers:

M_n, where $n = 2, 3, 5, 7, 13, 17, 19, 31, 61, 89, 107, 127, 521, 607, 1279, 2203, 2281, 3217, 4253, 4423, 9689, 9941, 11213, 19937, 21701, 23209, 44497, 86243, 110503, 132049, 216091, 756839, 859433, 1257787, 1398269, 2976221, 3021377, 6972593, 13466917, 20996011, 24036583, 25964951$.

With current technology, particularly mathematical software packages such as *Mathematica* or *Maple*, many of these computations can be done rather easily. For example, a one-line program in Mathematica, executing for 6.27 hours on a Pentium PC, was capable of verifying the primality of all M_n up to M_{1000}, and thus determining the first 14 Mersenne primes (up to M_{607}). It is not known whether an infinite number of the Mersenne numbers are prime.

It is known that $m^c - 1$ is composite if $m > 2$ or if c is composite; for if $c = de$, we have:

$$(m^c - 1) = (m^e - 1)(m^{e(d-1)} + m^{e(d-1)} + \ldots + m^{e(d-1)} + 1) \tag{3}$$

We can also show that $m^c + 1$ is composite if m is odd or if c has an odd factor. Certainly if m is odd, m^c is odd, and $m^c + 1$ is even and thus composite. If $c = d(2k + 1)$, then

$$m^c + 1 = (m^d + 1)(m^{2de} - m^{d(2e-1)} + m^{d(2e-2)} - \ldots + 1) \tag{4}$$

and $m^d + 1 > 1$.

Another set of numbers with interesting primality properties are the Fermat numbers, $F_n = 2^{2^n} + 1$. Fermat's conjecture was that they were primes. He was able to verify this for $F_1 = 5$, $F_2 = 17$, $F_3 = 257$, and $F_4 = 2^{16} + 1 = 65537$. But then, Euler showed that

Theorem 6. $641 \mid F_5$.

Proof. $641 = 2^4 + 5^4 = 5 \times 2^7 + 1$; thus $2^4 = 641 - 5^4$. Since $2^{32} = 2^4 \times 2^{28} = 641 \times 2^{28} - (5 \times 2^7)^4 = 641 \times 2^{28} - (641 - 1)^4 = 641\text{k} - 1$.

To this date, no other Fermat numbers F_n with $n > 4$ have been shown to be prime. It has been determined that the other Fermat numbers through F_{20} are composite.

MULTIPLICATIVE FUNCTIONS

Functions that preserve the multiplicative structure of the number systems studied in number theory are of particular interest, not only intrinsically, but also for their use in determining other relationships among numbers.

A function f defined on the integers that takes values in a set closed under multiplication is called a *number theoretic function*. If the function preserves multiplication for numbers that are relatively prime ($f(m) \times f(n) = f(m \times n)$), it is called a *multiplicative function*; it is called *completely multiplicative* if the restriction $\text{GCD}(m, n) = 1$ can be lifted.

Consider any number theoretic function f, and define a new function F by the sum of the values of f taken over the divisors of n

$$F(n) = \sum_{d|n} f(d) = \sum_{d|n} f(n/d), \text{ the latter being the former sum in reverse order} \tag{5}$$

Theorem 7. If f is a multiplicative function, then so is F.

Proof. Let $\text{GCD}(m, n) = 1$; then $d \mid mn$ can be uniquely expressed as gh, where $g \mid m, h \mid n$, with $\text{GCD}(g,h) = 1$.

$$\begin{aligned} F(mn) &= \sum_{d|mn} f(d) = \sum_{g|m}\sum_{h|n} f(gh) = \sum_{g|m}\sum_{h|n} f(g)\,f(h) \\ &= \sum_{g|m} f(g)\,f(h_1) + \ldots + \sum_{g|m} f(g)\,f(h_k) \\ &= F(m)\left(\sum_{h|n} f(h)\right) = F(m)F(n) \end{aligned} \tag{6}$$

Two multiplicative functions of note are the divisor function $\tau(n)$ defined as the number of positive divisors of n and the function $\sigma(n)$, defined as the sum of the positive divisors of n.

Theorem 8. τ and σ are multiplicative.

Proof. Both τ and σ are the "uppercase" functions for the obviously multiplicative functions $1(n) = 1$ for all n, and $i(n) = n$ for all n. In other words,

$$\tau(n) = \sum_{d|n} 1(d) \quad \text{and} \quad \sigma(n) = \sum_{d|n} i(d) \tag{7}$$

In order to compute τ and σ for a prime p, note that

$$\tau(p^n) = 1 + n (\text{because the divisors of } p^n \text{ are } 1, p, p^2, \ldots, p^n) \tag{8}$$

$$\sigma(p^n) = 1 + p + p^2 + \ldots + p^n = (p^{n+1} - 1)/(p - 1) \tag{9}$$

Thus, for any $n = p_1a^{n_1}\, p_2a^{n_2} \ldots p_ka^{n_k}$,

$$\tau(n) = \prod_{i=1}^{k}(1 + n_i) \quad \text{and} \quad \sigma(n) = \prod_{i=1}^{k}(p_i^{n_i+1} - 1)/(p_i - 1) \tag{10}$$

In very ancient times, numbers were sometimes considered to have mystical properties. Indeed, the Greeks identified numbers that they called perfect: numbers that were exactly the sums of all their proper divisors, in other words, that $\sigma(n) = n$. A few examples are $6 = 1 + 2 + 3$, $28 = 1 + 2 + 4 + 7 + 14$, and $496 = 1 + 2 + 4 + 8 + 16 + 31 + 62 + 124 + 248$. It is not known whether there are any odd perfect numbers, or if an infinite number of perfect numbers exists.

Theorem 9. n is even and perfect $\Leftrightarrow n = 2^{p-1}(2^p - 1)$ where both p and $2^p - 1$ are primes.

In other words, there is one perfect number for each Mersenne prime.

Another multiplicative function of considerable importance is the Möbius function μ.

$\mu(1) = 1$; $\mu(n) = 0$ if n has a square factor; $\mu(p_1, p_2 \ldots p_k) = (-1)^k$ if $p_1, \ldots, p_k$ are distinct primes.

Theorem 10. μ is multiplicative, and the “uppercase” function is 0 unless $n = 1$, when it takes the value 1.

Theorem 11. (Möbius Inversion Formula). If f is a number theoretic function and $F(n) = \sum_{d|n} f(d)$, then

$$f(n) = \sum_{d/n} F(d)\mu(n/d) = \sum_{d/n} F(n/d)\mu(n) \qquad (11)$$

Proof.

$$\sum_{d/n} \mu(d)F(n/d)$$

$$= \sum_{d_1d_2=n} \mu(d_1)F(n/d_2) \text{ (taking pairs } d_1d_2 = n) \qquad (12)$$

$$= \sum_{d_1d_2=n} [\mu(d_1) \sum_{d|d_2} f(d)] \text{ (definition of } F) \qquad (13)$$

$$= \sum_{d_r d|n} \mu(d_1)\, f(d) \text{ (multiplying the terms in brackets)} \qquad (14)$$

$$= \sum_{d|n} f(d) \sum_{d_1|(n/d)} \mu(d_1) \text{ (collecting multiples of } f(d)) \qquad (15)$$

$$= f(n)$$

Theorem 12. If F is a multiplicative function, then so is f.

A final multiplicative function of note is the Euler function $\phi(n)$. It is defined for n to be the number of numbers less than n and relatively prime to n. For primes p, $\phi(p) = p-1$.

Theorem 13. ϕ is multiplicative.

CONGRUENCE

The study of congruence leads to the definition of new algebraic systems derived from the integers. These systems, called *residue systems*, are interesting in and of themselves, but they also have properties that allow for important applications.

Consider integers a, b, n with $n > 0$. Note that a and b could be positive or negative. We will say that *a is congruent to b, modulo n* [written $a \equiv b \pmod{n}$] $\Leftrightarrow n|(a - b)$. Alternatively, a and b yield the same remainder when divided by n. In such a congruence, n is called the modulus and b is called a residue of a.

An algebraic system can be defined by considering classes of all numbers satisfying a congruence with fixed modulus. It is observed that congruence is an equivalence relation and that the definition of addition and multiplication of integers can be extended to the equivalence classes. Thus, for example, in the system with modulus 5 (also called mod 5 arithmetic), the equivalence classes are $\{\ldots,-5,0,5,\ldots\}$, $\{\ldots,-4,1,6,\ldots\}$, $\{\ldots,-3,2,7,\ldots\}$, $\{\ldots,-2,3,8,\ldots\}$, and $\{\ldots,-1,4,9,\ldots\}$. It is customary to denote the class by the (unique) representative of the class between 0 and $n-1$. Thus the five classes in mod 5 arithmetic are denoted 0, 1, 2, 3, 4. Formally, the mod n system can be defined as the algebraic quotient of the integers $\mathbb{Z}$ and the subring defined by the multiples of n ($n\mathbb{Z}$). Thus, the mod n system is often written $\mathbb{Z}/n\mathbb{Z}$. An alternative, and more compact notation, is $\mathbb{Z}_n$.

Addition and multiplication are defined naturally in $\mathbb{Z}_n$. Under addition, every $\mathbb{Z}_n$ forms an Abelian group [that is, the addition operation is closed, associative, and commutative; 0 is an identity; and each element has an additive inverse—for any a, $b = n-a$ always yields $a + b \equiv 0 \pmod{n}$].

In the multiplicative structure, however, only the closure, associativity, commutativity, and identity (1) are assured. It is not necessarily the case that each element will have an inverse. In other words, the congruence $ax \equiv 1 \pmod{n}$ will not always have a solution.

Technically, an algebraic system with the properties described above is called a *commutative ring with identity*. If it is also known that, if each (nonzero) element of $\mathbb{Z}_n$ has an inverse, the system would be called a *field*.

Theorem 14. Let a, b, n be integers with $n > 0$. Then $ax \equiv 1 \pmod{n}$ has a solution $\Leftrightarrow$ GCD$(a, n) = 1$. If x_0 is a solution, then there are exactly GCD(a,n) solutions given by $\{x_0, x_0 + n/\text{GCD}(a,n), x_0 + 2n/\text{GCD}(a,n), \ldots, x_0 + (\text{GCD}(a,n) -1)n/\text{GCD}(a,n)\}$.

Proof. This theorem is a restatement of Theorem 2.

For an element a in $\mathbb{Z}_n$ to have an inverse, alternatively to be a unit, by the above theorem, it is necessary and sufficient for a and n to be relatively prime; i.e., GCD$(a,n) = 1$. Thus, by the earlier definition of the Euler function, the number of units in $\mathbb{Z}_n$ is $\phi(n)$.

The set of units in $\mathbb{Z}_n$ is denoted $(\mathbb{Z}_n)^*$, and it is easily verified that this set forms an Abelian group under multiplication. As an example, consider $\mathbb{Z}_{12}$ or $\mathbb{Z}/12\mathbb{Z}$. Note that $(Z_{12})^* = \{1,5,7,11\}$, and that each element is its own inverse: $1 \times 1 \equiv 5 \times 5 \equiv 7 \times 7 \equiv 11 \times 11 \equiv 1 \pmod{12}$. Further more, closure is observed because $5 \times 7 \equiv 11$, $5 \times 11 \equiv 7$, and $7 \times 11 \equiv 5 \pmod{12}$.

Theorem 15. If p is a prime number, then $\mathbb{Z}_p$ is a field with p elements. If n is composite, $\mathbb{Z}_n$ is not a field.

Proof. If p is a prime number, every element $a \in (\mathbb{Z}_p)^*$ is relatively prime to p; that is, GCD(a,p) = 1. Thus $ax \equiv 1$ (mod p) always has a solution. As every element in $(\mathbb{Z}_p)^*$ has an inverse, $(\mathbb{Z}_p)^*$ is a field. If n is composite, there are integers $1 < k,\ l < n$ such that $kl = n$. Thus, $kl \equiv 0$ (mod n), and so it is impossible that k could have an inverse. Otherwise, $l \equiv (k^{-1}k) \times l \equiv k^{-1}(k \times l) \equiv k^{-1} \times 0 \equiv 0 \pmod{n}$, which contradicts the assumption that $l < n$.

One of the most important results of elementary number theory is the so-called *Chinese Remainder Theorem*(4). It is given this name because a version was originally derived by the Chinese mathematician Sun Tse almost 2000 years ago. The Chinese Remainder Theorem establishes a method of solving simultaneously a system of linear congruences in several modular systems.

Theorem 16 (Chinese Remainder). Given a system $x \equiv a_i$ (mod n_i), $i = 1,2,\ldots m$. Suppose that, for all $i = j$, GCD(n_i,n_j) = 1. Then there is a unique common solution modulo $n = n_1n_2\ldots n_m$.

Proof (By construction). Let $n_i' = n/n_i$, $i = 1,\ldots,m$. Note that GCD(n_i,n_i') = 1. Thus, an integer exists n_i'' such that $n_i'n_i'' \equiv 1$(mod n_i). Then

$$x \equiv a_1n_1'n_1'' + a_2n_2'n_2'' + \cdots + a_mn_m'n_m''(\bmod n) \quad (16)$$

is the solution. As $n_i \mid n_j'$ if $i \neq j$, $x \equiv a_in_i'n_i'' \equiv a_i$ (mod n_i). The solution is also unique. If both x and y are common solutions, then $x - y \equiv 0$ (mod n).

An interesting consequence of this theorem is that there is a $1 - 1$ correspondence, preserved by addition and multiplication, of integers modulo n, and m-tuples of integers modulo n_i(5). Consider $\{n_1,n_2,n_3,n_4\} = \{7,11,13,17\}$, and $n = 17017$. Then

$$95 \rightarrow (\mathrm{a}_1, \mathrm{a}_2, \mathrm{a}_3, \mathrm{a}_4) = (95 \bmod 7, 95 \bmod 11, 95 \bmod 13, 95 \bmod 17) = (4,7,4,10) \text{ also } 162 \rightarrow (1,8,6,9)$$

Performing addition and multiplication tuple-wise:

$$(4,7,4,10) + (1,8,6,9) = (5 \bmod 7,\ 15 \bmod 11,\ 10 \bmod 13, 19 \bmod 17) = (5,4,10,2); (4,7,4,10) \times (1,8,6,9) = (4 \bmod 7, 56 \bmod 11, 24 \bmod 13, 90 \bmod 17) = (4,1,11,5)$$

Now verify that $95 + 162 = 257$ and $95 \times 162 = 15{,}390$ are represented by (5,4,10,2) and (4,1,11,5) by reducing each number mod $n_1, \ldots, n_4$.

Another series of important results involving the products of elements in modular systems are the theorems of Euler, Fermat, and Wilson. Fermat's Theorem, although extremely important, is very easily proved; thus, it is sometimes called the "Little Fermat Theorem" in contrast to the famous Fermat's Last Theorem described earlier.

Theorem 17 (Euler). GCD If(a,n) = 1, then $a^{\phi(n)} \equiv 1 \pmod{n}$.

Theorem 18 (Fermat). If p is prime, then $a^p \equiv a \pmod{p}$.

Proof (of Euler's Theorem). Suppose $A = \{a_1,\ldots,a_{\phi(n)}\}$ is a list of the set of units in $\mathbb{Z}_n$. By definition, each of the a_i has an inverse a_i^{-1}. Now consider the product $b = a_1a_2\ldots a_{\phi(n)}$. It also has an inverse, in particular $b^{-1} = a_1^{-1}a_2^{-1}\cdots a_{\phi_{(n)}}^{-1}$. Choose any of the units; suppose it is a. Now consider the set $A' = \{aa_1, aa_2, aa_{\phi_{(n)}}\}$. We need to show that as a set, $A' = A$. It is sufficient to show that the aa_i are all distinct. As there are $\phi(n)$ of them, and they are all units, they represent all of the elements of A.

Suppose that $aa_i \equiv aa_j$ for some $i \neq j$. Then, as a is a unit, we can multiply by a^{-1}, yielding $(a^{-1}a)a_i \equiv (a^{-1}a)a_j$ or $a_i \equiv a_j$ (mod n), which is a contradiction. Thus, the aa_i are all distinct and $A = A'$.

Now compute

$$\prod_{i=1}^{\phi(n)}(aa_i) \equiv b(\bmod n) \text{ because } A = A' \quad (17)$$

$$a^{\phi(n)}b \equiv b(\bmod n)$$

$$a^{\phi_{(n)}}bb^{-1} \equiv bb^{-1}(\bmod n) \text{ multiplying by } b^{-1}$$
$$a^{\phi_{(n)}} \equiv 1(\bmod n) \quad (18)$$

Although the Chinese Remainder Theorem gives a solution for linear congruences, one would also like to consider nonlinear or higher degree polynomial congruences. In the case of polynomials in one variable, in the most general case,

$$f(x) \equiv 0(\bmod n) \quad (19)$$

If $n = p_1^{a1} \cdots p_k^{ak}$ is the factorization of n, then the Chinese Remainder Theorem assures solutions of (19) ⇔ each of

$$f(x) \equiv 0(\bmod p_i^{a_i})\ i = 1, 2, \ldots, k \quad (20)$$

has a solution.

As $\phi(p) = p - 1$ for p a prime, Fermat's Theorem is a direct consequence of Euler's Theorem.

Other important results in the theory of polynomial congruences are as follows:

Theorem 19 (Lagrange). If $f(x)$ is a nonzero polynomial of degree n, whose coefficients are elements of $\mathbb{Z}_p$ for a prime p, then $f(x)$ cannot have more than n roots.

Theorem 20 (Chevalley). If $f(x_1,\ldots,x_n)$ is a polynomial with degree less than n, and if the congruence

$$f(x_1, x_2, \ldots, x_n) \equiv 0(\bmod p)$$

has either zero or at least two solutions.

The Lagrange Theorem can be used to demonstrate the result of Wilson noted above.

Theorem 21 (Wilson). If p is a prime, then $(p-1)! \equiv -1$ (mod p).

Proof. If $p = 2$, the result is obvious. For p an odd prime, let

$$f(x) = x^{b-1} - (x-1)(x-2)\ldots(x-p+1) - 1.$$

Consider any number $1 \le k \le p - 1$. Substituting k for x causes the term $(x-1)(x-2)\ldots(x-p+1)$ to vanish; also, by Fermat's theorem, $k^{p-1} \equiv 1 (\mathrm{mod}\ p)$. Thus, $f(k) \equiv 0 (\mathrm{mod}\ p)$. But k has degree less than $p - 1$; and so by Lagrange's theorem, $f(x)$ must be identically zero, which means all of the coefficients must be divisible by p. The constant coefficient is

$$-1 - (p-1)!(\mathrm{mod}\ p)$$

and thus

$$(p-1)! \equiv -1 (\mathrm{mod}\ p)$$

QUADRATIC RESIDUES

Having considered general polynomial congruences, now we restrict consideration to quadratics. The study of quadratic residues leads to some useful techniques as well as having important and perhaps surprising results.

The most general quadratic congruence (in one variable) is of the form $ax^2 + bx + c \equiv 0$ (mod m). Such a congruence can always be reduced to a simpler form. For example, as indicated in the previous section, by the Chinese remainder theorem, we can assume the modulus is a prime power. As in the case $p = 2$ we can easily enumerate the solutions, we will henceforth consider only odd primes. Finally, we can use the technique of "completing the square" from elementary algebra to transform the general quadratic into one of the form $x^2 \equiv a$ (mod p).

If $p + a$, then if $x^2 \equiv a$ (mod p) is soluble, a is called a quadratic residue mod p; if not, a is called a quadratic nonresidue mod p.

Theorem 22. Exactly one half of the integers a, $1 \le a \le p - 1$, are quadratic residues mod p.

Proof. Consider the set of mod p values $QR = \{1^2, 2^2, \ldots, ((p-1)/2)^2\}$. Each of these values is a quadratic residue. If the values in QR are all distinct, there are at least $(p-1)/2$ quadratic residues. Suppose two of these values, say t and u, were to have $t^2 \equiv u^2$ (mod p). Then since $t^2 - u^2 \equiv 0$ (mod p) $\Rightarrow t + u \equiv 0$ (mod p) or $t - u \equiv 0$ (mod p). Since t and u are distinct, the second case is not possible; and since t and u must be both $< (p-1)/2$, so $t + u < p$ and neither is the first case. Thus there are at least $(p-1)/2$ quadratic residues.

If x_0 solves $x^2 \equiv a$ (mod p), then so does $p - x_0$, since $p^2 - 2px_0 + x_0^2 \equiv x_0^2 \equiv a(\mathrm{mod}\ p)$, and $p - x_0 T x_0$ (mod p). Thus we have found $(p-1)/2$ additional elements of Z_p, which square to elements of QR and therefore $p - 1$ elements overall. Thus there can be no more quadratic residues outside of QR, so the result is proved.

An important number theoretic function to evaluate quadratic residues is the Legendre symbol. For p an odd prime, the Legendre symbol for a (written alternatively (a / p) or $(\binom{a}{p})$) is

$$\binom{a}{p} = \begin{cases} +1 & \text{if } a \text{ is a quadratic residue mod } p \\ 0 & \text{if } p|a \\ -1 & \text{if } a \text{ is a quadratic nonresidue mod } p \end{cases}$$

One method of evaluating the Legendre symbol uses *Euler's criterion*. If p is an odd prime and GCD$(a,p) = 1$, then

$$\binom{a}{p} = 1 \Leftrightarrow a^{(p-1)/2} \equiv 1(\mathrm{mod}\ p)$$

Equivalently, $\binom{a}{p} \equiv a^{(p-1)/2}(\mathrm{mod}\ p)$.

Here are some other characteristics of the Legendre symbol:

Theorem 23. (i) $\binom{ab}{p} = \binom{a}{p}\binom{b}{p}$; (ii) if $a \equiv b$ (mod p), then $\binom{a}{p} = \binom{b}{p}$; (iii) $\binom{a^2}{p} = 1, \binom{1}{p} = 1$; (iv) $\binom{1}{p}(-1/p) = (-1)^{(p-1)/2}$.

Suppose we want to solve $x^2 \equiv 518$ (mod 17). Then, compute $\binom{518}{17} = \binom{8}{17} = \binom{2}{17}$. But $\binom{2}{17} = 1$ since $6^2 = 36 \equiv 2(\mathrm{mod}\ 17)$. Thus, $x^2 \equiv 518$ (mod 17) is soluble.

Computation of the Legendre symbol is aided by the following results. First, define an absolute least residue modulo p as the representation of the equivalence class of a mod p, which has the smallest absolute value.

Theorem 24 (Gauss' Lemma). Let GCD$(a,p) = 1$. If d is the number of elements of $\{a, 2a, \ldots, (p-1)a\}$ whose absolute least residues modulo p are negative, then

$$\binom{a}{p} = (-1)^d$$

Theorem 25. 2 is a quadratic residue (respectively, quadratic nonresidue) of primes of the form $8k \pm 1$ (respectively, $8k \pm 3$). That is,

$$\binom{2}{p} = (-1)^{(p^2-1)/8}$$

Theorem 26. (i) If $k > 1$, $p = 4k + 3$, and p is prime, then $2p + 1$ is also prime $\Leftrightarrow 2^p \equiv 1$ (mod $2p + 1$).

(ii) If $2p + 1$ is prime, then $2p + 1 \mid M_p$, the pth Mersenne number, and M_p is composite.

A concluding result for the computation of the Legendre symbol is one that, by itself, is one of the most famous—and surprising—results in all of mathematics. It is called *Gauss' Law of Quadratic Reciprocity*. What makes it so astounding is that it manages to relate prime numbers and their residues that seemingly bear no relationship to one another (6).

Suppose that we have two odd primes, p and q. Then, the Law of Quadratic Reciprocity relates the computation of their Legendre symbols; that is, it determines the quadratic residue status of each prime with respect to the other.

The proof, although derived from elementary principles, is long and would not be possible to reproduce here. Several sources for the proof are listed below.

Theorem 27 (Gauss' Law of Quadratic Reciprocity). $(\genfrac{}{}{0pt}{}{p}{q})(\genfrac{}{}{0pt}{}{q}{p}) = (-1)^{(p-1)(q-1)/4}$.

A consequence of the Law of Quadratic Reciprocity is as follows.

Theorem 28. Let p and q be distinct odd primes, and $a \geq 1$. If $p \equiv \pm\, q \pmod{4a}$, then $(\genfrac{}{}{0pt}{}{a}{p}) = (\genfrac{}{}{0pt}{}{a}{q})$.

An extension of the Legendre symbol is the Jacobi symbol. The Legendre symbol is defined only for primes p. By a natural extension, the Jacobi symbol, also denoted $({}^{a}{}_{n})$, is defined for any $n > 0$, assuming that the prime factorization of n is $p_1 \ldots p_k$, by

$$(\genfrac{}{}{0pt}{}{a}{n})\,[\text{jacobi symbol}] = (\genfrac{}{}{0pt}{}{a}{p_1})(\genfrac{}{}{0pt}{}{a}{p_2})\cdots(\genfrac{}{}{0pt}{}{a}{p_k})[\text{Legendre symbols}]$$

PRIME NUMBERS

The primes themselves have been a subject of much inquiry in number theory. We have observed earlier that there are an infinite number of primes, and that they are most useful in finite fields and modular arithmetic systems.

One subject of interest has been the development of a function to approximate the frequency of occurrence of primes. This function is usually called $\pi(n)$—it denotes the number of primes less than or equal to n.

In addition to establishing various estimates for $\pi(n)$, concluding with the so-called Prime Number Theorem, we will also state a number of famous unproven conjectures involving prime numbers.

An early estimate for $\pi(n)$, by Chebyshev, follows:

Theorem 29 (Chebyshev). If $n > 1$, then $n/(8 \log n) < \pi(n) < 6n/\log n$.

The Chebyshev result tells us that, up to a constant factor, the number of primes is of the order of $n/\log n$. In addition to the frequency of occurrence of primes, the greatest gap between successive primes is also of interest (7).

Theorem 30 (Bertrand's Partition). If $n \geq 2$, there is a prime p between n and $2n$.

Two other estimates for series of primes are as follows.

Theorem 31. $\sum_{p \leq n} (\log p)/p = \log n + O(1)$.

Theorem 32. $\sum_{p \leq n} 1/p = \log\log x + a + O(1/\log x)$

Another very remarkable result involving the generation of primes is from Dirichlet.

Theorem 33 (Dirichlet). Let a and b be fixed positive integers such that GCD$(a,b) = 1$. Then there are an infinite number of primes in the sequence $\{a + bn \mid n = 1, 2, \ldots\}$.

Finally, we have the best known approximation to the number of primes (8).

Theorem 34 (Prime Number Theorem). $\pi(n) \sim n/\log n$. The conjectures involving prime numbers are legion, and even some of the simplest ones have proven elusive for mathematicians. A few examples are the Goldbach conjecture, the twin primes conjecture, the interval problem, the Dirichlet series problem, and the Riemann hypothesis.

Twin Primes. Two primes p and q are called twins if $q = p + 2$. Examples are $(p,q) = (5,7)$; $(11,13)$; $(17,19)$; $(521,523)$. If $\pi_2(n)$ counts the number of twin primes less than n, the twin prime conjecture is that $\pi_2(n) \to \infty$ as $n \to \infty$. It is known, however, that there are infinitely many pairs of numbers (p,q), where p is prime, $q = p + 2$, and q has at most two factors.

Goldbach Conjecture. As stated, this conjecture is that every even number >2, is the sum of two primes. What is known is that every large even number can be expressed as $p + q$, where p is prime and q has at most two factors. Also, it is known that every large odd integer is the sum of three primes.

Interval Problems. It was demonstrated earlier that there is always a prime number between n and $2n$. It is not known, however, whether the same is true for other intervals, for example, such as n^2 and $(n + 1)^2$.

Dirichlet Series. In Theorem 33, a series containing an infinite number of primes was demonstrated. It was not known whether there are other series that have a greater frequency of prime occurrences, at least until recent research by Friedlander and Iwaniec (9), who showed that series of the form $\{a^2 + b^4\}$ not only have an infinite number of primes, but also that they occur more rapidly than in the Dirichlet series.

Riemann Hypothesis. Although the connection to prime numbers is not immediately apparent, the Riemann hypothesis has been an extremely important pillar in the theory of primes. It states that, for the complex function

$$\zeta(s) = \sum_{n=1}^{\infty} n^{-s} \quad s = \sigma + \mathrm{it} \in \mathbb{C}$$

there are zeros at $s = -2, -4, -6, \ldots$, and no more zeros outside of the "critical strip" $0 \leq \sigma \leq 1$. The Riemann hypothesis states that all zeros of ζ in the critical strip lie on the line $s = ½ + \mathrm{it}$.

Examples of important number theoretic problems whose answer depends on the Riemann hypothesis are (*1*) the existence of an algorithm to find a nonresidue mod p in polynomial time and (*2*) if n is composite, there is at least one b for which neither $b^t \equiv 1 (\mathrm{mod}\, n)\, nor\, b^{2^r t} \equiv -1\, (\mathrm{mod}\, n)$. This latter example is important in algorithms needed to find large primes (10).

DIOPHANTINE EQUATIONS

The term *Diophantine equation* is used to apply to a family of algebraic equations in a number system such as $\mathbb{Z}$ or $\mathbb{Q}$. To date, we have certainly observed many examples of Diophantine equations. A good deal of research in this subject has been directed at polynomial equations with integer or rational coefficients, the most famous of which being the class of equations $x^n + y^n = z^n$, the subject of Fermat's Last Theorem.

One result in this study, from Legendre, is as follows.

Theorem 35. Let $a, b, c, \in Z$ such that (i) $a > 0$, b, $c < 0$; (ii) a, b, and c are square-free; and (iii) GCD(a,b) = GCD(b,c) = GCD(a,c) = 1. Then

$$ax^2 + by^2 + cz^2 = 0$$

has a nontrivial integer solution $\Leftrightarrow -ab \in QR(c), -bc \in QR(a)\, and\, -ca \in QR(b)$.

Example. Consider the equation $3x^2 - 5y^2 - 7z^2 = 0$. With $a = 3$, $b = -5$, and $c = -7$, apply Theorem 35. Note that $ab \equiv -1 \pmod 7$, $ac \equiv -1 \pmod 5$, and $bc \equiv -1 \pmod 3$. Thus, all three products are quadratic residues, and the equation has an integer solution. Indeed, the reader may verify that $x = 3$, $y = 2$, and $z = 1$ is one such solution.

Another result, which consequently proves Fermat's Last Theorem in the case $n = 4$, follows. (Incidentally, it has also been long known that Fermat's Last Theorem holds for $n = 3$.)

Theorem 36. $x^4 + y^4 = z^2$ has no nontrivial solutions in the integers.

A final class of Diophantine equations is known generically as Mordell's equation: $y^2 = x^3 + k$. In general, solutions to Mordell's equation in the integers are not known. Two particular solutions are as follows.

Theorem 37. $y^2 = x^3 + m^2 - jn^2$ has no solution in the integers if

(i) $j = 4$, $m \equiv 3 \pmod 4$ and $p \mathbb{T}\, 3 \pmod 4$ when $p \mid n$.
(ii) $j = 1$, $m \equiv 2 \pmod 4$, n is odd, and $p \mathbb{T}\, 3 \pmod 4$ when $p \mid n$.

Theorem 38. $y^2 = x^3 + 2a^3 - 3b^2$ has no solution in the integers if $ab \neq 0$, $a \mathbb{T}\, 1 \pmod 3$, $3 \mid b$, a is odd if b is even, and $p = t^2 + 27u^2$ is soluble in integers t and u if $p \mid a$ and $p \equiv 1$ (mod 3).

ELLIPTIC CURVES

Many recent developments in number theory have come as the byproduct of the extensive research performed in a branch of mathematics known as elliptic curve theory (11).

An elliptic curve represents the set of points in some appropriate number system that are the solutions to an equation of the form $y^2 = Ax^3 + Bx^2 + Cx + D$ when $A, B, C, D \in \mathbb{Z}$.

A major result in this theory is the theorem of Mordell and Weil. If K is any algebraic field, and $C(K)$ the points with rational coordinates on an elliptic curve, then this object $C(K)$ forms a finitely generated Abelian group.

APPLICATIONS

In the modern history of cryptology, including the related area of authentication or digital signatures, dating roughly from the beginning of the computer era, there have been several approaches that have had enormous importance for business, government, engineering, and computing. In order of their creation, they are (*1*) the Data Encryption Standard or DES (1976); (*2*) the Rivest–Shamir–Adelman Public Key Cryptosystem, or RSA (1978); (*3*) the Elliptic Curve Public Key Cryptosystem or ECC (1993); and (*4*) Rijndael or the Advanced Encryption Standard, or AES (2001). RSA, DSS (defined below), and ECC rely heavily on techniques described in this article.

Data Encryption Standard (DES)

DES was developed and published as a U.S. national standard for encryption in 1976 (12). It was designed to transform 64-bit messages to 64-bit ciphers using 56-bit keys. Its structure is important to understand as the model for many other systems such as AES. In particular, the essence of DES is a family of nonlinear transformations known as the S-boxes. The S-box transformation design criteria were never published, however, and so there was often reluctance in the acceptance of the DES. By the mid-1990s, however, effective techniques to cryptanalyze the DES had been developed, and so research began to find better approaches.

Historically, cryptology required that both the sending and the receiving parties possessed exactly the same information about the cryptosystem. Consequently, that information that they both must possess must be communicated in some way. Encryption methods with this requirement, such as DES and AES, are also referred to as "private key" or "symmetric key" cryptosystems.

The Key Management Problem

Envision the development of a computer network consisting of 1000 subscribers where each pair of users requires a separate key for private communication. (It might be instructive to think of the complete graph on n vertices, representing the users; with the $n(n\ -1)/2$ edges corresponding to the need for key exchanges. Thus, in the 1000-user network, approximately 500,000 keys must be exchanged in some way, other than by the network!)

In considering this problem, Diffie and Hellman asked the following question: Is it possible to consider that a key might be broken into two parts, $k = (k_p, k_s)$, such that only k_p is necessary for encryption, while the entire key $k = (k_p, k_s)$ would be necessary for decryption (13)?

If it were possible to devise such a cryptosystem, then the following benefits would accrue. First of all, as the information necessary for encryption does not, a priori, provide an attacker with enough information to decrypt, then there is no longer any reason to keep it secret. Consequently k_p can be made public to all users of the network. A cryptosystem devised in this way is called a public key cryptosystem (PKC).

Furthermore, the key distribution problem becomes much more manageable. Consider the hypothetical network of 1000 users, as before. The public keys can be listed in a centralized directory available to everyone, because the rest of the key is not used for encryption; the secret key does not have to be distributed but remains with the creator of the key; and finally, both parts, public and secret, must be used for decryption.

Therefore, if we could devise a PKC, it would certainly have most desirable features.

In 1978, Rivest, Shamir, and Adelman described a public-key cryptosystem based on principles of number theory, with the security being dependent on the inherent difficulty of factoring large integers.

Factoring

Factoring large integers is in general a very difficult problem (14). The best-known asymptotic running-time solution today is $O(e^{((64n/9))^{1/3}(\log n)^{2/3}})$ for an n-bit number. More concretely, in early 2005, a certain 200-digit number was factored into two 100-digit primes using the equivalent of 75 years of computing time on a 2.2-GHz AMD Opteron processor.

Rivest–Shamir–Adelman Public Key Cryptosystem (RSA)

The basic idea of Rivest, Shamir, and Adelman was to take two large prime numbers, p and q (for example, p and q each being $\sim 10^{200}$, and to multiply them together to obtain $n = pq$. n is published. Furthermore, two other numbers, d and e, are generated, where d is chosen randomly, but relatively prime to the Euler function $\phi(n)$ in the interval [max(p,q) + 1, n −1]. As we have observed, $\phi(n) = (p - 1)\ (q - 1)$ (15).

Key Generation

1. Choose two 200-digit prime numbers randomly from the set of all 200-digit prime numbers. Call these p and q.
2. Compute the product $n = pq$. n will have approximately 400 digits.
3. Choose d randomly in the interval [max(p,q) + 1, n −1], such that GCD(d, $\phi(n)$) = 1.
4. Compute $e \equiv d^{-1}$ (modulo $\phi(n)$).
5. Publish n and e. Keep p, q, and d secret.

Encryption

1. Divide the message into blocks such that the bit-string of the message can be viewed as a 400-digit number. Call each block, m.
2. Compute and send $c \equiv m^e$ (modulo n).

Decryption

1. Compute $c^d \equiv (m^e)^d \equiv m^{ed} \equiv m^{k\phi(n)+1} \equiv m^{k\phi(n)} \times m \equiv m$ (modulo n)

Note that the result $m^{k\phi(n)} \equiv 1$ used in the preceding line is the Little Fermat Theorem.

Although the proof of the correctness and the security of RSA are established, there are several questions about the computational efficiency of RSA that should be raised.

Is it Possible to Find Prime Numbers of 200 Decimal Digits in a Reasonable Period of Time? The Prime Number Theorem 34 assures us that, after a few hundred random selections, we will probably find a prime of 200 digits.

We can never actually be certain that we have a prime without knowing the answer to the Riemann hypothesis; instead we create a test (the Solovay–Strassen test), which if the prime candidate passes, we assume the probability that p is not a prime is very low (16). We choose a number (say 100) numbers a_i at random, which must be relatively prime to p. For each ai, if the Legendre symbol $(\frac{a}{p}) = a_i^{(p-1)/2}$(mod p), then the chance that p is not a prime and passes the test is 1/2 in each case; if p passes all tests, the chances are $1/2^{100}$ that it is not prime.

Is it Possible to Find an e Which is Relatively Prime to $\phi(n)$? Computing the GCD(e,$\phi(n)$) is relatively fast, as is computing the inverse of e mod n. Here is an example of a (3 × 2) array computation that determines both GCD and inverse [in the example, GCD(1024,243) and 243^{-1} (mod 1024)]. First, create a (3 × 2) array where the first row are the given numbers; the second and third rows are the (2 × 2) identity matrix. In each successive column, subtract the largest multiple m of column k less than the first row entry of column (k − 1) to form the new column (for example, 1024 −4 × 243 = 52). When 0 is reached in the row A[1,*], say A[1,n], both the inverse (if it exists) and the GCD are found. The GCD is the element A[1,n −1]m and if this value is 1, the inverse exists and it is the value A[3,n −1] [243 × 59 ≡ 1 (mod 1024)].

Column	1	2	3	4	5	6	7
m			4	4	1	2	17
A[1,*]	1024	243	52	35	17	1	0
A[2,*]	1	0	1	4	5	−14	
A[3,*]	0	1	−4	17	−21	59	

Is it Possible to Perform the Computation $e \times d$ Where e and d are Themselves 200-digit Numbers? Computing m^e (mod n) consists of repeated multiplications and integer divisions. In a software package such as Mathematica, such a computation with 200-digit integers can be performed in 0.031 seconds of time on a Pentium machine.

One shortcut in computing a large exponent is to make use of the "fast exponentiation" algorithm: Express the exponent as a binary, $e = b_n b_{n-1} \ldots b_0$. Then compute m^e as follows:

```
$ans = m$
for $i = n - 1$ to 0 do
        $ans = ans \times ans$
        if $b_i = 1$ then $ans = ans \times x$
        end;
```

The result is ans. Note that the total number of multiplications is proportional to the log of e.

Example: Compute x^{123}.

$123 = (1111011)_{\text{binary}}$. So $n = 6$. Each arrow below represents one step in the loop. All but the fourth pass through the loop require squaring and multiplying by x, since the bits processed are 111011.

$$\begin{aligned} ans &= x \to x^2 \times x = x^3 \to x^6 \times x = x^7 \to x^{14} \times x \\ &= x^{15} \to x^{30} \to x^{60} \times x = x^{61} \to x^{122} \times x = x^{123} \end{aligned}$$

In a practical version of the RSA algorithm, it is recommended by Rivest, Shamir, and Adelman that the primes p and q be chosen to be approximately of the same size, and each containing about 100 digits.

The other calculations necessary in the development of an RSA cryptosystem have been shown to be relatively rapid. Except for finding the primes, the key generation consists of two multiplications, two additions, one selection of a random number, and the computation of one inverse modulo another number.

The encryption and decryption each require at most 2 $\log_2 n$ multiplications (in other words, one application of the Fast Exponentiation algorithm) for each message block.

DIGITAL SIGNATURES

It seems likely that, in the future, an application similar to public key cryptology will be even more widely used. With vastly expanded electronic communications, the requirements for providing a secure way of authenticating an electronic message—a digital signature—will be required far more often than the requirement for transmitting information in a secure fashion.

As with public key cryptology, the principles of number theory have been essential in establishing methods of authentication.

The authentication problem is the following: Given a message m, is it possible for a user u to create a "signature", s_u; dependent on some information possessed only by u, so that the recipient of the message (m,s_u) could use some public information for u (a public key), to be able to determine whether the message was authentic.

Rivest, Shamir, and Adelman showed that their public key encryption method could also be used for authentication.

For example, for A to send a message to B that B can authenticate, assume an RSA public key cryptosystem has been established with encryption and decryption keys e_A, d_A, e_B, d_B, and a message m to authenticate. A computes and sends $c \equiv m^{e_B d_A} (\bmod\, n)$. B both decrypts and authenticates by computing $(c^{e_A d_B}) \equiv (m^{e_B d_A})^{eAd_B} \equiv m^{e_B d_A e_A d_B} \equiv m^{e_B d_B} \equiv m (\bmod\, n)$.

However, several other authors, particularly El Gamal (17) and Ong et al. (18), developed more efficient solutions to the signature problem. More recently, in 1994, the National Institute of Standards and Technology, an agency of the United States government, established such a method as a national standard, now called the DSS or Digital Signature Standard (19).

The DSS specifies an algorithm to be used in cases where a digital authentication of information is required. We assume that a message m is received by a user. The objective is to verify that the message has not been altered, and that we can be assured of the originator's identity. The DSS creates for each user a public and a private key. The private key is used to generate signatures, and the public key is used in verifying signatures.

The DSS has two parts. The first part begins with a mechanism for hashing or collapsing any message down to one of a fixed length, say 160 bits. This hashing process is determined by a secure hash algorithm (SHA), which is very similar to a (repeated) DES encryption. The hashed message is combined with public and private keys derived from two public prime numbers. A computation is made by the signatory using both public and private keys, and the result of this computation, also 160 bits, is appended to the original message. The receiver of the message also performs a separate computation using only the public key knowledge, and if the receiver's computation correctly computes the appended signature, the message is accepted. Again, as with the RSA, the critical number theoretic result for the correctness of the method is the Little Fermat Theorem.

Elliptic Curve Public Key Cryptosystem (ECC)

One form of the general equation of an elliptic curve, the family of equations $y^2 = x^3 + ax + b$ $(a, b \in Z)$ has proven to be of considerable interest in their application to cryptology (20). Given two solutions $p = (x_1, y_1)$ and $Q = (x_2, y_2)$, a third point R in the Euclidean plane can be found by the following construction: Find a third point of intersection between the line PQ and the elliptic curve defined by all solutions to $y^2 = x^3 + ax + b$; then the point R is the reflection of this point of intersection in the x-axis. This point R may also be called $P + Q$, because the points so found follow the rules for an Abelian group by the Theorem of Mordell and Weil, with the identity $0 = P + (-P)$ being the point at infinity.

As an analogy to RSA, a problem comparable with the difficulty of factoring is the difficulty of finding k when $kP = P + P + \ldots + P$ (k times) is given. Specifically, for a cryptographic elliptic curve application, one selects an elliptic curve over a Galois field $GF(p)$ or $GF(2^m)$, rather than the integers. Then, as a public key, one chooses a secret k and a public p and computes $kP = Q$, with Q also becoming public.

One application, for example, is a variation of the widely used Diffie–Hellman secret sharing scheme (13). This scheme enables two users to agree on a common key without revealing any information about the key. If the two parties are A and B, each chooses at random a secret integer x_A and x_B. Then, A computes $y_A = x_A P$ in a public elliptic curve with

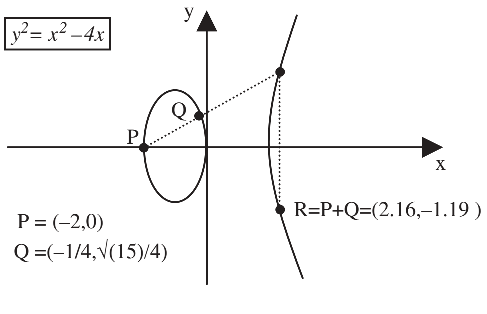

Figure 1. An example of addition of points on the elliptic curve $y^2 = x^3 - 4x$.

base point P. Similarly, B computes $y_B = x_B P$. A sends y_A to B and vice versa. Then, A computes $x_A y_B P$, and the resulting point $Q = (x_A y_B)P = (x_B y_A)P$ is the shared secret.

For computational reasons, it is advised to choose elliptic curves over specific fields. For example, a standard called P192 uses $GF(p)$, where $p = 2^{192} - 2^{64} + 1$ for efficient computation. Thus, x_A, x_B, y_A, y_B must all be less than p.

Advanced Encryption Standard or Rijndael (AES)

After it was generally accepted that a new U.S. standard was needed for symmetric key encryption, an international solicitation was made, with an extensive review process, for a new national standard. In late 2001, a system known as Rijndael, created by Vincent Rijmen and Joan Daemen, was selected as the U.S. Advanced Encryption Standard, or AES (21).

Although this method has some similarities to the DES, it has been widely accepted, particularly since the nonlinear S-boxes have, in contrast to the DES, a very understandable, although complex structure. The S-box in AES is a transformation derived from an operator in one of the so-called Galois fields $GF(2^8)$. It is a well-known result of algebra that all finite fields have several elements that is a prime power, that all finite fields with the same number of elements are isomorphic, and that a finite field with p^n elements can be represented as the quotient field of the ring of polynomials whose coefficients are mod p numbers, modulo an irreducible polynomial whose highest power is n.

CONVEX OPTIMIZATION

MOTIVATION AND A BRIEF HISTORY

An optimization problem can be stated in the so-called standard form as follows:

$$\begin{array}{l} \text{minimize } f(\mathbf{x}) : \mathbf{R}^n \rightarrow \mathbf{R} \\ \text{subject to } \boldsymbol{g}(\mathbf{x}) \leq 0,\ \boldsymbol{g} : \mathbf{R}^m \rightarrow \mathbf{R}^n \end{array} \tag{1}$$

representing the minimization of a function f of n variables under constraints specified by inequalities determined by functions $g = [g_1, g_2, \ldots, g_m]^{\mathrm{T}}$. The functions f and g_i are, in general, nonlinear functions. Note that "$\geq$" inequalities can be handled under this paradigm by multiplying each side by -1 and equalities by representing them as a pair of inequalities. The maximization of an objective function function $f(\mathbf{x})$ can be achieved by minimizing $-f(\mathbf{x})$. The set $\mathcal{F} = \{\mathbf{x} | \boldsymbol{g}(\mathbf{x}) \leq \mathbf{0}\}$ that satisfies the constraints on the nonlinear optimization problem is known as the feasible set or the feasible region. If $\mathcal{F}$ covers all of (a part of) $\mathbf{R}^n$, then the optimization is said to be *unconstrained (constrained)*. The above standard form may not directly be applicable to design problems where multiple conflicting objectives must be optimized. In such a case, multicriterion optimization techniques and Pareto optimality can be used to identify noninferior solutions (1). In practice, however, techniques to map the problem to the form in Equation (1) are often used.

When the objective function is a convex function and the constraint set is a convex set (both terms will be formally defined later), the optimization problem is known as a convex programming problem. This problem has the remarkable property of unimodality; i.e., any local minimum of the problem is also a global minimum. Therefore, it does not require special methods to extract the solution out of local minima in a quest to find the global minimum. Although the convex programming problem and its unimodality property have been known for a long time, it is only recently that efficient algorithms for solving of these problems have been proposed. The genesis of these algorithms can be traced back to the work of Karmarkar (2) that proposed a polynomial-time interior-point technique for linear programming, a special case of convex programming. Unlike the simplex method for linear programming, this technique was found to be naturally extensible from the problem of linear programming to general convex programming formulations. It was shown that this method belongs to the class of interior penalty methods proposed by Fiacco and McCormick (3) using barrier functions. The work of Renegar (4) showed that a special version of the method of centers for linear programming is polynomial. Gonzaga (5) showed similar results with the barrier function associated with a linear programming problem, with a proof of polynomial-time complexity. Nesterov and Nemirovsky (6) introduced the concept of self-concordance, studying barrier methods in their context. Further improvements in the computational complexity using approximate solutions and rank-one updates were shown in the work of Vaidya (7). The work of Ye (8) used a potential function to obtain the same complexity as Renegar's work without following the central path too closely.

DEFINITIONS OF CONVEXITY

Convex Sets

Definition. A set $C \in \mathbf{R}^n$ is said to be a **convex set** if, for every $\mathbf{x}_1,\ \mathbf{x}_2 \in C$ and every real number α, $0 \leq \alpha \leq 1$, the point $\alpha\ \mathbf{x}_1 + (1 - \alpha)\mathbf{x}_2 \in C$.

This definition can be interpreted geometrically as stating that a set is convex if, given two points in the set, every point on the line segment joining the two points is also a member of the set. Examples of convex and nonconvex sets are shown in Fig. 1.

Elementary Convex Sets

Ellipsoids. An ellipsoid $\mathrm{E}(\mathbf{x}, \mathcal{B}, \mathrm{r}) \in \mathbf{R}^n$ centered at point $\mathbf{x} \in \mathbf{R}^n$ is given by the equation

$$\{\mathbf{y} | (\mathbf{y} - \mathbf{x})^{\mathrm{T}} \mathcal{B} (\mathbf{y} - \mathbf{x}) \leq \mathrm{r}^2\}$$

If $\mathcal{B}$ is a scalar multiple of the unit matrix, then the ellipsoid is called a *hypersphere*. The axes of the ellipsoid are given by the eigenvectors, and their lengths are related to the corresponding eigenvalues of $\mathcal{B}$.

Hyperplanes. A hyperplane in n dimensions is given by the region

$$\mathbf{c}^{\mathrm{T}}\mathbf{x} = b,\ \mathbf{c} \in \mathbf{R}^n,\ b \in \mathbf{R}.$$

Half-Spaces. A half-space in n dimensions is defined by the region that satisfies the inequality

$$\mathbf{c}^{\mathrm{T}}\mathbf{x} \leq b,\ \mathbf{c} \in \mathbf{R}^n,\ b \in \mathbf{R}.$$

Polyhedra. A (convex) polyhedron is defined as an intersection of half-spaces and is given by the equation

$$\mathrm{P} = \{\mathbf{x} | A\mathbf{x} \leq \mathbf{b}\},\ A \in \mathbf{R}^{m \times n},\ \mathbf{b} \in \mathbf{R}^m,$$

corresponding to a set of m inequalities $\mathbf{a}_i^{\mathrm{T}}\mathbf{x} \leq \mathrm{b}_i$, $\mathbf{a}_i \in \mathbf{R}^n$. If the polyhedron has a finite volume, it is referred to as a *polytope*. An example of a polytope is shown in Fig. 2.

Some Elementary Properties of Convex Sets

Property. The intersection of convex sets is a convex set. The union of convex sets is not necessarily a convex set.

Property. (Separating hyperplane theorem) Given two nonintersecting convex sets A and B, a separating hyperplane $\mathbf{c}^{\mathrm{T}}\mathbf{x} = \mathbf{b}$ exists such that A lies entirely within the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

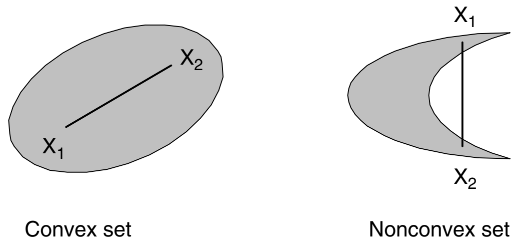

Figure 1. Convex and nonconvex sets.

half-space $\mathbf{c}^T\mathbf{x} \geq \mathbf{b}$ and B lies entirely within the half-space $\mathbf{c}^T\mathbf{x} \leq \mathbf{b}$. This is pictorially illustrated in Fig. 3.

Property. (Supporting hyperplane theorem) Given a convex set C and any point $\mathbf{x}$ on its boundary, a supporting hyerplane $\mathbf{c}^T\mathbf{x} = \mathbf{b}$ exists such that the convex set C lies entirely within the half-space $\mathbf{c}^T\mathbf{x} \leq \mathbf{b}$. This is illustrated in Fig. 4.

Definition. The **convex hull** of m points, $\mathbf{x}_1, \mathbf{x}_2 \ldots,$ $\mathbf{x}_\mathrm{m} \in \mathbf{R}^n$, denoted $co(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_\mathrm{m})$, is defined as the set of points $\mathbf{y} \in \mathbf{R}^n$ such that

$$\mathbf{y} = \sum_{i=1\,\mathrm{to}\,m} \alpha_i \mathbf{x}_i \qquad \alpha_i \geq 0 \,\forall\, i \qquad \sum_{i=1\,\mathrm{to}\,m} \alpha_i = 1.$$

The convex hull is thus the smallest convex set that contains the m points. An example of the convex hull of five points in the plane is shown by the shaded region in Fig. 5. If the set of points $\mathbf{x}_i$ is of finite cardinality (i.e., m is finite), then the convex hull is a polytope. Hence, a polytope is also often described as the convex hull of its vertices.

Convex Functions

Definition. A function f defined on a convex set Ω is said to be a **convex function** if, for every $\mathbf{x}_1, \mathbf{x}_2 \in \Omega$, and every α, $0 \leq \alpha \leq 1$,

$$\mathrm{f}(\alpha\, \mathbf{x}_1 + (1-\alpha)\mathbf{x}_2) \leq \alpha\, \mathrm{f}(\mathbf{x}_1) + (1-\alpha)\, \mathrm{f}(\mathbf{x}_2)$$

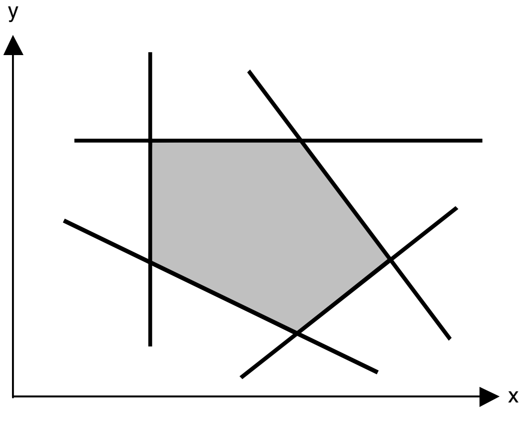

Figure 2. An example convex polytope in two dimensions as an intersection of five half-spaces.

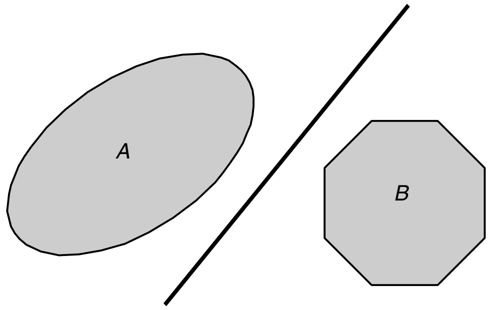

Figure 3. A separating hyperplane (line) in two dimensions between convex sets A and B.

f is said to be **strictly convex** if the above inequality is strict for $0 < \alpha < 1$.

Geometrically, a function is convex if the line joining two points on its graph is always above the graph. Examples of convex and nonconvex functions on $\mathbf{R}^n$ are shown in Fig. 6.

Some Elementary Properties of Convex Functions

Property. A function $f(\mathbf{x})$ is convex over the set S if and only if

$$f(\mathbf{x}) \geq f(\mathbf{x}_0) + [\nabla f(\mathbf{x}_0)]^T(\mathbf{x} - \mathbf{x}_0) \,\forall\, \mathbf{x},\, \mathbf{x}_0 \in S,$$

where ∇f corresponds to the gradient of f with respect to the vector $\mathbf{x}$. Strict convexity corresponds to the case in which the inequality is strict.

Property. A function $f(\mathbf{x})$ is convex over the convex set S if and only if

$$\nabla^2 f(\mathbf{x}_0) \geq 0 \,\forall\, \mathbf{x}_0 \in S$$

i.e., its Hessian matrix is positive semidefinite over S. For strict convexity, $\nabla^2 f(\mathbf{x}_0)$ must be positive definite.

Property. If $f(\mathbf{x})$ and $g(\mathbf{x})$ are two convex functions on the convex set S, then the functions $f+g$ and $\max(f, g)$ are convex over S.

Definition. The **level set** of a function $f(\mathbf{x})$ is the set defined by $f(\mathbf{x}) \leq c$ where c is a constant.

An example of the level sets of $f(\mathrm{x}, \mathrm{y}) = \mathrm{x}^2 + \mathrm{y}^2$ is shown in Fig. 7. Observe that the level set for $f(x,y) \leq c_1$ is contained in the level set of $f(x,y) \leq c_2$ for $c_1 < c_2$.

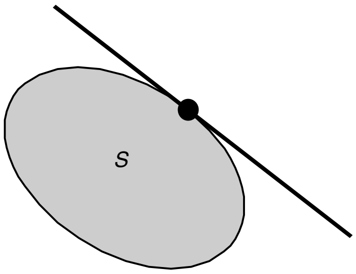

Figure 4. A supporting hyperplane (line) in two dimensions at the bounary point of a convex set S.

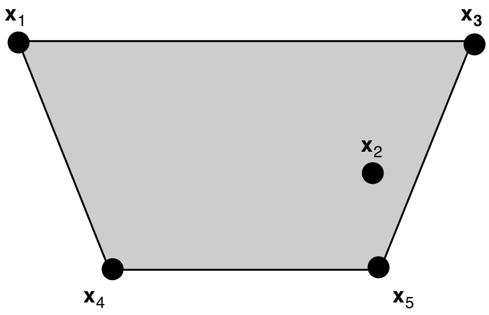

Figure 5. An example showing the convex hull of five points.

Property. If f is a convex function in the space $\mathcal{S}$, then the level set of f is a convex set in S. This is a very useful property, and many convex optimization algorithms depend on the fact that the constraints are defined by an intersection of level sets of convex functions.

Definition. A function g defined on a convex set Ω is said to be a **concave function** if the function $f = -g$ is convex. The function g is **strictly concave** if $-g$ is strictly convex.

For a fuller treatment on convexity properties, the reader is referred to Ref. (9).

CONVEX OPTIMIZATION

Convex Programming

Definition. A **convex programming problem** is an optimization problem that can be stated as follows:

$$\begin{aligned}&\text{minimize } f(\mathbf{x})\\&\text{such that } \mathbf{x} \in s\end{aligned} \qquad (2)$$

where f is a convex function and S is a convex set. This problem has the property that any local minimum of f over S is a global minimum.

Comment. The problem of maximizing a convex function over a convex set does not have the above property. However, it can be shown (10) that the maximum value for such a problem lies on the boundary of the convex set.

For a convex programming problem of the type in Equation (2), we may state without loss of generality that the objective function is linear. To see this, note that Equation (2) may equivalently be written as $\{\min t : f(\mathbf{x}) \le t, \mathbf{g}(\mathbf{x}) \le 0\}$.

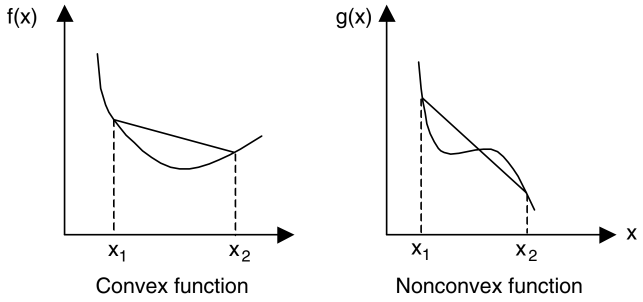

Figure 6. Convex and nonconvex functions.

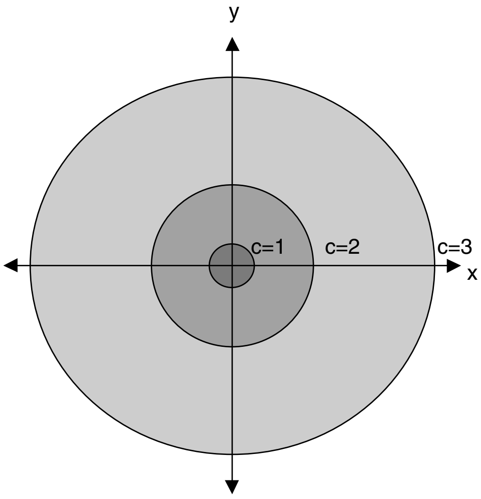

Figure 7. Level sets of $f(x,y) = x^2 + y^2$.

Linear programming is a special case of nonlinear optimization and, more specifically, a special type of convex programming problem where the objective and constraints are all linear functions. The problem is stated as

$$\begin{aligned}&\text{mnimize } \mathbf{c}^{\mathrm{T}}\mathbf{x}\\&\text{subject to } A\,\mathbf{x} \le \mathbf{b},\ \mathbf{x} \ge 0\\&\text{where } A \in \mathbf{R}^{m\times n},\ \mathbf{b} \in \mathbf{R}^{m},\ \mathbf{c} \in \mathbf{R}^{n},\ \mathbf{x} \in \mathbf{R}^{n}.\end{aligned} \qquad (3)$$

The feasible region for a linear program corresponds to a polyhedron in $\mathbf{R}^n$. It can be shown that an optimal solution to a linear program must necessarily occur at one of the vertices of the constraining polyhedron. The most commonly used technique for solution of linear programs, the simplex method (11), is based on this principle and operates by a systematic search of the vertices of the polyhedron. The computational complexity of this method can show an exponential behavior for pathological cases, but for most practical problems, it has been observed to grow linearly with the number of variables and sublinearly with the number of constraints. Algorithms with polynomial time worst-case complexity do exist; these include Karmarkar's method (2), and the Shor–Khachiyan ellipsoidal method (12). The computational times of the latter, however, are often seen to be impractical from a practical standpoint.

In the remainder of this section, we will describe various methods used for convex programming and for mapping problems to convex programs.

Path-Following Methods

This class of methods proceeds iteratively by solving a sequence of unconstrained problems that lead to the solution of the original problem. In each iteration, a technique based on barrier methods is used to find the optimal solution. If we denote the optimal solution in the kth iteration as $\mathbf{x}_k^*$, then the path $\mathbf{x}_1^*$, $\mathbf{x}_2^*$, $\ldots$ in $\mathbf{R}^n$ leads to the optimal solution, and hence, this class of techniques are known as path-following methods.

Barrier Methods. The barrier technique of Fiacco and McCormick (3) is a general technique to solve any constrained nonlinear optimization problem by solving a sequence of unconstrained nonlinear optimization problems. This method may be used for the specific case of minimizing a convex function over a convex set S described by an intersection of convex inequalities

$$S = \{\mathbf{x} | g_i(\mathbf{x}) \leq 0, i = 1, 2, \ldots, m\}$$

where each $g_i(\mathbf{x})$ is a convex function. The computation required of the method is dependent on the choice of the barrier function. In this connection, the logarithmic barrier function (abbreviated as the log barrier function) for this set of inequalities is defined as

$$\Phi(\mathbf{x}) = \begin{cases} -\sum_{i=1}^{n} \log[-g_i(\mathbf{x})] & \text{for } \mathbf{x} \in S \\ 0 & \text{otherwise} \end{cases}$$

Intuitively, the idea of the barrier is that any iterative gradient-based method that tries to minimize the barrier function will be forced to remain in the feasible region, due to the singularity at the boundary of the feasible region. It can be shown that $\Phi(\mathbf{x})$ is a convex function over S and its value approaches ∞. as $\mathbf{x}$ approaches the boundary of S. Intuitively, it can be seen that $\Phi(\mathbf{x})$ becomes smallest when $\mathbf{x}$ is, in some sense, farthest away from all boundaries of S. The value of $\mathbf{x}$ at which the function $\Phi(\mathbf{x})$ is minimized is called the *analytic center* of S.

Example. For a linear programming problem of the type described in Equation (3), with constraint inequalities described by $a_i^T \mathbf{x} \leq b_i$, the barrier function in the feasible region is given by

$$\Phi(\mathbf{x}) = -\sum_{i=1 \text{ to } n} \log(b_i - a_i^T \mathbf{x})$$

The value of $(b_i - a_i^T \mathbf{x})$ represents the slack in the *ith* inequality, i.e., the distance between the point $\mathbf{x}$ and the corresponding constraint hyperplane. The log barrier function, therefore, is a measure of the product of the distances from a point $\mathbf{x}$ to each hyperplane, as shown in Fig. 8(a). The value of $\Phi(\mathbf{x})$ is minimized when $\prod_{i=1 \text{ to } n}(b_i - a_i^T \mathbf{x})$ is maximized. Coarsely speaking, this occurs when the distance to each constraint hyperplane is sufficiently large.

As a cautionary note, we add that although the analytic center is a good estimate of the center in the case where all constraints present an equal contribution to the boundary, the presence of redundant constraints can shift the analytic center. The effect on the analytic center of repeating the constraint p five times is shown in Fig. 8(b).

We will now consider the convex programming problem specified as

$$\begin{aligned} &\text{minimize } f(\mathbf{x}) \\ &\text{such that} g_i(\mathbf{x}) \leq 0, i = 1, 2, \ldots, m \end{aligned}$$

where each $g_i(\mathbf{x})$ is a convex function. The traditional barrier method (3) used to solve this problem would formulate the corresponding unconstrained optimization problem

$$\text{minimize} B(\alpha) = \alpha \ f(\mathbf{x}) + \Phi(\mathbf{x})$$

and solve this problem for a sequence of increasing (constant) values of the parameter α. When α is zero, the problem reduces to finding the center of the convex set constraining the problem. As α increases, the twin objectives of minimizing $f(\mathbf{x})$ and remaining in the interior of the convex set are balanced. As α approaches ∞, the problem amounts to the minimization of the original objective function, f.

In solving this sequence of problems, the outer iteration consists of increasing the values of the parameter α. The inner iteration is used to minimize the value of $B(\alpha)$ at that value of α, using the result of the previous outer iteration as an initial guess. The inner iteration can be solved using Newton's method (10). For positive values of α, it is easy to see that $B(\alpha)$ is a convex function. The notion of a central path for a linearly constrained optimization problem is shown in Fig. 9.

Method of Centers. Given a scalar value $t > f(\mathbf{x}^*)$, the method of centers finds the analytic center of the set of inequalities $f(\mathbf{x}) \leq t$ and $g_i(\mathbf{x}) \leq 0$ by minimizing the

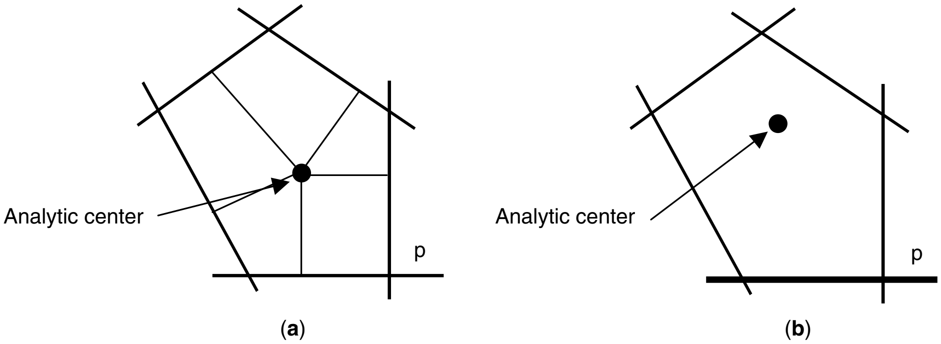

Figure 8. (a) Physical meaning of the barrier function for the feasible region of a linear program. (b) The effect of redundant constraints on the analytic center.

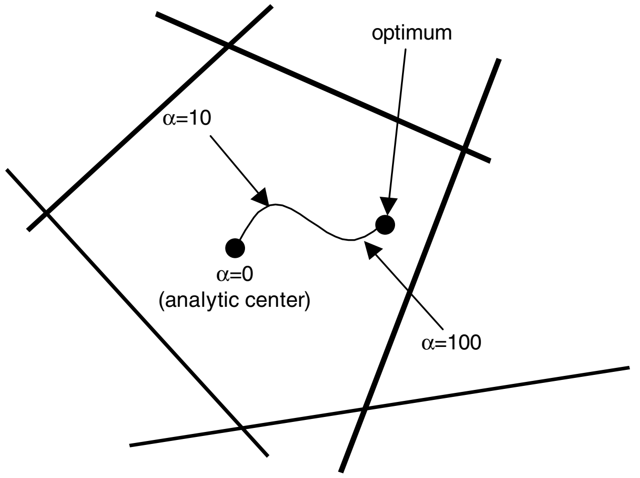

Figure 9. Central path for a linearly constrained convex optimization problem.

function

$$-\log(t - f(\mathbf{x})) + \Phi(\mathbf{x})$$

where $\Phi(\mathbf{x})$ is the log barrier function defined earlier. The optimal value $\mathbf{x}^*$ associated with solving the optimization problem associated with finding the analytic center for this barrier function is found and the value of t is updated to be a convex combination of t and $f(\mathbf{x}^*)$ as

$$t = \theta t + (1-\theta) f(\mathbf{x}^*),\ \theta > 0$$

The Self-Concordance Property and Step Length. The value of θ above is an adjustable parameter that would affect the number of Newton iterations required to find the optimum value of the analytic center. Depending on the value of θ chosen, the technique is classified as a short-step, medium-step, or long-step (possibly with even $\theta > 1$) method. For a short-step method, one Newton iteration is enough, whereas for longer steps, further Newton iterations may be necessary.

Nesterov and Nemirovsky (17) introduced the idea of the self-concordance condition, defined as follows.

Definition. A convex function $\varphi : S \to \mathbf{R}$ is **self-concordant** with parameter $a \geq 0$ (a-selfconcordant) on S; if φ is three times continuously differentiable on S and for all $\mathbf{x} \in S$ and $\mathbf{h} \in \mathbf{R}^m$, the following inequality holds:

$$|D^3\varphi(\mathbf{x})[\mathbf{h},\mathbf{h},\mathbf{h}]| \leq 2\,a^{-1/2}(D^2\varphi(\mathbf{x})[\mathbf{h},\mathbf{h}])^{3/2}$$

where $D^k\,\varphi(\mathbf{x})[\mathbf{h}_1, \mathbf{h}_2, \ldots \mathbf{h}_k]$ denotes the value of the kth differential of φ taken at $\mathbf{x}$ along the collection of directions $[\mathbf{h}_1, \mathbf{h}_2, \ldots \mathbf{h}_k]$.

By formulating logarithmic barrier functions that are self-concordant, proofs of the polynomial-time complexity of various interior point methods have been shown. An analysis of the computational complexity in terms of the number of outer and inner (Newton) iterations is presented in Refs. (6) and (13).

Other Interior Point Methods

Affine Scaling Methods. For a linear programming problem, the nonnegativity constraints $\mathbf{x} \geq 0$ are replaced by constraints of the type $\|X^{-1}(\mathbf{x}-\mathbf{x}_c)\| < \beta \leq 1$, representing an ellipsoid centered at $\mathbf{x_c}$. The linear program is then relaxed to the following form whose feasible region is contained in that of the original linear program:

$$\min\{\mathbf{c}^{\mathrm{T}}\,\mathbf{x} : A\mathbf{x} = \mathbf{b}, \|X^{-1}(\mathbf{x}-\mathbf{x}_c)\| < \beta \leq 1\}$$

Note that the linear inequalities in Equation (3) have been converted to equalities by the addition of slack variables. This form has the following closed-form solution:

$$\mathbf{x}(\beta) = \mathbf{x} - \beta\frac{XP_{AX}X\mathbf{c}}{\|P_{AX}X\mathbf{c}\|}$$

where $P_{AX} = (1 - XA^T(AX^2A^T)^{-1}AX)$. The updated value of $\mathbf{x}$ is used in the next iteration, and so on. The search direction $XP_{AX}X_{\mathbf{c}}$ is called the primal affine scaling direction and corresponds to the scaled projected gradient with respect to the objective function, with scaling matrix X. Depending on the value of β, the method may be a short-step or a long-step (with $\beta > 1$) method, and convergence proofs under various conditions are derived. For details of the references, the reader is referred to Ref. (13).

For a general convex programming problem of the type (note that the linear objective function form is used here),

$$\{\min f(\mathbf{y}) = \mathbf{b}^{\mathrm{T}}\mathbf{y} : g_i(\mathbf{y}) \leq 0\}$$

The constraint set here is similarly replaced by the ellipsoidal constraint $((\mathbf{y}-\mathbf{y}_c)^T H(\mathbf{y}-\mathbf{y}_c) \leq \beta^2$, where $\mathbf{y}_c$ is the center of the current ellipsoid, $\mathbf{y}$ is the variable over which the minimization is being performed, and H is the Hessian of the log-barrier function $-\sum_{i=1\,\mathrm{to}\,n}\log(-g_i(\mathbf{y}))$. The problem now reduces to

$$\{\min \mathbf{b}^{\mathrm{T}}\mathbf{y} : (\mathbf{y}-\mathbf{y}_c)^{\mathrm{T}}H(\mathbf{y}-\mathbf{y}_c) \leq \beta^2\}$$

which has a closed-form solution of the form

$$\mathbf{y}(\beta) = \mathbf{y} - \beta\frac{H^{-1}\mathbf{b}}{\sqrt{\mathbf{b}^{\mathrm{T}}H^{-1}\mathrm{b}}}$$

This is used as the center of the ellipsoid in the next iteration. The procedure continues iteratively until convergence.

Potential-Based Methods. These methods formulate a potential function that provides a coarse estimate of how far the solution at the current iterate is from the optimal value. At each step of a potential reduction method, a direction and step size are prescribed; however, the potential may be minimized further by the use of a line search (large steps). This is in contrast with a path-following method that must maintain proximity to a prescribed central path. An example of a potential-based technique is one that uses a weighted sum of the gap between the value of the primal optimization problem and its dual, and of the log-barrier function value as the potential. For a more detailed description of this and other potential-based methods, the reader is referred to Refs. (6) and (13).

Localization Approaches

Polytope Reduction. This method begins with a polytope $\mathcal{P} \in \mathbf{R}^n$ that contains the optimal solution $\mathbf{x}_{\text{opt}}$. The polytope P may, for example, be initially selected to be an n-dimensional box described by the set

$$\{\mathbf{x}|X_{\min} \leq \mathbf{x}(i) \leq X_{\max}\},$$

where $x_{\min}$ and $x_{\max}$ are the minimum and maximum values of each variable, respectively. In each iteration, the volume of the polytope is shrunk while keeping $\mathbf{x}_{\text{opt}}$ within the polytope, until the polytope becomes sufficiently small. The algorithm proceeds iteratively as follows.

Step 1. A *center* $\mathbf{x}_c$ deep in the interior of the polytope $\mathcal{P}$ is found.

Step 2. The feasibility of the center $\mathbf{x}_c$ is determined by verifying whether all of the constraints of the optimization problem are satisfied at $\mathbf{x}_c$. If the point $\mathbf{x}_c$ is infeasible, it is possible to find a separating hyperplane passing through $\mathbf{x}_c$ that divides $\mathcal{P}$ into two parts, such that the feasible region lies entirely in the part satisfying the constraint

$$\mathbf{c}^T\mathbf{x} \geq \beta$$

where $\mathbf{c} = -[\nabla g_p(\mathbf{x})]^T$ is the negative of the gradient of a violated constraint, g_p, and $\beta = \mathbf{c}^{\mathrm{T}}\mathbf{x}_c$. The separating hyperplane above corresponds to the tangent plane to the violated constraint. If the point $\mathbf{x}_c$ lies within the feasible region, then a hyperplane $\mathbf{c}^{\mathrm{T}}\mathbf{x} \geq \beta$ exists that divides the polytope into two parts such that $\mathbf{x}_{\text{opt}}$ is contained in one of them, with $\mathbf{c} = -[\nabla f(\mathbf{x})]^T$ being the negative of the gradient of the objective function and β being defined as $\beta = \mathbf{c}^T\mathbf{x}_c$ once again. This hyperplane is the supporting hyperplane for the set $f(\mathbf{x}) \leq f(\mathbf{x}_c)$ and thus eliminates from the polytope a set of points whose value is larger than the value at the current center. In either case, a new constraint $\mathbf{c}^T\mathbf{x} \geq \beta$ is added to the current polytope to give a new polytope that has roughly half the original volume.

Step 3. Go to Step 1 and repeat the process until the polytope is sufficiently small.

Note that the center in *Step 1* is ideally the center of gravity of the current polytope because a hyperplane passing through the center of gravity is guaranteed to reduce the volume of the polytope by a factor of $(1 - 1/e)$ in each iteration. However, because finding the center of gravity is prohibitively expensive in terms of computation, the analytic center is an acceptable approximation.

Example. The algorithm is illustrated by using it to solve the following problem in two dimensions:

$$\begin{aligned}&\text{minimize } f(x_1, x_2)\\ &\text{such that}(x_1, x_2) \in S\end{aligned}$$

where S is a convex set and f is a convex function. The shaded region in Fig. 10(a) is the set S, and the dotted lines show the level curves of f. The point $\mathbf{x}_{\text{opt}}$ is the solution to this problem. The expected solution region is first bounded by a rectangle with center $\mathbf{x}_c$, as shown in Fig. 10(a). The feasibility of $\mathbf{x}_c$ is then determined; in this case, it can be seen that $\mathbf{x}_c$ is infeasible. Hence, the gradient of the constraint function is used to construct a hyperplane through $\mathbf{x}_c$ such that the polytope is divided into two parts of roughly equal volume, one of which contains the solution $\mathbf{x}_c$. This is

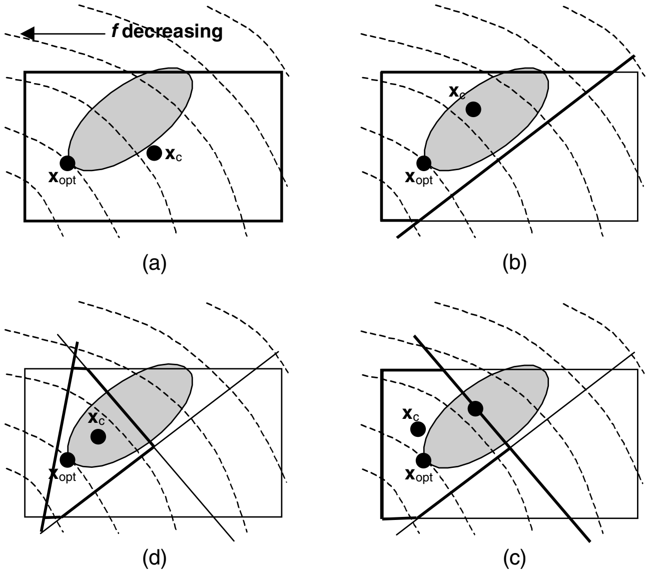

Figure 10. Cutting plane approach.

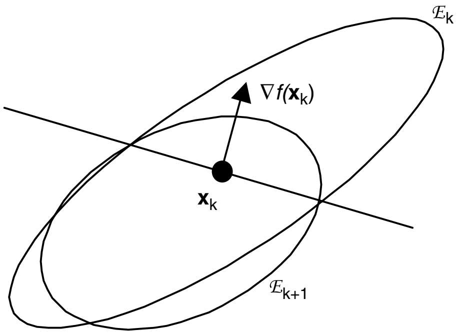

Figure 11. The ellipsoidal method.

illustrated in Fig. 10(b), where the region enclosed in darkened lines corresponds to the updated polytope. The process is repeated on the new smaller polytope. Its center lies inside the feasible region, and hence, the gradient of the objective function is used to generate a hyperplane that further shrinks the size of the polytope, as shown in Fig. 10(c). The result of another iteration is illustrated in Fig. 10(d). The process continues until the polytope has been shrunk sufficiently.

Ellipsoidal Method. The ellipsoidal method begins with a sufficiently large ellipsoid that contains the solution to the convex optimization problem. In each iteration, the size of the ellipsoid is shrunk, while maintaining the invariant that the solution lies within the ellipsoid, until the ellipsoid becomes sufficiently small. The process is illustrated in Fig. 11.

The kth iteration consists of the following steps, starting from the fact that the center $\mathbf{x}_k$ of the ellipsoid $\mathcal{E}_k$ is known.

Step 1. In case the center is not in the feasible region, the gradient of the violated constraint is evaluated; if it is feasible, the gradient of the objective function is found. In either case, we will refer to the computed gradient as $\nabla h(\mathbf{x}_k)$.

Step 2. A new ellipsoid containing the half-ellipsoid given by

$$\mathcal{E}_k \cap \{\mathbf{x} | \nabla h(\mathbf{x}_k)^T \mathbf{x} \leq \nabla h(\mathbf{x}_k)^T \mathbf{x}_k\}$$

is computed. This new ellipsoid $\mathcal{E}_{k+1}$ and its center $\mathbf{x}_{k+1}$ are given by the following relations:

$$\mathbf{X}_{k+1} = \mathbf{X}_k - \frac{1}{n+1} A_k \tilde{\mathbf{g}}_k$$
$$A_{k+1} = \frac{n^2}{n^2-1}(A_k - \frac{2}{n+1} A_k \tilde{\mathbf{g}}_k \tilde{\mathbf{g}}_k{}^T A_k)$$

where

$$\tilde{\mathbf{g}}_k = \frac{\nabla h(\mathbf{x}_k)}{\sqrt{\nabla h(\mathbf{x}_k)^T A_k \nabla h(\mathbf{x}_k)}}$$

Step 3. Repeat the iterations in Steps 1 and 2 until the ellipsoid is sufficiently small.

RELATED TECHNIQUES

Quasiconvex Optimization

Definition. A function $f : S \rightarrow \mathbf{R}$, where S is a convex set, is **quasiconvex** if every level set $L_a = \{\mathbf{x} | f(\mathbf{x}) \leq a\}$ is a convex set. A function g is **quasiconcave** if $-g$ is quasiconvex over S. A function is **quasilinear** if it is both quasiconvex and quasiconcave.

Examples. Clearly, any convex (concave) function is also quasiconvex (quasiconcave).

Any monotone function $f : \mathbf{R} \rightarrow \mathbf{R}$ is quasilinear.

The linear fractional function $f(\mathbf{x}) = (\mathbf{a}^T\mathbf{x} + b)/(\mathbf{c}^T\mathbf{x} + d)$, where $\mathbf{a}, \mathbf{c}, \mathbf{x} \in \mathbf{R}^n$, is quasilinear over the half-space $\{\mathbf{x} | \mathbf{c}^T\mathbf{x} + d > 0\}$.

Other Characterizations of Quasiconvexity. A function f defined on a convex set Ω is quasiconvex if, for every $\mathbf{x}_1$, $\mathbf{x}_2 \in \Omega$,

1. For every α, $0 \leq \alpha \leq 1$, $f(\alpha\,\mathbf{x}_1 + (1-\alpha)\mathbf{x}_2) \leq \max[f(\mathbf{x}_1), f(\mathbf{x}_2)]$.
2. If f is differentiable, $f(\mathbf{x}_1) \leq f(\mathbf{x}_2) \Rightarrow (\mathbf{x}_2 - \mathbf{x}_1)^T \nabla f(\mathbf{x}_1) \leq 0$.

Property. If f, g are quasiconvex over Ω, then the functions αf for $\alpha > 0$, and max(f,g) are also quasiconvex over Ω. The composed function $g(f(\mathbf{x}))$ is quasiconvex provided g is monotone increasing. In general, the function $(f+g)$ is *not* quasiconvex over Ω.

As in the case of convex optimization, the gradient of a quasiconvex objective can be used to eliminate a half-space from consideration. The work in Ref. (14) presents an adaptation of the ellipsoidal method to solve quasiconvex optimization problems.

Semidefinite Programming

The problem of semidefinite programming (15) is stated as follows:

$$\begin{array}{l} \text{minimize}\, \mathbf{c}^T\mathbf{x} \\ \text{subject to}\, F(\mathbf{x}) \geq 0 \\ \text{where}\, F(\mathbf{x}) \in \mathbf{R}^{m \times m},\ \mathbf{c},\ \mathbf{x} \in \mathbf{R}^n \end{array} \tag{4}$$

Here, $F(\mathbf{x}) = F_0 + F_1x_1 + \ldots + F_nX_n$ is an affine matrix function of $\mathbf{x}$ and the constraint $F(\mathbf{x}) \geq 0$ represents the fact that this matrix function must be positive semidefinite, i.e., $\mathbf{z}^T F(\mathbf{x})\mathbf{z} \geq 0$ for all $\mathbf{z} \in \mathbf{R}^n$. The constraint is referred to as a linear matrix inequality. The objective function is linear, and hence convex, and the feasible region is convex because if $F(\mathbf{x}) \geq 0$ and $F(\mathbf{y}) \geq 0$, then for all $0 \leq \lambda \leq 1$, it can be readily seen that $\lambda F(\mathbf{x}) + (1-\lambda)F(\mathbf{y}) \leq 0$.

A linear program is a simple case of a semidefinite program. To see this, we can rewrite the constraint set; $A\mathbf{x} \geq \mathbf{b}$ (note that the "$\geq$" here is a component-wise inequality and is not related to positive semidefiniteness), as $F(\mathbf{x}) = \mathbf{diag}(A\,\mathbf{x} - \mathbf{b})$; i.e., $F_0 = \mathbf{diag}(\mathbf{b})$, $F_{\mathrm{j}} = \mathbf{diag}(\mathbf{a}_{\mathrm{j}})$, $\mathrm{j} = 1, \ldots, n$, where $A = [\mathbf{a}_1\, \mathbf{a}_2\, \ldots \mathbf{a}_{\mathrm{n}}] \in \mathbf{R}^{m \times n}$.

Semidefinite programs may also be used to represent nonlinear optimization problems. As an example, consider the problem

$$\begin{array}{l} \text{minimize} \dfrac{(\mathbf{c}^T\mathbf{x})^2}{\mathbf{d}^T\mathbf{x}} \\ \text{subject to} A\mathbf{x} + \mathbf{b} \geq 0 \end{array}$$

where we assume that $\mathbf{d}^T\mathbf{x} > 0$ in the feasible region. Note that the constraints here represent, as in the case of a linear program, component-wise inequalities. The problem is first rewritten as minimizing an auxiliary variable t subject to the original set of constraints and a new constraint

$$\frac{(\mathbf{c}^T\mathbf{x})^2}{\mathbf{d}^T\mathbf{x}} \leq t$$

The problem may be cast in the form of a semidefinite program as

$$\begin{array}{ll} & \text{minimize } t \\ \text{subject to} & \begin{bmatrix} \mathbf{diag}(A\mathbf{x} + \mathbf{b}) & 0 & 0 \\ 0 & t & \mathbf{c}^T\mathbf{x} \\ 0 & \mathbf{c}^T\mathbf{x} & \mathbf{d}^T\mathbf{x} \end{bmatrix} \geq 0 \end{array}$$

The first constraint row appears in a manner similar to the linear programming case. The second and third rows use Schur complements to represent the nonlinear convex constraint above as the 2 × 2 matrix inequality

$$\begin{bmatrix} t & \mathbf{c}^T\mathbf{x} \\ \mathbf{c}^T\mathbf{x} & \mathbf{d}^T\mathbf{x} \end{bmatrix} \geq 0$$

The two "tricks" shown here, namely, the reformulation of linear inequations and the use of Schur complements, are often used to formulate optimization problems as semidefinite programs.

Geometric Programming

Definition. A **posynomial** is a function h of a positive variable $\mathbf{x} \in \mathbf{R}^m$ that has the form

$$h(\mathbf{x}) = \sum_{\mathrm{j}} \gamma_{\mathrm{j}} \prod_{i=1 \text{ to } n} x_i^{\alpha(i,j)}$$

where the exponents $\alpha(i, j) \in \mathbf{R}$ and the coefficients $\gamma_j > 0$, $\gamma_j \in \mathbf{R}$.

For example, the function $f(x,y,z) = 7.4\,x + 2.6\,y^{3.18}z^{-4.2} + \sqrt{3}\,y^{-2}y^{-1.4}z^{\sqrt{5}}$ is a posynomial in the variables x, y, and z. Roughly speaking, a posynomial is a function that is similar to a polynomial, except that the coefficients γ_j must be positive, and an exponent $\alpha(i, j)$ could be any real number and not necessarily a positive integer, unlike a polynomial.

A posynomial has the useful property that it can be mapped onto a convex function through an elementary variable transformation, $x(i) = e^{z(i)}$(16). Such functional forms are useful because in the case of an optimization problem where the objective function and the constraints are posynomial, the problem can easily be mapped onto a convex programming problem.

For some geometric programming problems, simple techniques based on the use of the arithmetic-geometric inequality may be used to obtain simple closed-form solutions to the optimization problems (17). The arithmetic–geometric inequality states that if $u_1, u_2, \ldots, u_n > 0$, then the arithmetic mean is no smaller than the geometric mean; i.e.,

$$(u_1 + u_2 + \ldots + u_n)/n \geq ((u_1)(u_2) \ldots (u_n))^{1/n},$$

with equality occurring if and only if $u_1 = u_2 = \ldots = u_n$.

A simple illustration of this technique is in minimizing the outer surface area of an open box of fixed volume (say, four units) and sides of length x_1, x_2, x_3. The problem can be stated as

$$\begin{array}{ll} \text{minimize} & x_1x_2 + 2\,x_1x_3 + 2\,x_1x_3 \\ \text{subject to} & x_1x_2x_3 = 4 \end{array}$$

By setting $u_1\ x_1, x_2,\ u_2 = 2x_1\,x_3,\ u_3 = 2x_1x_3$, and applying the condition listed above, the minimum value of the objective function is $3((u_1)(u_2)(u_3))^{1/3} = 3(4\,x_1^2x_2^2x_3^2) = 12$. It is easily verified that this corresponds to the values $x_1 = 2$, $x_2 = 2$, and $x_3 = 1$. We add a cautionary note that some, but not all, posynomial programming problems may be solved using this simple solution technique. For further details, the reader is referred to Ref. (17).

An extension of posynomials is the idea of *generalized posynomials* (18), which are defined recursively as follows:

A generalized posynomial of order 0, $G_0(\mathbf{x})$, is simply a posynomial, defined earlier; i.e.,

$$G_0(\mathbf{x}) = \sum_j \gamma_{\mathrm{j}} \prod_{i=1 \text{ to } n} x_i^{\alpha(i,j)}$$

A generalized posynomial of order $k > 1$ is defined as

$$G_k(\mathbf{x}) = \sum_j \lambda_j \prod_{i=1 \text{ to } n} [G_{(k-1),i}(\mathbf{x})]^{\alpha(i,j)}$$

where $G_{(k-1),i}(\mathbf{x})$ is a generalized posynomial of order less than or equal to $k - 1$, each exponent $\alpha(i, j) \in \mathbf{R}$, and the coefficients $\gamma_j > 0$, $\gamma_j \in \mathbf{R}$.

Like posynomials, generalized posynomials can be transformed to convex functions under the transform $x(i) = e^{z(i)}$, but with the additional restriction that $\alpha(i, j) \geq 0$ for each i, j. For a generalized posynomial of order 1, observe that the term in the innermost bracket, $G_{0,i}(\mathbf{x})$, represents a posynomial function. Therefore, a generalized posynomial of order 1 is similar to a posynomial, except that the place of the $x(i)$ variables is taken by posynomial. In general, a generalized posynomial of order k is similar to a posynomial, but $x(i)$ in the posynomial equation is replaced by a generalized posynomial of a lower order.

Optimization Involving Logarithmic Concave Functions

A function *f* is a logarithmic concave (log-concave) function if log(*f*) is a concave function. Logconvex functions are similarly defined. The maximization of a log-concave function over a convex set is therefore a unimodal problem; i.e., any local minimum is a global minimum. Log-concave functional forms are seen among some common probability distributions on $\mathbf{R}^n$, for example:

(a) The Gaussian or normal distribution

$$f(\mathbf{x}) = \frac{1}{\sqrt{(2\pi)^n \det\Sigma}} e^{-0.5(\mathbf{x}-\mathbf{x}_c)^T\Sigma^{-1}(\mathbf{x}-\mathbf{x}_c)}$$

where $\Sigma \geq 0$.

(b) The exponential distribution

$$f(\mathbf{x}) = \left(\prod_{i=1\,\mathrm{to}\,n} \lambda(i)\right) e^{-(\lambda(1)x(1)+\lambda(2)x(2)+\ldots+\lambda(n)x(n))}$$

The following properties are true of log-concave functions:

1. If *f* and *g* are log-concave, then their product *f*.*g* is log-concave.
2. If $f(\mathbf{x})$ is log-concave, then the integral $\int_S f(\mathbf{x})d\mathbf{x}$ is log-concave provided S is a convex set.
3. If $f(\mathbf{x})$ and $g(\mathbf{x})$ are log-concave, then the convolution $\int_S f(\mathbf{x}-\mathbf{y})g(\mathbf{y})d\mathbf{y}$ is log-concave if S is a convex set (this follows from Steps 1 amd 2).

Convex Optimization Problems in Computer Science and Engineering

There has been an enormous amount of recent interest in applying convex optimization to engineering problems, particularly as the optimizers have grown more efficient. The reader is referred to Boyd and Vandenberghe's lecture notes (19) for a treatment of this subject. In this section, we present a sampling of computer science and computer engineering problems that can be posed as convex programs to illustrate the power of the technique in practice.

Design Centering

While manufacturing any system, it is inevitable that process variations will cause design parameters, such as component values, to waver from their nominal values. As a result, after manufacture, the system may no longer meet some behavioral specifications, such as requirements on the delay, gain, and bandwidth, which it has been designed to satisfy. The procedure of design centering attempts to select the nominal values of design parameters to ensure that the behavior of the system remains within specifications, with the greatest probability and thus maximize the manufacturing yield.

The random variations in the values of the design parameters are modeled by a probability density function, $\psi(\mathbf{x}, \mathbf{x}_c) : \mathbf{R}^n \to [0, 1]$, with a mean corresponding to the nominal value of the design parameters. The yield of the manufacturing process Y as a function of the mean $\mathbf{x}_c$ is given by

$$Y(\mathbf{x}_c) = \int_{\mathcal{F}} \psi(\mathbf{x}, \mathbf{x}_c)d\mathbf{x}$$

where $\mathcal{F}$ corresponds to the feasible region where all design constraints are satisfied.

A common assumption made by geometrical design centering algorithms for integrated circuit applications is that $\mathcal{F}$ is a convex bounded body. Techniques for approximating this body by a polytope P have been presented in Ref. (20). When the probability density functions that represent variations in the design parameters are Gaussian in nature, the design centering problem can be posed as a convex programming problem. The design centering problem is formulated as (21)

$$\text{maximize}\, Y(\mathbf{x}_c) = \int_P \psi(\mathbf{x}, \mathbf{x}_c)d\mathbf{x}$$

where $\mathcal{P}$ is the polytope approximation to the feasible region $\mathcal{R}$. As the integral of a logconcave function over a convex region is also a log-concave function (22), the yield function $Y(\mathbf{x})$ is log-concave, and the above problem reduces to a problem of maximizing a log-concave function over a convex set. Hence, this can be transformed into a convex programming problem.

VLSI Transistor and Wire Sizing

Convex Optimization Formulation. Circuit delays in integrated circuits often have to be reduced to obtain faster response times. Given the circuit topology, the delay of a combinational circuit can be controlled by varying the sizes of transistors, giving rise to an optimization problem of finding the appropriate area-delay tradeoff. The formal statement of the problem is as follows:

$$\begin{array}{l} \text{minimize}\, \mathit{Area} \\ \text{subject to}\, \mathit{Delay} \leq T_{\mathrm{spec}} \end{array} \tag{5}$$

The circuit area is estimated as the sum of transistor sizes; i.e.,

$$\mathit{Area} = \sum_{i=1\,\mathrm{to}\,n} x_i$$

where x_i is the size of the ith transistor and n is the number of transistors in the circuit. This is easily seen to be a posynomial function of the x_i's. The circuit delay is estimated using the Elmore delay estimate (23), which calculates the delay as maximum of path delays. Each path delay is a sum of resistance-capacitance products. Each resistance term is of the form a/x_i, and each capacitance term is of the type $\Sigma b_i x_i$, with the constants a and b_i being positive. As a result, the delays are posynomial functions of the x_i's, and the feasible region for the optimization problem is an intersection of constraints of the form

$$(\textit{posynomial function in}\, x_i\text{'s}) \leq t_{\text{spec}}$$

As the objective and constraints are both posynomial functions in the x_i's, the problem is equivalent to a convex programming problem. Various solutions to the problem have been proposed, for instance, in Refs. (24) and (25). Alternative techniques that use curve-fitted delay models have been used to set up a generalized posynomial formulation for the problem in Ref. (21).

Semidefinite Programming Formulation. In Equation (5), the circuit delay may alternatively be determined from the dominant eigenvalue of a matrix $G^{-1}C$, where G and C are, respectively, matrices representing the conductances (corresponding to the resistances) and the capacitances referred to above. The entries in both G and C are affine functions of the x_i's. The dominant time constant can be calculated as the negative inverse of the largest zero of the polynomial $\det(s\ C + G)$. It is also possible to calculate it using the following linear matrix inequality:

$$T^{\text{dom}} = \min\{T | TG - C \geq 0\}$$

Note that the "≥ 0" here refers to the fact that the matrix must be positive definite. To ensure that $T^{\text{dom}} \leq T_{\max}$ for a specified value of $T_{\max}$, the linear matrix inequality $T_{\max} = G(\mathbf{x}) - C(\mathbf{x}) \geq 0$ must be satisfied. This sets up the problem in the form of a semidefinite program as follows (26):

$$\begin{aligned}
&\text{minimize} \sum_{i=1}^{n} l_i x_i \\
&\text{subject to}\, T_{\max} G(\mathbf{x}) - C(\mathbf{x}) \geq 0 \\
&\mathbf{x}_{\min} \leq \mathbf{x} \leq \mathbf{x}_{\max}
\end{aligned}$$

Largest Inscribed Ellipsoid in a Polytope

Consider a polytope in $\mathbf{R}^n$ given by $\mathcal{P} = \{\mathbf{x} | \mathbf{a}_i^T \mathbf{x} \leq b_i,\, i = 1, 2, \ldots, L\}$ into which the largest ellipsoid $\mathcal{E}$, described as follows, is to be inscribed:

$$\mathcal{E} = \{B\ \mathbf{y} + \mathbf{d} | \|\mathbf{y}\| \leq 1\}, B = B^T > 0$$

The center of this ellipsoid is $\mathbf{d}$, and its volume is proportional to $\det(B)$. The objective here is to find the entries in the matrix B and the vector $\mathbf{d}$. To ensure that the ellipsoid is contained within the polytope, it must be ensured that for all $\mathbf{y}$ such that $\|\mathbf{y}\| \leq 1$,

$$\mathbf{a}_i^T (B\mathbf{y} + \mathbf{d}) \leq b_i$$

Therefore, it must be true that $sup_{\|\mathbf{y}\| \leq 1} (\mathbf{a}_i^T B\ \mathbf{y} + \mathbf{a}_i^T \mathbf{d}) \leq \mathrm{b}_i$, or in other words, $\|B\, \mathbf{a}_i\| \leq b_i - \mathbf{a}_i^T \mathbf{d}$. The optimization problem may now be set up as

$$\begin{aligned}
&\text{maximize log det}\, B \\
&\text{subject to}\, B = B^T > 0 \\
&\|B\, \mathbf{a}_i\| \leq b_i - \mathbf{a}_i\, \mathbf{d},\ \mathrm{i} = 1, 2, \ldots, L
\end{aligned}$$

This is a convex optimization problem (6) in the variables B and $\mathbf{d}$, with a total dimension of $n(n+1)/2$ variables corresponding to the entries in B and n variables corresponding to those in $\mathbf{d}$.

CONCLUSION

This overview has presented an outline of convex programming. The use of specialized techniques that exploit the convexity properties of the problem have led to rapid recent advances in efficient solution techniques for convex programs, which have been outlined here. The applications of convex optimization to real problems to engineering design have been illustrated.

DYNAMIC PROGRAMMING

The objective of the DP algorithm is to solve the sequential decision problem optimally. The problem typically uses an automaton model. Therefore, we start by constructing an automaton model of a sequential decision process. Then the principle of optimality is explained as a basic and driving concept to establish a DP algorithm for the sequential decision process. To explain how the principle works in establishing the algorithm, we focus on the relationship between the representation of the automaton and its optimal solution algorithm by DP. At this stage, the DP algorithm still seems abstract. We describe a more concrete DP algorithm to optimally solve a so-called nonlinear time alignment problem, which is widely used in many application domains. The relationship between an automaton model and the DP algorithm of nonlinear time alignment is also described.

Many types of DP algorithms have been developed due to the various applications that are possible. We use a DP algorithm as an example to show how a basic DP algorithm can be extended to create another algorithm applicable to another field.

This article comprises sections that describe these subtopics: (*1*) automaton model of sequential decision process as a simple framework for dealing with DP, (*2*) principle of optimality as key concept of DP, (*3*) baseline algorithm as a simplest realization of DP, (*4*) time-alignment algorithm as one of the most popular applications using DP, (*5*) numerical computation of time-alignment algorithm for understanding each step of computation, (*6*) continuous dynamic programming as a useful extension of time-alignment algorithm, and (*7*) other applications including Markov decision process.

AUTOMATON MODEL OF SEQUENTIAL DECISION PROCESS

A sequential decision process can be modeled by an automaton composed of four components: state S_k decision $q_k \in Q$, state transition $S_k = T_k(S_{k-1}, q_k)$, and gain $g_k(S_{k-1}, q_k)$, where Q is a set of decisions and $1 \leq k \leq K$ Then the total gain function of the so-called additive gain model is defined as follows and is used to evaluate the decision sequence:

$$G = \sum_{k=1}^{K} g_k(S_{k-1}, q_k)$$

The additive gain model is widely used in real application domains. The relationship of these four components and the total gain G is shown in Fig. 1.

Dynamic programming can be understood simply through the procedure for developing an algorithm that gives the maximum value of G. A dynamic programming algorithm is a realization of the so-called principle of optimality proposed by R. Bellman (1, 2); therefore, that principle is described first.

PRINCIPLE OF OPTIMALITY

Understanding the principle of optimality is heuristically easy. Assume that the path formed by A and B as shown in Fig. 2, is *the full optimal path* uniquely determined from initial state S_0 to terminal state S_k and including state S_k. If two other optimal paths exist, namely A' (not A) from S_0 to S_k and B' (not B) from S_k to S_K, then the path formed by the two paths A' and B' becomes another full optimal path from S_0 to S_K. This mechanism contradicts the assumption that the path formed by A and B is the full optimal path uniquely determined from S_0 to S_K. The principle of optimality guarantees that an arbitrary state S_k on the full optimal path from S_0 to S_K can uniquely divide a full optimal path into two optimal partial paths.

Formal Definition of the Principle of Optimality

Let q_1 be an initial decision. Then the optimal path to reach state S_{k-1} gives a maximum gain $G^*_{k-1}(S_0, q_1)$ for $2 \leq k \leq K$ The principle of optimality defines the following equation for $2 \leq k \leq K$:

$$G^*_k(S_0) = \max_{q_1 \in Q} G^*_{k-1}(S_0, q_1)$$

The equation for $k = 1$ is defined using a gain function $G_1(S_0, q_1)$ by

$$G^*_1(S_0) = \max_{q_1 \in Q} G_1(S_0, q_1)$$

The maximum gain, $G^*_K(S_0)$, has only two parameters, K and S_0 [see (3)].

The Curse of Dimensionality

When obtaining an optimal solution of optimization problem, DP can reduce the computational burden compared with that of naÿve algorithms. But the computational burden of DP increases rapidly with numbers of states and decisions because the problem domain is still combinatorial. This is called “the curse of dimensionality.” Some methods (4,5) have been proposed to avoid the obstacle in practical applications.

BASE-LINE DP ALGORITHM OF ITERATIVE COMPUTATION

When applying the principle of optimality to an automaton of a sequential decision process, as shown in Fig. 1, we can obtain the following iterative computation.

q_K
Transition: $S_k = T_k(S_{k-1.}q_k)$
Total gain: $G = \sum_{k=1}^{K} g_k(S_{k-1.}q_k)$

Figure 1. Automaton model of sequential decision process.

First, we describe total gain G of an additive gain model as follows:

$$G = g_1(S_0, q_1) + g_2(S_1, q_2) + g_3(S_2, q_3) + \cdots \\ + g_K(S_{K-1}, q_K)$$

The states $S_k, k = 0, 1, 2, \ldots, K-1$, are not the states on the full optimal path shown in Fig. 2. A state S_k in this section is regarded as a *working* state.

Second, let G_1 be g_1+g_2 assuming that state S_0 in G is given. Then G_1 has two variables, q_1 and q_2, recalling that $S_1 = T_1(S_0, q_1)$. If G_1 is maximized with respect to q_1 assuming that q_2 is a fixed value, then $G_1^*(q_2) = \max_{q_1} G_1(q_1, q_2)$ and $q_1^* = q_1^*(q_2) = \arg\{\max_{q_1} G_1(q_1, q_2)\}$ are obtained, where the superscript asterisks denote optimality. Let G_2 be $G_1^*(q_2) + g_3(S_2, q_3)$; then G_2 has two variables, q_2 and q_3, recalling that $S_2 = T_2(S_1, q_2)$. If we maximize G_2 with respect to q_2 assuming that q_3 is a fixed value, then $G_2^*(q_3) = \max_{q_2} G_2(q_2, q_3)$ and $q_2^* = q_2^*(q_3) = \arg\{\max_{q_2} G_2(q_2, q_3)\}$ are obtained. Then the following equation holds for k, $2 \leq k \leq K-1$:

$$G_k^*(q_{k+1}) = \max_{q_k}\{G_{k-1}^*(q_k) + g_{k+1}(S_{k.}q_{k+1})\}$$

where $q_k^* = q_k^*(q_{k+1}) = \arg\{\max_{q_k} G_k(q_k, q_{k+1})\}$

Third, let us consider the case where $k = K-1$. The function $G_{K-1}(= G_{K-2}^*(q_{K-1}) + g_K(S_{K-1}, q_K))$ takes into account all gain functions, and G_{K-1} has two variables q_{K-1}, q_K. If we maximize G_{K-1} with respect to q_{K-1} assuming that q_K is a fixed value, then $G_{K-1}^*(q_K) = \max_{q_{K-1}} G_{K-1}(q_{K-1}, q_K)$ and $q_{K-1}^* = q_{K-1}^*(q_K) = \arg\{\max_{q_{K-1}} G_{K-1}(q_{K-1}, q_K)\}$ are obtained. Here, q_K is still a variable.

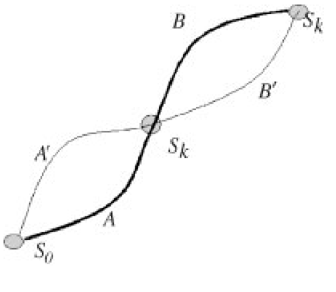

Figure 2. Schematic diagram of the principle of optimality.

Finally, optimal value q_K^* is determined by maximizing $G_{K-1}^*(q_K)$ with respect to q_K under the constraints of both terminal state S_K and transition $S_K = T_K(S_{K-1}, q_K)$ if such constraints are given. Here, q_K^* is not a variable but a *value*. After optimal value q_K^* is determined, q_{K-1}^* is determined by $q_{K-1}^* = q_{K-1}^*(q_K^*)$. Here, q_{K-1}^* is also no longer a function of q_K, being different from that of forward computation. This backward computation continues to determine values $q_{K-2}^*, q_{K-3}^*, q_{K-4}^* \ldots, q_1^*$. At the same time, the optimal state sequence $S_0, S_1^*, S_2^*, S_3^*, \ldots, S_{K-1}^*, S_K^*$, is determined by using $S_k^* = T_k(S_{K-1}^*, q_k^*), k = 1, 2, \ldots, K$ where $S_0^* = S_0$. The maximum value of G,G,* is also determined by using q_k^* and S_k^*, $k = 1, 2, \ldots, K$.

The above iterative procedure considers all possible combinations of $q_1, q_2, q_3, \ldots, q_{K-1}, q_K$ to obtain the maximum value of G applying the principle of optimality. It is also confirmed when we consider that the sequence $S_0, S_1, S_2, S_3, \ldots, S_{K-1}, S_K$ in Fig. 2 is taken by the sequence $S_0, S_1^*, S_2^*, S_3^*, \ldots, S_{K-1}^*, S_K^*$ obtained in this section. In other words, each kth step of the iterative computation discovers state S_k on the full optimal path in Fig. 2 satisfying the principal of optimality.

The key factor for understanding the procedural aspects of iterative DP computation consists of three parts:

1) consideration of G_k with two variables, q_{k-1} and q_k,
2) treatment of q_k as a fixed value when determining the optimum q_{k-1} in $G_k(q_{k-1}, q_k)$ in the forward computation, and
3) backward determination of values q_k^* from $k = K-1$ to $k = 1$ using the formula $q_k^* = q_k^*(q_{k+1}^*) = \arg\{\max_{q_k} G_k(q_k, q_{k+1}^*)\}$,where $q_k^*(q_k+1)$ and $G_k(q_k, q_{k+1})$ should be stored (memoization) at each kth step of the forward computation.

Constraints

We must consider two kinds of constraints, local and global, when establishing an iterative computation of DP. The constraints model the requirements provided by each application.

1) A local constraint is represented by $T_k(S_{k-1}, q_k)$. It determines the relationship between S_{k-1} and q_k to reach S_k.
2) A global constraint is represented by spatial allocation or algebraic structure of states $\{S_0, S_1, S_2, S_3, \ldots, S_{K-1}, S_K\}$. It is independent of local constraints. Assignment of conditions for S_0 and S_K is a global constraint.

Because the explanations in this section may not be sufficient to gain a thorough understanding of DP, we present more concrete examples.

TIME ALIGNMENT

In the fields of speech recognition (6), biological information processing (7), and other applications including artificial intelligence and information retrieval, so-called nonlinear

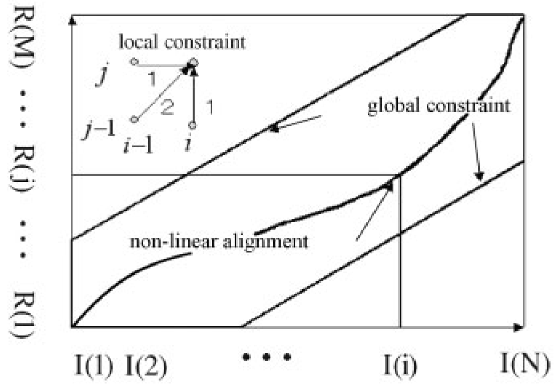

Figure 3. Nonlinear time alignment using dynamic programming.

alignment algorithms based on DP are widely used. Each of them is a different realization of dynamic programming for a different sequential decision problem.

We consider a simple algorithm of a time alignment problem to explain how DP is implemented in such application domains. The main objective of this time alignment problem is to obtain an optimal correspondence between two time sequences that minimizes the total sum of the mutual distance by choosing optimal time pairs from two time sequences under local and global constraints, as shown in Fig. 3. In the figure, $\{I(i) : 1 \leq i \leq N\}$ is an input time sequence of a feature vector, whereas $\{R(j) : 1 \leq j \leq M\}$ is another sequence of a feature vector called a reference time sequence. The bold line in Fig. 3 shows a sequence of optimal pairs composed of $(i_k^*, j_k^*), (k = 1, 2, \ldots, K)$, where the optimality means minimization of the total sum of distance function, considering possible pairs (i, j) under the following conditions:

1) Boundary conditions $(i_1^*, j_1^*) = (1, 1)$ and $(i_K^*, j_K^*) = (N, M)$ are satisfied,
2) Local paths are determined using a local constraint, and
3) The optimal path must be included in the area determined by global constraint.

The nonlinear time-alignment problem belongs to the class of sequential decision problems, and its solution creates an automaton as the other representation mentioned above. The automaton and its DP algorithm are two representations of a sequential decision process, and they are coupled tightly with each other.

Through the correspondence between them we can understand how DP is actually implemented. Therefore, we make an automaton of a nonlinear time-alignment problem by taking into account the correspondences between components of the two representations.

First, state S_k of the automaton of Fig. 1 corresponds to a location (i,j) on a two-dimensional array of the alignment problem, where i and j are discrete points on time axes of input and reference time sequences, respectively. A decision q_k of the automaton of Fig. 1 corresponds to selection of a path among a set of local paths to reach location (i, j). In Fig. 3, the set of local paths consists of three paths, namely, paths from location $(i-1, j), (i-1, j-1)$, or $(i, j-1)$ to (i, j). The selection of a path is the result of evaluating each path based on a criterion described later.

Second, a transition $S_k = T_k(S_{k-1}, q_k)$ of Fig. 1 corresponds to a transition from one of three locations $(i-1, j), (i-1, j-1), (i, j-1)$, to location (i,j) by selecting a path, and S_{k-1} corresponds to all three locations.

Finally, we consider a distance function instead of a gain function $g_k(S_{k-1}, q_k)$. Here, we recall the automaton model of the sequential decision process and its iterative computation of dynamic programming mentioned above. Let us assign a variable G_k^* of the iterative computation to a state S_k of the automaton model. Then a similar assignment for the alignment problem leads to the correspondence of a variable $D(i,j)$ to a location (i, j) by introducing $D(i, j)$ as a minimum accumulated distance. To introduce $D(i,j)$, we use the normalized sum of weighted distance, defined by

$$J = \frac{1}{W}\sum_{k=1}^{K} w_k d_k(i_k, j_k)$$

The boundary conditions, $(i_1, j_1) = (1, 1), (i_K, j_K) = (N, M)$, and the total sum of weights $W = \sum w_k$ are used. If we use weight w_k attached to each local path shown in Fig. 3, then value W takes a constant value $N+M$ for an arbitrary path from $(i_1, j_1) = (1, 1)$ to $(i_K, j_K) = (N, M)$ because of the property of rectilinear city block distance. Therefore, weight W_k takes a value of 1 for transition from $(i-1, j)$ or $(i, j-1)$ to (i, j) and 2 for transition from $(i-1, j-1)$ to (i, j), as shown in Fig. 3, because weights attached to local paths are parts of rectilinear city block distance. The term $w_k d_k(i_k, j_k)$ corresponds to a gain function $g_k(S_{k-1}, q_k)$. In a real application, $d(i, j) = d(I(i), R(j))$ is usually defined by a distance measure between feature vectors $I(i)$ and $R(j)$. Then we can obtain the following iterative form of dynamic programming regarding $D(i, j)$ along with the transition of the state by choosing one of the following paths:

$$D(i, j) = \min\begin{cases} D(i-1, j) + d(i, j) \\ D(i-1, j-1) + 2d(i, j) \\ D(i, j-1) + d(i, j) \end{cases}$$

The boundary condition of the above equation is $D(0, j) = D(i, 0) = \infty; i = 1, 2, \ldots, N; j = 1, 2, \ldots, M$. The role of decision q_k in the automaton model is regarded as selection of the minimum of three values in the alignment model. In other words, decision q_k does not appear explicitly in the alignment model. The selection is determined by finding the minimum among three candidates, each of which is composed of $D(i, j)$ and $d(i, j)$.

Local Constraint and Semimonotonic Property

Generally, the form of iterative computation depends mainly on the type of local constraint. The local constraint shown in Fig. 3 has the property of semimonotonic increase of the location parameter (i, j) in local transition: $i_k \leq i_{k+1}$ and $j_k \leq j_{k+1}$ hold for any transition from (i_k, j_k) to (i_{k+1}, j_{k+1}). The semimonotonic property of a time parameter is a natural characteristic of a time sequence because of causality. Embedding the property into the local constraint guarantees retention of the property of a semimonotonic increase in time parameters in optimally corresponding sequences. In most real applications, we must consider a global constraint for the states to properly execute the iterative computation for *D(i, j)* and eliminate the effects of irregular situations. In Fig. 3, the global constraint determines the area bordered by six solid lines in which actual working states are allowed, and such constraint is realized by the assignment of an infinite value for all $D(i,j)$ beyond the area during the computation.

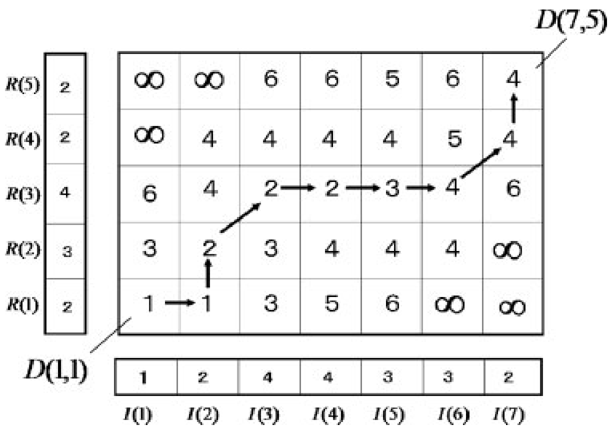
Recognition

The value $\frac{1}{M+N}D(N,M)$ becomes the output, which indicates the minimum value of J obtained by choosing the optimal path from $(i_1,j_1)=(1,1)$ to $(i_K,j_K)=(N,M)$. When m reference sequences are used to represent m classes and one input sequence, then m output values are obtained. These m values can be compared and the minimum found to determine the nearest class because their values are normalized for different lengths of reference sequence.

NUMERICAL EXAMPLE

Figure 4 shows a simple numerical example of nonlinear time alignment. The input and reference time sequences are $I(i)=1,2,4,4,3,3,2$ and $R(j)=2,3,4,2,2$, respectively. The distance measure is defined by $d(i,j)=|I(i)-R(j)|$, and the start and end states are given by $(i_1,\ j_1)=(1,1)$ and $(i_k,j_k)=(7,5)$. A global constraint for the states is modeled by the assignment of infinite value ∞ around two corners of the array. Figure 4 shows a 5×7 array of values assigned to $D(i,j)$ as the result of iterative computation, where parameter i indicates the horizontal axis, and parameter j indicates the vertical axis and counts from the bottom of the array.

The numerical computation takes the following procedure. We use a variable of 6×8 array including marginal components, namely, $D(i,j): i=0,1,2,3,4,5,6,7;$ $j=0,1,2,3,4,5$. The initial condition of marginal components of $D(i,j)$ is determined by $D(i,0)=\infty, i=0,1,2,3,4,5,6,7$ and $D(0,j)=\infty, j=0,1,2,3,4,5$.



R(5)	2	∞	∞	6	6	5	6	4
R(4)	2	∞	4	4	4	4	5	4
R(3)	4	6	4	2	2	3	4	6
R(2)	3	3	2	3	4	4	4	∞
R(1)	2	1	1	3	5	6	∞	∞
		1	2	4	4	3	3	2
		I(1)	I(2)	I(3)	I(4)	I(5)	I(6)	I(7)

Figure 4. Numerical example of time alignment.

To avoid extreme nonlinear alignment we establish a global constraint such as $D(1,4)=D(1,5)=D(2,5)=D(6,1)=D(7,1)=D(7,2)=\infty$. We initially determine $D(1,1)=|I(1)-R(1)|=|1-2|=1$. Then an iterative computation starts from $i=1$ to $i=7$ for $j=,1,2,3,4,5$.

In the case of $i=1$ and $j=2,3,4,5$, the following equation

$$D(1,j)=\min\begin{cases}D(0,j)+d(1,j)\\ D(0,j-1)+2d(1,j)\\ D(1,j-1)+d(1,j)\end{cases}$$

determines the values of the first column $(i=1)$, namely, $D(1{,}2)=1{+}2=3$, $D(1{,}3)=3{+}3=6, D(1{,}4)=D(1{,}5)=\infty$ using $d(1,2)=2, d(1,3)=3, d(1,4)=1, d(1,5)=1$. The result $D(1,4)=D(1,5)=\infty$, is because of the global constraint.

In the case of $i=2$ and $j=1,2,3,4,5$, the equation

$$D(2,j)=\min\begin{cases}D(1,j)+d(2,j)\\ D(1,j-1)+2d(2,j)\\ D(2,j-1)+d(2,j)\end{cases}$$

determines the values of the second column $(i=2)$, namely, $D(2{,}1)=1+0, D(2{,}2)=1{+}1=2, D(2{,}3)=2{+}2=4, D(2{,}4)=4+0=4, D(2{,}5)=\infty$ using $d(2,1)=0, d(2,2)=1, d\times(2,3)=2, d\ (2,4)=d(2,5)=0$. The result $D(2,5)=\infty$ is because of the global constraint.

We continue this computation until $i=7$. Then for the case $j=1,2,3,4,5$, the equation

$$D(7,j)=\min\begin{cases}D(6,j)+d(7,j)\\ D(6,j-1)+2d(7,j)\\ D(7,j-1)+d(7,j)\end{cases}$$

determines the values of the seventh column $(i=7)$, namely, $D(7,1)=\infty, D(7,2)=\infty, D(7,3)=6, D(7,4)=4$, $D(7,5)=4$ using $d(7,1)=0, d(7,2)=1, d(7,3)=2, d(7{,}4)=d(7,5)=0$. The result $D(7,1)=D(7,2)=\infty$ is because of the global constraint.

The final results of the time alignment are the minimum of $J=D(7,5)/(7+5)=4/12=1/3$, and the alignment trajectory indicates a chain of arrows in the figure between two sequences obtained by tracing back from location $(7,5)$ to $(1,1)$. Moreover, the value of K becomes 9. The tracing back from the terminal location $(7,5)$ selects the local optimal path for $D(7,5)$ in the equation

$$D(7,5)=\min\begin{cases}D(6,5)+d(7,5)\\ D(6,4)+2d(7,5)\\ D(7,4)+d(7,5),\end{cases}$$

where $d(7,5) = 0$ and $D(6,5) + d(7,5) = 6, D(6,4) + 2d(7,5) = 5, D(7,4) + d(7,5) = 4$. It is clear that the backtracing path from (7,5) reaches location (7,4). Then we continue tracing back from location (7,4) using the equation

$$D(7,4) = \min \begin{cases} D(6,4) + d(7,4) \\ D(6,3) + 2d(7,4) \\ D(7,3) + d(7,4) \end{cases}$$

where $d(7,4) = 0$ and $D(6,4) + d(7,4) = 5, D(6,3) + 2d(7,4) = 4, D(7,3) + d(7,4) = 6$. It is clear that the backtracing path recovers location (6,3). We continue the same neighborhood-bound computation until reaching location (1,1). Then the complete path of tracing back is obtained and also $K = 9$ is determined. The arrow sequence of Fig. 4 indicates alignment path from (1,1) to (7,5) using the reverse of complete backtrace.

CONTINUOUS DYNAMIC PROGRAMMING

The time-alignment algorithm would seem to be very useful in many application domains. However, the algorithm described in the previous section still has restricted properties when considered for application to other real-world time-alignment problems. Therefore, many extended algorithms have been developed. One of them is called continuous dynamic programming (CDP) (8). CDP extends the previously described alignment problem, with an input sequence of a fixed length, to accept an endless stream of an input time sequence while the reference sequence is still a fixed interval of a time sequence. In other words, CDP performs segmentation-free matching between an endless input sequence and a reference sequence with fixed length without a priori segmentation of the input stream. The automaton model of CDP is simply described by taking a set of states, $\{(i,j) : -\infty < i < +\infty, 1 \leq j \leq T\}$, while the alignment problem outlined in the previous section takes a rectangular array $\{(i,j) : 1 \leq i \leq N, 1 \leq j \leq M\}$ as the set of states. Then the iterative algorithm of CDP is described using the parameters t,τ instead of i, j so that input and reference time sequences are respectively denoted $f(t), -\infty < t < +\infty$, and $Z(\tau), 1 \leq \tau \leq T$. We use the type of local constraint with weights shown in Fig. 5 and the local distance function $d(t,\tau) = d(f(t), Z(\tau))$, but no global constraint is imposed on the states. However, at each time t the local constraint creates a moving triangular area, as shown in Fig. 5. This area is made from possible combinations of local constraints so that the optimal path is included. The moving triangular area behaves similarly to a global constraint by restricting the admissible area of the (t,τ)-plane at time t. Moreover, the local constraint in Fig. 5 guarantees the property of monotonic increase in the alignment trajectory constructed by possible combinations of local paths to reach (t,T).

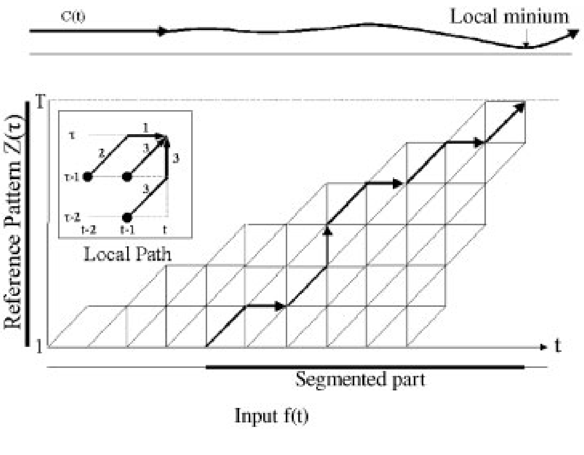


Figure 5. Continuous dynamic programming.

An accumulated minimum distance $P(t,\tau)$ is introduced and assigned to location (t,τ). Then the iterative computation of CDP is expressed by

$$P(t,1) = 3d(t,1),$$

$$P(t,2) = \min \begin{cases} P(t-2,1) + 2d(t-1,2) + d(t,2) \\ P(t-1,1) + 3d(t,2) \\ P(t,1) + 3d(t,2) \end{cases}$$

$$P(t,\tau) = \min \begin{cases} P(t-2,\tau-1) + 2d(t-1,\tau) + d(t,\tau) \\ P(t-1,\tau-1) + 3d(t,\tau) \\ P(t-1,\tau-2) + 3d(t,\tau-1) + 3d(t,\tau) \end{cases}$$

$$(3 \leq \tau \leq T)$$

where the initial condition is given by

$$P(-1,\tau) = P(0,\tau) = \infty \quad (1 \leq \tau \leq T)$$

The normalized minimum accumulated distance at time t is determined by

$$C(t) = \frac{P(t,T)}{3T}$$

where the total sum of weights is a constant value $3T$ for any optimal path because the weights in the local constraint take city block distances, as shown in Fig. 5. A simple comparison with the relationship between J and $D(i,j)$ in the previous section reveals that the output of CDP at time t can be expressed by

$$C(t) = \frac{1}{3T} \min_{(t_1,\tau_1) \leq (t_2,\tau_2) \leq \cdots \leq (t_K.\tau_K)} \left\{ \sum_{k=1}^{K} w_k d(t_k,\tau_k) \right\}$$

where causal monotonicity $(t_k,\tau_k) \leq (t_{k+1},\tau_{k+1})$ means that both $t_k \leq t_{k+1}$ and $\tau_k \leq \tau_{k+1}$ hold.

Segmentation-Free Recognition

The variable $C(t)$ is regarded as the output stream of CDP that is used to *frame-wisely* recognize a category represented by a reference pattern $\{Z(\tau) : \tau = 1, 2, \ldots, T\}$ and also detect an interval in an endless input stream at time t^* when $C(t)$ takes a local minimum at t^* under threshold value h. Here, the detection is dependent only on the local minimum of $C(t)$. At the same time, by tracing back the trajectory starting at location (t^*, T), we can find the location $(t_s^*, 1)$ on the two-dimensional array $\{(t, \tau) : -\infty < t < +\infty, 1 \leq \tau \leq T\}$. Then it is possible to segment the interval $[t_s^*, t^*]$ in the input stream that is optimally aligned to the reference time interval. To carry out the backtracing processing, it is necessary to recall the optimal local paths to reach location (t^*, T) from location $(t_s^*, 1)$, where $(t_s^*, 1)$ is determined as the end state of the backtracing. The detection of the interval $[t_s^*, t^*]$ is a segmentation that needs no assumption beforehand for segmentation.Therefore, this processing performs segmentation-free or spotting recognition of the reference time sequence that represents a category, such as a word. In other words, CDP simultaneously performs both segmentation and recognition by detecting a local minimum of the output stream of CDP.

We must now describe an important factor regarding CDP in which the segmentation-free recognition is based not on a global but a local minimum of the output stream of CDP. The detection of the local minimum is easily accomplished. From the viewpoint of real-time processing, this scope is suitable for its realization, because it means simply monitoring the stream of $C(t)$. The detection works well to perform segmentation-free recognition or retrieval of intervals frame-wisely from a database of sequences that are similar to a query sequence of a fixed length (8).

OTHER APPLICATIONS

Modifications of Local Distance and Constraints

The time-alignment algorithm described can be modified to solve a problem of string matching by using another type of local distance measure that deals with insertion, erasure, and confusion (replacement) between symbols in two strings.

Global and local constraints of time-alignment problems mentioned above are relatively simple, but generally, local and global constraints in many applications take different types. In creating DP algorithms based on more complex or different constraints, constraints are usually transformed into those of the baseline algorithm. One method to transform a given problem into the problem solved by the baseline algorithm is to transform a global constraint into a local constraint. For instance, consider the case that a global constraint of the automaton model of Fig. 1 imposes the relationship $q_1 + q_2 + \cdots + q_k = C$, ($C$: constant value), assuming that each decision q_k takes a value, and a local constraint is taken such as $q_k \geq 0$ for $k = 1, 2, \cdots, K$. We introduce a variable P_k with the relationship $q_k = p_k - p_{k-1}$. Then the global constraint changes to a part of the local constraint, namely $p_K = C$, and the rest of the local constraint is composed of $p_1 \geq 0$, $p_k \geq p_{k-1}$ for $k = 2, 3 \cdots, K$ and $S_k = T_k(S_{k-1}, p_k)$ while gain g_k becomes a function of $(p_k \geq p_{k-1})$and S_{k-1}. In other words,we have the expression $g_1(p_1), g_2(p_1, p_2), g_3(p_2, p_3), \ldots, g_K(p_{K-1}, p_k)$, so the DP algorithm to solve the transformed problem is formally equivalent to the baseline algorithm of DP. The key factor for understanding the procedural aspects mentioned in baseline DP algorithm is also valid.

Markov Decision Process

DP is applicable to a stochastic decision model. A simple algorithm for Markov decision process has been described (9). Let us define N states, $S_1, S_2, S_3, \ldots, S_i, \ldots, S_N$, and M decisions, $d_1, d_2, d_3, \ldots, d_m, \ldots, d_M$. The set of decisions is denoted by D and any decision is applicable to each S_i. A decision $d_m \in D$ for state S_j determines both transition probability $r_{ij}(m)$ from state S_i to S_j and gain $g_{ij}(m)$ of state S_j. Then each kth step of the optimal decision process with total gain $G_i^*(k)$ starting state from S_i satisfies the recursive equation of DP:

$$G_i^*(k+1) = \max_{d_m \in D} \left\{ \sum_{j=1}^{N} r_{ij}(m)(g_{ij}(m) + G_j^*(k)) \right\}$$

Building Block

Alternatively, DP can be embedded into another algorithm. For instance, a Hidden Markov Model uses a DP kernel as its important search engine called the Viterbi algorithm. Moreover we find the usage of DP in the following problems and algorithms: the Cocke-Younger-Kasami algorithm, the Earley algorithm, the knapsack problem, computer chess, games, traveling salesman problem, optimizing the order of chain matrix multiplication, stereo image matching, and image registration. Therefore, we often use DP as a building block to construct larger algorithms for specific purposes.

F

FORMAL LOGIC

INTRODUCTION

Logic studies the validity of arguments. A typical case in point is that of syllogisms: logical arguments in which, starting from two premises, a conclusion is reached. For example, given that

> There are horses in Spain.
> All horses are mammals.

it can be inferred that

> There are mammals in Spain.

Of course, if instead of the second premise we had the weaker one

> Some horses are mammals.

where the universal (*all*) has been replaced with an existential (*some/exists*), then the argument would not be valid. In Ancient Greece, Aristotle exhaustively considered all possible combinations of universals and existentials in syllogisms, allowing also for the possibility of negations, and collected those corresponding to valid inferences in a classification theorem. For many centuries, that classification (slightly enhanced by the scholastics during the Middle Ages) was all there was to know about logic.

In its origin, the term "formal" logic used to be a reference to the form of the arguments. The validity of an argument depends exclusively on the *form* of the premises and on the conclusion, not on whether these are true or false. In the previous example, if we were to replace "horses" with "unicorns," the argument would still be valid, regardless of the fact that unicorns do no exist.

Nowadays, however, "formal" refers to the use of the formal and rigorous methods of mathematics in the study of logic that began to be put into practice in the second half of the nineteenth century with George Boole and, especially, Gottlob Frege (see Ref. 1). This trend started with a shift to a symbolic notation and artificial languages, and gradually it evolved until, in 1933 with Tarski (2), it culminated with the withdrawal from an absolute notion of Truth and instead focused on the particular truths of concrete structures or models.

Propositional logic

Arguably, the simplest logic is *propositional logic*, and we will use it to introduce the underlying elements of every logic. Given a set $A = \{p, q, r, \ldots\}$ of *atomic propositions,* the language of propositional logic is constructed according to the following rules:

$$\varphi ::= p \in A \mid \neg p \mid \varphi \vee \varphi \mid \varphi \wedge \varphi \mid \varphi \to \varphi \mid \varphi \leftrightarrow \varphi$$

$\neg$ means 'No' $\to$ means 'Implies/Then'
$\vee$ means 'Or' $\leftrightarrow$ means 'If and only if'
$\wedge$ means 'And'

For example, let us assume that p represents "The chef is competent," q represents "The ingredients are expired," and r represents "The cake is delicious." Then, the premise "If the chef is competent and the ingredients are not expired, then the cake will be delicious" could be represented in the language of propositional logic as follows:

$$(p \wedge \neg q) \to r$$

Furthermore, if we assume that the chef is actually competent, that is, if we assume p as the second premise, we can conclude that "If the cake is not delicious, the ingredients are expired", or, formally:

$$\neg r \to q$$

But how and why can we conclude that this last sentence follows from the previous two premises? Or, more generally, how can we determine whether a formula φ is a valid consequence of a set of formulas $\{\varphi_1, \ldots, \varphi_n\}$? Modern logic offers two possible ways, which used to be fused in the time of syllogisms: the model-theoretic approach and the proof-theoretic one.

In model theory, it is necessary to assign a meaning to the formulas, to define a *semantics* for the language. The central notion is that of *truth* and of deciding the circumstances under which a formula is true. The more complex the logic, the more difficult this assignment is and hence the more complex the semantics. In propositional logic, we have to start by assigning arbitrary values to the atomic propositions: A *valuation* V is defined as a function that maps atomic propositions to either 0 (meaning, intuitively, false) or 1 (true). The meaning $\mathcal{I}^V(\varphi)$ of an arbitrary formula φ is defined recursively:

$$\begin{array}{lcl}
\mathcal{I}^V(p) & = & V(p) \\
\mathcal{I}^V(\neg\varphi) & = & \begin{cases} 1 & \text{if } \mathcal{I}^V(\varphi) = 0 \\ 0 & \text{if } \mathcal{I}^V(\varphi) = 1 \end{cases} \\
\mathcal{I}^V(\varphi \vee \psi) & = & \begin{cases} 1 & \text{if } \mathcal{I}^V(\varphi) = 1 \quad \text{or} \quad \mathcal{I}^V(\psi) = 1 \\ 0 & \text{otherwise} \end{cases} \\
\mathcal{I}^V(\varphi \wedge \psi) & = & \begin{cases} 1 & \text{if } \mathcal{I}^V(\varphi) = 1 \quad \text{and} \quad \mathcal{I}^V(\psi) = 1 \\ 0 & \text{otherwise} \end{cases} \\
\mathcal{I}^V(\varphi \to \psi) & = & \begin{cases} 1 & \text{if } \mathcal{I}^V(\varphi) = 0 \quad \text{or} \quad \mathcal{I}^V(\psi) = 1 \\ 0 & \text{otherwise} \end{cases} \\
\mathcal{I}^V(\varphi \leftrightarrow \psi) & = & \begin{cases} 1 & \text{if } \mathcal{I}^V(\varphi) = \mathcal{I}^V(\psi) \\ 0 & \text{otherwise} \end{cases}
\end{array}$$

For example, if $V(p) = V(q) = 0$ and $V(r) = 1$, then $\mathcal{I}^V(\neg p) = 1$, $\mathcal{I}^V(\neg p \wedge q) = 0$, and $\mathcal{I}^V(r \to (\neg p \wedge q)) = 0$.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

If $\mathcal{I}^V(\varphi) = 1$, then it is said that V is a *model* of φ, or that V *satisfies* φ; it is a "world" in which φ is true. A formula is said to be *valid* if it is true under all circumstances, that is, if every valuation is a model of φ:

$$\varphi \text{ is valid if } \mathcal{I}^V(\varphi) = 1 \text{ for all valuations } V$$

For instance, it is easy to check that $p \rightarrow (q \rightarrow p)$ is a valid formula. Similarly, if V is a model of all the formulas in a set Γ, then V is said to be a model of Γ. A formula φ is a *semantic consequence* of a set Γ of formulas, written $\Gamma \models \varphi$, if every model of Γ is also a model of φ or, alternatively, if φ is true whenever all formulas in Γ are true:

$$\Gamma \models \varphi \text{ if } \mathcal{I}^V(\varphi) = 1 \text{ whenever } \mathcal{I}^V(\psi) = 1 \text{ for all } \psi \in \Gamma.$$

In the proof-theoretic approach, the central concept is that of *proof*: to show that a statement follows from some others, one has to make use of a *deduction system*. Deduction systems are syntactic in nature, caring only about the form of sentences and not about what they represent or their possible meaning. One such system, the *axiomatic method*, distinguishes a subset of formulas, called *axioms*, formed by all sentences that match any of the following patterns:

$$\begin{array}{l} \varphi \rightarrow (\psi \rightarrow \varphi) \\ (\varphi \rightarrow (\psi \rightarrow \chi)) \rightarrow ((\varphi \rightarrow \psi) \rightarrow (\varphi \rightarrow \chi)) \\ (\neg \varphi \rightarrow \neg \psi) \rightarrow (\psi \rightarrow \varphi) \end{array}$$

Given a set of formulas Γ, a formula φ is said to be a *logical consequence* of Γ, written $\Gamma \vdash \varphi$, if there is a sequence of formulas $\varphi_1, \varphi_2, \ldots, \varphi_n$ such that:

1. $\varphi_n = \varphi$.
2. For all $i \leq n$, either φ_i is an axiom, or φ_i belongs to Γ, or $j, k < i$ exist such that $\varphi_k = \varphi_j \rightarrow \varphi_i$.

This corresponds to an iterative process in which we can add to the set of provable sentences, at every stage, either an axiom (whose validity is clear according to the defined semantics), an element of Γ (a hypothesis we are assuming as given), or a formula φ_i whenever we have previously proved φ_j and that φ_j implies φ_i.

The axiomatic method is not the only deduction system. In *natural deduction*, rules are associated with the connectives: introduction rules, to prove formulas containing the connective, and elimination rules, to obtain consequences from a formula with a given connective. For example, the following are prototypical:

$$\frac{\varphi \;\; \psi}{\varphi \wedge \psi} \quad \frac{\varphi \wedge \psi}{\varphi} \quad \frac{\varphi \wedge \psi}{\psi} \quad \frac{}{\varphi} \;\; \text{if } \varphi \in \Gamma$$

The first rule is the introduction rule for the logical "and," and it captures the idea that if φ and ψ can both be proved, so can their conjunction; the next two are elimination rules, stating that from a conjunction, both its conjuncts can be derived; the last allows the derivation of a hypothesis. Similar rules are associated with the remaining connectives. Compared with the axiomatic method, natural deduction has a richer set of rules: As a result, it is easier to prove things *in* the logic using natural deduction, but the simplicity of the axiomatic method comes in handy if one is interested in proving something *about* the logic. Although the presentations of deduction systems vary, they all allow the derivation of the same set of sentences (assuming they are properly designed).

Let us return to the example of the chef and the cake. In symbols, the argument can now be expressed as follows:

$$\{(p \wedge \neg q) \rightarrow r, p\} \models \neg r \rightarrow q$$

Although it is a bit tedious, one can consider all eight possible assignments of values to p, q, and r and check that it is actually a semantic consequence.

But then the following question can be raised. How come the argument cannot be expressed instead as follows:

$$\{(p \wedge \neg q) \rightarrow r, p\} \vdash \neg r \rightarrow q$$

Indeed, we have defined two different notions of consequence, semantic and logical, and although both are reasonable, they do not seem to have much in common: Which one should be chosen? This is an important *metalogical* question. Fortunately, in the case of propositional logic, it does not matter for it can be proved that

$$\Gamma \vdash \varphi \quad \text{if and only if} \quad \Gamma \models \varphi$$

The implication from left to right, that asserts that any proof-theoretic logical consequence is also a semantic consequence, is known as the *soundness of propositional logic*. The implication from right to left, which claims that any semantic consequence has a syntactic derivation, is the *completeness of propositional logic*.

Assume that we have a finite set Γ of assumptions. We then have two methods at our disposal to decide whether a given formula follows from Γ. Either we build a syntactic proof, or we show that all models of the assumptions also satisfy the formula. In particular, since we are working with a finite set of formulas, there is only a finite number of atomic propositions involved. We can consider all possible valuations and study whether there is one that satifies Γ but not φ. Hence, for propositional logic, the validity problem is *decidable*, in the precise sense that there is an effective procedure or algorithm that solves it (see the article on Computability).

This ends the presentation of propositional logic. Summing up, the most important elements introduced, common to all logics are as follows: a syntax that defines the language; a semantics to assign meaning to the formulas; logical and semantic consequences and relationships between them; and the validity problem.

PREDICATE LOGIC

The simplicity of propositional logic comes at a price. Its expressive power is limited; in particular, it cannot deal with syllogisms like that at the beginning of this article:

> There are horses in Spain.
> All horses are mammals.

which implies that

> There are mammals in Spain.

In propositional logic we would have to formalize the first premise by means of an atomic proposition p, the second with q, and the conclusion r would not be a valid consequence.

To remedy this issue, predicate logic (also known as first-order logic) introduces *predicates* and *quantifiers*. Assume that we use $H(x)$, $S(x)$, and $M(x)$ to express that x is a horse, x dwells in Spain, and x is a mammal, respectively. Then, the syllogism can be presented as a valid argument in predicate logic as follows:

$$\begin{array}{c} \exists x(H(x)\wedge S(x)) \\ \forall x(H(x)\rightarrow M(x)) \\ \hline \exists x(M(x)\wedge S(x)) \end{array}$$

where the quantifier $\forall$ means "for all" and $\exists$ means "there exists."

But predicate logic goes beyond syllogisms. It not only allows multiple premises, but also predicates with an arbitrary number of arguments. For example, a statement like "the ancestor of an ancestor is also an ancestor" has no room in the syllogistic theory, whereas it can be dealt with in predicate logic by using a binary predicate $A(x, y)$ with the meaning x is an ancestor of y:

$$A(x,y)\wedge A(y,z)\rightarrow A(x,z)$$

In predicate logic, one can distinguish two levels: terms and formulas. Terms denote individuals, whereas formulas are statements about those individuals. Terms are constructed from a set of variables $(x_0, x_1, x_2, \ldots)$ and a set of constants and function symbols with arbitrary arities:

$$t ::= x \mid c \mid f(t_1,\ldots,t_n) \qquad f \text{ function symbol of arity } n$$

Thus, if *mother* is a unary function symbol, the fact that one's mother is an ancestor can be expressed with $A(\mathit{mother}(x), x)$.

Formulas, in turn, are constructed from terms and a set of predicate symbols:

$$\begin{aligned} \varphi ::= {} & t_1 = t_2 \\ & \mid R(t_1,\ldots,t_n) \mid \neg\varphi \mid \varphi\vee\varphi \mid \varphi\wedge\varphi \mid \varphi\rightarrow\varphi \mid \varphi\leftrightarrow\varphi \mid \forall x\varphi \mid \exists x\varphi \end{aligned}$$

where R is a predicate symbol of arity n. The resulting set of formulas depends on the concrete sets of function and predicate symbols, F and P. We will write $L(F, P)$ to denote the set of formulas, or language, built using the sets F and P, or just L if no ambiguity develops. For example, if *peter* is a constant that represents a concrete boy and S is a binary predicate that stands for "sibling," the sentence

$$\forall x(S(x,\mathit{peter})\rightarrow \forall z(A(z,\mathit{peter})\leftrightarrow A(z,x)))$$

expresses that *peter* has the same ancestors as his siblings.

For another, less-contrived example, consider the function symbols 0 (constant), *suc* (unary), and $+$, $*$(binary), and the predicate $<$ (binary), which give rise to the language of arithmetic for obvious reasons. Commutativity of addition is then expressed as follows:

$$\forall x\,\forall y + (x,y) = +(y,x)$$

Although awkward, this is the correct notation; however, we will usually stick to the standard infix notation and write $+(x, y)$ as $x + y$.

Note that quantifiers are variable binding operators in the same sense as the summation symbol $\sum$ in an expression like $\sum_{x=1}^{9} x$, where the variable x cannot "vary" and take any arbitrary value. (This will become more clear once the semantics of quantifiers is presented in the next section.) In $\forall x\varphi$ and $\exists x\varphi$, the formula φ is said to be the scope of the quantifier. Then, an occurrence of a variable in an arbitrary formula is said to be *free* if it falls under the scope of no quantifier; otherwise, that occurrence is called *bound*.

Semantics

First of all, the universe of discourse, the elements to be referred to by terms, has to be fixed; then, function and predicate symbols from the sets F and P have to be interpreted over it. More precisely, a structure $\mathcal{A}$ is a tuple

$$\langle A, c^A, \ldots, f^A, \ldots, R^A \ldots\rangle$$

such that

- A is a nonempty set;
- for every constant $c\in F, c^A \in A$;
- for every n-ary function symbol $f\in F$, f^A is a function from A^n to A;
- for every n-ary predicate symbol $R\in P, R^A$ is a subset of A^n.

An obvious structure $\mathcal{N}$ for the language of arithmetic consists of the set $\mathcal{N}$ of natural numbers as universe, with 0^N the number zero, suc^N the successor operation, $+^N$ and $*^N$ addition and multiplication of natural numbers, and $<^N$ the "less-than" relation. Note, however, that the structure can be arbitrary. Another valid structure is $\mathcal{M}$, where:

- the universe M is the set of digits $0, 1, 2, \ldots, 9$;
- 0^M is the digit 9;
- suc^M returns 0 when applied to 9 and the following digit in the usual order otherwise;
- $+^M$, when applied to two digits, returns the smallest one;
- $*^M$ returns the greatest digit;
- $<^M$ is the set of all pairs (u, v) with u greater than v.

More generally, the set A can consist of letters, derivable functions, matrices, or whatever elements one chooses.

Before meaning can be ascribed to terms, yet another component is needed: an *assignment* mapping variables to elements of A. Then, an *interpretation* $\mathcal{I} = (\mathcal{A}, V)$ is a pair formed by a structure and an assignment V. The meaning of a term in a given interpretation, that is, the individual it refers to in the universe, can now be defined recursively:

$$\mathcal{I}(x) = V(x)$$
$$\mathcal{I}(c) = c^A$$
$$\mathcal{I}(f(t_1,\ldots,t_n)) = f^A(\mathcal{I}(t_1),\ldots,\mathcal{I}(t_n))$$

Let us consider the previously defined structure $\mathcal{N}$, and let V be an assignment such that $V(x) = 3$ and $V(y) = 5$. In the interpretation $\mathcal{I} = (\mathcal{N}, V), \mathcal{I}(x * suc(suc(0))) = 6$ and $\mathcal{I}(x + suc(y)) = 9$. On the other hand, in the interpretation $\mathcal{J} = (\mathcal{M}, W)$, where $W(x) = 3$ and $W(y) = 5$, those same two terms get very different meanings: $\mathcal{J}(x*suc(suc(0))) = 3$ and $\mathcal{J}(x + suc(y)) = 3$.

A last piece of machinery is needed. Given an assignment V, a variable x, and an element a of the universe, we write $V[a/x]$ for the assignment that maps x to a and coincides with V in the remaining variables. The truth value of a formula, 0 (false) or 1 (true), with respect to an interpretation $\mathcal{I}$ can finally be defined:

- $\mathcal{I}(t_1 = t_2) = 1$ if $\mathcal{I}(t_1) = \mathcal{I}(t_2)$, and 0 otherwise;
- $\mathcal{I}(R(t_1,\ldots,t_n)) = 1$ if $(\mathcal{I}(t_1),\ldots,\mathcal{I}(t_n)) \in R^A$;
- $\mathcal{I}(\neg\varphi), \mathcal{I}(\varphi \wedge \psi), \mathcal{I}(\varphi \vee \psi), \mathcal{I}(\varphi \to \psi), \mathcal{I}(\varphi \leftrightarrow \psi)$ are defined analogously to the propositional case ;
- $\mathcal{I}(\forall x\varphi) = 1$ if $\mathcal{J}(\varphi) = 1$ for all $a \in A$, where $\mathcal{J} = (\mathcal{A}, V[a/x])$;
- $\mathcal{I}(\exists x\varphi) = 1$ if $a \in A$ exists with $\mathcal{J}(\varphi) = 1$, where $\mathcal{J} = (\mathcal{A}, V[a/x])$.

As in propositional logic, if $\mathcal{I}(\varphi)$ is 1, we say that $\mathcal{I}$ is a model of φ or that $\mathcal{I}$ satisfies φ, and we denote it by $\mathcal{I} \models \varphi$. We write $\Gamma \models \varphi$ if every model of all formulas in Γ is also a model of φ.

Note that assignments are only needed to ascribe a meaning to free occurrences of variables. If there are none, the interpretation of a formula is the same regardless of the assignment. Now it can be checked that the formulas

$$\forall x(0 < suc(x)) \quad \text{and} \quad \forall x \exists y(x < y)$$

are both true in the interpretation $\mathcal{N}$ but false in $\mathcal{M}$.

Proof Theory

Deduction systems for predicate logic extend those of propositional logic to take care of predicates and quantifiers. In the axiomatic method, the main difference originates from the extension of the set of axioms.

A valuation in predicate logic is a function from the set of formulas to the set $\{0, 1\}$ that respects the meaning of propositional connectives; that is, $f(\neg\varphi) = 1 - f(\varphi)$, $f(\varphi \wedge \psi) = 1$ if and only if $f(\varphi) = f(\psi) = 1, \ldots$. The set of axioms is then the set of formulas with one of the following forms:

1. Formulas that are mapped to 1 by all valuations.
2. $\forall x(\varphi \to \psi) \to (\forall x\varphi \to \forall x\psi)$.
3. $\varphi \to \forall x\varphi$, with no free occurrences of x in φ.
4. $\exists x(x = t)$ where t is a term that does not contain x.
5. $t_1 = t_2 \to (\varphi \to \psi)$ where φ contains no quantifiers and ψ is obtained from φ by replacing an occurrence of t_1 in φ with t_2.

A derivation of φ from Γ is a sequence $\varphi_1,\ldots,\varphi_n$ such that:

1. $\varphi_n = \varphi$.
2. For all $i \leq n$, either:
   a. φ_i is an axiom;
   b. φ_i belongs to Γ;
   c. j, $k < i$ exist such that $\varphi_k = \varphi_j \to \varphi_i$;
   d. $j < i$ exists and a variable x such that φ_i is $\forall x\varphi_j$.

The formula φ is then a logical consequence of Γ, and it is denoted with $\Gamma \vdash \varphi$.

Likewise, a system of natural deduction for predicate logic is obtained, essentially, by extending the propositional one with the rules

$$\frac{\varphi}{\forall x\varphi} \quad \frac{\forall x\varphi}{\varphi[t/x]}$$

subject to a couple of technical conditions that are omitted and where $\varphi[t/x]$ means that every free occurrence of x in φ is replaced by t.

Completeness and Decidability

Deduction systems are designed so that they are sound, that is, so that a logical consequence is also a semantic consequence, and it is not hard to show that this is the case in predicate logic. The converse implication, completeness, is much harder to prove, but it was also shown to hold for predicate logic by Gödel (3) in 1929. Therefore, for a set of formulas Γ and a formula φ,

$$\Gamma \vdash \varphi \quad \text{if and only if} \quad \Gamma \models \varphi$$

Faced with the problem of deciding whether a given formula is a consequence of a set of premises, we again have the same two alternatives as in propositional logic: either build a derivation or consider the models involved. Now, however, there is a crucial difference. The set of models is not finite, and thus, in general, it will not be possible from their study to conclude whether a formula is a semantic consequence of the premises. Hence, if we intend to obtain a mechanical procedure, an algorithm, to decide the validity of a formula, we are only left with the proof-theoretic approach.

Assume that we want to determine whether a formula φ is valid, that is, whether $\vdash \varphi$ (it can be derived from no hypothesis). By using the axiomatic method, we can enumerate all valid formulas. First, all derivations φ_1 that use axioms of length up to, say 10, are listed; since there can only be a finite number of these, the process ends. Next, derivations φ_1 and φ_1, φ_2 with axioms of length up to 11 are considered; again, there is only a finite number of such derivations. In the next step, derivations of up to three steps with axioms of length less than or equal to 12 are listed; and so on. The process is tedious, but it is mechanizable and considers all posible derivations. If φ is valid, then it has a corresponding derivation and this procedure will eventually produce it. But what if φ is not valid? Then the procedure will not terminate and will offer no clue as to the validity of φ. Indeed, that it is no accident but an unavoidable shortcoming of any procedure to decide the validity of a formula is the content of the *undecidability theorem* proved independently by Church and Turing (4, 5) in 1936.

Note that this does not mean that it is not possible to decide whether a given formula is valid, but that it is not possible to develop a general procedure that always works. For example, if all predicates considered are monadic (take one argument), the resulting language is decidable, and in this case, a computer could be programmed to solve the validity problem.

A GLIMPSE OF OTHER LOGICS

Second-Order and Higher Order Logic

In predicate logic, variables range over the elements of the universe in the structure; this is why it is also called first-order logic. But in mathematics it is often necessary to refer, not to single individuals, but to collections of these. As a result, it is sometimes convenient to consider an extension of predicate logic with second-order variables that range over subsets or, more generally, over n-ary relations of the universe.

The syntax and semantics of second-order logic are defined similarly to those of predicate logic. Now, if X is an n-ary variable and $t_1, \ldots, t_n$ are terms, $X(t_1, \ldots, t_n)$ is also a formula. Second-order logic is more expressive than predicate logic. For example, the structure of the natural numbers cannot be characterized by means of predicate formulas because the induction principle can only be approximated by means of all formulas of the form

$$\varphi(0) \wedge \forall x(\varphi(x) \rightarrow \varphi(suc(x))) \rightarrow \forall x \varphi$$

In second-order logic, however, the induction principle is formally captured by the single formula

$$\forall X(X(0) \wedge \forall x(X(x) \rightarrow X(suc(x))) \rightarrow \forall x X(x))$$

where X is a unary variable, and the structure of natural numbers is characterizable.

Second-order logic allows the expression of mathematical facts in a more natural way; however, this additional expressive power makes the logic much more complex, with many useful properties of predicate logic no longer holding. In particular, there is no deduction system both sound and complete; of course, this is no obstacle for setting up correct and useful (although incomplete) systems. Also, the validity problem is even more undecidable (in a precise technical sense, see the Computability article) than in the first-order case.

Although second-order logic allows for quantifying over predicates, higher order logic (historically, proposed a couple of decades earlier than predicate logic) goes a step beyond and considers, and allows quantification over, predicates that take other predicates as arguments, and predicates that take predicates that take predicates, ... The resulting logic is, again, very complex but extremely expressive, and it has proved to be very useful in computer science.

Intuitionistic Logic

In traditional (also called classical) mathematics, nonconstructive arguments are valid proof methods. It is possible to show that there has to exist an element satisfying a certain property without actually producing a witness to it, and the statement that either a proposition or its negation holds is admitted as true even if none of them has been proved. Some mathematicians object against such principles when working with infinite sets and advocate the practice of constructive procedures. In particular:

- a statement of the form $\exists x \varphi$ is not proved until a concrete term t has been constructed such that $\varphi[t/x]$ is proved;
- a proof of a disjunction $\varphi \vee \psi$ is a pair $\langle a, b \rangle$ such that if $a = 0$ then b proves φ, and if $a \neq 0$ then b proves ψ.

Intuitionistic logic captures the valid principles of inference for constructive mathematics. In this new setting, familiar statements cease to hold. For example, $\varphi \vee \neg \varphi$ is not universally true, and, although the implication $(\neg\varphi \vee \neg\psi) \rightarrow \neg(\varphi \wedge \psi)$ can still be proved, it is not possible to strenghten it to a biconditional. Perhaps surprisingly, a deductive system for intuitionistic logic can be obtained from a classical one just by preventing the *law of double negation*

$$\neg \neg \varphi \rightarrow \varphi$$

or any other equivalent to it, from being used as an axiom.

In this sense, intuitionistic logic is a subset of classical logic. On the other hand, classical logic can also be embedded in intuitionistic logic. For every formula φ, a formula ψ can be constructed such that φ is derivable in the classical calculus if and only if ψ is derivable in the intuitionistic one.

Since the deduction system has been restricted, it is still sound with respect to the semantics for predicate logic, but it is no longer complete. Several semantics for intuitionistic logic have been defined, the simplest of which is probably the one introduced by Kripke. For propositional intuitionistic logic, a *Kripke structure* is a partially ordered set $\langle K, \leq \rangle$ together with an assignment V of atomic propositions to the elements of K such that, if $k \leq k', V(k) \subseteq V(k')$. One can think of the elements in K as stages in time and then $V(k)$ would be the "basic facts" known at instant k. Satisfaction of a formula by a model, called *forcing* and representing the knowledge at a certain stage, is defined recursively:

- k forces p if $p \in V(k)$.
- k forces $\neg \varphi$ if for no $k' \geq k$ does k' force φ.
- k forces $\varphi \wedge \psi$ if k forces φ and k forces ψ.

- k forces $\varphi \vee \psi$ if k forces φ or k forces ψ.
- k forces $\varphi \rightarrow \psi$ if, for every $k' \geq k$, if k' forces φ, then k' forces ψ.

The intuition for all clauses except the second and the fifth is clear. One knows $\varphi \rightarrow \psi$ at instant k, even if none of φ or ψ is yet known, if one knows that for all future instants one can establish ψ if φ can be established. As for the negation, $\neg\varphi$ is known when no evidence for φ can be found at a later stage.

A Kripke structure forces a formula if all its elements do so, and the intuitionistic calculus is sound and complete with respect to forcing. Kripke structures and forcing can be extended to predicate logic so that the corresponding deduction system also becomes sound and complete. Like their classical counterparts, intuitionistic propositional logic is decidable, whereas intuitionistic predicate logic is not.

Predicate Logic in Perspective

In mathematics, predicate logic has been a great success, to the point of being often deemed as *the* logic. It is in principle sufficient for mathematics, has a sound and complete deduction system, and satisfies important semantic results. Indeed Lindstrom's theorems show that there can be no logical system with more expressive power than predicate logic and with the same good semantic properties.

By contrast, computer science (and other fields) has seen a cornucopia of logics suited for different purposes. To cite a few:

- *Modal logic*. It is a logic to reason about concepts such as possibility or necessity.
- *Temporal logic*. It is a brand of modal logic with operators to talk about the passage of time.
- *Fuzzy logic*. To deal with approximate, or vague concepts such as the distinction between "warm" and "hot."
- *Probabilistic logic*. In which the truth values of formulas are probabilities.
- *Nonmonotonic logic*. In this logic, an established piece of knowledge may have to be retracted if additional facts are later known.

Moreover, these logics come in different flavors, usually admitting propositional, first-order, higher order, and intuitionistic presentations, as well as combinations of these and many ad hoc variants.

LOGIC AND COMPUTER SCIENCE

Although profound and important, the practical significance for mathematics of the results obtained during the blossoming of logic in the twentieth century has been limited. By contrast, logic has risen to prominence in computer science where it is expected to play a role analogous to that of calculus in physics. Specification and programming rank among its most important areas of application, which also include fields as diverse as descriptive complexity, compiler techniques, databases, or type theory (6).

Specification and Verification

Computer programs are extremely complex entities, and reasoning about them, except for the smallest instances, is no easy feat. A given computer program poses two related problems: deciding what it is supposed to do and then checking whether it does it. Logic can help here, first, with the formal specification of the expected behavior of a program and, second, in the process of verifying that the program indeed abides by its specification.

In its first use, logic can be seen as a tool to resolve ambiguities. Assume that a programmer is asked to write a program that, given two integers a and b, returns the quotient and remainder of dividing a by b. The behavior of the program when a and b are positive should be obvious, but if one of them is negative, say $a = 5$ and $b = -2$, and the mathematical training of the programmer is a bit shaky, he might be inclined to admit -3 and -1 as valid quotient and remainder. Furthermore, what should the behavior be when the divisor is 0? A bullet-proof, unambiguos specification of the behavior of the program would look like:

$$\begin{array}{l} \varphi \equiv a, b \text{ integers} \\ \textbf{fun } \mathit{division}(a,b) \textbf{ returns } \langle q, r \rangle \\ \psi \equiv (q, r \text{ integers}, a = b * q + r, 0 \leq r < |b|) \vee (b = 0 \wedge q = r = -1) \end{array}$$

In this specification, the *precondition* φ requires the arguments to be integers, whereas the *postcondition* ψ imposes that q and r are the appropriate quotient and remainder if $b \neq 0$, and sets them both to -1 if b is 0 to mark the error condition. Alternatively, one could assume/require that b is never instantiated with 0 as value:

$$\begin{array}{l} \varphi \equiv a, b \text{ integers}, \ b \neq 0 \\ \textbf{fun } \mathit{division}(a,b) \textbf{ returns } \langle q, r \rangle \\ \psi \equiv q, r \text{ integers}, a = b * q + r, 0 \leq r < |b| \end{array}$$

In this case, the postcondition ψ leaves unspecified the behavior of the program if b is 0, so that it should be used only at one's own risk.

In general, the precondition imposes some requirements on the input, whereas the postcondition states all properties that can be assumed about the output. Anything not reflected in them falls outside the programmer's responsibility. To express the precondition and postcondition, any logic can be used.

A specification imposes a contract on the programmer who, given that programming is an error-prone task, would like to have a means to verify that his final code actually satisfies those requirements (see the Formal Program Verification article). The prototypical example of the use of logic in this regard is *Hoare logic*, designed for imperative programming languages. It defines a derivation system consisting of a set of rules of the form

$$\frac{\text{Condition}}{\varphi \; \mathit{instruction} \; \psi}$$

for every instruction in the programming language, establishing the conditions under which a precondition φ and postcondition ψ hold. For example, to the assignment instruction it corresponds the rule

$$\frac{}{\varphi[e/x]\, x := e\, \varphi}$$

which states that some property holds for variable x after the instruction is executed only if it already held when the expression e was substituted for x. Similarly, for sequential composition of instructions, we have the rule

$$\frac{\varphi\, instruction_1\, \psi \quad \psi\, instruction_2\, \chi}{\varphi\, instruction_1\, ;\, instruction_2\, \chi}$$

which states the conditions required for χ to hold after executing $instruction_1$ followed by $instruction_2$. Ideally, to show that a program P satisfies a specification $\varphi P \psi$, one would start with ψ and the final line of P and proceed backward by applying the corresponding rule in the calculus. The fact that programs are hundreds of thousands of lines long and that the application of some of the rules require human intervention makes this direct approach unfeasible in practice.

A different flavor in which logic supports the verification process comes in the form of *proof assistants* or *theorem provers* (see the Automated Theorem Proving article). These are usually embedded within verification systems that allow for formally specifying functions and predicates, to state mathematical theorems and to develop formal proofs. Many of these systems are based on higher order logic, but some use predicate logic. These environments do not directly work with the program code but instead focus on the algorithms that implement, by translating them into an appropriate logical language and then formally proving the properties they are required to satisfy. These systems are very powerful, and some impressive results have been achieved in the verification of certain hardware architectures and protocols, but they present as a major drawback their dependency on user interaction.

In contrast to theorem provers, model checkers are fully automated and their underlying logic is some variation of temporal logic. *Model checking* was proposed in the early 1980s to verify complex hardware controllers and has also come to be used in the verification of software since then. A model checker explores all posible states in a system to check for a counterexample of the desired property and herein lies its limitation: Whereas hardware controllers have a finite, if huge, number of states, typical programs have an infinite number. Even for hardware systems, the number of states can grow exponentially giving rise to what is known as the *explosion problem*. Hence, the devise of abstraction techniques that significantly reduce the size of a system to make it amenable to model checking, without altering its "main" properties, is an active area of research.

Programming

Logic also serves as the foundation of programming languages and has given rise to the *declarative paradigm*.

Logic Programming. Imagine a problem for which all assumptions and requirements have been expressed as predicate logic formulas and gathered in a set Γ. For this problem, we are interested in determining whether a solution exists, an element that under the given requirements satisfies a certain condition. Formally, we are interested in the entailment

$$\Gamma \vdash \exists x\, \varphi(x)$$

Furthermore, we are probably interested not only in finding out if such an element exists but also in a concrete instance, that is, a term t such that $\Gamma \vdash \varphi[t/x]$.

In general, from $\Gamma \vdash \exists x\, \varphi$, it does not follow that $\varphi[t/x]$ for some term t; think of $\Gamma = \{\exists x\, R(x)\}$ for a counterexample. *Logic programming* is the area of research that studies the conditions that guarantee the existence of t and the ways of obtaining it (see the Answer Set Programming article). In logic programming, the formulas in Γ are restricted to *universal Horn formulas* of the forms

$$\forall x_1 \ldots \forall x_n \varphi \quad \text{and} \quad \forall x_1 \ldots \forall x_n (\varphi_1 \wedge \ldots \wedge \varphi_m \to \varphi)$$

whereas the goal is an existential formula

$$\exists x_1 \ldots \exists x_n (\varphi_1 \wedge \ldots \wedge \varphi_m)$$

and all φ_i and φ have the form $t = t'$ or $R(t_1, \ldots, t_n)$. Under these conditions, if the goal can be proved, then concrete terms $t_1, \ldots, t_n$ exist for which φ holds. In principle, these terms can be found by systematically applying the rules of any of the deduction systems presented earlier. However, given the restricted form of Horn formulas, a rule of inference more suitable for logic programming called *resolution* has been developed that computes all terms that make $\varphi_1 \wedge \ldots \wedge \varphi_m$ true. Recall that the validity problem in predicate logic is undecidable; this is reflected in logic programming in the fact that every implementation of resolution may loop forever if there are no solutions to the problem.

As an example of a logic program, let us consider the problem of finding paths in a directed graph. Assuming we use constants $a, b, \ldots, f$ to represent the nodes and corresponding binary predicates *arc* and *path*, the conditions of the problem can be represented as follows (omitting quantifiers, as customary in this context):

$$\begin{array}{l} arc(a,b) \\ arc(a,c) \\ arc(b,d) \\ arc(e,f) \\ arc(f,e) \\ arc(x,y) \to path(x,y) \\ arc(x,z) \wedge path(z,y) \to path(x,y) \end{array}$$

A path from x to y is specified either as a direct arc between the nodes or as an arc from x to an intermediate node z followed by a path from z to y. Now, to obtain all nodes reachable from a, the goal $path(a,x)$ would be used and the resolution procedure would return b, c, and d as possible values for x.

Imposing additional restrictions on the form of the formulas has led to the definition of query languages for deductive databases.

Functional Programming. *Functional programming* languages are based on the *lambda calculus*. Although there are many variants and they all favor an operational interpretation, lambda calculi can be endowed with both semantics and sound and complete deduction systems (but note that it took almost 40 years to define a semantics for the original, untyped lambda calculus), thus partaking in the main logical features. Unlike predicate logic, functions are first-class citizens in the lambda calculus and can therefore be passed as arguments to other functions and returned as results.

Functional languages come in many different flavors (see the Functional Programming article), but the central notion in all of them is that of definition $t \equiv s$, which is interpreted operationally as a rule that allows the transformation of the term in the left-hand side t into the one in the right-hand side s in a process called *rewriting*. A program consists simply of a set of definitions. For example, the program

$$\begin{aligned}
&\mathit{square} : \mathit{Integer} \to \mathit{Integer}\\
&\mathit{square}\ x \equiv x * x\\
&\mathit{apply} : (\mathit{Integer} \to \mathit{Integer}) \to \mathit{Integer}\\
&\mathit{apply}\ f\ x \equiv f\ x
\end{aligned}$$

defines a function *square* that returns the square of its argument, and a function *apply* that takes a function *f* and an integer as arguments and applies *f* to that integer. The term *apply square* 2 would then be rewritten first to *square* 2 and then to $2 * 2$ (which the compiler would evaluate to 4). For some terms, however, the process of reduction may never stop:

$$\begin{aligned}
&\mathit{infinity} : \mathit{Integer}\\
&\mathit{infinity} \equiv \mathit{infinity} + 1
\end{aligned}$$

Terms such as this do not denote well-defined values in the normal mathematical sense. Another potential difficulty lies in the possible existence of different rewriting sequences for the same term. Given definitions $t \equiv t'$ and $t \equiv t''$, in principle t could be reduced to either t' or t'', and there are no guarantees that these two terms can be further reduced to a common one. In functional programming, if two different rewriting sequences terminate, then they *converge*; that is, they lead to the same result.

Other Paradigms and Tidbits. Logic and functional programming are the two main representatives of declarative programming. Their main advantage is their logical foundation, which makes it possible to mathematically reason about the programs themselves and enormously facilitates the verification process. This has led many researchers to seek ways of enhancing their expressive power while remaining in the corresponding framework and thus retaining their good properties, and has produced languages in which convergence may not happen and nondeterminism is allowed or where (some) *a priori* infinite computations can be dealt with. Also, both approaches have been integrated in what is known as *functional logic programming;* here the computational process is guided not by resolution nor rewriting, but by a technique called *narrowing*.

Some languages have withdrawn from predicate logic and the lambda calculus and are based on *equational logic*, which is quite a restrictive subset of them both and precludes the use of functions. The loss in expressivity is made up with the gain in efficiency and simplicity of the mathematical reasoning about the programs. More recently, a whole family of languages has been designed based on yet another logic, *rewriting logic*, which extends equational logic with rules to allow a natural treatment of concurrency and nondeterminism. Unlike equations, a rule $t \to s$ does not express the identity between the meanings of the two terms but rather that the state represented by t evolves to that represented by s.

CODA

The previous sections may convey the impression that a logic is a precisely defined entity, when there is actually no consensus about what constitutes a logic. It is true that most logics have both a model and a proof-theory, but that is not always the case and, even when it is, one of the approaches may be clearly emphasized over the other. For Quine (7) on more philosophical grounds, even a full-fledged logic like second-order logic should be regarded as a mathematical theory since its logical truths by themselves capture substantial mathematical statements. Together with the explosion in the number of proposed logics, this diversity has spurred work in research with a unifying aim that has resulted in the development of:

- logical frameworks that are logics in which other logics can be represented and used, and
- extremely abstract formalisms, such as *institutions*, that intend to capture the defining characteristics of any logic.

A detailed discussion on these topics, as well as on many others not mentioned in this article, can be found in the comprehensive surveys (8–10).

Much of the impetus for the development of mathematical logic came from the desire of providing a solid foundation for mathematics. Nowadays it is computer science that has taken the leading role, and it will be the applications and needs in this area that are bound to guide the future of formal logic.

FRACTALS

Even though no consensus exists on a mathematical definition of what constitutes a fractal, it is usually clear what one means by a fractal. A fractal object has strong scaling behavior. That is, some relation exists between the "behavior" at one scale and at (some) finer scales.

Benoit Mandelbrot suggested defining a fractal as an object that has a fractional dimension (see the section on Fractal Dimension). This definition captures the idea that a fractal has complex behavior at all size scales.

Figure 1 illustrates some geometric fractals (that is, the "behavior" is geometrical). The first two images are exactly self-similar fractals. Both of them consist of unions of shrunken copies of themselves. In the first fractal (the one that looks like a complicated plus sign), five copies of the large figure combine together, and in the second fractal (the *twindragon tile*), it only requires two copies. The third fractal in the figure is not exactly self-similar. It is made up of two distorted copies of the whole. The fourth fractal is an image of a Romanesco Broccoli, which is an amazingly beautiful vegetable! The fractal structure of this plant is evident, but it is clearly not an exact fractal.

In Fig. 2, the well-known Mandelbrot Set is explored by successively magnifying a small portion from one frame into the next frame. The first three images in the series indicate the region that has been magnified for the next image. These images illustrate the fact that the Mandelbrot Set has infinitely fine details that look similar (but not exactly the same) at all scales.

One amazing feature of many fractal objects is that the process by which they are defined is not overly complicated. The fact that these seemingly complex systems can arise from simple rules is one reason that fractal and "chaotic" models have been used in many areas of science. These models provide the possibility to describe complex interactions among many simple agents. Fractal models cannot efficiently describe all complex systems, but they are incredibly useful in describing some of these systems.

THE MANDELBROT SET

The *Mandelbrot Set* (illustrated in the first frame of Fig. 2), named after Benoit Mandelbrot (who coined the term *fractal* and introduced fractals as a subject), is one of the most famous of all fractal objects. The Mandelbrot Set is definitely not an exactly self-similar fractal. Zooming in on the set continues to reveal details at every scale, but this detail is never exactly the same as at previous scales. It is conformally distorted, so it has many features that are the same, but not exactly the same.

Although the definition of the Mandelbrot Set might seem complicated, it is (in some sense) much less complicated than the Mandelbrot Set itself. Consider the polynomial with complex coefficients $Q_c(x) = x^2 + c$, where $c = a + bi$ is some (fixed) complex number. We are interested in what happens when we iterate this polynomial starting at $x = 0$. It turns out that one of two things happens, depending on c. Either $Q_c^n(0) \to \infty$ or it stays bounded for all time. That is, either the iterates get larger and larger, eventually approaching infinitely large, or they stay bounded and never get larger than a certain number. The Mandelbrot Set is defined as

$$M = \{c : Q_c^n(0) \nrightarrow \infty\}$$

that is, it is those c in the complex plane for which the iteration does not tend to infinity. Most images of the Mandelbrot Set are brilliantly colored. This coloration is really just an artifact, but it indicates *how fast* those points that are not in the Mandelbrot Set tend to infinity. The Mandelbrot Set itself is usually colored black. In our gray-level images of the Mandelbrot Set (Fig. 2), the Mandelbrot Set is in black.

FRACTAL DIMENSION

Several parameters can be associated with a fractal object. Of these parameters, fractal dimension (of which there are several variants) is one of the most widely used. Roughly speaking, this "dimension" measures the scaling behavior of the object by comparing it to a power law.

An example will make it more clear. Clearly the line segment $L = [0,1]$ has dimension equal to one. One way to think about this is that, if we scale L by a factor of s, the "size" of L changes by a factor of s^1. That is, if we reduce it by a factor of 1/2, the new copy of L has 1/2 the length of the original L.

Similarly the square $S = [0,1] \times [0,1]$ has dimension equal to two because, if we scale it by a factor of s, the "size" (in this case area) scales by a factor of s^2. How do we know that the "size" scales by a factor of s^2? If $s = 1/3$, say, then we see that we can tile S by exactly $9 = 3^2$ reduced copies of S, which means that each copy has "size" $(1/3)^2$ times the size of the original.

For a fractal example, we first discuss a simple method for constructing geometric fractals using an "initiator" and a "generator." The idea is that we start with the "initiator" and replace each part of it with the "generator" at each iteration. We see this in Figs. 3 and 4. Figure 3 illustrates the initiator and generator for the von Koch curve, and Fig. 4 illustrates the iterative stages in the construction, where at each stage we replace each line segment with the generator. The limiting object is called the *von Koch curve.*

In this case, the von Koch curve K is covered by four smaller copies of itself, each copy having been reduced in size by a factor of three. Thus, for $s = 1/3$, we need four reduced copies to tile K. This gives

$$\begin{aligned} \text{size of original copy } &= 4 \times \text{ size of smaller copy} \\ &= 4 \times (1/3)^D \text{ size of orginal copy} \end{aligned}$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

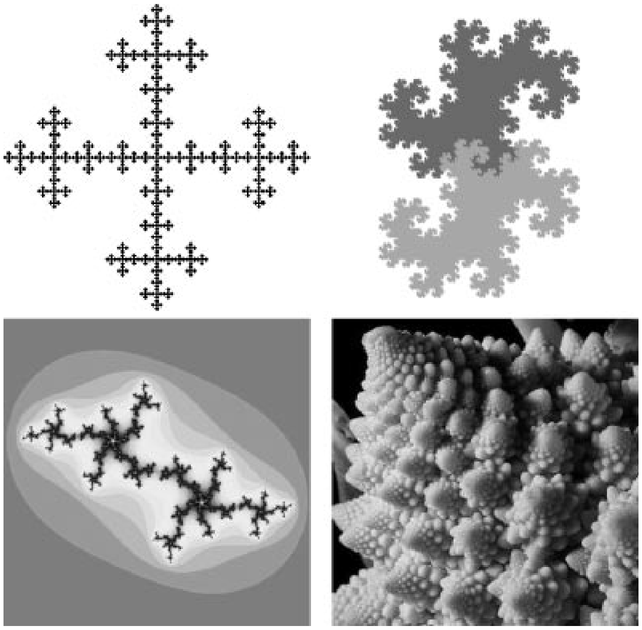

Figure 1. Some fractal shapes.

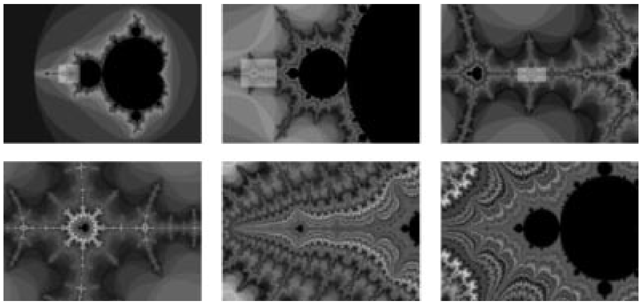

Figure 2. Zooming into the Mandelbrot Set.

so $4(1/3)^D = 1$ or $D = \log(3)/\log(2)$. That is, for the von Koch curve, if we shrink it by a factor of 1/3, then the "size" gets reduced by a factor of $(1/3)^{\log(4)/\log(3)} = 1/4$. In this sense, the von Koch curve has dimension $\log(4)/\log(3) \approx 1.2619$, so it has a dimension that is fractional and is a "fractal."

This way of computing a fractal dimension is very intuitive, but it only works for sets that are exactly self-similar (and thus is called the *similarity dimension*). We need a different method/definition for the fractal dimension of objects that are not exactly self-similar. The diffusion-limited aggregation (DLA) fractal shown later in Fig. 16 is a fractal, but it is not strictly self-similar.

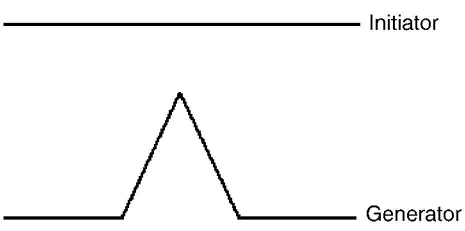

Figure 3. The *initiator* and *generator* for the von Koch curve.

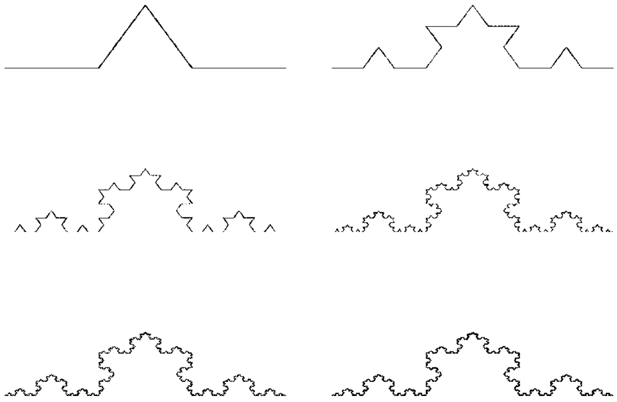

Figure 4. Construction of the von Koch curve.

One very common way to estimate the dimension of such an object is the *box counting method*. To do this, cover the image with a square grid (of side length ε) and count how many of these boxes are occupied by a point in the image. Let $N(\varepsilon)$ be this number. Now repeat this for a sequence of finer and finer grids (letting ε tend to 0). We want to fit the relation $N(\varepsilon) = a\varepsilon^{-D}$, so we take logarithms of both sides to get $\log(N) = \log(a) - D\log(\varepsilon)$. To estimate D, we plot $\log(N(\varepsilon))$ versus $\log(\varepsilon)$ and find the slope of the least-squares line.

For the object in Fig. 16, we have the data in Table 1, which gives a fractal dimension of 1.60.

Table 1.

ε	$N(\varepsilon)$
1/2	4
1/4	16
1/8	52
2^{-4}	174
2^{-5}	580
2^{-6}	1893
2^{-7}	6037
2^{-8}	17556
2^{-9}	44399
2^{-10}	95432

It is interesting to apply this method to exactly self-similar objects, such as the von Koch curve. For this curve, it is convenient to use boxes of size $\varepsilon = 3^{-n}$ and to align them so that they form a nice covering of the von Koch curve (that is, we do not necessarily have to have the boxes form a grid). Assume that the initial lengths of the line segments in the generator for the von Koch curve are all equal to 1/3. In this case, it is easy to see that we require 4^n boxes of side length $1/3^n$ to cover the curve, so we solve

$$4^n = a(1/3^n)^{-D} \Rightarrow a = 1,\ D = \log(4)/\log(3)$$

as before.

IFS FRACTALS

The Iterated Function Systems (IFS, for short) are a mathematical way of formalizing the notion of self-similarity. An IFS is simply a collection of functions from some "space" to itself, w_i: $X \to X$. Usually it is required that these functions are contractive, in that the distance between the images of any two points is strictly less than the distance between the original points. Mathematically, w is a contraction if there is some number s with $0 \leq s < 1$ and $d(w(x), w(y)) \leq sd(x,y)$ for any x and y, where $d(x,y)$ somehow measures the distance between the points x and y. In this case, it is well known (by the *Banach Contraction Theorem*) that there is a unique *fixed point* $\bar{x}$ with $w(\bar{x}) = \bar{x}$.

Given an IFS $\{w_i\}$, the *attractor* of the IFS is the unique set A (A should be nonempty and compact, to be technically precise), which satisfies the *self-tiling* (or fixed point) condition

$$A = w_1(A) \cup w_2(A) \cup \cdots \cup w_n(A)$$

so that A is made up of "smaller" copies of itself (smaller by the individual w_i, that is). Under some general conditions this attractor always exists and is uniquely specified by the functions w_i in the IFS. Furthermore, one can recover the attractor A by starting with any set B and iterating the IFS. The iteration proceeds by first generating the n distorted and smaller copies of B (distorted and shrunk by the individual w_i's) and combining them to get a new set B_1

$$B_1 = w_1(B) \cup w_2(B) \cup \cdots \cup w_n(B)$$

Repeating this, we get a sequence of sets $B_2, B_3, \ldots, B_n, \ldots,$ which will converge to the attractor A.

To illustrate, take the three contractions w_1, w_2, w_3 given by

$$w_1(x,y) = (x/2, y/2), \quad w_2(x,y) = (x/2 + 1/2, y/2),$$
$$w_3(x,y) = (x/2, y/2 + 1/2)$$

Each of these three maps shrinks all distances by a factor of two (because we are reducing in both the horizontal and the vertical direction by a factor of 2). These maps are examples of *similarities*, because they preserve all angles and lines but only reduce lengths; geometric relationships within an object are (mostly) preserved.

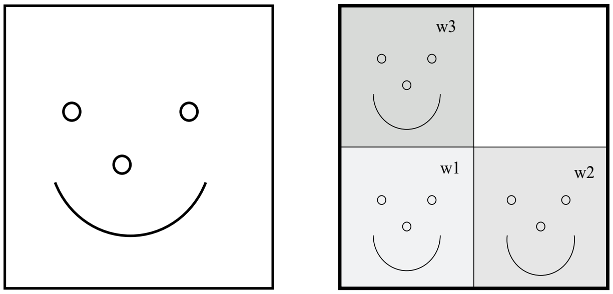

Figure 5. Action of the three maps.

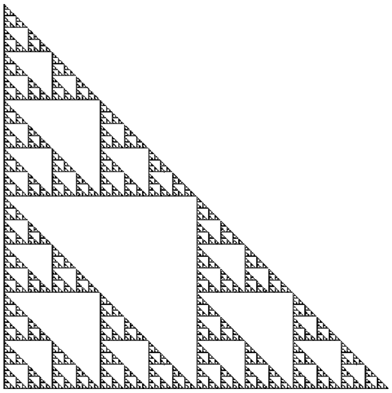

Figure 6. The Sierpinski Gasket.

We think of these maps as acting on the unit square, that is, all points (x, y) with $0 \leq x \leq 1$ and $0 \leq y \leq 1$. In this case, the action of each map is rather simple and is illustrated in Fig. 5. For instance, map w_2 takes whatever is in the square, shrinks it by a factor of two in each direction, and then places it in the lower right-hand corner of the square.

The attractor of this 3-map IFS is the Sierpinski Gasket, which is illustrated in Fig. 6. The self-tiling property is clear, because the Sierpinski Gasket is made up of three smaller copies of itself. That is, $S = w_1(S) \cup w_2(S) \cup w_3(S)$.

Now, one amazing thing about IFS is that iterating the IFS on any initial set will yield the same attractor in the limit. We illustrate this in Fig. 7 with two different starting images. The attractor of the IFS is completely encoded by the IFS maps themselves; no additional information is required.

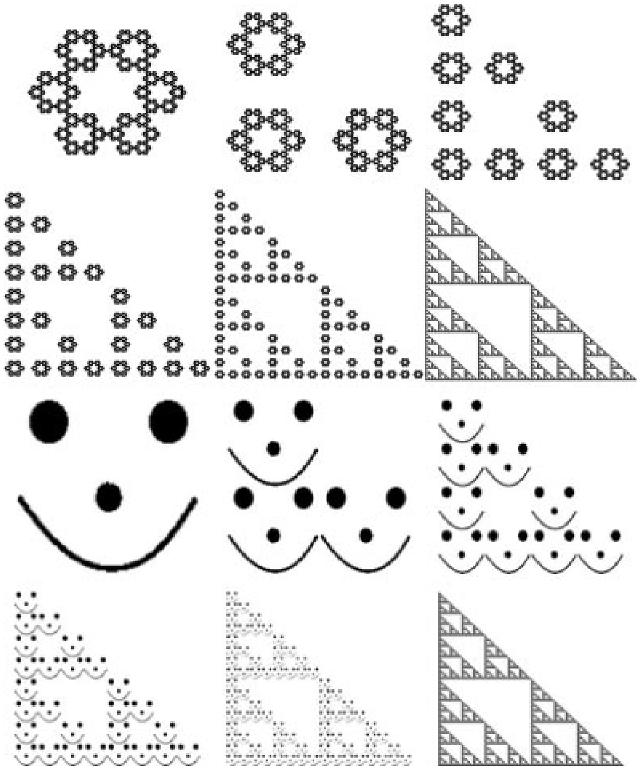

Figure 7. Two different deterministic iterations.

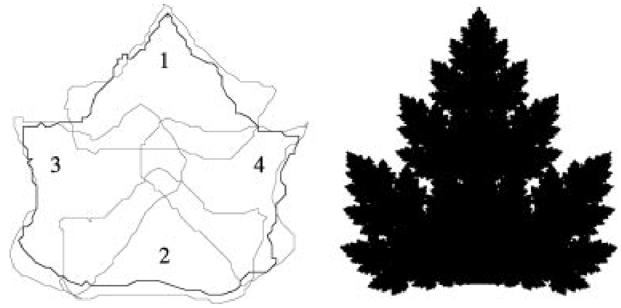

Figure 8. Collage for maple leaf and attractor of the IFS.

The Collage Theorem

Given an IFS it is easy to compute the attractor of the IFS by iteration. The inverse problem is more interesting, however. Given a geometric object, how does one come up with an IFS whose attractor is close to the given object?

The Collage Theorem provides one answer to this question. This theorem is a simple inequality but has strong practical applications.

Collage Theorem. Suppose that T is a contraction with contraction factor $s < 1$ and A is the attractor of T (so that $T(A) = A$). Then for any B we have

$$d(A,B) \leq \frac{d(T(B),B)}{1-s}$$

What does this mean? In practical terms, it says that, if we want to find an IFS whose attractor is close to a given set B, then what we do is look for an IFS that does not "move" the set B very much. Consider the maple leaf in Fig. 8. We see that we can "collage" the leaf with four transformed copies of itself. Thus, the IFS that is represented by these four transformations should have an attractor that is close to the maple leaf. The second image in Fig. 8 is the attractor of the given IFS, and it is clearly very similar to a maple leaf.

As another example, it is easy to find the collage to generate the attractor in Fig. 9. It requires 11 maps in the IFS.

However, the real power of the Collage Theorem comes in when one wants to find an IFS for more complicated self-affine fractals or for fractal objects that are not self-similar. One such application comes when using IFS for image representation (see the section on Fractals and Image Compression).

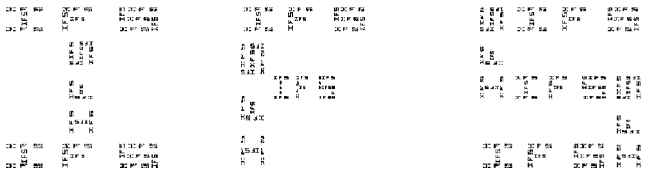

Figure 9. An easy collage to find.

Fractal Functions

Geometric fractals are interesting and useful in many applications as models of physical objects, but many times one needs a functional model. It is easy to extend the IFS framework to construct fractal functions.

There are several different IFS frameworks for constructing fractal functions, but all of them have a common core, so we concentrate on this core. We illustrate the ideas by constructing fractal functions on the unit interval; that is, we construct functions $f : [0, 1] \to \mathbb{R}$. Take the three mappings $w_1(x) = x/4$, $w_2(x) = x/2 + 1/4$, and $w_3(x) = x/4 + 3/4$ and notice that $[0, 1] = w_1[0, 1] \cup w_2[0, 1] \cup w_3[0, 1]$, so that the images of [0, 1] under the w_i's tile [0, 1].

Choose three numbers $\alpha_1, \alpha_2 \alpha_3$ and three other numbers $\beta_1, \beta_2, \beta_3$ and define the operator T by

$$T(f)(x) = \alpha_i f(w_i^{-1}(x)) + \beta_i \quad \text{if } x \in w_i([0, 1])$$

where $f : [0, 1] \to \mathbb{R}$ is a function. Then clearly $T(f)$: $[0, 1] \to \mathbb{R}$ is also a function, so T takes functions to functions.

There are various conditions under which T is a contraction. For instance, if $|\alpha_i| < 1$ for each i, then T is contractive in the supremum norm given by

$$\| f\|_{\text{sup}} = \sup_{x \epsilon [0, 1]} | f(x)|$$

so $T^n(f)$ converges uniformly to a unique fixed point $\bar{f}$ for any starting function f.

Figure 10 illustrates the limiting fractal functions in the case where $\alpha_1 = \alpha_2 = \alpha_3 = 0.3$ and $\beta_1 = -\beta_2 = \beta_3 = -1$.

It is also possible to formulate contractivity conditions in other norms, such as the L^p norms. These tend to have weaker conditions, so apply in more situations. However, the type of convergence is clearly different (the functions need not converge pointwise anywhere, for instance, and may be unbounded).

The same type of construction can be applied for functions of two variables. In this case, we can think of such functions as grayscale images on a screen. For example,

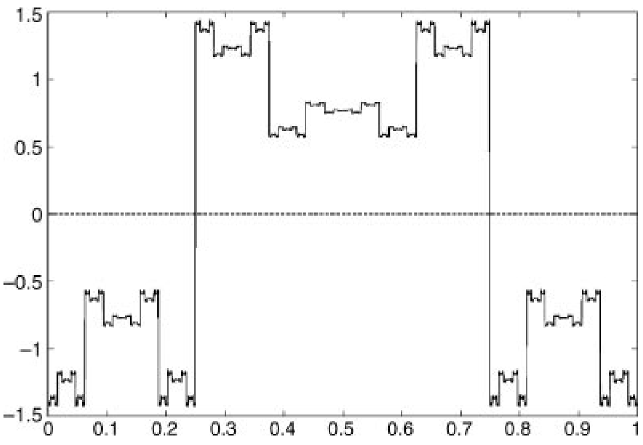

Figure 10. The attractor of an IFS on functions.

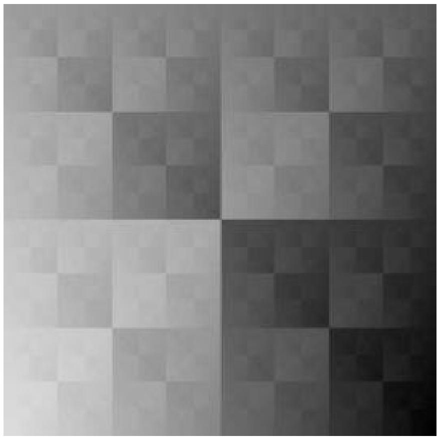

Figure 11. The attractor of an IFS on functions $f : \mathbb{R}^2 \to \mathbb{R}$.

using the four "geometric" mappings

$$w_1(x,y) = \left(\frac{x}{2},\frac{y}{2}\right), \quad w_2(x,y) = \left(\frac{x+1}{2},\frac{y}{2}\right),$$

$$w_3(x,y) = \left(\frac{x}{2},\frac{y+1}{2}\right), \quad w_4(x,y) = \left(\frac{x+1}{2},\frac{y+1}{2}\right)$$

and the α and β values given by

α	0.5	0.5	0.4	0.5
β	80	40	132	0

we get the attractor function in Fig. 11. The value 255 represents white and 0 represents black.

FRACTALS AND IMAGE COMPRESSION

The idea of using IFS for compressing images occurred to Barnsley and his co-workers at the Georgia Institute of Technology in the mid-1980s. It seems that the idea arose from the amazing ability of IFS to encode rather complicated images with just a few parameters. As an example, the fern leaf in Fig. 12 is defined by four affine maps, so it is encoded by 24 parameters.

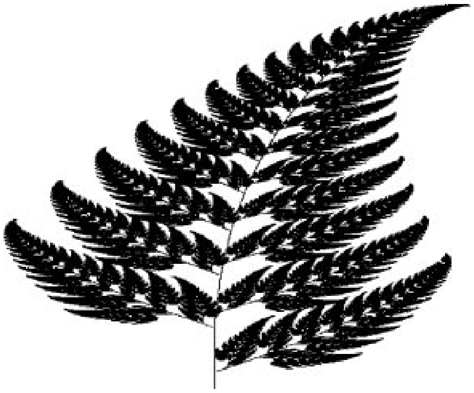

Figure 12. The fern leaf.

Of course, this fern leaf is an exact fractal and most images are not. The idea is to try to find approximate self-similarities, because it is unlikely there will be many exact self-similarities in a generic image. Furthermore, it is also highly unlikely that there will be small parts of the image that look like reduced copies of the entire image. Thus, the idea is to look for "small" parts of the image that are similar to "large" parts of the same image. There are many different ways to do this, so we describe the most basic here.

Given an image, we form two partitions of the image. First, we partition the image into "large" blocks, we will call these the *parent blocks*. Then we partition the image into "small" blocks; here we take them to be one half the size of the large blocks. Call these blocks *child blocks*. Figure 13 illustrates this situation. The blocks in this figure are made large enough to be clearly observed and are much too large to be useful in an actual fractal compression algorithm.

Given these two block partitions of the image, the *fractal block encoding* algorithm works by scanning through all the small blocks and, for each such small block, searching among the large blocks for the best match. The likelihood of finding a good match for all of the small blocks is not very high. To compensate, we are allowed to modify the large block. Inspired by the idea of an IFS on functions, the algorithm is:

```
1. for SB in small blocks do
2. for LB in large blocks do
```

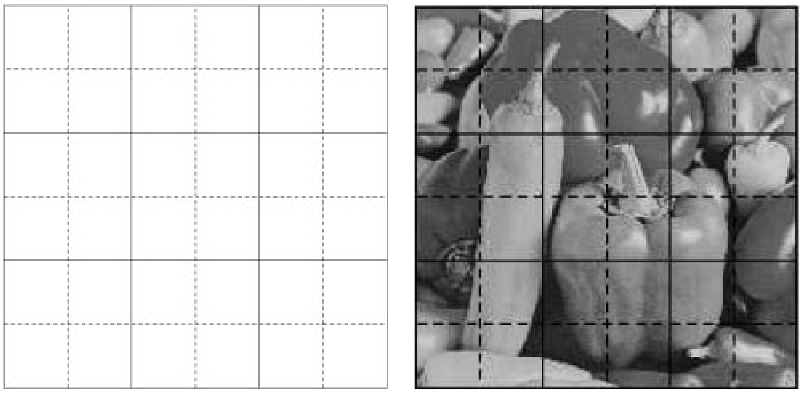

Figure 13. The basic block decomposition.

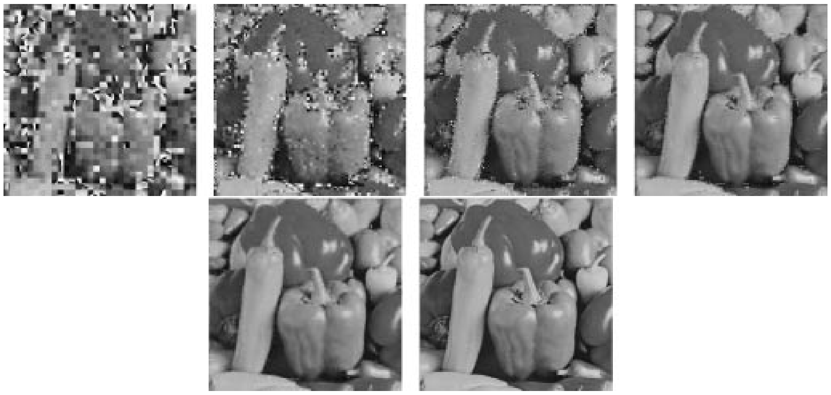

Figure 14. Reconstruction: 1, 2, 3, 4, and 10 iterations and the original image.

```
3. Downsample LB to the same size as SB
4. Use leastsquares to find the best parameters $\alpha$ and $\beta$
   for this combination of LB and SB. That is, to make
   SB $\approx \alpha$LB $+ \beta$.
5. Compute error for these parameters. If error is smaller
   than for any other LB, remember this pair along
   with the $\alpha$ and $\beta$.
6. end for
7. end for
```

At the end of this procedure, for each small block, we have found an optimally matching large block along with the α and β parameters for the match. This list of triples (large block, α, β) forms the encoding of the image. It is remarkable that this simple algorithm works! Figure 14 illustrates the first, second, third, fourth, and tenth iterations of the reconstruction. One can see that the first stage of the reconstruction is basically a downsampling of the original image to the "small" block partition. The scheme essentially uses the β parameters to store this coarse version of the image and then uses the α parameters along with the choice of which parent block matched a given child block to extrapolate the fine detail in the image from this coarse version.

STATISTICALLY SELF-SIMILAR FRACTALS

Many times a fractal object is not self-similar in the IFS sense, but it is self-similar in a statistical sense. That is, either it is created by some random self-scaling process (so the steps from one scale to the next are random) or it exhibits similar statistics from one scale to another. In fact, most naturally occurring fractals are of this statistical type.

The object in Fig. 15 is an example of this type of fractal. It was created by taking random steps from one scale to the next. In this case, it is a subset of an exactly self-similar fractal.

These types of fractals are well modeled by random IFS models, where there is some randomness in the choice of the maps at each stage.

MORE GENERAL TYPES OF FRACTALS

IFS-type models are useful as approximations for self-similar or almost self-similar objects. However, often these models are too hard to fit to a given situation. For these cases we have a choice—we can either build some other type of model governing the growth of the object OR we can give up on finding a model of the interscale behavior and just measure aspects of this behavior.

An example of the first instance is a simple model for DLA, which is illustrated in Fig. 16. In this growth model, we start with a seed and successively allow particles to drift

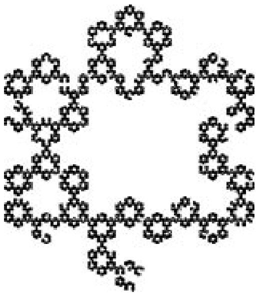

Figure 15. A statistically self-similar fractal.

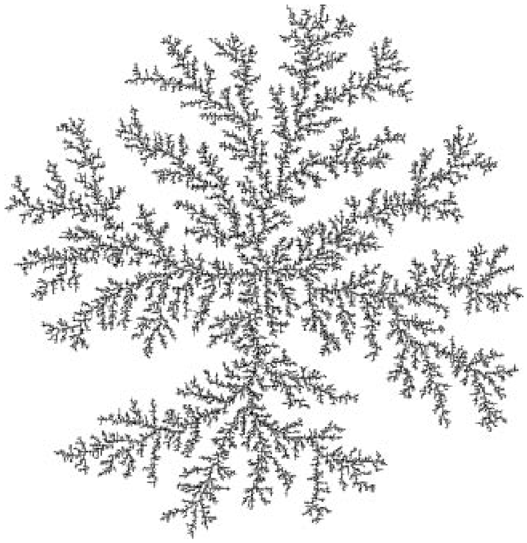

Figure 16. A DLA fractal.

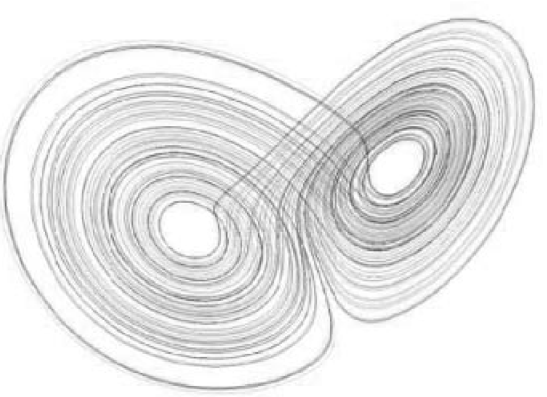

Figure 17. The Lorentz attractor.

around until they "stick" to the developing object. Clearly the resulting figure is fractal, but our model has no explicit interscale dependence. However, these models allow one to do simulation experiments to fit data observed in the laboratory. They also allow one to measure more global aspects of the model (like the fractal dimension).

Fractal objects also frequently arise as so-called *strange attractors* in chaotic dynamical systems. One particularly famous example is the butterfly shaped attractor in the Lorentz system of differential equations, seen in Fig. 17. These differential equations are a toy model of a weather system that exhibits "chaotic" behavior. The attractor of this system is an incredibly intricate filigree structure of curves. The fractal nature of this attractor is evident by the fact that, as you zoom in on the attractor, more and more detail appears in an approximately self-similar fashion.

FRACTAL RANDOM PROCESSES

Since the introduction of fractional Brownian motion (fBm) in 1968 by Benoit Mandelbrot and John van Ness, self-similar stochastic processes have been used to model a variety of physical phenomena (including computer network traffic and turbulence). These processes have power spectral densities that decay like $1/f^{\alpha}$.

A fBm is a Gaussian process $x(t)$ with zero mean and covariance

$$E(x(t)x(s)] = (\sigma^2/2)\,[|t|^{2H} + |s|^{2H} - |t-s|^{2H}]$$

and is completely characterized by the *Hurst exponent H* and the variance $E[x(1)^2] = \sigma^2$. fBm is statistically sell-similar in the sense that, for any scaling $a > 0$, we have

$$x(at) = a^H x(t)$$

where by equality we mean equality in distribution. (As an aside and an indication of one meaning of H, the sample paths ol fBm with parameter H are almost surely Hölder continuous with parameter H, so the larger the value of H, the smoother the sample paths of the fBm). Because of this scaling behavior, fBm exhibits very strong long-time dependence. It is also clearly not a stationary (time-invariant) process, which causes many problems with traditional methods of signal synthesis, signal estimation, and parameter estimation. However, wavelet-based methods work rather well, as the scaling and finite time behavior of wavelets matches the scaling and nonstationarity of the fBm. With an appropriately chosen (i.e., sufficiently smooth) wavelet, the wavelet coefficients of an fBm become a stationary sequence without the long range dependence properties. This aids in the estimation of the Hurst parameter H.

Several generalizations of fBm have been defined, including a multifractal Brownian motion (mBm). This particular generalization allows the Hurst parameter to be a changing function of time $H(t)$ in a continuous way. Since the sample paths of fBm have Hölder continuity H (almost surely), this is particularly interesting for modeling situations where one expects the smoothness of the sample paths to vary over time.

FRACTALS AND WAVELETS

We briefly mention the connection between fractals and wavelets. Wavelet analysis has become a very useful part of any data analyst's toolkit. In many ways, wavelet analysis is a supplement (and, sometimes, replacement) for Fourier analysis; the wavelet functions replace the usual sine and cosine basis functions.

The connection between wavelets and fractals comes because wavelet functions are nearly self-similar functions. The so-called "scaling function" is a fractal function, and the "mother wavelet" is simply a linear combination of copies of this scaling function. This scaling behavior of wavelets makes it particularly nice for examining fractal data, especially if the scaling in the data matches the scaling in the wavelet functions. The coefficients that come from a wavelet analysis are naturally organized in a hierarchy of information from different scales, and hence, doing a wavelet analysis can help one to find scaling relations in data, if such relations exist.

Of course, wavelet analysis is much more than just an analysis to find scaling relations. There are many different wavelet bases. This freedom in choice of basis gives greater flexibility than Fourier analysis.

GEOMETRIC PROGRAMMING

INTRODUCTION

Nonlinear programming deals with optimization problems in which both the objective and constraint functions are nonlinear. Of the many special cases of a nonlinear program, geometric programs are a class that involves a highly nonlinear function called a posynomial (as detailed later). Functions of this type were first formalized by Duffin et al. (1) in the seminal work entitled *Geometric Programming*. In that book, many intriguing properties of posynomial functions are given along with many applications to engineering design. Subsequent work developed in two significantly different directions: Signomial programming and Generalized Geometric Programming, both of which are reviewed in this article (2).

Signomial programming, which was first developed by Passy and Wilde (3), sought to relax the restriction of the functions treated by geometric programming to the form of polynomials. With the relaxation to polynomials, one loses convexity and, hence, one can only hope for a local minimum, not a global minimum. Generalized geometric programming proceeds to generalize the type of function considered from posynomial to convex. This generalization maintains the convexity of the problem, and hence, one can find the global solution to the mathematical program.

The relationship among the various developments may outwardly seem tenuous, because geometric programming should not be thought of as a class of mathematical programs but instead as a method of analysis of mathematical programs. In this respect, geometric programming has much in common with dynamic programming. Dynamic programming makes use of recursive functions. Geometric programming makes use of linearity, separability, convexity, and duality.

Linearity

Most mathematical programming is conducted over linear vector spaces. The usual choice is Euclidean n-dimensional space (E_n). Here, a vector is represented by an n-tuple of real components. Taking any two vectors x_1 and x_2 that belong to the space, and real scalars α and β, a linear vector space has the property that the linear combination $\alpha x_1 + \beta x_2$ belongs to the space. In the context of functions, a function $\ell(x)$ is said to be linear if for any scalars α and β, $\ell(\alpha x + \beta y) = \alpha\ell(x) + \beta\ell(y)$. Linear functions have many important properties. They are both convex and concave. Furthermore, a first-order Taylor series expansion approximates the linear function exactly. The value of linearity to mathematical programming is best exemplified by the fruitful area of linear programming.

Separability

A function $f(x_1, x_2, \ldots, x_n)$ is separable if it can be written as $f(x_1, x_2, \ldots, x_n) = f_1(x_1) + f_2(x_2) + \cdots + f_n(x_n)$. This property is important as it allows one to treat an n-dimensional function as n functions of one-dimension, which is much simpler from a computational point of view.

Convexity

A set A is convex if for any $x_1, x_2 \in A$ and $0 \leq \lambda \leq 1$, $\lambda x_1 + (1-\lambda)x_2 \in A$. To extend the concept to a function $f(x)$ defined for $x \in C$, a convex set, we require the following definition. The epigraph of a function f defined on C is the set A defined by: $A = \{(\alpha, x) | \alpha \geq f(x), x \in C\}$. $f(x)$ is a convex function if A is a convex set. Convex functions have several powerful properties. The most important for mathematical programs with a convex objective function and a convex constraint set is that any local minimum is also a global minimum. Additional properties of convexity will be given in the section on Generalized Geometric Programming.

Duality

For a linear space $X = E_n$, linear functions may be written in the form $\langle a, x \rangle = \sum_{i=1}^{n} a_i x_i$, where a is a vector parameter. The set of all linear functions (parameterized by the vector a) is a space and is called the dual space (X^*). The duality develops from the fact that $\langle a, x \rangle$ is symmetric in a and x. For finite dimensional spaces, the set of linear functions on X^* turns out to be the original space X. Hence there is a symmetric relationship between X and X^*.

Of importance to mathematical programming is the pairing of sub-spaces in primal and dual spaces with respect to the inner product. Let χ be a subspace of X. Then $\chi^{\perp} = \{y | \langle y, x \rangle = 0, \forall x \in \chi\}$ is called the orthogonal complementary subspace of χ. Any point in $\chi^{\perp}$ is orthogonal to any point in χ by construction. If $y_1, y_2 \in \chi^{\perp}$ and α, β are scalars, then it is easy to observe that $\alpha y_1 + \beta y_2 \in \chi^{\perp}$.

The importance of the concepts of linearity, separability, convexity, and duality in the development of geometric programming will remain obscure in the sections on unconstrained polysynomial programming constrained polysynomial programming and signomial programming. However, their paramount role will become clear in the section on Generalized geometric programming. The last section uses this generalized theory to rederive the theory of posynomial programs, and the central role played by these concepts will be clarified even more. Throughout this article, theory will be reinforced by examples drawn mainly from the area of inventory theory. The examples presented are relatively simple to highlight the use of geometric programming theory. The article concludes with examples from many other areas.

UNCONSTRAINED POSYNOMIAL PROGRAMMING

Here we consider the following nonlinear problem:

$$\text{Minimize } g(t) = \sum_{i=1}^{n} u_i \qquad (1)$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

where $u_1, i = 1, \ldots, n$, are posynomials defined by

$$u_i = c_i \prod_{j=1}^{m} t_j^{a_{ij}} \tag{2}$$

$c_i > 0, \forall i, t_j > 0, \forall j$, and a_{ij} are arbitrary real constants; $t = (t_1, \ldots, t_m)^{\mathrm{T}}$ and T denotes a transpose. In the usual situation, $g(t)$ represents a composite cost made up of component costs u_i, $i = 1, \ldots, n$. We term this the primal problem.

In principle, the primal problem could be solved by the methods of differential calculus. This problem will develop a set of nonlinear equations which, in general, are difficult to solve. Hence, in practice, one would invariably resort to a numerical solution by an iterative descent-type method. Here, we propose to construct a geometric programming dual program to the primal. In certain cases, this proposition admits a trivial solution to the problem. Furthermore, this dual problem has an interesting and informative practical interpretation. A central idea here is the arithmetic–geometric mean inequality, henceforth termed the *geometric inequality*. In fact, the name "geometric programming" comes from the importance of this inequality to the original theory. It states that

$$\sum_{i=1}^{n} \delta_i v_i \geq \prod_{i=1}^{n} (v_i)^{\delta_i} \tag{3}$$

where $\sum_{i=1}^{n} \delta_i = 1, \quad \delta_i \geq 0, \quad \forall i, \quad v_i > 0, \quad \forall i$. Equality is attained when $v_1 = v_2 = \cdots = v_n$. It is convenient to set $v_i = u_i / \delta_i, \ \forall i$ in Equation (3) to obtain

$$\sum_{i=1}^{n} u_i \geq \prod_{i=1}^{n} (u_i/\delta_i)^{\delta_i} \tag{4}$$

In this form, we can use the geometric inequality to obtain a lower bound on our primal optimization problem. Hence, substituting Equation (2) into Equation (1) and using Equation (4), we have that

$$g(t) \geq \prod_{i=1}^{n} (c_i/\delta_i)^{\delta_i} \prod_{j=1}^{m} t_j^{\sum_{i=1}^{n} a_{ij}\delta_i} \tag{5}$$

If we choose the weights, $\delta_i, \ \forall i$, such that

$$\sum_{i=1}^{n} a_{ij}\delta_i = 0, \quad j = 1, \ldots, m \tag{6}$$

then the variables t_j, $j = 1, \ldots, m$ on the right hand side of inequality (5) may be eliminated. In this case, we have that

$$g(t) \geq \prod_{i=1}^{n} (c_i/\delta_i)^{\delta_i} = v(\delta) \tag{7}$$

where $v(\delta)$ is the dual function which gives a lower bound on the minimum of $g(t)$. Equation (7) implies that

$$\min g(t) \geq \max v(\delta) \tag{8}$$

under conditions $t > 0, \ \delta \geq 0, \ \sum_{i=1}^{n} \delta_i = 1$ and Equation (6).

It may be shown that there exists an optimal t^* [in the sense of minimizing $g(t)$] and an optimal δ^* [in the sense of maximizing $v(\delta)$] to satisfy inequality (8) at equality. In this case the relation between t^* and δ^* is given by

$$\delta_i^* = u_i(t^*)/g(t^*) \tag{9}$$

Hence the following dual program to the original primal program may be constructed:

$$\text{Maximize } v(\delta) = \prod_{i=1}^{n} (c_i/\delta_i)^{\delta_i} \tag{10}$$

subject to the normalization condition

$$\sum_{i=1}^{n} \delta_i = 1, \quad \delta_i \geq 0 \tag{11}$$

and the orthogonality condition

$$\sum_{i=1}^{n} a_{ij}\delta_i = 0, \quad j = 1, \ldots, m \tag{12}$$

At optimality $g(t^*) = v(\delta^*)$.

From Equation (9), we can interpret the dual variables at optimality, $\delta_i^*, \forall i$, as the relative contribution of each component cost u_i to the composite cost $g(t)$. Furthermore, we obtain the following relationship between the primal and dual variables

$$\text{In}(\delta_i^* v(\delta^*)/c_i) = \sum_{j=1}^{m} a_{ij} \log t_j^* \tag{13}$$

This equation is a system of linear equations in $\log t_j$, $j = 1, \ldots, m$, which are readily solvable once the dual program has been solved.

We note that the dual program maximizes a nonlinear function subject to linear equality constraints. A dual variable δ_i is associated with each term $i = 1, \ldots, n$ in the primal formulation. In the case that the number of terms in the primal n is equal to the number of variables in the primal m plus one (i.e., $n = m + 1$) the linear constraints admit a unique solution δ^*, and the optimization problem in the dual is trivial. The quantity $n - (m + 1)$ is termed the degree of difficulty of a geometric program and is, in some sense, a measure of the computational complexity of the dual program.

Example. We consider the well known "Economic Lot Size" problem from inventory theory. Items are withdrawn continuously from inventory at a known constant rate a. Items are ordered in equal numbers Q at a time and production is instantaneous. The problem is to determine how often to make a production run and how much to order, Q, each time to minimize the cost C per unit time, where $C = aK/Q + hQ/2 + ac$, and K is the fixed set-up cost, h is the inventory holding cost per item per unit time, and c is the variable production cost per item. Neglecting the constant part, ac, we require to

$$\text{Minimize}\, C_1 = aK/Q + hQ/2$$

This equation is an unconstrained posynomial program. The corresponding dual program, from Equations (10), (11), and (12), is to maximize

$$\begin{aligned}
&(aK/\delta_1)^{\delta_1}(h/2\delta_2)^{\delta_2}\\
&\text{subject to}\, \delta_1 + \delta_2 = 1 \quad \text{(normality)}\\
&-\delta_1 + \delta_2 = 0 \quad \text{(orthogonality)}\\
&\delta_1 \geq 0, \quad \delta_2 \geq 0
\end{aligned}$$

Here the constraint equations can be uniquely solved to yield $\delta_1^* = \delta_2^* = 1/2$, and no maximization problem exists. We have a program with zero degree of difficulty. The interpretation of this result is that at optimality, the set-up cost per unit time and the holding cost per unit time contribute equal amounts to the optimal cost, that is, the optimal distribution of cost is an invariant with respect to the cost coefficients. Hence, from Equations (10) and (13), the optimal cost is $\sqrt{2aKh}$, and the optimal order quantity is $\sqrt{2aK/h}$.

Suppose now that the production process is a lengthy one so that the assumption of instantaneous availability is no longer acceptable. Furthermore, the size of the lot determines the length of the production process, and this in turn determines the in-process inventory holding cost. In this case, a modified economic lot size model could be to minimize $C_1 = aK/Q + hQ/2 + IQT/2$, where I is the in-process inventory holding cost per unit time, and T is the length of the production process, given by $T(Q) = nQ + m$, where n and m are empirically determined constants. In this case, we have the unconstrained posynomial program:

$$\text{Minimize}\, C_1 = aK/Q + Q(h/2 + Im/2) + InQ^2/2$$

The corresponding dual program is given by

$$\text{Maximize}\, (aK/\delta_1)^{\delta_1}((h + Im)/2\delta_2)^{\delta_2}(In/2\delta_3)^{\delta_3}$$

subject to

$$\begin{aligned}
&\delta_1 + \delta_2 + \delta_3 = 1\\
&-\delta_1 + \delta_2 + 2\delta_3 = 0\\
&\delta_1 > 0, \quad \delta_2 > 0, \quad \delta_3 > 0
\end{aligned}$$

Here, we have two equations and three unknowns; in effect, a degree of difficulty of one. One could proceed to solve this problem as an unconstrained maximization problem in one variable or as a constrained maximization. However, insight may be gained without going into this detail. Manipulation of the constraint equations gives the following inequalities: $0.5 \leq \delta_1 \leq 1.0$ and $0.33 \leq \delta_1 \leq 0.66$, which imply that at optimality, the set-up cost makes a contribution between 50% and 66% to the optimal composite cost. Similar insights may be obtained from the other dual variables.

CONSTRAINED POSYNOMIAL PROGRAMMING

Here we consider the minimization of a posynomial form subject to constraints that are also posynomials, which is the primal formulation.

$$\text{Minimize}\, g_0(\mathrm{t}) \tag{14}$$

$$\text{subject to}\, g_k(\mathrm{t}) \leq 1, \quad k = 1, \ldots, \mathrm{p} \tag{15}$$

$$t_j > 0, \quad j = 1, \ldots, m \tag{16}$$

where

$$g_k(t) = \sum_{i \in [k]} c_i \prod_{j=1}^{m} t_j^{a_{ij}}, \quad k = 0, \ldots, p \tag{17}$$

$$\begin{aligned}
&[k] = \{m_k, m_k + 1, \ldots, n_k\}, \quad k = 0, \ldots, p\\
&\text{and}\\
&m_0 = 1, m_1 = n_0 + 1, \ldots, m_p = n_{p-1} + 1, n_p = n.
\end{aligned} \tag{18}$$

$\{[k]\}$, $k = 0, 1, \ldots, p$ is a sequential partition of the integers 1 to n. As before a_{ij} are arbitrary real exponents and the coefficients c_i are positive.

To handle constraints, we need a generalization of the geometric inequality in which the δ_i's are not normalized. We let

$$\lambda_k = \sum_{i \in [k]} \delta_i \tag{19}$$

for a particular constraint k. Hence the geometric inequality Equation (4) may be written in a convenient form as

$$\left(\sum_{i \in [k]} u_i\right)^{\lambda_k} \geq \prod_{i \in [k]} (u_k/\delta_i)^{\delta_i} \lambda_k^{\lambda_k} \tag{20}$$

Combining Equations (15), (17), and (20) we have that

$$1 \geq g_k(t)^{\lambda_k} \geq \prod_{i \in \{k\}} \left(c_i \prod_{j\, 1}^{m} t_j^{a_{ij}}/\delta_i\right)^{\delta_i} \lambda_k^{\lambda_k} \tag{21}$$

for any constraint $k = 1, \ldots, p$. For the objective function, we normalize the $\delta_i, i \in [0]$. Hence

$$g_0(t) \geq \prod_{i \in [0]} \left(c_i \prod_{j=1}^{n} t_j^{a_{ij}}/\delta_i\right)^{\delta_i} \tag{22}$$

and

$$\sum_{i \in [0]} \delta_i = 1 \tag{23}$$

Combining results from Equations (21) and (22), we obtain the inequality

$$g_0(t) \geq \prod_{i=1}^{n} (c_i/\delta_i)^{\delta_i} \prod_{k=1}^{p} \lambda_i^{\lambda_k} \tag{24}$$

Hence, using the same lines of reasoning as for the unconstrained problem, the dual problem is given by:

$$\text{Maxmize}\, v(\delta) = \prod_{i=1}^{n} (c_i/\delta_i)^{\delta_i} \prod_{k=1}^{p} \lambda_k^{\lambda_k} \tag{25}$$

subject to the linear constraints

$$\sum_{i \in [0]} \delta_i = 1 \quad \text{(normalization)} \tag{26}$$

$$\sum_{i=1}^{n} a_{ij}\delta_i = 0, \quad j = 1, \ldots, m \quad \text{(orthogonality)} \tag{27}$$

$$\delta_i \geq 0, \quad i = 1, \ldots, n \tag{28}$$

We note that the primal problem is a highly nonlinear mathematical program, whereas the dual is the maximization of a concave function subject to linear constraints. Once again, if $n = m + 1$, the program has zero degree of difficulty, and the dual program is trivial. It may be shown in Equation (3) that at optimality the primal variables t^* and the dual variables δ^* are related by

$$c_i \prod_{j=1}^{m} t_j^{*a_{ij}} = \begin{cases} \delta_i^* v(\delta^*), & i \in [0] \\ \delta_i^*/\lambda_k(\delta^*), & i \in [k], \lambda_k(\delta^*) > 0,\, k = 1, \ldots, p \end{cases} \tag{29}$$

Hence $\delta_i^*, i \in [0]$ gives the relative contribution of each component cost to the composite cost. Also at optimality, the primal and dual objective functions are equal in value [i.e., $g_0(t^*) = v(\delta^*)$].

Example. We consider an economic lot size model with multiproducts and a resource constraint. In this case, we have the following constrained posynomial program:

$$\text{Minimize} \sum_{i=1}^{N} (a_i K_i/Q_i + h_i Q_i/2)$$

subject to a resource constraint

$$\sum_{i=1}^{N} b_i Q_i \leq W$$

where b_i and W are given constants. From Equations (25–28), we find the corresponding dual program:

$$\begin{aligned}
&\text{Maximize} \prod_{i=1}^{N} (a_i K_i/\delta_i)^{\delta_i} \prod_{i=N+1}^{2N} (h_i/2\delta_i)^{\delta_i} \prod_{i=2N+1}^{3N} (b_i/W\delta_i)^{\delta_i} \lambda^{\lambda} \\
&\text{subject to} \sum_{i=1}^{2N} \delta_i = 1 \\
&\lambda = \sum_{i=2N+1}^{3N} \delta_i \\
&-\delta_i + \delta_{N+i} + \delta_{2N+i} = 0, \quad i = 1, \ldots, N \\
&\delta_i \geq 0, \quad i = 1, \ldots, 3N
\end{aligned}$$

SIGNOMIAL PROGRAMMING

Although posynomial programming has found application in a variety of areas, many problems of interest have fallen outside the posynomial form. Often, it was the positivity condition on the coefficients that were violated. However, the benefits of posynomial programming were too tempting to be rejected. Passy and Wilde (2) introduced a generalization of posynomial programming, in which the coefficients of the terms were not required to be positive. This class of programs is called signomial. In signomial programming, a global minimum cannot be guaranteed. However, the properties of the dual subspace are maintained.

Duffin et al. (3) have developed methods for the analysis of signomials and an algorithm for solving them (at least for a local solution, if not for a global solution). To use the analysis, signomial programs must first be converted into posynomial programs. Any signomial $f(t)$ can be written as a difference of two posynomials, say $r(t)$ and $s(t)$ hence

$$\begin{aligned}
f(t) &\leq 1 \leftrightarrow r(t) - s(t) \leq 1 \leftrightarrow r(t) \leq s(t) + 1 \\
f(t) &\geq 1 \leftrightarrow r(t) - s(t) \geq 1 \leftrightarrow r(t) \geq s(t) + 1 \\
f(t) &\leq 0 \leftrightarrow r(t) - s(t) \leq 0 \leftrightarrow r(t) \leq s(t)
\end{aligned}$$

Because $r(t)$, $s(t)$, and $s(t) + 1$ are all non-negative for all values of t, in each case a new variable τ can be introduced so that

$$\begin{aligned}
&r(t) \leq \tau \leq s(t) + 1 \leftrightarrow r(t)/\tau \leq 1 \text{ and } 1 \leq s(t)/\tau + 1/\tau \\
&r(t) \geq \tau \geq s(t) + 1 \leftrightarrow r(t)/\tau \leq 1 \text{ and } 1 \leq s(t)/\tau \\
&r(t) \leq \tau \leq s(t) \leftrightarrow r(t)/\tau \leq 1 \text{ and } 1 \leq s(t)/\tau
\end{aligned}$$

These transformations on a signomial produce a posynomial program with reversed constraints:

$$\text{Minimize}\, g_0(t) \tag{30}$$

$$\text{subject to}\, g_k(t) \leq 1 \quad k = 1, \ldots, p \tag{31}$$

$$g_k(t) \geq 1 \quad k = p + 1, \ldots, r \tag{32}$$

$$t > 0 \tag{33}$$

where the functions $g_k(t)$ are posynomials defined by Equation (17). The difference in this formulation is the reversed constraints [Equation (32)]. Although the constraints [Equation (31)] define a convex region, the reversed constraints make the region nonconvex. The dual to the primal program defined by Equations (30)–(33) is given by:

$$\text{Maximize } v(\delta) = \prod_{i\in[0]}(c_i/\delta_i)^{\delta_i}\prod_{k=1}^{p}\prod_{i\in[k]}(c_i\lambda_k/\delta_i)^{\delta_k}\prod_{k=p+1}^{r}\prod_{i\in[k]}(c_i\lambda_k/\delta_i)^{-\delta_i} \tag{34}$$

subject to same constraints as for posynomials, namely

$$\sum_{i\in[0]}\delta_i = 1 \tag{35}$$

$$\lambda_k = \sum_{i\in[k]}\delta_i,\ k = 1,\ldots,r \tag{36}$$

$$\sum_{k=1}^{p}\sum_{i\in[k]}a_{ij}\delta_i - \sum_{k=p+1}^{r}\sum_{i\epsilon[k]}a_{ij}\delta_i = 0,\quad j = 1,\ldots,m \tag{37}$$

$$\delta_i \geq 0,\quad i = 1,\ldots,n \tag{38}$$

We note that $\log v(\delta)$ is concave in the variables associated with the regular constraints $k = 1,\ldots,p$ and the objective function. However, it is convex in the variables associated with the reversed constraints $k = p+1,\ldots,r$. In the posynomial case, the dual program required finding the maximum of a concave function subject to linear constraints. Here we are looking for the maximum of several saddle points of a concave-convex function subject to linear constraints. If the program has degree of difficulty of zero, then it is possible that a solution can be found readily but, in the general case, the program is very difficult to solve. To cope with this problem, Duffin et al. (3) apply the arithmetic–harmonic mean inequality to convert the reversed constraints into regular constraints. This approximation has the advantage that the linear constraints in the dual are the same for all such approximations. As such, the sequence of all regular posynomial programs generated is monotone and decreases in the value of the objective function. Thus one can only improve any feasible solution.

The arithmetic–harmonic inequality, given parameters $\alpha_i,\quad i\in[k]$, positive and $\sum_{i\in[k]}\alpha_i = 1$, is

$$\left(\sum_{i\in[k]}u_i\right)^{-1} \leq \prod_{i\in[k]}(\alpha_i/u_i)^{\alpha_i} \leq \sum_{i\in[k]}\alpha_i^2/u_i \tag{39}$$

with equality holding when

$$\alpha_i = u_i/\left(\sum_{i\in[k]}u_i\right) \tag{40}$$

The means in Equation (30) are the harmonic, geometric and arithmetic respectively. Consider any reversed constraint

$$g_k(t) \geq 1 \quad or \quad (g_k(t))^{-1} \leq 1$$

We set $g_k(t,\alpha) = \sum_{i\in[k]}\alpha_i^2/u_i$, which is a posynomial for fixed α. We note that $g_k(t,\alpha) \leq 1$ implies that $g_k(t) \geq 1$. Using Equation (40) for any t such that $g_k(t) \geq 1$, one can generate an α such that $g_k(t,\alpha) \leq 1$. Hence, by use of the arithmetic–harmonic inequality, we may reduce a posynomial program with reversed constraints to a regular posynomial program parameterized with respect to α, viz.

$$\text{Minimize}\quad g_0(t) \tag{41}$$

$$\text{subject to}\quad g_k(t) \leq 1,\quad k = 1,\ldots,p \tag{42}$$

$$g_k(t,\alpha) \leq 1,\quad k = p+1,\ldots,r \tag{43}$$

$$t > 0 \tag{44}$$

To obtain a monotone-decreasing sequence of programs, we solve the program above for a particular α and then reset the αs using Equation (40).

Example. We return to the multiproduct economic lot size problem given in the section on Constrained polysynomial programming. Here, we add consideration of the distribution effort. Sales are now a function of the allocation of effort to distribution, and we seek to maximize profit. The problem becomes:

$$\begin{array}{ll} \text{Maximize} & \sum_{i=1}^{N}((p_i - c_i)a_iD_i^{d_i} - D_i - K_ia_iD_i^{d_i}/Q_i - h_iQ_i/3) \\ \text{subject to} & \sum_{i=1}^{N}b_iQ_i \leq W \\ Q_i \geq 0, & D_i \geq 0,\quad \forall i \end{array}$$

Here $p_i - c_i$ is the sales price minus the cost for product i, $a_iD_i^{d_i}$ are the sales generated by a distribution effort of D_i and a_i and d_i are parameters. All other symbols have been defined previously. This model is a signomial program and is equivalent to the following program:

$$\begin{array}{ll} \text{Minimize} & 1/P \\ \text{subject to} & \sum_{i=1}^{N}b_iQ_i/W \leq 1 \end{array}$$

$$\begin{array}{l} \sum_{i=1}^{N}(p_i - c_i)a_iD_i^{d_i} - D_i - K_ia_iD_i^{d_i}/Q_i - h_iQ_i/2 \geq P \\ Q_i \geq 0,\quad D_i \geq 0,\quad \forall i \end{array} \tag{45}$$

P is a new variable that indicates profit. Taking the negative terms in Equation (45) to the right hand side and inserting a new variable R between the sides of the inequality as in the theory, we obtain the program:

$$\begin{aligned} &\text{Minimize} \quad 1/P \\ &\text{subject to} \quad \sum_{i=1}^{N} b_i Q_i/W \le 1 \end{aligned}$$

$$\begin{aligned} &P/R + \sum_i (D_i/R + K_i a_i D_i^{d_i}/(Q_i R) + h_i Q_i/(2R)) \le 1 \\ &\sum_i (p_i - c_i) a_i D_i^{d_i}/R \ge 1 \qquad (46) \\ &Q_i \ge 0, \quad D_i \ge 0 \quad \forall i \end{aligned}$$

Our original signomial program is now in the form of a posynomial program with one reversed constraint [Equation (46)]. This equation may be harmonized to become

$$\sum_i \alpha_i^2 R/((p_i - c_i) a_i D_i^{d_i}) \le 1 \qquad (47)$$

where the $\alpha_i > 0$ (and $\sum_i \alpha_i = 1$) are parameters to be varied. To find a local solution, we take a feasible set of distribution efforts D_i to evaluate α_i which is given by [see equation (40)].

$$\alpha_i = (p_i - c_i) a_i D_i^{d_i} \Bigg/ \left(\sum_i (p_i - c_i) a_i D_i^{d_i} \right), \quad \forall i \qquad (48)$$

We now solve the posynomial program with Equation (46) replaced by Equation (47). With the resulting value of D_i obtained, we reset α_i from Equation (48) and resolve the program with this new value of α_i. We repeat this procedure until no significant change is observe in the solution.

GENERALIZED GEOMETRIC PROGRAMMING

Generalized geometric programming deals with the analysis of convex mathematical programs. Commonly these appear in the form as follows:

$$\text{Minimize}\, g_0(z) \qquad (49)$$

$$\text{subject to}\, g_i(z) \le 0, \quad i \in I \qquad (50)$$

$$z \in C \qquad (51)$$

where C is a convex set, and $g_i, i \in \{0\} \cup I$ are convex functions. In the generalized geometric programming approach, we first *separate* the arguments of the constraints and objective functions. We introduce the following notation:

$$\begin{aligned} z &= x^0 = x^i, \quad \forall i \in I \\ x &= x^0 \times \underset{i \in I}{x^i} \in X. \end{aligned}$$

$$\begin{aligned} &\chi = \{x | x^0 = x^i, \, \forall i \in I\} \quad \text{a subspace of} \quad X \\ &C_i = C, \quad \forall i \in \{0\} \cup I \end{aligned}$$

The program defined by Equations (49)–(51) may now be rewritten as:

$$\text{Minimize} \quad g_0(x^0) \qquad (52)$$

$$\text{subject to} \quad g_i(x^i) \le 0 \quad i \in I \qquad (53)$$

$$x^i \in C_i, \quad i \in \{0\} \cup I \qquad (54)$$

$$x \in \chi \qquad (55)$$

This formulation *separates* the constraints and the objective function excepting for the subspace condition which ties the problem together. The subspace captures the *linearity* of the problem.

At this stage we require further ideas relating to *convexity*. Recall from the section on convexity the definition of an epigraph to a pair $[g, C]$ of a convex function g defined on a convex set C. Each nonvertical hyperplane that supports the epigraph of a convex function g at a boundary point $[x', g(x')]$ produces a subgradient of g at x' , i.e., a vector $y \in R^*$ with

$$g(x') + \langle y, x - x' \rangle \le g(x), \quad \forall x \in C \qquad (56)$$

The subgradient set $[\partial g(x')]$ that consists of all such vectors y is generally a closed convex subset of E_n, which contains only a single vector iff g is differentiable at x'. In this case the single vector is the usual gradient vector $\nabla g(x')$.

A convex function $[g, C]$ is said to be closed if its epigraph is a closed set. We shall assume that all functions are closed.

The conjugate transform $[h, D]$ of an arbitrary convex function $[g, C]$ is defined by:

$$h(y) = \sup_{x \in C} (\langle y, x \rangle - g(x)) \qquad (57)$$

and

$$D = \{y | \sup_{x \in C} (\langle y, x \rangle - g(x)) < +\infty\} \qquad (58)$$

We note that $h(y) = \langle y, x' \rangle - g(x')$ for each $y \in \partial g(x')$.

By construction $[h, D]$ is a closed convex function defined on a convex set. Another consequence of the conjugate transform is the conjugate inequality which states that

$$g(x) + h(y) \ge \langle x, y \rangle \qquad (59)$$

for $x \in C$ and $y \in D$, with equality iff $y \in \partial g(x)$ or equivalently $x \in \partial h(y)$. To handle constraints, we require the conjugate transform of a particular function $[0, g(x) \le 0, x \in C]$. This transform is related to the transform of $[g, C]$ and is called the positive homogeneous extension of $[h^+, D^+]$. This extension is denoted by $[h', D']$ where

$$h^+(y,\lambda) = \begin{cases} \lambda h(y/\lambda), & \lambda > 0 \\ \sup\limits_{x\in C} \langle y,x\rangle, & \lambda = 0 \end{cases} \tag{60}$$

and

$$D^+ = \{(y,\lambda) | y/\lambda \in D, \lambda > 0\} \cup \{(y,0) | \sup_{x\in C} \langle y,x\rangle < \infty\} \tag{61}$$

The conjugate inequality in this case is given by

$$0 + h^+(y,\lambda) \geq \langle x,y\rangle \tag{62}$$

for $(y,\lambda)\in D^+$ and $x \in C$ with equality iff $y \in \lambda\partial g(x)$ or $x \in \partial h^+(y,\lambda)$.

We now apply these ideas of conjugate transform theory to the program defined by Equations (52)–(55). This program is the primal mathematical program. For the objective function, we have from Equation (59) that

$$g_0(x^0) + h_0(y^0) \geq \langle x^0, y^0\rangle \tag{63}$$

and for each constraint, from Equation (62), we have that

$$0 + h_i^+(y^i,\lambda_i) \geq \langle x^i, y^i\rangle, \quad i \in I \tag{64}$$

Adding the inequalities in Equations (63) and (64), we have that

$$g_0(x^0) + h_0(y^0) + \sum_{i\in I} h_i^+(y^i,\lambda_i) \geq \langle x,y\rangle \tag{65}$$

where $x = x^0 \times_{i\in I} x^i$ and $y = y^0 \times_{i\in I} y^i$. By restricting $x \in \chi$ and $y \in \chi^\perp$, Equation (65) becomes

$$g_0(x^0) + h_0(y^0) + \sum_{i\in I} h_i^+(y^i,\lambda_i) \geq 0 \tag{66}$$

with equality when

$$y^0 \in \partial g_0(x^0) \quad \text{or} \quad x^0 \in \partial h_0(y^0) \tag{67}$$

and

$$y^i \in \lambda_i \partial g_i(x^i) \quad \text{or} \quad x^i \in \partial h_i^+(y^i,\lambda_i), \quad i \in I \tag{68}$$

Hence the geometric programming dual to the primal program [equations (52)–(55)] is given by:

$$\text{Minimize} \quad h_0(y^0) + \sum_{i\in I} h_i^+(y^i,\lambda_i) \tag{69}$$

$$\underset{y\in\chi^\perp}{\text{subject to}} \quad y^0 \in D_0, \quad (y^i,\lambda_i) \in D_i^+, \quad i \in I \tag{70}$$

The dual program can have certain advantages over the original primal program:

- The nonlinear constraints are incorporated into the objective function.
- If χ is of dimension n and χ is of dimension m, then $\chi^\perp$, the orthogonal complement of χ, is of dimension $n - m$. With the possibility of $n - m$ being much smaller than m and the elimination of explicit nonlinear constraints, the dual may turn out to be a much simpler problem to solve.
- The fact that the primal and dual objectives sum to zero at optimality, that is $g_0(x^0) + h_0(y^0) + \sum_{i\in I} h_i^+(y^i,\lambda_i) = 0$ provides a good stopping criterion for an algorithm. The conditions for optimality are

$$\begin{array}{lll} x^0 \in C_0 & & y^0 \in D_0 \\ g_i(x_i) \leq 0,\ x^i \in C_i & & (y_i,\lambda_i) \in D_i^+,\ i \in I \\ x \in \chi & & y \in \chi^\perp \\ x^0 \in \partial h_0(y^0) & \text{or} & y^0 \in \partial g_0(x^0) \\ x^i \in \partial h_i(y^i,\lambda_i) & \text{or} & y^i \in \lambda_i \partial g_i(x^i),\ i \in I \end{array} \tag{71}$$

From these conditions, one may calculate the optimal solution for one problem from the optimal solution of the other.

It is important to note the roles played by the four concepts of linearity, separability, convexity, and duality in generalized geometric programming theory. Linearity may occur naturally in the problem (e.g., as linear constraints), or it may be induced by the need to separate the variables as in the program at the beginning of this section. Any linearity is usually captured conveniently in the subspace condition. Separability is necessary to facilitate a simple computation of conjugate transforms. Convexity (and closure) guarantees that there is no duality gap, that is the primal and dual objectives sum to zero at optimality. Duality is the goal of generalized geometric programming theory.

Example. A well-known problem in inventory control is to select a set $\{x_i; t = 1, \ldots, T\}$ of production levels to minimize, over a planning horizon of length T, the sum of production and holding costs while meeting demand. Formally the problem may be posed as follows:

$$\text{Minimize} \sum_{t=1}^{T} c(x_t) + h_t y_t \tag{72}$$

subject to the inventory balance dynamics

$$\begin{aligned} & y_1 = x_1 - d_1 \\ & y_t - y_{t-1} = x_t - d_t,\ t = 2, \ldots, T-1 \\ & -y_{T-1} = x_T - d_T \end{aligned} \tag{73}$$

and the non-negativity constraints

$$\begin{aligned} & y_t \geq 0, \quad t = 1, \ldots, T \\ & x_t \geq 0, \quad t = 1, \ldots, T \end{aligned} \tag{74}$$

Here y_t denotes the inventory level in period t, d_t is the demand in period t, $c(x_t)$ is the production cost (assumed convex and strictly monotonically increasing) and h_t is the holding cost per unit in period t.

To invoke the theory of generalized geometric programming, we need to put the constraints from Equation (73) into a subspace. Hence we introduce a new variable $\alpha_t, t = 1, \ldots, T$, and restrict it to a one point domain $\{d_t\}$, $t = 1, \ldots, T$. This variable is then associated with an additive component of the objective function, which is identically zero. Hence, we obtain a subspace condition

$$\begin{aligned} & y_1 - x_1 + \alpha_1 = 0 \\ & y_t - y_{t-1} - x_t + \alpha_t = 0, \quad t = 2, \ldots, T-1 \\ & -y_{T-1} - x_T + \alpha_T = 0 \end{aligned} \tag{75}$$

It is convenient to treat the non-negativity constraints $x_t \geq 0, y_t \geq 0, t = 1, \ldots, T$, in an implicit way (i.e., $C_0 = \{x_t | x_t \geq 0, y_t \geq 0, d_t = \alpha_t, t = 1, \ldots, T\}$). Our problem is now in a form that is directly suitable for application of the theory. We note that in this problem no explicit constraints are evident. The dual objective is given by

$$\sup_{\substack{x_t, y_t, \alpha_t \\ x_t \geq 0 \\ y_t \geq 0}} \sum_t (x_t u_t + y_t v_t + \alpha_t \beta_t - c(x_t) - h_t y_t)$$

$$\begin{aligned} &= \sup_{x_t \geq 0} \sum_t (x_t u_t - c(x_t)) + \sup_{\alpha_t} \sum_t \alpha_t \beta_t + \sup_{y_t \geq 0} \sum_t (y_t v_t - h_t y_t) \\ &= \sum_t c^*(u_t) + d_t \beta_t \end{aligned}$$

where

$$c^*(u_t) = \sup_{\substack{x_t \geq 0 \\ u_t \in \partial c(x_t)}} x_t u_t - c(x_t)$$

and

$$v_t \leq h_t$$

Usually $c(x_t)$ is a quadratic function and $c^*(u_t)$ is readily calculated. Furthermore we require the orthogonal complement to the subspace defined by Equation (61), i.e.

$$\{(u_t, v_t, \beta_t) | \sum_t (u_t x_t + v_t y_t + \beta_t \alpha_t) = 0, \quad \forall x_t, y_t, \alpha_t\}$$

satisfying Equation (75). A straightforward calculation shows that

$$\begin{aligned} v_t &= p_t - p_{t+1}, & t &= 1, \ldots, T-1 \\ u_t &= -p_t, & t &= 1, \ldots, T \\ \beta_t &= p_t, & t &= 1, \ldots, T \end{aligned}$$

Hence the dual problem is

$$\text{Minimize} \quad \sum_{t=1}^{T} c^*(-p_t) + d_t p_t$$

$$\text{subject to} \quad p_t - p_{t+1} - h_t \leq 0, \quad t = 1, \ldots, T-1$$

For constant h_t, we have a minimization over a monotonically increasing set of decision variables.

THE ANALYSIS OF POSYNOMIAL PROGRAMMING BY GENERALIZED GEOMETRIC PROGRAMMING

Recall that in the preceding section we used the convexity of the functions of a convex mathematical program by applying separability and then using linearity and duality to derive a potentially simpler problem. To bring this structure out in posynomial programming, we consider the following convex function:

$$\sum_{i \in [k]} \delta_i \log \delta_i / c_i \tag{76}$$

defined on

$$\delta_i \geq 0, \quad i \in [k] \quad \text{and} \quad \sum_{i \in [k]} \delta_i = 1 \tag{77}$$

Here the parameters $c_i > 0$, $i \in [k]$. The conjugate transform of the function defined by Equation (76) taken over the set defined by Equation (77) may be shown to be

$$\log \sum_{i \in [k]} c_i \exp(z_i) \tag{78}$$

Hence the conjugate inequality from Equation (59) is:

$$\sum_{i \in [k]} \delta_i \log \delta_i / c_i + \log \left(\sum_{i \in [k]} c_i \exp(z_i) \right) \geq \sum_{i \in [k]} \delta_i z_i \tag{79}$$

with equality when

$$\delta_i = c_i \exp(z_i) / \left(\sum_{i \in [k]} c_i \exp(z_i) \right) \tag{80}$$

To handle constraints of the form

$$\log \sum_{i \in [k]} c_i \exp(z_i) \leq 0 \tag{81}$$

we require the positive homogeneous extension of function [Equation (76)] defined over the set [Equation (77)], which is given by

$$\sum_{i \in [k]} \delta_i \log(\delta_i/(\lambda_k c_i)) \tag{82}$$

defined for

$$\lambda_i = \sum_{i \in [k]} \delta_i,\ \delta_i \geq 0,\ i \in [k] \tag{83}$$

To relate functions of the form in Equation (64) to posynomial geometric programs discussed in Section 3 we set

$$x_j = \log t_j,\ \forall j \tag{84}$$

and

$$z_i = \sum_{j=1}^{m} a_{ij} x_j, \quad \forall i \tag{85}$$

in Equations (14) and (15). Equation (85) is the subspace condition in the generalized theory. Making the above substitution and taking logs, our posynomial program is as follows:

$$\begin{aligned} &\text{Minimize} \quad \log \sum_{i \in [0]} c_i \exp(z_i) \\ &\text{subject to} \quad \log \sum_{i \in [k]} c_i \exp(z_i) \leq 0, \quad i = 1, \ldots, p \\ &z \in X = \{z | z_i = \sum_{j=1}^{m} a_{ij} x_j, j = 1, \ldots, n\} \end{aligned}$$

In the above form, the theory of generalised geometric programming may be invoked since we have already calculated the relevant conjugate transforms [see Equations (76), (77), (82) and (83)]. Hence, using Equations (69), (70), and (71), the dual to a posynomial program is given by

$$\begin{aligned} &\text{Minimize} \quad \sum_{i=1}^{n} \delta_i \log \delta_i / c_i - \sum_{k=1}^{p} \lambda_k \log \lambda_k \\ &\text{subject to} \quad \sum_{i \in [0]} \delta_i = 1 \\ &\delta_i \geq 0,\ \forall i \\ &\lambda_k = \sum_{i \in [k]} \delta_i,\ k = 1, \ldots, p \\ &\delta \in X^{\perp} = \{\delta | \sum_{i=1}^{n} a_{ij} \delta_i = 0, j = 1, \ldots, m\} \end{aligned}$$

The above objective function is equivalent to maximizing

$$\prod_{i=1}^{n} (c_i/\delta_i)^{\delta_i} \prod_{k=1}^{p} \lambda_k^{\lambda_k}$$

which is the original form of the dual objective function for posynomial programming [see Equations (25)–(28)]. Furthermore, it is straightforward to obtain the optimality conditions between the primal and dual variables, Equation (29) from the general optimality conditions in the section on Generalized geometric programming.

APPLICATIONS

In the previous sections, we have shown the development of the theory of geometric programming. Included in the references are various books and papers that describe applications of geometric programming. Here, we provide a couple of relevant applications and then a survey of geometric programming applications.

Transformer Design

Transformer design is a major application of geometric programming. Geometric programming produces a minimum cost design that can be quickly redesigned when costs or specifications of materials change. Consider the design of a simple interlocking coil and core transformer. We wish to convert a primary electric power with voltage V_p and current J_p into a secondary electric power of voltage V_s and current J_s. To design a transformer with such specifications, we use fundamental relationships of electricity and magnetism. Faraday's Law of Induction is

$$\oint E \cdot ds = 10^{-8} \dot{B} A_{Fc}$$

The electromotive force equals the ratio of voltage over the number of turns of the copper wire for the primary and secondary circuits. We have

$$\oint E \cdot ds = V_p / N_p$$

and

$$\oint E \cdot ds = V_s / N_s$$

Thus $V_p/N_p = V_s/N_s$.

Ampere's Law for an electric current with the integral taken around both the primary and secondary coils is

$$\oint H \cdot ds = 0.4\pi J_{\text{total}}$$

Because J_{total} is approximately zero, we have

$$J_p N_p = J_s N_s$$

Combining this result with that of voltage and turns we have primary power approximately equal to secondary power.

$$J_pV_p = J_sV_s$$

With this knowledge of electromagnetics, we are ready to construct the geometric program for the transformer design. We must have a large enough cross-sectional area of the iron core to be able to generate a sufficient electromotive force, which means that

$$10^{-8}\dot{B}A_{\text{Fe}} \geq V_p/N_p$$

With the assumption that there is a equal split between the primary and secondary coils the requirement for copper must satisfy the following inequality:

$$iA_{\text{Cu}}/2 \geq N_pJ_p$$

Replace $\dot{B}$ by $\omega B/2^{t/2}$ with B being the magnetic flux amplitude and ω the circular frequency. Combining the above two inequalities, we can eliminate N_p.

$$2^{-3/2} \cdot 10^{-8}\omega BiA_{\text{Fe}}A_{\text{Cu}} \geq J_pV_p$$

We must also limit magnetic loss and ohmic loss to have a functioning transformer.

$$D\omega B^{3.5}V_{\text{Fe}} \leq M_l$$

The magnetic loss constraint is approximate for the level of 20,000 gauss.

$$\rho i^2V_{\text{Cu}} \leq O_l$$

The cross-sectional areas and volumes can be related to the transformer dimensions by using the mean iron length L_{Fe} and mean copper length L_{Cu}, as well as the dimensions of the iron core window and the copper coil window.

$$\begin{aligned}
&A_{\text{Fe}} = a'\dot{b}' \\
&A_{\text{Cu}} = ab \\
&2a + 2b + 2a' + \Delta \leq L_{\text{Fe}} \\
&2a' + 2b' + \pi a/2 + \Delta' \leq L_{\text{Cu}} \\
&V_{\text{Fe}} = L_{\text{Fe}}A_{\text{Fe}} \\
&V_{\text{Cu}} = L_{\text{Cu}}A_{\text{Cu}}
\end{aligned}$$

Putting this all together into a geometric program we will minimize the cost of materials subject to design constraints and eliminate variables to simplify the formulation.

$$\text{Min}\, C_{\text{Cu}}abL_{\text{Cu}} + C_{\text{Fe}}a'b'L_{\text{Fe}}$$

subject to

$$\begin{aligned}
&D\omega a'b'B^{3.5}L_{\text{Fe}}/M_l \leq 1 \\
&\rho i^2abL_{\text{Cu}}/O_t \leq 1 \\
&J_pV_p2^{3/2} \cdot 10^8\omega^{-1}B^{-1}i^{-1}(a'b')^{-1}a^{-1}b^{-1} \leq 1 \\
&2a/L_{\text{Fe}} + 2b/L_{\text{Fe}} + 2a'/L_{\text{Fe}} + \Delta/L_{\text{Fe}} \leq 1 \\
&2a'/L_{\text{Cu}} + 2b'/L_{\text{Cu}} + \pi a/2L_{\text{Cu}} + \Delta'/L_{\text{Cu}} \leq 1
\end{aligned}$$

Parameter	Definition	Units
Vp	Primary voltage	Volts
Jp	Primary current	Ampres
Vs	Secondary voltage	Volts
Js	Secondary current	Ampres
J_{total}	Primary and secondary current	Ampres
H	Magnetomotive force	Oersteds
M_l	Magnetic loss	Gauss
D	Magnetic loss factor	
O_l	Ohmic loss	Ohms
ω	Circular frequency	Integer
ρ	Resistivity	Ohm cm
C_{Cu}	Copper cost per cm^3	$
C_{Fe}	Iron cost per cm^3	$
Δ	Clearance for Iron	Cm
Δ'	Clearance for Copper	Cm

Tables 1 and 2 show of parameters and variables. Eight design variables remain in the formulation, and there are 13 terms. The degree of difficulty for this problem is 4 (this is the dimension of the dual geometric program). It can be solved using a standard nonlinear programming package or one specifically designed for geometric programming. Because it is a geometric program, we are assured of finding the optimum solution. Additional analysis of this and other transformer designs can be found in Duffin et al.(3).

Information Theory

C. E. Lemke recognized that the dual geometric program was of the form of chemical equilibrium or free energy models in chemistry. Shannon used a similar formulation to model problems in information theory. Here, we will look at the problem of finding the most efficient source for

Variables	Design Variable	Units
E	Electric field	Volts per centimeter
B	Magnetic flux density	Gauss
A_{Fe}	Cross-sectional area of the iron core	Cm^2
Np	Number of primary turns	Integer
Ns	Number of secondary turns	Integer
i	Current current density	Amperes per cm^2
A_{Cu}	Cross-sectional area of copper coils	Cm^2
a	Width of iron core window	Cm
b	Height of iron core window	Cm
L_{Fe}	Mean iron length	Cm
a'	Width of copper coil window	Cm
b'	Height of copper coil window	Cm
L_{Cu}	Mean copper length	Cm
V_{Fe}	Volume of iron	Cm^3
V_{Cu}	Volume of Copper	Cm^3

communications as a dual of a geometric program in infinite dimensions.

The problem is first formulated as an entropy maximation problem with m moment constraints.

$$\operatorname{Max} H(p) = -\int_{-\infty}^{+\infty} p(x) \ln p(x) dx$$

subject to

$$\int_{-\infty}^{+\infty} p(x) dx = 1$$
$$p(x) \geq 0$$
$$\int_{-\infty}^{+\infty} f_i(x) p(x) dx = \alpha_i,\ i = 1, \ldots, m$$

Here, we are optimizing over the probability distribution p.

The dual of the above problem is the following geometric program:

$$\operatorname{Min} G(q) = \ln \int_{-\infty}^{+\infty} \exp[q(x)] dx$$

subject to

$$q(x) = -\sum_i z_i(f_i(x) - \alpha_i)$$

With the z_i are m scalar variables. This mathematical program can be reduced to an unconstrained finite dimensional optimization problem:

$$\operatorname{Min} G(z) = \ln \int_{-\infty}^{+\infty} \exp[-\sum_i z_i(f_i(x) - \alpha_i)] dx$$

Because it is a geometric program, we know that the global optimum can be found. At optimality the we can recognize that the optimal primal distribution will take the form:

$$p(x) = \frac{\exp[-\sum_i z_i(f_i(x) - \alpha_i)]}{\int_{-\infty}^{+\infty} \exp[-\sum_i z_i(f_i(x') - \alpha_i)] dx'}$$

Thus, we know that the solution to this communications problem comes from the exponential family.

Survey of Geometric Programming Applications

Engineering Design. The reason for geometric programming was Zener's interest in engineering design problems. Electrical engineering design appears in both books (1,4) in the form of transformer design. In fact, the method can be used for other devices that involve the use of induction coils. More recently, it has been used in circuit design and manufacture (5,6). The second example was mechanical engineering. Duffin et al. (1) used geometric programming to design an ocean thermal energy conversion system. Power turbines and cooling towers can be designed using geometric programming (7). Control system design is a geometric program (8). Steel plate girders can be designed by geometric programming as well (9).

In Zener's book (4), the third application of geometric programming was civil engineering (bridges and buildings). Also designed are floor and roof systems, frames structures, hydraulic networks and pipelines, and wastewater treatment (10).

Lemke identified the dual of a geometric program as having the same form as chemical equilibrium. The consequence of this comment is included in the textbook (3) as an appendix. Wilde and his students (11) introduced geometric programming to chemical engineering. Chemical engineering applications appear in the Beightler and Phillips textbook (12). Geometric programming has been used in ethylene plant optimization. Chemical reactors, complex chemical equilibria, and mineral processing can also benefit from geometric programming.

Passy (13) was the first person to apply geometric programming to industrial engineering problems [see also Jung et al. (14)]. Machining economics (tool life) has been modelled using geometric programming (15). It is used in bottleneck scheduling (16). Replacement (reliability) problems can be solved by geometric programming (17). Optimal tolerancing (18) can be solved as a geometric program. Generalized geometric programming can solve location problems (19).

Geometric programming has been applied to nuclear engineering, naval architecture, aeronautical engineering, and agricultural engineering. A collection of papers on optimal design (using geometric programming) was published in 1973 (20).

Business. In 1974, Balachandran and Gensch (21) first analyzed the marketing mix problem using geometric programming. Capital budgeting benefits from geometric programming analysis (22,23). Accounting estimates and valuations are found by entropy (24,25). Cost benefit analysis can be analyzed using generalized geometric programming (26). A variety of applications from the management sciences, using geometric programming, are presented in a book (27).

Transportation and Regional Planning. Jefferson (1972) was the first to apply geometric programming to transportation planning and trip distribution (28). The application of geometric programming to entropy models for trip distribution and regional planning was particularly worthwhile. See for example, Refs. 29 and 30.

Information and Communications. In 1977, Scott and Jefferson (31) were the first to apply geometric programming to information theory. Modern communications problems can be modeled as geometric programs (32,33).

Stochastic Models and Statistics. In 1966, Avriel (34) was the first to work on stochastic geometric programming.

Stochastic geometric programming has been applied to industrial engineering and finance (22, 35). Probability can be analyzed by geometric programming (36). Geometric programming aids in estimation and sampling (25).

Curve Fitting. Peterson and Ecker (37) first applied geometric programming concepts to l_p-approximation (37). Geometric programming provides an effective framework for curve fitting with spline functions (38,39).

ALGORITHMS

Initially, the geometric programs were small, and the dual program was only a single point or up to a few dimensions. Problems could be solved by hand or with a simple program. As geometric programming grew in popularity, people wanted to solve larger problems and problems modeled as signomials. By the mid-1970s, the computer code of choice written by Dembo et al. (40) used cutting planes to approximate the posynomials with a single term (called a monomial) and linear programming. It could solve moderate-sized problems efficiently. For signomials, it could improve on a starting solution but there was no guarantee on the solution being globally optimal.

In the 1990s, interior point methods were applied with success to geometric programming. Nesterov and Nemirovsky (41) developed an interior point method for convex programs that could solve geometric programs. Separately Zhu et al. (42) provided a good stable interior point algorithm built on the work of Fang et al. (43). Next Kortanek et al. (44) developed an infeasible interior point algorithm that searches for the Karush-Kuhn-tucker point for the geometric program and that makes use of the sparse structure of the logarithmic dual objective function (this is the form described in the section entitled "The analysis of posynomial programming by generalized geometric programming"). Anderson and Ye (45) have also developed a solution method for large-scale geometric programs with a single-phase interior point method.

The research into algorithms for geometric programs has taught us that geometric programs are nicely structured problems, and if one makes the transformations used in the section entitled "The analysis of posynomial programming by generalised geometric programming", they can be solved easily. If one does not have access to special geometric programming packages, then a general nonlinear programming package can solve moderate-sized problems. These packages are available on most computers by simply using the nonlinear feature of your spreadsheet program on your. AMPL personal computer provides an excelent modeling language and a GRG nonlinear programming package to solve medium-sized problems. MOSEK can be interfaced with AMPL to allow one to work on large geometric programs.

CONCLUSIONS

Geometric programming has evolved from the study of posynomial programs to signomial programs and, through generalized geometric programming, to convex programs. The areas of application are ever growing (over 500 publications use geometric programming across its 40-year history). The reason for its popularity is that it is fairly easy to formulate many problems as geometric programs because it advantageously captures the inherent structure found in real problems. Many programs so formulated can be converted into convex programs. They can now be solved easily using special purpose algorithms or by generally available nonlinear programming packages, even if they are large. Geometric programming provides a dual that can help in understanding the problem and in the sensitivity analysis of the solution. Thus geometric programming remains an important method in optimization. See the Further Reading list at the end of the chapter for more information.

G

GRAPH THEORY AND ALGORITHMS

GRAPH THEORY FUNDAMENTALS

A *graph* $G(V,E)$ consists of a set V of *nodes* (or *vertices*) anda set E of pairs of nodes from V, referred to as *edges*. An edge may have associated with it a direction, in which case, the graph is called *directed* (as opposed to *undirected*), or a *weight*, in which case, the graph is called *weighted*. Given an undirected graph $G(V,E)$, two nodes $u,v \in V$ for which an edge $e = (u, v)$ exists in E are said to be *adjacent* and edge e is said to be *incident* on them. The *degree* of a node is the number of edges adjacent to it. A (*simple*) *path* is a sequence of distinct nodes $(a_0, a_1, \ldots, a_k)$ of V such that every two nodes in the sequence are adjacent. A (*simple*) *cycle* is a sequence of nodes $(a_0, a_1, \ldots, a_k, a_0)$ such that $(a_0, a_1, \ldots, a_k)$ is a path and a_k, a_0 are adjacent. A graph is *connected* if there is a path between every pair of nodes. A graph $G'(V',E')$ is a *subgraph* of graph $G(V, E)$ if $V' \subseteq V$ and $E' \subseteq E$. A *spanning tree* of a connected graph $G(V, E)$ is a subgraph of G that comprises all nodes of G and has no cycles. A graph $G'(V', E')$ is a *subgraph* of graph $G(V, E)$ if $V' \subseteq V$ and $E' \subseteq E$. An *independent set* of a graph $G(V, E)$ is a subset $V' \subseteq V$ of nodes such that no two nodes in V' are adjacent in G. A *clique* of a graph $G(V, E)$ is a subset $V' \subseteq V$ of nodes such that any two nodes in V' are adjacent in G. Given a subset $V' \subseteq V$, the *induced subgraph of* $G(V, E)$ by V' is a subgraph $G'(V', E')$, where E' comprises all edges (u, v) in E with $u, v \in V'$.

In a directed graph, each edge (sometimes referred to as *arc*) is an ordered pair of nodes and the graph is denoted by $G(V, A)$. For an edge $(u, v) \in A, v$ is called the *head* and u the *tail* of the edge. The number of edges for which u is a tail is called the *out-degree* of u and the number of edges for which u is a head is called the *in-degree* of u. A (*simple*) *directed path* is a sequence of distinct nodes $(a_0, a_1, \ldots, a_k)$ of V such that (a_i, a_{i+1}), $\forall i,\ 0 \leq i \leq k-1$, is an edge of the graph. A (*simple*) *directed cycle* is a sequence of nodes $(a_0, a_1, \ldots, a_k, a_0)$ such that $(a_0, a_1, \ldots, a_k)$ is a directed path and $(a_k,\ a_0) \in A$. A directed graph is *strongly connected* if there is a directed path between every pair of nodes. A directed graph is *weakly connected* if there is an undirected path between every pair of nodes.

Graphs (1–5) are a very important modeling tool that can be used to model a great variety of problems in areas such as operations research (6–8), architectural level synthesis (9), computer-aided Design (CAD) for very large-scale integration (VLSI) (9,10) and computer and communications networks (11).

In operations research, a graph can be used to model the assignment of workers to tasks, the distribution of goods from warehouses to customers, etc. In architectural level synthesis, graphs are used for the design of the data path and the control unit. The architecture is specified by a graph, a set of resources (such as adders and multipliers), and a set of constraints. Each node corresponds to an operation that must be executed by an appropriate resource, and a directed edge from u to v corresponds to a constraint and indicates that task u must be executed before task v. Automated data path synthesis is a scheduling problem where each task must be executed for some time at an appropriate resource. The goal is to minimize the total time to execute all tasks in the graph subject to the edge constraints. In computer and communications networks, a graph can be used to represent any given interconnection, with nodes representing host computers or routers and edges representing communication links.

In CAD for VLSI, a graph can be used to represent a digital circuit at any abstract level of representation. CAD for VLSI consists of logic synthesis and optimization, verification, analysis and simulation, automated layout, and testing of the manufactured circuits (12). Graphs are used in multilevel logic synthesis and optimization for combinational circuits, and each node represents a function that is used for the implementation of more than one output (9). They model synchronous systems by means of finite state machines and are used extensively in sequential logic optimization (9). Binary decision diagrams are graphical representations of Boolean functions and are used extensively in verification. Algorithms for simulation and timing analysis consider graphs where the nodes typically correspond to gates or flip-flops. Test pattern generation and fault grading algorithms also consider graphs where faults may exist on either the nodes or the edges. In the automated layout process (10), the nodes of a graph may represent modules of logic (partitioning and floor-planning stages), gates or transistors (technology mapping, placement, and compaction stages), or simply pins (routing, pin assignment, and via minimization stages).

There are many special cases of graphs. Some of the most common ones are listed below. A *tree* is a connected graph that contains no cycles. A *rooted tree* is a tree with a distinguished node called a *root*. All nodes of a tree that are distinguished from the root and are adjacent to only one node are called *leaves*. Trees are used extensively in the automated layout process of intergated circuits. The clock distribution network is a rooted tree whose root corresponds to the clock generator circuit and whose leaves are the flip-flops. The power and ground supply networks are rooted trees whose root is either the power or the ground supply mechanism and whose leaves are the transistors in the layout. Many problem formulations in operations research, architectural level synthesis, CAD for VLSI, and networking allow for fast solutions when restricted to trees. For example, the simplified version of the data path scheduling problem where all the tasks are executed on the same type of resource is solvable in polynomial time if the task graph is a rooted tree. This restricted scheduling problem is also common in multiprocessor designs (9).

A *bipartite graph* is a graph with the property that its node set V can be partitioned into two disjoint subsets V_1 and V_2, $V_1 \cup V_2 = v$, such that every edge in E comprises

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

one node from V_1 and one node from V_2. Bipartite graphs appear often in operations research (6–8) and in VLSI CAD applications (9,10).

A *directed acyclic graph* is a directed graph that contains no directed cycles. Directed acyclic graphs can be used to represent combinational circuits in VLSI CAD. Timing analysis algorithms in CAD for VLSI or software timing analysis algorithms of synthesizable hardware description language code operate on directed acyclic graphs.

A *transitive graph* is a directed graph with the property that for any nodes $u, v, w \in V$ for which there exist edges $(u, v), (v, w) \in A$, edge (u, w) also belongs to A. Transitive graphs find applications in resource binding of tasks in architectural level synthesis (9) and in fault collapsing for digital systems testing (12).

A *planar graph* is a graph with the property that its edges can be drawn on the plane so as not to cross each other. Many problems in the automated layout for VLSI are modeled using planar graphs. Many over-the-cell routing algorithms require the identification of circuit lines to be routed on a single layer. Single-layer routing is also desirable for detailed routing of the interconnects within each routing layer (10).

A *cycle graph* is a graph that is obtained by a cycle with chords as follows: For every chord (a,b) of the cycle, there is a node $v_{(a,b)}$ in the cycle graph. There is an edge $(v_{(a,b)}, v_{(c,d)})$ in the cycle graph if and only if the respective chords (a, b) and (c, d) intersect. Cycle graphs find application in VLSI CAD, as a channel with two terminal nets, or a switchbox with two terminal nets can be represented as a cycle graph. Then the problem of finding the maximum number of nets in the channel (or switchbox) that can be routed on the plane amounts to finding a maximum independent set in the respective cycle graph (10).

A *permutation graph* is a special case of a cycle graph. It is based on the notion of a *permutation diagram*. A permutation diagram is simply a sequence of N integers in the range from 1 to N (but not necessarily ordered). Given an ordering, there is a node for every integer in the diagram and there is an edge (u,v) if and only if the integers u,v are not in the correct order in the permutation diagram. A permutation diagram can be used to represent a special case of a *permutable channel* in a VLSI layout, where all nets have two terminals that belong to opposite channel sides. The problem of finding the maximum number of nets in the permutable channel that can be routed on the plane amounts to finding a maximum independent set in the respective permutation graph. This, in turn, amounts to finding the maximum increasing (or decreasing) subsequence of integers in the permutation diagram (10).

Graphs have also been linked with random processes, yielding what is known as *random graphs*. Random graphs consist of a given set of nodes while their edges are added according to some random process. For example, $G(n,p)$ denotes a random graph with n nodes but whose edges are chosen independently with probability p. Typical questions that arise in the study of random graphs concern their probabilistic behavior. For example, given n and p we may want to find the probability that $G(n,p)$ is connected (which has direct application to the reliability of a network whose links fail probabilistically). Or we may want to determine whether there is a threshold on some parameter (such as the average node degree) of the random graph after which the probability of some attribute (such as connectivity, colorability, etc) changes significantly.

ALGORITHMS AND TIME COMPLEXITY

An *algorithm* is an unambiguous description of a finite set of operations for solving a computational problem in a finite amount of time. The set of allowable operations corresponds to the operations supported by a specific computing machine (computer) or a model of that machine.

A *computational problem* comprises a set of parameters that have to satisfy a set of well-defined mathematical constraints. A specific assignment of values to these parameters constitutes an *instance* of the problem. For some computational problems, there is no algorithm as defined above to find a solution. For example, the problem of determining whether an arbitrary computer program terminates in a finite amount of time given a set of input data cannot be solved (it is “undecidable”) (13). For the computational problems for which there does exist an algorithm, the point of concern is how “efficient” is that algorithm. The *efficiency* of an algorithm is primarily defined in terms of how much time the algorithm takes to terminate. (Sometimes, other considerations such as the space requirement in terms of the physical information storage capacity of the computing machine are also taken into account, but in this exposition we concentrate exclusively on time.)

To formally define the efficiency of an algorithm, the following notions are introduced.

The *size* of an instance of a problem is defined as the total number of symbols for the complete specification of the instance under a finite set of symbols and a “succinct” encoding scheme. A “succinct” encoding scheme is considered to be a logarithmic encoding scheme, in contrast to a unary encoding scheme. The time requirement (*time complexity*) of an algorithm is expressed then as a function $f(n)$ of the size n of an instance of the problem and gives the total number of “basic” steps that the algorithm needs to go through to solve that instance. Most of the time, the number of steps is taken with regard to the worst case, although alternative measures like the average number of steps can also be considered. What constitutes a “basic” step is purposely left unspecified, provided that the time the basic step takes to be completed is bounded from above by a *constant*, that is, a value not dependent on the instance. This hides implementation details and machine-dependent timings and provides the required degree of general applicability.

An algorithm with time complexity $f(n)$ is said to be of the *order of* $g(n)$ [denoted as $O(g(n))$], where $g(n)$ is another function, if there is a constant c such that $f(n) \leq c \cdot g(n)$, for all $n \geq 0$. For example, an algorithm for finding the minimum element of a list of size n takes time $O(n)$, an algorithm for finding a given element in a sorted list takes time $O(\log n)$, and algorithms for sorting a list of elements can take time $O(n^2)$, $O(n \log n)$, or $O(n)$ (the latter when additional information about the range of the elements is known). If moreover, there are constants c_L and c_H such that $c_L \cdot g(n) \leq f(n) \leq c_H \cdot g(n)$, for all $n \geq 0$, then $f(n)$ is said to be $\Theta(g(n))$.

The smaller the "order-of" function, the more efficient an algorithm is generally taken to be, but in the analysis of algorithms, the term "efficient" is applied liberally to any algorithm whose "order-of" function is a polynomial $p(n)$. The latter includes time complexities like $O(n \log n)$ or $O(n\sqrt{n})$, which are clearly bounded by a polynomial. Any algorithm with a nonpolynomial time complexity is not considered to be efficient. All nonpolynomial-time algorithms are referred to as *exponential* and include algorithms with such time complexities as $O(2^n)$, $O(n!)$, $O(n^n)$, $O(n^{\log n})$ (the latter is sometimes referred to as *subexponential*). Of course, in practice, for an algorithm of polynomial-time complexity $O(p(n))$ to be actually efficient, the degree of polynomial $p(n)$ as well as the constant of proportionality in the expression $O(p(n))$ should be small. In addition, because of the worst-case nature of the $O()$ formulation, an "exponential" algorithm might exhibit exponential behavior in practice only in rare cases (the latter seems to be the case with the simplex method for linear programming). However, the fact on the one hand that most polynomial-time algorithms for the problems that occur in practice tend indeed to have small polynomial degrees and small constants of proportionality, and on the other that most nonpolynomial algorithms for the problems that occur in practice eventually resort to the trivial approach of exhaustively searching (enumerating) all candidate solutions, justifies the use of the term "efficient" for only the polynomial-time algorithms.

Given a new computational problem to be solved, it is of course desirable to find a polynomial-time algorithm to solve it. The determination of whether such a polynomial-time algorithm actually exists for that problem is a subject of primary importance. To this end, a whole discipline dealing with the classification of the computational problems and their interrelations has been developed.

P, NP, and *NP*-Complete Problems

The classification starts technically with a special class of computational problems known as decision problems. A computational problem is a *decision problem* if its solution can actually take the form of a "yes" or "no" answer. For example, the problem of determining whether a given graph contains a simple cycle that passes through every node is a decision problem (known as the Hamiltonian cycle problem). In contrast, if the graph has weights on the edges and the goal is to find a simple cycle that passes through every node and has a minimum sum of edge weights is not a decision problem but an *optimization* problem (the corresponding problem in the example above is known as the Traveling Salesman problem). An optimization problem (sometimes also referred to as a *combinatorial optimization problem*) seeks to find the best solution, in terms of a well-defined objective function $Q()$, over a set of feasible solutions. Interestingly, every optimization problem has a "decision" version in which the goal of minimizing (or maximizing) the objective function $Q()$ in the optimization problem corresponds to the question of whether a solution exists with $Q() \leq k$ (or $Q() \geq k$) in the decision problem, where k is now an additional input parameter to the decision problem. For example, the decision version of the Traveling Salesman problem is, given a graph and an integer K, to find a simple cycle that passes through every node and whose sum of edge weights is no more than K.

All decision problems that can be solved in polynomial time comprise the so-called class P (for "Polynomial"). Another established class of decision problems is the *NP* class, which consists of all decision problems for which a polynomial-time algorithm can *verify* if a candidate solution (which has polynomial size with respect to the original instance) yields a "yes" or "no" answer. The initials "*NP*" stand for "Non-deterministic Polynomial" in that if a yes-answer exists for an instance of an *NP* problem, that answer can be obtained *nondeterministically* (in effect, "guessed") and then verified in polynomial time. Every problem in class P belongs clearly to *NP*, but the question of whether class *NP* strictly contains P is a famous unresolved problem. It is conjectured that $NP \neq P$, but there has been no actual proof until now. Notice that to simulate the nondeterministic "guess" in the statement above, an obvious deterministic algorithm would have to enumerate all possible cases, which is an exponential-time task. It is in fact the question of whether such an "obvious" algorithm is actually the best one can do that has not been resolved.

Showing that an *NP* decision problem actually belongs to P is equivalent to establishing a polynomial-time algorithm to solve that problem. In the investigation of the relations between problems in P and in *NP*, the notion of *polynomial reducibility* plays a fundamental role. A problem R is said to be *polynomially reducible* to another problem S if the existence of a polynomial-time algorithm for S implies the existence of a polynomial-time algorithm for R. That is, in more practical terms, if the assumed polynomial-time algorithm for problem S is viewed as a subroutine, then an algorithm that solves R by making a polynomially bounded number of calls to that subroutine and taking a polynomial amount of time for some extra work would constitute a polynomial-time algorithm for R.

There is a special class of *NP* problems with the property that if and only if *any one* of those problems could be solved polynomially, then so would *all NP* problems (i.e., *NP* would be equal to P). These *NP* problems are known as NP-*complete*. An *NP*-complete problem is an *NP* problem to which every other *NP* problem reduces polynomially. The first problem to be shown *NP*-complete was the Satisfiability problem (13). This problem concerns the existence of a truth assignment to a given set of Boolean variables so that the conjunction of a given set of disjunctive clauses formed from these variables and their complements becomes true. The proof (given by Stephen Cook in 1971) was done by showing that every *NP* problem reduces polynomially to the Satisfiability problem. After the establishment of the first *NP*-complete case, an extensive and ongoing list of *NP*-complete problems has been established (13).

Some representative NP-complete problems on graphs that occur in various areas in digital design automation, computer networks, and other areas in electrical and computer engineering are listed as follows:

- Longest path: Given a graph $G(V, E)$ and an integer $K \leq |V|$, is there a simple path in G with at least K edges?
- Vertex cover: Given a graph $G(V, E)$ and an integer $K \leq |V|$, is there a subset $V' \subseteq V$ such that $|V'| \leq K$ and for each edge $(u,v) \in E$, at least one of u, v belongs to V'?
- Clique: Given a graph $G(V, E)$ and an integer $K \leq |V|$, is there a clique C among the nodes in V such that $|C| \geq K$?
- Independent set: Given a graph $G(V, E)$ and an integer $K \leq |V|$, is there a subset $V' \subseteq V$ such that $|V'| \geq K$ and no two nodes in V' are joined by an edge in E?
- Feedback node set: Given a directed graph $G(V, A)$ and an integer $K \leq |V|$, is there a subset $V' \subseteq V$ such that $|V'| \leq K$ and every directed cycle in G has at least one node in V'?
- Hamiltonian cycle: Given a graph $G(V, E)$, does G contain a simple cycle that includes all nodes of G?
- Traveling Salesman: Given a weighted graph $G(V, E)$ and a bound K, is there a path that visits each node exactly once and has a total sum of weights no more than K?
- Graph colorability: Given a graph $G(V, E)$ and an integer $K \leq |V|$, is there a "coloring" function $f: V \rightarrow 1, 2, \ldots, K$ such that for every edge $(u,v) \in E$, $f(u) \neq f(v)$?
- Graph bandwidth: Given a graph $G(V,E)$ and an integer $K \leq |V|$, is there a one-to-one function $f: V \rightarrow 1, 2, \ldots, |V|$ such that for every edge $(u,v) \in E$, $|f(u) - f(v)| \leq K$?
- Induced bipartite subgraph: Given a graph $G(V, E)$ and an integer $K \leq |V|$, is there a subset $V' \subseteq V$ such that $|V'| \geq K$ and the subgraph induced by V' is bipartite?
- Planar subgraph: Given a graph $G(V, E)$ and an integer $K \leq |E|$, is there a subset $E' \subseteq E$ such that $|E'| \geq K$ and the subgraph $G'(V,E')$ is planar?
- Steiner tree: Given a weighted graph $G(V, E)$, a subset $V' \subseteq V$, and a positive integer bound B, is there a subgraph of G that is a tree, comprises at least all nodes in V', and has a total sum of weights no more than B?
- Graph partitioning: Given a graph $G(V, E)$ and two positive integers K and J, is there a partition of V into disjoint subsets $V_1, V_2, \ldots, V_m$ such that each subset contains no more than K nodes and the total number of edges that are incident on nodes in two different subsets is no more than J?
- Subgraph isomorphism: Given two graphs $G(V_G, E_G)$ and $H(V_H, E_H)$, is there a subgraph $H'(V_{H'}, E_{H'})$ of H such that G and H' are isomorphic (i.e., there is a one-to-one function $f: V_G \rightarrow V_{H'}$ such that $(u,v) \in E_G$ if and only if $(f(u), f(v)) \in E_{H'}$)?

The interest in showing that a particular problem R is NP-complete lies exactly in the fact that if it finally turns out that NP strictly contains P, then R cannot be solved polynomially (or, from another point of view, if a polynomial-time algorithm happens to be discovered for R, then $NP = P$). The process of showing that a decision problem is NP-complete involves showing that the problem belongs to NP and that some known NP-complete problem reduces polynomially to it. The difficulty of this task lies in the choice of an appropriate NP-complete problem to reduce from as well as in the mechanics of the polynomial reduction. An example of an NP-complete proof is given below.

Theorem 1. The Clique problem is NP-complete

Proof. The problem belongs clearly to NP, because once a clique C of size $|C| \geq K$ has been guessed, the verification can be done in polynomial (actually $O(|C|^2)$) time. The reduction is made from a known NP-complete problem, the 3-Satisfiability problem, or 3SAT (13). The latter problem is a special case of the Satisfiability problem in that each disjunctive clause comprises exactly three literals.

Let φ be a 3SAT instance with n variables $x_1, \ldots, x_n$ and m clauses $C_1, \ldots, C_m$. For each clause C_j, $1 \leq j \leq m$ seven new nodes are considered, each node corresponding to one of the seven minterms that make C_j true. The total size of the set V of nodes thus introduced is $7m$. For every pair of nodes u, v in V, an edge is introduced if and only if u and v correspond to different clauses and the minterms corresponding to u and v are compatible (i.e., there is no variable in the intersection of u and v that appears as both a negated and an unnegated literal in u and v).

The graph $G(V, E)$ thus constructed has $O(m)$ nodes and $O(m^2)$ edges. Let the lower bound K in the Clique problem be $K = m$. Suppose first that φ is satisfiable; that is, there is a true–false assignment to the variables $x_1, \ldots, x_n$ that make each clause true. This characteristic means that, in each clause C_j, exactly one minterm is true and all such minterms are compatible. The set of the nodes corresponding to these minterms has size m and constitutes a clique, because all compatible nodes have edges among themselves.

Conversely, suppose that there is a clique C in $G(V, E)$ of size $|C| \geq m$. As there are no edges among any of the seven nodes corresponding to clause C_j, $1 \leq j \leq m$, the size of the clique must be exactly $|C| = m$; that is, the clique contains exactly one node from each clause. Moreover, these nodes are compatible as indicated by the edges among them. Therefore, the union of the minterms corresponding to these nodes yields a satisfying assignment for the 3SAT instance. □

It is interesting to note that seemingly related problems and/or special cases of many NP-complete problems exhibit different behavior. For example, the Shortest Path problem, related to the Longest Path problem, is polynomially solvable. The Longest Path problem restricted to directed acyclic graphs is polynomially solvable. The Graph Colorability problem for planar graphs and for $K = 4$ is also polynomially solvable.

On the other hand, the Graph Isomorphism problem, related to the Subgraph Isomorphism but now asking if the two given graphs G and H are isomorphic, is thought to be neither an *NP*-complete problem nor a polynomially solvable problem, although this has not been proved. There is a complexity class called Isomorphic-complete, which is thought to be entirely disjoint from both *NP*-complete and *P*. However, polynomial-time algorithms exist for Graph Isomorphism when restricted to graphs with node degree bounded by a constant (14). In practice, Graph Isomorphism is easy except for pathologically difficult graphs.

NP-Hard Problems

A generalization of the *NP*-complete class is the *NP*-hard class. The *NP*-hard class is extended to comprise optimization problems and decision problems that do not seem to belong to *NP*. All that is required for a problem to be *NP*-hard is that some *NP*-complete problems reduce polynomially to it. For example, the optimization version of the Traveling Salesman problem is an *NP*-hard problem, because if it were polynomially solvable, the decision version of the problem (which is *NP*-complete) would be trivially solved in polynomial time.

If the decision version of an optimization problem is *NP*-complete, then the optimization problem is *NP*-hard, because the "yes" or "no" answer sought in the decision version can readily be given in polynomial time once the optimum solution in the optimization version has been obtained. But it is also the case that for most *NP*-hard optimization problems, a reverse relation holds; that is, these *NP*-hard optimization problems can reduce polynomially to their *NP*-complete decision versions. The strategy is to use a binary search procedure that establishes the optimal value after a logarithmically bounded number of calls to the decision version subroutine. Such *NP*-hard problems are sometimes referred to as NP-*equivalent*. The latter fact is another motivation for the study of *NP*-complete problems: A polynomial-time algorithm for any *NP*-complete (decision) problem would actually provide a polynomial-time algorithm for all such *NP*-equivalent optimization problems.

Algorithms for *NP*-Hard Problems

Once a new problem for which an algorithm is sought is proven to be *NP*-complete or *NP*-hard, the search for a polynomial-time algorithm is abandoned (unless one seeks to prove that $NP = P$), and the following basic four approaches remain to be followed:

(1) Try to improve as much as possible over the straightforward exhaustive (exponential) search by using techniques like branch-and-bound, dynamic programming, cutting plane methods, and Lagrangian techniques.

(2) For optimization problems, try to obtain a polynomial-time algorithm that finds a solution that is provably close to the optimal. Such an algorithm is known as an *approximation algorithm* and is generally the next best thing one can hope for to solve the problem.

(3) For problems that involve numerical bounds, try to obtain an algorithm that is polynomial in terms of the instance size *and* the size of the maximum number occurring in the encoding of the instance. Such an algorithm is known as *pseudopolynomial-time algorithm* and becomes practical if the numbers involved in a particular instance are not too large. An *NP*-complete problem for which a pseudopolynomial-time algorithm exists is referred to as *weakly* NP-*complete* (as opposed to *strongly* NP-*complete*).

(4) Use a polynomial-time algorithm to find a "good" solution based on "rules of thumb" and insight. Such an algorithm is known as a "heuristic." No proof is provided about how good the solution is, but well-justified arguments and empirical studies justify the use of these algorithms in practice.

In some cases, before any of these approaches is examined, one should check whether the problem of concern is actually a polynomially or pseudopolynomially solvable special case of the general *NP*-complete or *NP*-hard problem. Examples include polynomial algorithms for finding a longest path in a directed acyclic graph, and finding a maximum independent set in a transitive graph. Also, some graph problems that are parameterized with an integer k exhibit the *fixed-parameter tractability* property; that is, for each fixed value of k, they are solvable in time bounded by a polynomial whose degree is independent of k. For example, the problem of whether a graph G has a cycle of length at least k, although *NP*-complete in general, is solvable in time $O(n)$ for fixed k, where n is the number of nodes in G. [For other parameterized problems, however, such as the Dominating Set, where the question is whether a graph G has a subset of k nodes such that every node not in the subset has a neighbor in the subset, the only solution known has time complexity $O(n^{k+1})$.]

In the next section, we give some more information about approximation and pseudopolynomial-time algorithms.

POLYNOMIAL-TIME ALGORITHMS

Graph Representations and Traversals

There are two basic schemes for representing graphs in a computer program. Without loss of generality, we assume that the graph is directed [represented by $G(V,A)$]. Undirected graphs can always be considered as bidirected. In the first scheme, known as the *Adjacency Matrix* representation, a $|V| \times |V|$ matrix M is used, where every row and column of the matrix corresponds to a node of the graph, and entry $M(a, b)$ is 1 if and only if $(a, b) \in A$. This simple representation requires $O(|V|^2)$ time and space.

In the second scheme, known as the *Adjacency List* representation, an array $L[1..|V|]$ of linked lists is used. The linked list starting at entry $L[i]$ contains the set of all nodes that are the heads of all edges with tail node i. The time and space complexity of this scheme is $(|V| + |E|)$.

Both schemes are widely used as part of polynomial-time algorithms for working with graphs (15). The Adjacency List representation is more economical to construct, but locating an edge using the Adjacency Matrix representation is very fast [takes $O(1)$ time compared with the $O(|V|)$ time required using the Adjacency List representation]. The choice between the two depends on the way the algorithm needs to access the information on the graph.

A basic operation on graphs is the *graph traversal*, where the goal is to systematically visit all nodes of the graph. There are three popular graph traversal methods: *Depth-first search (DFS), breadth-first search (BFS)*, and *topological search*. The last applies only to directed acyclic graphs. Assume that all nodes are marked initially as unvisited, and that the graph is represented using an adjacency list L.

Depth-first search traverses a graph following the deepest (forward) direction possible. The algorithm starts by selecting the lowest numbered node v and marking it as visited. DFS selects an edge (v, u), where u is still unvisited, marks u as visited, and starts a new search from node u. After completing the search along all paths starting at u, DFS returns to v. The process is continued until all nodes reachable from v have been marked as visited. If there are still unvisited nodes, the next unvisited node w is selected and the same process is repeated until all nodes of the graph are visited.

The following is a recursive implementation of subroutine of *DFS*(v) that determines all nodes reachable from a selected node v. $L[v]$ represents the list of all nodes that are the heads of edges with tail v, and array $M[u]$ contains the visited or unvisited status of every node u.

```
Procedure DFS($v$)
$M[v]$ := visited;
FOR each node $u \in L[v]$DO
    IF $M[u]$ = unvisited THEN Call DFS($u$);
END DFS
```

The time complexity of *DFS*(v) is $O(|V_v| + |E_v|)$, where $|V_v|, |E_v|$ are the numbers of nodes and edges that have been visited by *DFS*(v). The total time for traversing the graph using DFS is $O(|E| + |V|) = O(|E|)$.

Breadth-first search visits all nodes at distance k from the lowest numbered node v before visiting any nodes at distance k+1. Breadth-first search constructs a breadth-first search tree, initially containing only the lowest numbered node. Whenever an unvisited node w is visited in the course of scanning the adjacency list of an already visited node u, node w and edge (u, w) are added to the tree. The traversal terminates when all nodes have been visited. The approach can be implemented using queues so that it terminates in $O(|E|)$ time.

The final graph traversal method is the topological search, which applies only to directed acyclic graphs. In directed acyclic graphs, nodes have no incoming edges and nodes have no outgoing edges. Topological search visits a node only if it has no incoming edges or all its incoming edges have been explored. The approach can be also be implemented to run in $O(|E|)$ time.

Design Techniques for Polynomial-Time Algorithms

We describe below three main frameworks that can be used to obtain polynomial-time algorithms for combinatorial optimization (or decision) problems: (1) greedy algorithms; (2) divide-and-conquer algorithms; and (3) dynamic programming algorithms. Additional frameworks such as linear programming are available, but these are discussed in other parts of this book.

Greedy Algorithms. These algorithms use a greedy (straightforward) approach. As an example of a greedy algorithm, we consider the problem of finding the chromatic number (minimum number of independent sets) in an interval graph. An interval is a line aligned to the y-axis, and each interval i is represented by its left and right endpoints, denoted by l_i and r_i, respectively. This representation of the intervals is also referred to as the interval diagram.

In an interval graph, each node corresponds to an interval and two nodes are connected by an edge if the two intervals overlap. This problem finds immediate application in VLSI routing (10). The minimum chromatic number corresponds to the minimum number of tracks so that all intervals allocated to a track do not overlap with each other.

The greedy algorithm is better described on the interval diagram instead of the interval graph; i.e., it operates on the intervals rather than or the respective nodes on the interval graph. It is also known as the left-edge algorithm because it first sorts the intervals according to their left-edge values l_i and then allocates them to tracks in ascending order of l_i values.

To allocate a track to the currently examined interval i, the algorithm serially examines whether any of the existing tracks can accommodate it. (The existing tracks have been generated to accommodate all intervals j such that $l_j \leq l_i$.) Net i is greedily assigned to the first existing track that can accommodate it. A new track is generated, and interval i is assigned to that track only if i has a conflict with each existing track.

It can be shown that the algorithm results to minimum number of tracks; i.e., it achieves the chromatic number of the interval graph. This happens because if more than one track can accommodate interval i, then any assignment will lead to an optimal solution because all nets k with $l_k \geq l_i$ can be assigned to the unselected tracks.

Divide-and-Conquer. This methodology is based on a systematic partition of the input instance in a top–down manner into smaller instances, until small enough instances are obtained for which the solution of the problem degenerates to trivial computations. The overall optimal solution, i.e., the optimal solution on the original input instance, is then calculated by appropriately working on the already calculated results on the subinstances. The recursive nature of the methodology necessitates the solution of one or more recurrence relations to determine the execution time.

As an example, consider how divide-and-conquer can be applied to transform a *weighted binary tree* into a *heap*. A weighted binary tree is a rooted directed tree in which every nonleaf node has out-degree 2, and there is a value (weight) associated with each node. (Each nonleaf node is also referred to as *parent*, and the two nodes it points to are referred to as its *children*.) A heap is a weighted binary tree in which the weight of every node is no smaller than the weight of either of its children.

The idea is to recursively separate the binary tree into subtrees starting from the root and considering the subtrees rooted at its children, until the leaf nodes are encountered. The leaf nodes constitute trivially a heap. Then, inductively, given two subtrees of the original tree that are rooted at the children of the same parent and have been made to have the heap property, the subtree rooted at the parent can be made to have the heap property too by simply finding which child has the largest weight and exchanging that weight with the weight of the parent in case the latter is smaller than the former.

Dynamic Programming. In dynamic programming, the optimal solution is calculated by starting from the simplest subinstances and combining the solutions of the smaller subinstances to solve larger subinstances, in a bottom-up manner. To guarantee a polynomial-time algorithm, the total number of subinstances that have to be solved must be polynomially bounded. Once a subinstance has been solved, any larger subinstance that needs that subinstance's solution, does not recompute it, but looks it up in table where it has been stored. Dynamic programming is applicable only to problems that obey the *principle of optimality*. This principle holds whenever in an optimal sequence of choices, each subsequence is also optimal. The difficulty in this approach is to come up with a decomposition of the problem into a sequence of subproblems for which the principle of optimality holds and can be applied in polynomial time.

We illustrate the approach by finding the maximum independent set in a cycle graph in $O(n^2)$ time, where n is the number of chordal endpoints in the cycle (10). Note that the maximum independent set is *NP*-hard on general graphs.

Let $G(V, E)$ be a cycle graph, and $v_{ab} \in V$ correspond to a chord in the cycle. We assume that no two chords share an endpoint, and that the endpoints are labeled from 0 to $2n-1$, where n is the number of chords, clockwise around the cycle. Let G_{ij} be the subgraph induced by the set of nodes $v_{ab} \in V$ such that $i \leq a, b \leq j$.

Let $M(i, j)$ denote a maximum independent set of $G_{i,\,j}$. $M(i,j)$ is computed for every pair of chords, but $M(i, a)$ must be computed before $M(i, b)$ if $a < b$. Observe that, if $i \geq j$, $M(i, j) = 0$ because $G_{i,\,j}$ has no chords. In general, to compute $M(i, j)$, the endpoint k of the chord with endpoint j must be found. If k is not in the range $[i, j-1]$, then $M(i, j) = M(i, j-1)$ because graph $G_{i,\,j}$ is identical to graph $G_{i,j-1}$. Otherwise we consider two cases: (*1*) If $v_{kj} \in M(i, j)$, then $M(i,j)$ does not have any node v_{ab}, where $a \in [i, k-1]$ and $b \in [k+1, j]$. In this case, $M(i, j) = M(i, k-1) \cup M(K = 1,\quad j-1) \cup v_{kj}$. (*2*) If $v_{kj} \notin M(i, j)$, then $M(i, j) = M(i, j-1)$. Either of these two cases may apply, but the largest of the two maximum independent sets will be allocated to $M(i,j)$. The flowchart of the algorithm is given as follows:

```
Procedure MIS($V$)
FOR $j = 0$ TO $2n - 1$ DO
   Let $(j, k)$ be the chord whose one endpoint is $j$;
   FOR $i = 0$ TO $j - 1$ DO
      IF $i \leq k \leq j-1$ AND $|M(i,k-1)| + 1 + |M(k+1,j-1)| >$
         $|M(i,j-1)|$ THEN $M(i,j) = M(i, k-1) \cup v_{kj} \cup M(k+$
         $1,j-1)$;
      ELSE $M(i,j) = M(i,j-1)$;
END MIS
```

Basic Graph Problems

In this section, we discuss more analytically four problems that are widely used in VLSI CAD, computer networking, and other areas, in the sense that many problems are reduced to solving these basic graph problems. They are the *shortest path problem*, the *flow problem*, the *graph coloring problem*, and the *graph matching problem*.

Shortest Paths. The instance consists of a graph $G(V, E)$ with lengths $l(u, v)$ on its edges (u, v), a given source $s \in V$, and a target $t \in V$. We assume without loss of generality that the graph is directed. The goal is to find a shortest length path from s to t. The weights can be positive or negative numbers, but there is no cycle for which the sum of the weights on its edges is negative. (If negative length cycles are allowed, the problem is *NP*-hard.) Variations of the problem include the all-pair of nodes shortest paths and the m shortest path calculation in a graph.

We present here a dynamic programming algorithm for the shortest path problem that is known as the Bellman–Ford algorithm. The algorithm has $O(n^3)$ time complexity, but faster algorithms exist when all the weights are positive [e.g., the Dijkstra algorithm with complexity $O(n \cdot \min\{\log|E|, |V|\})$] or when the graph is acyclic (based on topological search and with linear time complexity). All existing algorithms for the shortest path problem are based on dynamic programming. The Bellman–Ford algorithm works as follows.

Let $l(i, k)$ be the length of edge (i, j) if directed edge (i, j) exists and ∞ otherwise. Let $s(j)$ denote the length of the shortest path from the source s to node j. Assume that the source has label 1 and that the target has label $n = |V|$. We have that $s(1) = 0$. We also know that in a shortest path to any node j there must exist a node k, $k \neq j$, such that $s(j) = s(k) + l(k, j)$. Therefore,

$$s(j) = \min_{k \neq j}\{s(k) + l(k, j)\}, j \geq 2$$

Bellman–Ford's algorithm, which eventually computes all $s(j)$, $1 \leq j \leq n$, calculates optimally the quantity

$s(j)^{m+1}$ defined as the length of the shortest path to node j subject to the condition that the path does not contain more than $m + 1$ edges, $0 \leq m \leq |V| - 2$. To be able to calculate quantity $s(j)^{m+1}$ for some value $m + 1$, the $s(j)^m$ values for all nodes j have to be calculated.

Given the initialization $s(1)^1 = 0, s(j)^1 = l(1, j),\ j \neq 1$, the computation of $s(j)^{m+1}$ for any values of j and m can be recursively computed using the formula

$$s(j)^{m+1} = \min\{s(j)^m, \min\{s(k)^m + l(k, j)\}$$

The computation terminates when $m = |V| - 1$, because no shortest path has more than $|V| - 1$ edges.

Flows. All flow problem formulations consider a directed or undirected graph $G = (V, E)$, a designated source s, a designated target t, and a nonnegative integer capacity $c(i, j)$ on every edge (i, j). Such a graph is sometimes referred to as a *network*. We assume that the graph is directed. A *flow* from s to t is an assignment F of numbers $f(i, j)$ on the edges, called the amount of flow through edge (i, j), subject to the following conditions:

$$0 \leq f(i, j) \leq c(i, j) \qquad (1)$$

Every node i, except s and t, must satisfy the *conservation of flow*. That is,

$$\sum_j f(j, i) - \sum_j f(i, j) = 0 \qquad (2)$$

Nodes s and t satisfy, respectively,

$$\begin{aligned} \sum_j f(j, i) - \sum_j f(i, j) &= -v, \text{ if } i = s; \\ \sum_j f(j, i) - \sum_j f(i, j) &= v, \text{ if } i = t \end{aligned} \qquad (3)$$

where $v = \sum_j f(s, j) = \sum_j f(j, t)$ is called the value of the flow.

A flow F that satisfies Equations (1–3) is called *feasible*. In the Max Flow problem, the goal is to find a feasible flow F for which v is maximized. Such a flow is called a *maximum flow*. There is a problem variation, called the Minimum Flow problem, where Equation (1) is substituted by $f(i, j) \geq c(i, j)$ and the goal is to find a flow F for which v is minimized. The minimum flow problem can be solved by modifying algorithms that compute the maximum flow in a graph.

Finally, another flow problem formulation is the Minimum Cost Flow problem. Here each edge has, in addition to its capacity $c(i, j)$, a *cost* $p(i, j)$. If $f(i, j)$ is the flow through the edge, then the cost of the flow through the edge is $p(i, j) \cdot f(i, j)$ and the overall cost C for a flow F of a value v is $\sum_{i,j} p(i, j) \cdot f(i, j)$. The problem is to find a *minimum cost flow* F for a given value v.

Many problems in VLSI CAD, computer networking, scheduling, and so on can be modeled or reduced to one of these three flow problem variations. All three problems can be solved in polynomial time using as subroutines shortest path calculations. We describe below for illustration purposes an $O(|V|^3)$ algorithm for the maximum flow problem. However, faster algorithms exist in the literature. We first give some definitions and theorems.

Let P be an *undirected* path from s to t; i.e., the direction of the edges is ignored. An edge $(i, j) \in P$ is said to be a *forward* edge if it is directed from s to t and *backward* otherwise. P is said to be an *augmenting path* with respect to a given flow F if $f(i, j) < c(i, j)$ for each forward edge and $f(i, j) > 0$ for each backward edge in P.

Observe that if the flow in each forward edge of the augmenting path is increased by one unit and the flow in each backward edge is decreased by one unit, the flow is feasible and its value has been increased by one unit. We will show that a flow has maximum value if and only if there is no augmenting path in the graph. Then the maximum flow algorithm is simply a series of calls to a subroutine that finds an augmenting path and increments the value of the flow as described earlier.

Let $S \subset V$ be a subset of the nodes. The pair (S, T) is called a *cutset* if $T = V - S$. If $s \in S$ and $t \in T$, the (S, T) is called an (s, t) *cutset*. The *capacity of the cutset* (S, T) is defined as $c(S, T) = \sum_{i \in S} \sum_{j \in T} c(i, j)$, i.e., the sum of the capacities of all edges from S to T. We note that many problems in networking, operations research, scheduling, and VLSI CAD (physical design, synthesis, and testing) are formulated as minimum capacity (s, t) cutset problems. We show below that the minimum capacity (s, t) problem can be solved with a maximum flow algorithm.

Lemma 1. *The value of any (s, t) flow cannot exceed the capacity of any (s, t) cutset.*

Proof. Let F be an (s, t) flow with value v. Let (S, T) be an (s, t) cutset. From Equation 3 the value of the flow v is also $v = \sum_{i \in S}(\sum_j f(i, j) - \sum_j f(j, i)) = \sum_{i \in S} \sum_{j \in S}(f(i, j) - f(j, i)) + \sum_{i \in S} \sum_{j \in T}(f(i, j) - f(j, i)) = \sum_{i \in S} \sum_{j \in T}(f(i, j) - f(j, i))$, because $\sum_{i \in S} \sum_{j \in S}(f(i, j) - f(j, i))$ is 0. But $f(i, j) \leq c(i, j)$ and $f(j, i) \geq 0$. Therefore, $v \leq \sum_{i \in S} \sum_{j \in S} c(i, j) = c(S, T)$.□

Theorem 2. *A flow F has maximum value v if and only if there is no augmenting path from s to t.*

Proof. If there is an augmenting path, then we can modify the flow to get a larger value flow. This contradicts the assumption that the original flow has a maximum value.

Suppose on the other hand that F is a flow such that there is no augmenting path from s to t. We want to show that F has the maximum flow value. Let S be the set of all nodes j (including s) for which there is an augmenting path from s to j. By the assumption that there is an augmenting path from s to t, we must have that $t \notin S$. Let $T = V - S$ (recall that $t \in T$). From the definition of S and T, it follows that $f(i, j) = c(i, j)$ and $f(j, i) = 0,\ \forall i \in S, j \in T$.

Now $v = \sum_{i \in S}(\sum_j f(i, j) - \sum_j f(j, i)) = \sum_{i \in S} \sum_{j \in S} (f(i, j) - f(j, i)) + \sum_{i \in S} \sum_{j \in T}(f(i, j) - f(j, i)) = \sum_{i \in S} \sum_{j \in T} (f(i, j) - f(j, i)) = \sum_{i \in S} \sum_{j \in S} c(i, j)$, because $c(i, j) = f(i, j)$ and $f(j, i) = 0,\ \forall i, j$. By Lemma 1, the flow has the maximum value.□

Next, we state two theorems whose proof is straightforward.

Theorem 3. *If all capacities are integers, then a maximum flow F exists, where all f(i,j) are integers.*

Theorem 4. *The maximum value of an (s, t) flow is equal to the minimum capacity of an (s, t) cutset.*

Finding an augmenting path in a graph can be done by a systematic graph traversal in linear time. Thus, a straightforward implementation of the maximum flow algorithm repeatedly finds an augmenting path and increments the amount of the (s, t) flow. This is a pseudopolynomial-time algorithm (see the next section), whose worst-case time complexity is $O(v \cdot |E|)$. In many cases, such an algorithm may turn out to be very efficient. For example, when all capacities are uniform, then the overall complexity becomes $O(|E|^2)$.

In general, the approach needs to be modified using the Edmonds–Karp modification (6), so that each flow augmentation is made along an augmenting path with a minimum number of edges. With this modification, it has been proven that a maximum flow is obtained after no more than $|E| \cdot |V|/2$ augmentations, and the approach becomes fully polynomial. Faster algorithms for maximum flow computation rely on capacity scaling techniques and are described in Refs. 8 and 15, among others.

Graph Coloring. Given a graph $G(V, E)$, a *proper k-coloring* of G is a function f from V to a set of integers from 1 to k (referred to as *colors*) such that $f(u) \neq f(v)$, if $(u, v) \in E$. The minimum k for which a proper k-coloring exists for graph G is known as the *chromatic number* of G. Finding the chromatic number of a general graph and producing the corresponding coloring is an *NP*-hard problem. The decision problem of graph k-colorability is *NP*-complete in the general case for fixed $k \geq 3$. For $k = 2$, it is polynomially solvable (bipartite matching). For planar graphs and for $k = 4$, it is also polynomially solvable.

The graph coloring problem finds numerous applications in computer networks and communications, architectural level synthesis, and other areas. As an example, the Federal Communications Commission (FCC) monitors radio stations (modeled as nodes of a graph) to make sure that their signals do not interfere with each other. They prevent interference by assigning appropriate frequencies (each frequency is a color) to each station. It is desirable to use the smallest possible number of frequencies. As another example, several resource binding algorithms for data path synthesis at the architectural level are based on graph coloring formulations (9).

There is also the version of *edge coloring:* A *proper k-edge-coloring* of G is a function f from E to a set of integers from 1 to k such that $f(e_1) \neq f(e_2)$, if edges e_1 and e_2 share a node. In this case, each color class corresponds to a *matching* in G, that is, a set of pairwise disjoint edges of G. The minimum k for which a proper k-edge-coloring exists for graph G is known as the *edge-chromatic number* of G. It is known (Vizing's theorem) that for any graph with maximum node degree d, there is a $(d + 1)$-edge coloring. Finding such a coloring can be done in $O(n^2)$ time. Notice that the edge-chromatic number of a graph with maximum node degree d is at least d. It is *NP*-complete to determine whether the edge-chromatic number is d, but given Vizing's algorithm, the problem is considered in practice solved.

Graph Matching. A *matching* in a graph is a set $M \subset E$ such that no two edges in M are incident to the same node.

The Maximum Cardinality Matching problem is the most common version of the matching problem. Here the goal is to obtain a matching so that the size (cardinality) of M is maximized.

In the Maximum Weighted Matching version, each edge $(i, j) \in V$ has a nonnegative integer weight, and the goal is to find a matching M so that $\sum_{e \in M} w(e)$ is maximized.

In the Min-Max Matching problem, the goal is to find a maximum cardinality matching M where the minimum weight on an edge in M is maximized. The Max-Min Matching problem is defined in an analogous manner.

All above matching variations are solvable in polynomial time and find important applications. For example, a variation of the min-cut graph partitioning problem, which is central in physical design automation for VLSI, asks for partitioning the nodes of a graph into sets of size at most two so that the sum of the weights on all edges with endpoints in different sets is minimized. It is easy to see that this partitioning problem reduces to the maximum weighted matching problem.

Matching problems often occur on bipartite $G(V_1 \cup V_2, E)$ graphs. The maximum cardinality matching problem amounts to the *maximum assignment* of elements in V_1 ("workers") on to the elements of V_2 ("tasks") so that no "worker" in V_1 is assigned more than one "task." This finds various applications in operations research.

The maximum cardinality matching problem on a bipartite graph $G(V_1 \cup V_2, E)$ can be solved by a maximum flow formulation. Simply, each node $v \in V_1$ is connected to a new node s by an edge (s, v) and each node $u \in V_2$ to a new node t by an edge (u, t). In the resulting graph, every edge is assigned unit capacity. The maximum flow value v corresponds to the cardinality of the maximum matching in the original bipartite graph G.

Although the matching problem variations on bipartite graphs are amenable to easily described polynomial-time algorithms, such as the one given above, the existing polynomial-time algorithms for matchings on general graphs are more complex (6).

Approximation and Pseudopolynomial Algorithms

Approximation and pseudopolynomial-time algorithms concern mainly the solution of problems that are proven to be *NP*-hard, although they can sometimes be used on problems that are solvable in polynomial time, but for which the corresponding polynomial-time algorithm involves large constants.

An α-approximation algorithm A for an optimization problem R is a polynomial-time algorithm such that, for any instance I of R, $\frac{|S_A(I) - S_{\mathrm{OPT}}(I)|}{S_{\mathrm{OPT}}(I)} \leq \alpha + c$, where $S_{\mathrm{OPT}}(I)$ is the cost of the optimal solution for instance I, $S_A(I)$ is the cost of the solution found by algorithm A, and c is a constant.

As an example, consider a special but practical version of the Traveling Salesman problem that obeys the triangular inequality for all city distances. Given a weighted graph $G(V, E)$ of the cities, the algorithm first finds a minimum spanning tree T of G (that is, a spanning tree that has minimum sum of edge weights). Then it finds a minimum weight matching M among all nodes that have odd degree in T. Lastly, it forms the subgraph $G'(V, E')$, where E' is the set of all edges in T and M and finds a path that starts from and terminates to the same node and passes through every edge exactly once (such a path is known as "Eulerian tour"). Every step in this algorithm takes polynomial time. It has been shown that $\frac{|S_A(I)-S_{\mathrm{OPT}}(I)|}{S_{\mathrm{OPT}}(I)} \leq \frac{1}{2}$.

Unfortunately, obtaining a polynomial-time approximation algorithm for an *NP*-hard optimization problem can be very difficult. In fact, it has been shown that this may be impossible for some cases. For example, it has been shown that unless $NP = P$, there is no α-approximation algorithm for the general Traveling Salesman problem for any $\alpha > 0$.

A pseudopolynomial-time algorithm for a problem R is an algorithm with time complexity $O(p(n, m))$, where $p()$ is a polynomial of two variables, n is the size of the instance, and m is the magnitude of the largest number occuring in the instance. Only problems involving numbers that are not bounded by a polynomial on the size of the instance are applicable for solution by a pseudopolynomial-time algorithm. In principle, a pseudopolynomial-time algorithm is exponential given that the magnitude of a number is exponential to the size of its logarithmic encoding in the problem instance, but in practice, such an algorithm may be useful in cases where the numbers involved are not large.

NP-complete problems for which a pseudopolynomial-time algorithm exists are referred to as *weakly* NP-*complete*, whereas *NP*-complete problems for which no pseudopolynomial-time algorithm exists (unless $NP = P$) are referred to as *strongly* NP-*complete*. As an example, the Network Inhibition problem, where the goal is to find the most cost-effective way to reduce the ability of a network to transport a commodity, has been shown to be strongly NP-complete for general graphs and weakly *NP*-complete for series-parallel graphs (16).

Probabilistic and Randomized Algorithms

Probabilistic algorithms are a class of algorithms that do not depend exclusively on their input to carry out the computation. Instead, at one or more points in the course of the algorithm where a choice has to be made, they use a pseudorandom number generator to select "randomly" one out of a finite set of alternatives for arriving at a solution. Probabilistic algorithms are fully programmable (i.e., they are not nondeterministic), but in contrast with the deterministic algorithms, they may give different results for the same input instance if the initial state of the pseudorandom number generator differs each time.

Probabilistic algorithms try to reduce the computation time by allowing a small probability of error in the computed answer ("Monte Carlo" type) or by making sure that the running time to compute the correct answer is small for the large majority of input instances ("Las Vegas" type). That is, algorithms of the Monte Carlo type always run fast, but the answer they compute has a small probability of being erroneous, whereas algorithms of the Las Vegas type always compute the correct answer but they occasionally may take a long time to terminate. If there is an imposed time limit, Las Vegas-type algorithms can alternatively be viewed as always producing either a correct answer or no answer at all within that time limit.

An example of a probabilistic algorithm on graphs is the computation of a minimum spanning in a weighted undirected graph by the algorithm of (17). This algorithm computes a minimum spanning tree in $O(m)$ time, where m is the number of edges, with probability $1 - e^{-\Omega(m)}$.

Randomization is also very useful in the design of heuristic algorithms. A typical example of a randomized heuristic algorithm is the simulated annealing method, which is very effective for many graph theoretic formulations in VLSI design automation (10). In the following we outline the use of simulated annealing in the graph balanced bipartitioning problem, where the goal is to partition the nodes of a graph in two equal-size sets so that the number of edges that connect nodes in two different sets is minimized. This problem formulation is central in the process of obtaining a compact layout for the integrated circuit whose components (gates or modules) are represented by the graph nodes and its interconnects by the edges.

The optimization in balanced bipartitioning with a very large number of nodes is analogous to the physical process of annealing where a material is melted and subsequently cooled down, under a specific schedule, so that it will crystallize. The cooling must be slow so that thermal equilibrium is reached at each temperature so that the atoms are aranged in a pattern that resembles the global energy minimum of the perfect crystal.

While simulating the process, the energy within the material corresponds to a partitioning score. The process starts with a random initial partitioning. An alternative partitioning is obtained by exchanging nodes that are in opposite sets. If the change in the score δ is negative, then the exchange is accepted because this represents reduction in the energy. Otherwise, the exchange is accepted with probability $e^{-\delta/t}$; i.e., the probability of acceptance decreases with the increase in temperature t. This method allows the simulated annealing algorithm to climb out of local optimums in the search for a global optimum.

The quality of the solution depends on the initial value of the temperature value and the cooling schedule. Such parameters are determined experimentally. The quality of the obtained solutions is very good, altough the method (being a heuristic) cannot guarantee optimality or even a provably good solution.

INFORMATION ALGEBRA

INTRODUCTION

Many apparently very different problems from computer science can be solved by fast generic algorithms because they develop from instances of a very general abstract structure called *information algebra*. To illustrate in a simple way these generic problems and the nature of the fast algorithms derived from them, we consider the following example:

Let $f(X_1, X_2)$, $g(X_2, X_3)$, and $h(X_2, X_4, X_5)$ be given real-valued functions, where $X_1, \ldots, X_5$ are variables that take values from a finite set X with n elements. Such discrete functions can be represented in tabular form. Suppose we are given the task to compute the values of $\alpha(X_1, X_2)$ and $\beta(X_2, X_3)$, which are defined as follows:

$$\begin{aligned}\alpha(X_1,X_2) &= \sum_{X_3,X_4,X_5} f(X_1,X_2)g(X_2,X_3)h(X_2,X_4,X_5)\\ \beta(X_2,X_3) &= \sum_{X_1,X_4,X_5} f(X_1,X_2)g(X_2,X_3)h(X_2,X_4,X_5)\end{aligned} \tag{1}$$

Here, the summation over a list of variables adds up to the summation over all possible assignments to those variables, and the task consists in the computation of the values of α and β for all possible assignments to X_1, X_2 and X_2, X_3, respectively. If we compute the sums directly as they are written here, then both sums require the multiplication of $O(n^5)$ values, which results in a table with the same number of elements, and then $O(n^5)$ additions. This method can be done much more efficiently. So, the first sum can be computed as

$$\alpha(X_1,X_2) = f(X_1,X_2) \left(\left(\sum_{X_3} g(X_2, X_3)\right)\left(\sum_{X_4,X_5} h(X_2, X_4, X_5)\right)\right) \tag{2}$$

Here, we need $O(n^2)$ multiplications and the tables have never more than n^2 elements and only $O(n^3)$ additions. This result is different with respect to the first, direct computation. Of course, we need to verify that Equation (2) yields in fact the same result as Equation (1). This method involves essentially the distributive law of arithmetic. Similarly, the second sum can be computed as

$$\beta(X_2, X_3) = g(X_2, X_3) \sum_{X_1} \left(f(X_1, X_2)\left(\sum_{X_4,X_5} h(X_2, X_4, X_5)\right)\right) \tag{3}$$

But it needs again only $O(n^2)$ multiplications; the resulting tables have never more that n^2 elements, and only $O(n^3)$ additions are needed. Once more, this result represents an important gain. The gain obtained by clever use of the distributive law becomes even more important if we are charged with computations that contain hundreds or thousands of variables.

Distributive laws hold in more general mathematical structures than simple arithmetic, and consequently, fast algorithms based on this law can be developed in more general structures. In the next section, we propose an abstract algebraic framework that proves to be sufficient to enable the generic fast algorithms we have in mind. These algorithms are described in a generic way in the section on Local Computation. In the section on Semiring Valuations we present an important class of models of this axiomatic frame, which contains also the example discussed above. These abstract generic structures cover a great many problems of computer science, which include basic problems from relational databases, constraint systems, propositional and predicate logic, as well as many other logic systems. More problems are located in the field of numerical analysis, which includes systems of linear equations and linear inequalities, decoding algorithms as for instance Viterbi's algorithm, fast Fourier transforms, and belief propagation algorithms from artificial intelligence. Not to be forgotten are methods based on probability networks, possibility theory and fuzzy sets, belief functions from Dempster-Shafer theory of evidence, and many more.

AXIOMATICS

We abstract the illustrating example in the previous section with the interpretation as a framework for the processing of information. In all the examples of computational problems referred to at the end of the previous section, in some way or another information is processed. Now, information pertains to questions, for instance to the possible values of certain variables $X_1, X, \ldots X_m$ out of a set r of variables. Let Φ be a set of elements whose generic elements are denoted by small Greek letters like $\phi, \psi, \ldots$. Each element of Φ pertains to some subset $s \subseteq r$ of variables. This subset is determined by the *labeling* function $d : \Phi \to D$, where D is the powerset of r. The elements of Φ can be thought of as pieces of information ϕ that pertains to sets of variables $d(\phi)$. We call $d(\phi)$ also the domain of ϕ. For instance, the functions f, g, and h in the example of the previous section could be recognized as such pieces of informations that refer to the sets of variables $\{X_1, X_2\}$, $\{X_2, X_3\}$, and $\{X_2, X_4, X_5\}$, respectively.

We consider now a two-sorted algebra (Φ, D) with three operations that are defined as follows:

1. *Labeling*: $\Phi \to D$, $\phi \to d(\phi)$,
2. *Combination*: $\Phi \times \Phi \to \Phi$, $(\phi, \psi) \to \phi \otimes \psi$,
3. *Projection*: $\Phi \times D \to \Phi$, $(\phi, s) \to \phi^{\downarrow s}$, defined $s \subseteq d(\phi)$.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Combination can be thought of as the operation of aggregation of information. In the example of the first section for instance, the combination is defined as multiplication:

$$(f\otimes g)(X_1, X_2, X_3) = f(X_1,X_2)g(X_2, X_3).$$

Projection represents extraction of information regarding a specified set of variables. In the introductory example, projection is defined as summation:

$$f^{\downarrow\{X_1\}}(X_1) = \sum_{X_2} f(X_1,X_2)$$

Now these operations must satisfy certain axioms:

1. *Semigroup*: The operation of combination is commutative and associative, that is,

$$\phi\otimes\psi = \psi\otimes\phi,\ (\phi\otimes\psi)\otimes\eta = \phi\otimes(\psi\otimes\eta).$$

2. *Labeling*: $d(\phi\otimes\psi) = d(\phi)\cup d(\psi)$.
3. *Projection*: $d(\phi^{\downarrow s}) = s$.
4. *Transitivity of projection*: If $t\subseteq s\subseteq d(\phi)$, then

$$(\phi^{\downarrow s})^{\downarrow t} = \phi^{\downarrow t}.$$

5. *Distributivity of combination over projection*: If $d(\phi) = s$, $d(\psi) = t$ and $u\in D$ such that $s\subseteq u\subseteq s\cup t$, then

$$(\phi\otimes\psi)^{\downarrow u} = \phi\otimes\psi^{\downarrow u\cap t}.$$

The main axioms are (4) and especially (5). Axiom (4) states that projection can be done in steps. Axiom (5) is the generalized distributive law that allows fast algorithms (see the section Local Computation). It suggests that projection can, in certain important cases, be done before combination. In terms of the example of the first section, it reads as follows:

$$\sum_{X_3} f(X_1,X_2)g(X_2,X_3) = f(X_1,X_2)\sum_{X_3} g(X_2,X_3)$$

According to axiom (1), Φ is a commutative semigroup under combination. Axiom (2) says that domains of aggregated pieces of information are joined. Finally, axiom (3) assures that the domain of a projected information is the domain on which it is projected. This algebraic structure captures already essential elements of what is expected of a concept of information regarding aggregation (combination) and focusing (projection). Because one important element is still missing, which we would expect for a concept of information (see the section on idempotency), we call a two-sorted algebra (Φ, D) satisfying the axioms (1)–(5) a *valuation algebra* and not yet a proper information algebra. However, valuation algebras represent the framework that defines the generic fast algorithms we have in mind and that will be discussed in the section entitled "Local computation".

Some valuation algebras have additional properties. Some models have *neutral elements* e_s on any domain s, such that $e_s\otimes\phi = \phi$ for all elements with $d(\phi) = s$. These elements represent *vacuous information* with respect to the variables in s. Sometimes, *null elements* z_s are on every domain $s\in D$, such that $z_s\otimes\phi = z_s$ for all elements with $d(\phi) = s$. These elements represent falsity or contradiction; elements such that $\phi\otimes\psi = z_s$ must be considered to represent contradictory information.

In the next section, an important class of valuation algebras will be presented. This class contains also many important examples. More examples are given in the last section.

The general inference problem associated with a valuation algebra (Φ, D) can be stated as follows: We are given a finite set of pieces of information $\phi_1,\dots\phi_m\in\Phi$ with domains $s_i = d(\phi_i)$ for $i = 1,\cdots,m$ and one or several domains $x_1,\dots,x_k\in D$. Then, the following projections have to be computed:

$$(\phi_1\otimes\cdots\otimes\phi_m)^{\downarrow x_j} \text{ for } j = 1,\dots,k \tag{4}$$

This formula is called the *projection problem*. The domains s_i are called data domains and the x_j goal domains. The tasks of computing $\alpha(X_1,X_2)$ and $\beta(X_2,X_3)$ in the first section are examples of projection problems as it will be explained in the next section. Just as in these examples, the naive computation based on the expression given in Equation (4) is not efficient and in many cases is intractable. But again, the distributivity axiom together with the transitivity axiom allow for efficient algorithms to solve the projection problem. This method will be explained in the section entitled "Local compution."

We remark that we can adjoin an element e with domain *d(e)* $=\emptyset$ to a valuation algebra (Φ, D) and define $\phi\otimes e = e\otimes\phi = \phi$ for all $\phi\in\Phi$, as well as $e\otimes e = e$ and $e^{\downarrow\emptyset} = e$. Clearly, the augmented algebra $(\Phi\cup\{e\}, D)$ is still a valuation algebra. The element e is called the *identity element*.

SEMIRING VALUATIONS

Often, configurations of possible values of a set s of variables are evaluated by values from a *commutative semiring*. A commutative semiring is a set A with two binary operations $+$ and $\times$, where both operations are commutative and associative and where $\times$ distributes over $+$ so that for *a,b,c* $\in A$,

$$a\times(b+c) = a\times b + a\times c$$

Often, we simply speak of a semiring, but we always mean a commutative one. With respect to the introduction, in which more efficient computations are found by use of the distributive law, we may say that a semiring constitutes the simplest mathematical structure where the distributive law still holds. Below, several important examples of semirings are given, and we also point out that a *ring* is a semiring with additive inverses, and a *field* is a ring with multiplicative inverses.

To formulate the idea of a semiring valuation more precisely, assume as before that the variables $X_1, \ldots, X_m$ take values in a finite set X. A mapping $\mathrm{x} : s \to X$ is called a tuple on the variable set s. The set of all s-tuples will be denoted by X^s. If s is the empty set, then we define $\diamond$ to be the only s-tuple. If x is a tuple on s and t a subset of s, then $\mathrm{x}^{\downarrow t}$ denotes the tuple on t obtained from the s-tuple x by restriction to the indices in t. If we want to emphasize the decomposition of a s-tuple x into disjoint components that belong to the subsets t and $s \setminus t$ of s, we write $\mathrm{x} = (\mathrm{x}^{\downarrow t}, \mathrm{x}^{\downarrow s\setminus t})$. A *semiring valuation* on s is then a mapping $\phi : X^s \to A$, where A is a semiring. Let Φ_s denote the set of all semiring valuations on s and

$$\Phi_A = \bigcup_{s \subseteq r} \Phi_s$$

We define now a two-sorted algebra (Φ_A, D), where D is as before the powerset of r. In fact, we define the three operations required for a valuation algebra as follows:

1. *Labeling*: $d(\phi) = s$, if $\phi \in \Phi_s$.
2. *Combination*: The semiring valuation $\phi \otimes \psi$, where ϕ and ψ are semiring valuations on s and t, respectively, is defined for all $s \cup t$-tuple x by
$$(\phi \otimes \psi)(\mathrm{x}) = \phi(\mathrm{x}^{\downarrow s}) \times \psi(\mathrm{x}^{\downarrow t})$$
3. *Projection*: The semiring valuation $\phi^{\downarrow t}$, were ϕ is a semiring valuation on s and $t \subseteq s$, is defined for any t-tuple x by
$$\phi^{\downarrow t}(\mathrm{x}) = \sum_{y \in X^{s\setminus t}} \phi(\mathrm{x}, \mathrm{y})$$

The semiring properties are then sufficient to guarantee that the axioms of a valuation algebra are satisfied. Thus, for any semiring A, the algebra (Φ_A, D) is a valuation algebra. If ϕ and ψ are semiring valuations on s and t respectively, then the combination law of the semiring valuation algebra takes the following form; if x is an s-tuple and $s \subseteq u \subseteq s \cup t$,

$$\sum_{\mathrm{z} \in X^{t\setminus u}} \phi(\mathrm{x}) \times \psi(\mathrm{x}^{\downarrow t \cap u}, \mathrm{z}) = \phi(\mathrm{x}) \times \sum_{\mathrm{z} \in X^{t\setminus u}} \psi(\mathrm{x}^{\downarrow t \cap u}, \mathrm{z})$$

Table 1. Semiring example catalog

A	+	×	
$\mathbb{R}_{\geq 0}$	+	·	Arithmetic semiring
$\mathbb{R} \cup \{\pm\infty\}$	max	min	Bottleneck semiring
$\mathbb{B} = \{0, 1\}$	$\vee$	$\wedge$	Boolean semiring
$\mathbb{N} \cup \{0, \infty\}$	min	+	Tropical semiring
$\mathbb{R} \cup \{-\infty\}$	max	+	Tropical semiring
[0, 1]	max	t-norm	T-norm semiring

This method follows directly from the distributive law in semirings. If ϕ is a semiring valuation and $t \subseteq s \subseteq d(\phi) = u$, then the transitivity of projection in the semiring valuation algebra becomes

$$\sum_{\mathrm{z} \in X^{s\setminus t}} \left(\sum_{\mathrm{y} \in X^{u\setminus s}} \phi(\mathrm{x}, \mathrm{y}, \mathrm{z}) \right) = \sum_{\mathrm{y} \in X^{u\setminus s}, \, \mathrm{z} \in X^{s\setminus t}} \phi(\mathrm{x}, \mathrm{y}, \mathrm{z})$$

This result is a consequence of the associativity and commutativity of addition.

In Table 1, a couple of semiring examples are given. The example of the first section is based on the arithmetic semiring. This example yields the valuation algebra underlying probability networks, in particular Bayesian networks, and shows that the problem of computing $\alpha(X_1, X_2)$ and $\beta(X_2, X_3)$ in the first section are indeed instances of the general projection problem in valuation algebras. The Boolean semiring induces the valuation algebra for classic constraint systems and the tropical semirings model optimization problems. Moreover, taking maximization for addition and an arbitrary *t-norm* for multiplication leads always to a semiring. A t-norm (triangular norm) is a binary operation on the unit interval that is associative, commutative, and nondecreasing in both arguments. The corresponding t-norm semirings induce valuation algebras used in maximum likelihood estimation in general, and in particular in decoding theory. But they also cover possibility theory and fuzzy set theory.

LOCAL COMPUTATION

In this section, an efficient algorithm for the projection problem [Equation (4)] in a valuation algebra is described. It uses the concept of a join (or junction) tree. A labeled tree $T = (V, E, \lambda)$ with nodes V, edges $E \subseteq V \times V$, and with labels $\lambda : V \to D$ is called a *join tree*, if

$$\lambda(u) \cap \lambda(v) \subseteq \lambda(w)$$

for every node w on the path between nodes u and v in the tree T. A join tree is *covering* a projection problem [Equation (4)], if for every data domain s_i, there is a node $v \in V$ such that $s_i \subseteq \lambda(v)$, and similarly for every goal domain x_j, there is also a node $u \in V$ such that $x_j \subseteq \lambda(u)$. In this case, we may assign any data domain s_i to a covering node, that is, we can define a mapping $a : \{1, \ldots, m\} \to V$ such that $s_i \subseteq \lambda(a(i))$. If several nodes cover s_i, then we select arbitrarily one of them. Similarly, we can define a mapping $b : \{1, \ldots, n\} \to V$, such that $x_j \subseteq \lambda(b(j))$. Then define for any node $v \in V$

$$\psi(v) = \bigotimes_{i:a(i)=v} \phi_i$$

If no index i exists such that $a(i) = v$, then $\psi(v) = e$, the adjoined identity element (introduced in the second section). Then it holds that

$$\phi_1 \otimes \cdots \otimes \phi_m = \underset{v \in V}{\otimes} \psi(v)$$

Now, an efficient algorithm for solving the projection problem for a selected and fixed goal domain x_j can be formulated: Fix the node $b(j)$ and orient all edges of the covering join tree toward it. Then, every node v, except $b(j)$, has a unique neighbor (child) $ch(v)$ toward $b(j)$. Imagine a storage location associated with each node v and describe its content by $\sigma(v)$. Initially set $\sigma(v) := \psi(v)$ for all $v \in V$.

The algorithm can now be described by the following two rules:

1. Each node v sends a message $\mu(v) := \sigma(v)^{\downarrow d(\psi(v)) \cap \lambda(ch(v))}$ to its neighbor $ch(v)$, when it has received all messages from its parents. Leaf nodes can send messages right away.
2. The receiving node $ch(v)$ updates its storage by $\sigma(ch(v)) := \sigma(ch(v)) \otimes \mu(v)$.

When the root node $b(j)$ has received all messages, the algorithm stops. The solution of the projection problem for the goal domain x_j is then obtained as $\sigma(b(j))^{\downarrow x_j}$. The efficiency of this algorithm stems from the fact that never a combination or projection operation takes place on a domain larger than the domains $\lambda(v)$ of the covering join tree. These domains are usually much smaller than the combined domain $s_1 \cup \ldots \cup s_m$ of the combination $\phi_1 \otimes \cdots \otimes \phi_m$, which occurrs in the naive solution of the projection problem.

As an example, reconsider Equations (2) and (3) for an efficient computation of $\alpha(X_1, X_2)$ and $\beta(X_2, X_3)$, respectively. It turns out that these computations correspond to possible runs of the algorithm above. For an illustration we refer to Fig. 1, which the messages sent among the nodes of the covering join trees are depicted as arrows.

It may be noted that this algorithm allows for parallel and distributed computing. The projection problem for other goal domains x_i different from x_j are obtained in the same way by selecting $b(i)$ as root node. This method involves reorienting certain edges with respect to the first computation. But edges can remain unchanged, as shown in Fig. 1. This result means that the messages on these edges can be reused. In summary, by caching the computations, the solution of several projection problems can be optimized further considerably. Several architectures are known for this (1, 2). Some of them exploit properties of the underlying valuation algebra, such as the possibility of division.

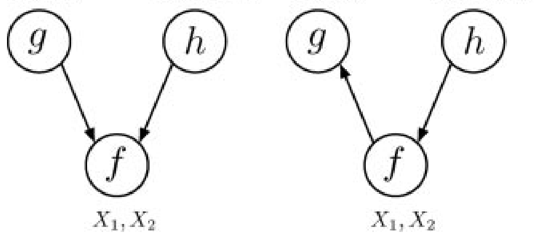

Figure 1. Graphical representation of the efficient computation of $\alpha(X_1, X_2)$ (on the left) and $\beta(X_2, X_3)$ (on the right) as given in Equations (2) and (3), respectively.

IDEMPOTENCY

An information in the usual sense of the word does not change if it is repeated. That is, an idempotency law such as $\phi \otimes \phi = \phi$ holds. More precisely, a piece of information combined with a part of itself should give nothing new. This information can be formulated in an additional axiom:

6. *Idempotency of combination*: If $d(\phi) = s$ and $t \subseteq s$, then

$$\phi \otimes \phi^{\downarrow t} = \phi$$

A valuation algebra with this additional axiom is called an *information algebra*. It has many interesting properties. First, especially efficient architectures of local computation exist for information algebras (1, 2). Second, in information algebras, an *information order* can be introduced by defining $\phi \leq \psi$, reading ϕ is less informative than ψ, if $\phi \otimes \psi = \psi$. This method puts information algebra in relation to domain theory, and the related theory of information systems (3, 4).

Relational algebra from relational database theory is a prototype of an information algebra. Furthermore, many logic systems induce information algebras, which includes classic propositional and predicate logic. Systems of linear equalities or inequalities generate associated information algebras, as well as certain semiring valuation algebras, for instance the constraints systems that arise from to the Boolean semiring, and many more.

LINEAR AND NONLINEAR PROGRAMMING

INTRODUCTION

An *optimization problem* is a mathematical problem in which data are used to find the values of n variables so as to minimize or maximize an overall objective while satisfying a finite number of imposed restrictions on the values of those variables. For example:

Linear Program (LP1)		Nonlinear Program (NLP1)	
maximize $x_1 + x_2$		minimize $-3x_1 - 2x_2$	
subject to $x_1 + 3x_2 \leq 6$	(a)	subject to $x_1^2 + x_2^2 \leq 9$	(a)
$2x_1 + x_2 \leq 4$	(b)	$x_1^2 - 6x_1 + x_2^2 \leq 6$	(b)
$x_1 \geq 0$	(c)	x_1 unrestricted	
$x_2 \geq 0$	(d)	$x_2 \geq 0$	(c)

The expression being maximized or minimized is called the *objective function*, whereas the remaining restrictions that the variables must satisfy are called the *constraints*. The problem on the left is a *linear program* (*LP*) because the objective function and all constraints are *linear* and all variables are *continuous*; that is, the variables can assume any values, including fractions, within a given (possibly infinite) interval. In contrast, the problem on the right is a *nonlinear program* (*NLP*) because the variables are continuous but the objective function or at least one constraint is not linear. Applications of such problems in computer science, mathematics, business, economics, statistics, engineering, operations research, and the sciences can be found in Ref. 1.

LINEAR PROGRAMMING

The geometry of LP1 is illustrated in Fig. 1(a). A *feasible solution* consists of values for the variables that simultaneously satisfy all constraints, and the *feasible region* is the set of all feasible solutions. The *status* of every LP is always one of the following three types:

- **Infeasible**, which means that the feasible region is empty; that is, there are no values for the variables that simultaneously satisfy all of the constraints.
- **Optimal**, which means that there is an **optimal solution**; that is, there is a feasible solution that also provides the best possible value of the objective function among all feasible solutions. (The optimal solution for LP1 shown in Fig. 1(a) is $x_1 = 1.2$ and $x_2 = 1.6$.)
- **Unbounded**, which means that there are feasible solutions that can make the objective function as large (if maximizing) or as small (if minimizing) as desired.

Note that the feasible region in Fig. 1(a) has a finite number of *extreme points* (the black dots), which are feasible points where at least n of the constraints hold with equality. Based on this observation, in 1951, George Dantzig (2) developed the *simplex algorithm (SA)* that, in a finite number of arithmetic operations, will determine the status of any LP and, if optimal, will produce an optimal solution. The SA is the most commonly used method for solving an LP and works geometrically as follows:

Step 0 (Initialization). Find an initial extreme point, say a vector $\mathbf{x} = (x_1, \ldots x_n)$, or determine none exists; in which case, stop, the LP is infeasible.

Step 1 (Test for Optimality). Perform a relatively simple computation to determine whether $\mathbf{x}$ is an optimal solution and, if so, stop.

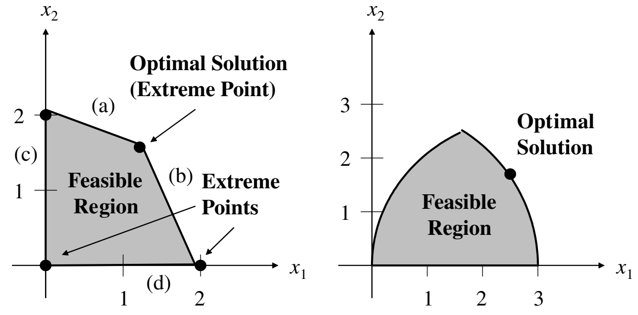
Step 2 (Move to a Better Point). If $\mathbf{x}$ is not optimal, use that fact to

- **(a) (Direction of Movement).** Find a direction in the form of a vector $\mathbf{d} = (d_1, \ldots d_n)$ that points from $\mathbf{x}$ along an *edge* of the feasible region so that the objective function value improves as you move in this direction.
- **(b) (Amount of Movement).** Determine a real number t that represents the maximum amount you can move from $\mathbf{x}$ in the direction $\mathbf{d}$ and stay feasible. If $t = \infty$, stop, the LP is unbounded.
- **(c) (Move).** Move from $\mathbf{x}$ to the new extreme point $\mathbf{x} + t\mathbf{d}$, and return to Step 1.

The translation of these steps to algebra constitutes the SA. Because the SA works with algebra, all inequality constraints are first converted to equality constraints. To do so, a nonnegative *slack variable* is added to (subtracted from) each $\leq$ ($\geq$) constraint. For given feasible values of the original variables, the value of the slack variables represents the difference between the left and the right sides of the inequality constraint. For example, the constraint $x_1 + 3x_2 \leq 6$ in LP1 is converted to $x_1 + 3x_2 + s_1 = 6$, and if $x_1 = 2$ and $x_2 = 0$, then the value of the slack variable is $s_1 = 4$, which is the difference between the left side of $x_1 + 3x_2$ and the right side of 6 in the original constraint. The algebraic analog of an extreme point is called a *basic feasible solution*.

Step 0 of the SA is referred to as *phase 1*, whereas Steps 1 and 2 are called *phase 2*. Phase 2 is finite because there are a finite number of extreme points and no such point visited by the SA is repeated because the objective function strictly improves at each iteration, provided that $t > 0$ in Step 2(b) (even in the *degenerate* case when $t = 0$, the algorithm can be made finite). Also, a finite procedure for phase 1 is to use the SA to solve a special *phase 1 LP* that involves only phase 2. In summary, the SA is finite.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.



(a) The Geometry of LP1 **(b) The Geometry of NLP1**

Figure 1. The geometry of LP1 and NLP1.

See Ref. 3 for improvements in the computational efficiency and numerical accuracy of the SA. Many commercial software packages use the SA, from Solver, an add-in to a Microsoft (Redmond, WA) Excel spreadsheet, to CPLEX (ILOG, Mountain View, CA) and LINDO (LINDO Systems, Inc., Chicago, IL), stand-alone professional codes for solving large real-world problems with many thousands of variables and constraints. These packages provide the optimal solution and other economic information used in *postoptimality and sensitivity analysis* to answer questions of the form, “What happens to the optimal solution and objective function value if some of the data change?” Such questions are asked because the data are often estimated rather than known precisely. Although you can always change data and resolve the problem, you can sometimes answer these questions without having to use a computer when only one objective function coefficient or one value on the right-hand side (rhs) of a constraint is changed.

Much postoptimality analysis is based on *duality theory*, which derives from the fact that associated with every original *primal LP* having n variables and m constraints is another *dual LP* that has m variables and n constraints. Where the primal problem is to be maximized (minimized), the dual problem is to be minimized (maximized), for example:

Primal LP

$$\begin{array}{ll} \text{min} & c_1x_1 + \cdots + c_nx_n \\ \text{s.t.} & a_{11}x_1 + \cdots + a_{1n}x_n \geq b_1 \\ & \vdots \quad \vdots \quad \vdots \quad \vdots \\ & a_{m1}x_1 + \cdots + a_{mn}x_n \geq b_m \\ & x_1 \ , \cdots \ , \quad x_n \geq 0 \end{array}$$

Dual LP

$$\begin{array}{ll} \text{max} & b_1u_1 + \cdots + b_mu_m \\ \text{s.t.} & a_{11}u_1 + \cdots + a_{m1}u_m \leq c_1 \\ & \vdots \quad \vdots \quad \vdots \quad \vdots \\ & a_{1n}u_1 + \cdots + a_{mn}u_m \leq c_n \\ & u_1 \ , \cdots \ , \quad u_n \geq 0 \end{array}$$

Duality theory is used in the following ways:

1. As a test for optimality in Step 1 of the SA. (If $\mathbf{x}$ is feasible for the primal LP and $\mathbf{u}$ is feasible for the dual LP, and the objective function values of the primal and dual at $\mathbf{x}$ and $\mathbf{u}$ are equal, then $\mathbf{x}$ and $\mathbf{u}$ are optimal solutions for their respective problems.)
2. To determine the status of an LP without having to use a computer. (For example, if the primal LP is feasible and the dual LP is infeasible, then the primal LP is unbounded.)
3. To provide economic information about the primal LP. (For example, the optimal value of a dual variable, also called the *shadow price* of the associated primal constraint, represents the change in the optimal objective function value of the primal LP per unit of increase in the right-hand side of that constraint—within a certain range of values around that right-hand side—if all other data remain unchanged.)
4. To develop finite algorithms for solving the dual LP and, in so doing, provide a solution to the primal LP, assuming that both problems have optimal solutions.

Although efficient for solving most real-world problems, many versions of the SA can, in the worst case, visit an exponential (in terms of n) number of extreme points (see Ref. 4 for the first such example). It is an open question as to whether there is a version of the SA that, in the worst case, is polynomial (in the size of the data) although Borgwardt (5) proved that a version of the SA is polynomial on average. In 1979, Khachian (6) proposed the first polynomial algorithm for solving every LP. Karmarkar (7) subsequently developed the first polynomial algorithm that was also efficient in practice. These *interior point methods* (*IPM*) go through the inside of the feasible region [see Fig. 1(a)] rather than along the edges like the SA does. Computational experience with current versions of these IPMs indicate that they can be more efficient than the SA for solving specially-structured large LPs but generally are not more efficient than the SA for other LPs. See Refs. 8 and 9 for a discussion of IPMs and Ref. 10 for linear programming and the SA.

NONLINEAR PROGRAMMING

An NLP differs from an LP in both the problem structure and the ability to obtain solutions. Although an LP always has constraints (otherwise, the LP is unbounded), an NLP can be *unconstrained*—that is, have no constraints—or *constrained*, for example, find $\mathbf{x} = (x_1, \ldots, x_n)$ to:

Unconstrained Problem (NLP2)

$$\text{minimize} \quad f(\mathbf{x})$$

Constrained Problem (NLP3)

$$\begin{array}{lll} \text{minimize} & f(\mathbf{x}) & \\ \text{subject to} & g_1(\mathbf{x}) & \leq \ 0 \\ & \vdots & \vdots \ \ \vdots \\ & g_m(\mathrm{x}) & \leq \ 0 \end{array}$$

Other differences between an LP and an NLP arise due to nonlinearities in the objective function and constraints of an NLP. Where an LP must be either infeasible, optimal, or unbounded, with a nonlinear objective function, an NLP can additionally approach, but never attain, its smallest possible objective function value. For example, when minimizing $f(x) = e^{-x}$, the value of f approaches 0 as x approaches $+\infty$ but never attains the value 0.

The linear objective function and constraints in an LP allow for a computationally efficient test for optimality to determine whether a given feasible solution $\mathbf{x} = (x_1, \ldots, x_n)$ is optimal. In contrast, given a feasible point $\mathbf{x}$ for an NLP with general nonlinear functions, there is no known efficient test to determine whether $\mathbf{x}$ is a *global minimum of an NLP*, that is, a point such that for every feasible point $\mathbf{y} = (y_1, \ldots, y_n)$, $f(\mathbf{x}) \leq f(\mathbf{y})$. There is also no known efficient test to determine whether $\mathbf{x}$ is a *local minimum*, that is, a feasible point such that there is a real number $\delta > 0$ for which every feasible point $\mathbf{y}$ with $\|\mathbf{x} - \mathbf{y}\| < \delta$ satisfies $f(\mathbf{x}) \leq f(\mathbf{y})$ [where $\|\mathbf{x} - \mathbf{y}\| = \sum_{i=1}^{n} (x_i - y_i)^2$].

In the absence of an efficient test for optimality, many NLP algorithms instead use a *stopping rule* to determine whether the algorithm should terminate at the current feasible point $\mathbf{x}$. As described in the next two sections, these stopping rules are typically necessary conditions for $\mathbf{x}$ to be a local minimum and usually have the following desirable properties:

- It is computationally practical to determine whether the current feasible solution $\mathbf{x}$ satisfies the stopping rule.
- If $\mathbf{x}$ does not satisfy the stopping rule, then it is computationally practical to find a direction in which to move from $\mathbf{x}$, stay feasible at least for a small amount of movement in that direction, and simultaneously improve the objective function value.

Be aware that if $\mathbf{x}$ is a feasible point for an NLP that satisfies the stopping rule, this *does not* mean that $\mathbf{x}$ is a global minimum (or even a local minimum) of the NLP. Additional conditions on the nonlinear functions—such as *convexity*—are required to ensure that $\mathbf{x}$ is a global minimum. Indeed, it is often the case that nonconvex functions make it challenging to solve an NLP because there can be many local minima. In such cases, depending on the initial values chosen for the variables, algorithms often terminate at a local minimum that is not a global minimum. In contrast, due to the (convex) linear functions in an LP, the simplex algorithm always terminates at an optimal solution if one exists, regardless of the initial starting feasible solution.

A final difficulty caused by nonlinear functions is that algorithms for attempting to solve such problems are usually not finite (unlike the simplex algorithm for LP). That is, NLP algorithms usually generate an infinite sequence of feasible values for the variables, say $X = (\mathbf{x}^0, \mathbf{x}^1, \mathbf{x}^2, \ldots)$. Under fortunate circumstances, these points will *converge*, that is, get closer to specific values for the variables, say $\mathbf{x}^*$, where $\mathbf{x}^*$ is a local or global minimum for the NLP, or at least satisfies the stopping rule. In practice, these algorithms are made to stop after a finite number of iterations with an approximation to $\mathbf{x}^*$.

In the following discussion, details pertaining to developing such algorithms are presented for the unconstrained NLP2 and the constrained NLP3, respectively. From here on, it is assumed that the objective function f and all constraint functions $g_1, \ldots, g_m$ are differentiable. See Refs. 11 and 12 for a discussion of *nondifferentiable optimization*, also called *nonsmooth optimization*.

Unconstrained Nonlinear Programs

The unconstrained problem NLP2 differs from an LP in that (*1*) the objective function of NLP2 is not linear and (*2*) every point is feasible for NLP2. These differences lead to the following algorithm for attempting to solve NLP2 by modifying the simplex algorithm described previously:

Step 0 (Initialization). Start with any values, say $\mathbf{x} = (x_1, \ldots, x_n)$, for NLP2 because NLP2 has no constraints that must be satisfied.

Step 1 (Stopping Rule). Stop if the current point $\mathbf{x} = (x_1, \ldots, x_n)$ for NLP2 satisfies the following *stopping rule*, which uses the partial derivatives of f and is a necessary condition for $\mathbf{x}$ to be a local minimum:

$$\nabla f(\mathbf{x}) = \left(\frac{\partial f}{\partial x_1}(\mathbf{x}), \ldots, \frac{\partial f}{\partial x_n}(\mathbf{x})\right) = (0, \ldots, 0).$$

Note that finding a point $\mathbf{x}$ where $\nabla f(\mathbf{x}) = (0, \ldots, 0)$ is a problem of solving a system of n nonlinear equations in the n unknowns $x_1, \ldots, x_n$, which can possibly be done with Newton's method or some other algorithm for solving a system of nonlinear equations.

Step 2 (Move to a Better Point). If $\nabla f(\mathbf{x}) \neq (0, \ldots, 0)$, use that fact to

(a) (Direction of Movement). Find a *direction of descent* $\mathbf{d}$ so that all small amounts of movement from $\mathbf{x}$ in the direction $\mathbf{d}$ result in points that have smaller objective function values than $f(\mathbf{x})$. (One such direction is $\mathbf{d} = -\nabla f(\mathbf{x})$, but other directions that are usually computationally more efficient exist.)

(b) (Amount of Movement). Perform a possibly infinite algorithm, called a *line search*, that may or may not be successful, to find a value of a real number $t > 0$ that provides the smallest value of $f(\mathbf{x} + t\mathbf{d})$. If $t = \infty$, stop without finding an optimal solution to NLP2.

(c) (Move). Move from $\mathbf{x}$ to the new point $\mathbf{x} + t\mathbf{d}$, and return to Step 1.

The foregoing algorithm may run forever, generating a sequence of values for the variables, say $X = (\mathbf{x}^0, \mathbf{x}^1, \mathbf{x}^2, \ldots)$. Under fortunate circumstances, these points will converge to specific values for the variables, say $\mathbf{x}^*$, where $\mathbf{x}^*$

is a local or global minimum for NLP2 or at least satisfies $\nabla f(\mathbf{x}) = (0, \ldots, 0)$.

Constrained Nonlinear Programs

Turning now to constrained NLPs, as seen by comparing Fig. 1(a) and (b), the feasible region of a constrained NLP can be different from that of an LP and the optimal solution need not be one of a finite number of extreme points. These differences lead to the following algorithm for attempting to solve NLP3 by modifying the simplex algorithm described previously:

Step 0 (Initialization). There is no known finite procedure that will find an initial feasible solution for NLP3 or determine that NLP3 is infeasible. Thus, a possibly infinite algorithm is needed for this step and, under favorable circumstances, produces a feasible solution.

Step 1 (Stopping Rule). Stop if the current feasible solution $\mathbf{x} = (x_1, \ldots, x_n)$ for NLP3 satisfies the following *stopping rule*: Real numbers $u_1, \ldots, u_m$ exist such that the following **Karush–Kuhn–Tucker (KKT) conditions** hold at the point **x** (additional conditions on *f* and g_i, such as convexity, are required to ensure that **x** is a global minimum):

(a) (feasibility) For each $i = 1, \ldots, m, g_i(\mathbf{x}) \leq 0$ and $u_i \geq 0$.

(b) (complementarity) For each $i = 1, \ldots, m$, $u_i g_i(\mathbf{x}) \leq 0$.

(c) (gradient condition) $\nabla f(\mathbf{x}) + \sum_{i=1}^{m} u_i \nabla g_i(\mathbf{x}) = (0, \ldots, 0)$.

Note that when there are no constraints, the KKT conditions reduce to $\nabla f(\mathbf{x}) = (0, \ldots, 0)$. Also, when *f* and g_i are linear, and hence NLP3 is an LP, the values $\mathbf{u} = (u_i, \ldots, u_m)$ that satisfy the KKT conditions are optimal for the dual LP. That is, conditions (a) and (c) of the KKT conditions ensure that **x** is feasible for the primal LP and **u** is feasible for the dual LP, whereas conditions (b) and (c) ensure that the objective function value of the primal LP at **x** is equal to that of the dual LP at **u**. Hence, as stated in the first use of duality theory in the "Linear Programming" section, **x** is optimal for the primal LP and **u** is optimal for the dual LP.

Step 2 (Move to a Better Point). If **x** is not a KKT point, use that fact to

(a) (Direction of Movement). Find a *feasible direction of improvement***d** so that all small amounts of movement from **x** in the direction **d** result in feasible solutions that have smaller objective function values than *f*(**x**).

(b) (Amount of Movement). Determine the maximum amount t^* you can move from **x** in the direction **d**, and stay feasible. Then perform a possibly infinite algorithm, called a *constrained line search*, in an attempt to find a value of *t* that minimizes $f(\mathbf{x} + t\mathbf{d})$ over the interval $[0, t^*]$. If $t = \infty$, stop without finding an optimal solution to NLP3.

(c) (Move). Move from **x** to the new feasible point $\mathbf{x} + t\mathbf{d}$, and return to Step 1.

The foregoing algorithm may run forever, generating a sequence of values for the variables, say $X = (\mathbf{x}^0, \mathbf{x}^1, \mathbf{x}^2, \ldots)$. Under fortunate circumstances, these points will converge to specific values for the variables, say $\mathbf{x}^*$, where $\mathbf{x}^*$ is a local or global minimum for NLP3 or a KKT point.

In addition to the foregoing *methods of feasible directions*, many other approaches have been developed for attempting to solve NLP2 and NLP3, including conjugate gradient methods, penalty and barrier methods, sequential quadratic approximation algorithms, and fixed-point algorithms (see Ref. 13 for details). A discussion of interior point methods for solving NLPs can be found in Ref. 14. Commercial software packages from Solver in Excel and GRG exist for attempting to solve such problems and can currently handle up to about 100 variables and 100 constraints. However, if an NLP has special structure, it may be possible to develop an efficient algorithm that can solve substantially larger problems.

Topics related to LP and NLP include integer programming (in which the value of one or more variable must be integer), network programming, combinatorial optimization, large-scale optimization, fixed-point computation, and solving systems of linear and nonlinear equations.

LOCALITY PRINCIPLE

Locality is a universal behavior of all computational processes: They tend to refer repeatedly to subsets of their resources over extended time intervals. System designers have exploited this behavior to optimize performance in numerous ways, which include caching, clustering of related objects, search engines, organization of database, spam filters, and forensics.

Every executing computation generates references to objects, such as memory pages, disk sectors, database records, and web pages. These references are not uniform: Some objects are referenced more often than others, and references to each object come in bursts. Another way to say this is that execution of a computation consists of a series of phases; phase i has holding time Ti and locality set Li. The locality set is the set of objects referenced in the phase. A particular object is referenced only in the phases in which it is a member of the locality set. Thus, the history of the computation appears as a sequence,

$$(L1, T2), (L2, T2), (L3, T3), \ldots, (Li, Ti), \ldots$$

The locality set of a multithreaded computation at a particular time is the union of the individual thread locality sets at that time.

Knowledge of a computation's locality behavior has several significant benefits:

- The local storage of a processor (cache) needs to contain only the current localities, not the entire object space. The cache provides in significant savings in local storage without loss of performance.
- If the phase boundaries are unknown (the usual case), the best predictor of objects the computation will use in the immediate future is its current locality set.
- Objects that tend to be in the same locality sets can be grouped in storage systems so that they can be loaded together (efficiently) into a processor's cache.

There are two aspects of locality: *(1) temporal locality* means that references to the same objects are grouped in time, and *(2) spatial locality* means that objects close to each other tend to be referenced together. These two aspects give the phase-transition definition above.

Locality is among the oldest systems principles in computer science. It was discovered in 1966 during efforts to make early virtual memory systems work well. Working-set memory management was the first exploitation of this principle; it prevented thrashing while maintaining near optimal system throughput, and eventually it enabled virtual memory systems to be reliable, dependable, and transparent. Today the locality principle is being applied to computations that adapt to the neighborhoods in which users are situated, inferring those neighborhoods by observing user actions, and then optimizing performance for users.

The remainder of this article reviews the history of the locality principle and its new applications in context-aware computing.

MODELS OF LOCALITY

A model of locality is a description of a mechanism to generate the locality behavior of a computation without having to run the computation. The earliest notion of locality was a nonuniform distribution of references over a computation's objects. Thus, the objects could be ordered so that their probabilities of use follow the relation

$$p1 > p2 > p3 > \ldots > pk > \ldots$$

When these probabilities are measured, they often follow a Zipf Law, which means that pk is proportional to $1/k$.

This law is called a *static representation* of locality because a single distribution of probabilities holds for all time; there is no differentiation into phases. Empirically, when a computation is modeled this way, the model overestimates the average locality size by factors of 2 or 3.

In contrast are *dynamic representations* that recognize phases and allow for different probability distributions in each phase. Dynamic models tend to estimate average locality size well.

The phase-transition model is a successful dynamic model. It consists of a *macromodel* that generates phase and transition intervals and their holding times, and a *micromodel* that generates references from a locality set associated with the phase. The holding times in the states are random variables, with the average holding in the phase state being much longer than in the transition state. While in the phase state, the model uses a static representation for a single locality set, such as the distribution above. During the transition phase, the model allows for random references to all objects (1).

The working set model defines a program's working set at time t, $W(t,T)$, as the set of objects referenced in the time window of length T extending backward from the current time t. It is usually possible to choose the window size T so that it is contained within phases most of time, in which case the working set measures the current locality set. Thus, the working set is a good way to track the localities and phases of a program dynamically (2).

HISTORY

Locality was discovered from efforts to make virtual memory systems work well. Virtual memory was first developed in 1959 on the Atlas system at the University of Manchester (3). Its superior programming environment doubled or tripled programmer productivity. Its automatic caching boosted performance (4). But its finicky performance was

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

sensitive to the choice of replacement algorithm and to the ways compilers grouped code on to pages. Worse, when it was coupled with multiprogramming, it was prone to thrashing, the near-complete collapse of system throughput because of heavy paging (5). The locality principle guided the design of robust replacement algorithms, compiler code generators, and thrashing-proof systems. It transformed virtual memory from an unpredictable to a robust technology that regulated itself dynamically and optimized throughput without user intervention.

Atlas included the first demand-paged virtual memory, which automated the process of transferring pages between random access memory (RAM) and disk. The designers grappled with two performance problems, either one of which could scuttle the system: One was addresses to locations, the other pages already loaded into RAM. They quickly found a solution to the translation problem using page tables stored in RAM and address caches in the central processing unit (CPU). The replacement problem was much more difficult.

Because the disk access time was about 10,000 times slower than the CPU instruction cycle, each page fault added a significant delay to a job's completion time. Therefore, minimizing page faults was critical to system performance. The ideal page to replace from main memory is the one that will not be used again for the longest time. But next-use time cannot be known with certainty. The Atlas system used a "learning algorithm" that hypothesized a loop cycle for each page, measured each page's period, and estimated which page was not needed for the longest time.

The learning algorithm was controversial. It performed well on programs with well-defined loops and poorly on many other programs. In numerous experimental studies well into the 1960s, researchers sought to determine what replacement rules might work best over the widest possible range of programs. Belady's study in 1966 (6) was the most comprehensive and scientific. Eventually, it became apparent that the volatility resulted from variations in compiling methods: The way in which a compiler grouped code blocks onto pages strongly affected the program's performance under a given replacement strategy (7).

The major computer makers were drawn to multiprogrammed virtual memory because of its superior programming environment. RCA, General Electric, Burroughs, and Univac all included virtual memory in their operating systems of the mid-1960s. Because a bad replacement algorithm could cost a million dollars of lost machine time over the life of a system, they all had a keen interest in finding good replacement algorithms.

Imagine their chagrin when by 1966 these companies reported a new, unexplained, catastrophic problem they called thrashing. It was a sudden collapse of throughput as the multiprogramming level rose. It had nothing to do with the choice of replacement policy. A thrashing system spent most of its time resolving page faults and little running the CPU. Thrashing was far more damaging than a poor replacement algorithm. It scared the daylights out of the computer makers.

IBM avoided these uncertainties by excluding virtual memory from its OS360 in 1964. Instead, it sponsored at its Watson laboratory one of the most comprehensive experimental systems projects of all time. Led by Bob Nelson, Les Belady, and David Sayre, the project team built the first virtual-machine operating system and used it to study the performance of virtual memory. (The term "virtual memory" seems to have come from this project.) By 1966 they had tested every replacement policy that anyone had ever proposed and a few more they invented. Many of their tests involved the use bits built into page tables. By periodically scanning and resetting the bits, the replacement algorithm distinguishes recently referenced pages from others. Belady concluded that policies that favor recently used pages performed better than other policies; least recently used replacement was consistently the best performer among those tested (6). He said that this resulted from reference clustering locality behavior. His colleagues verified that many programs exhibited locality behavior (6).

At MIT Project MAC in 1966, Peter Denning hypothesized that the controversies over replacement algorithms could be settled by defining an intrinsic memory demand: "This process needs p pages at time t." Intrinsic demand was the first notion of "working set." Individual replacement algorithms could then be rated by their abilities to detect working sets. Inspired by Belady's concept of locality, Denning formally defined a process's working set as the set of pages used during a fixed-length sampling window in the immediate past (2). A working set could be measured by periodically reading and resetting the use bits in a page table.

This method solved thrashing because if every process is guaranteed its working set, then no process can overload the paging disk and system throughput can be maintained (5). Thrashing is impossible for a working-set policy. Experiments with real operating systems confirmed that this policy gives high efficiency and prevents thrashing (9).

The working-set idea worked because the pages observed in the backward window were highly likely to be used again in the immediate future. Was this assumption justified? The idea that reference behavior could be described as a sequence of phases and locality sets seemed natural because programmers planned overlays using diagrams that showed subsets and time phases (Fig. 1). But what was strikingly interesting was that programs showed this behavior even when it was not explicitly preplanned. Each program had its own distinctive usage pattern, like a voiceprint (Fig. 2).

Two effects could make this happen: *(1)* temporal clustering caused by looping and executing within modules with private data and *(2)* spatial clustering caused by related values being grouped into arrays, sequences, modules, and other data structures. Both these reasons followed from the human practice of 'divide and conquer'—breaking a large problem into parts and working separately on each part. The locality bit maps captured someone's problem-solving method in action. The working set measures an approximation of a program's intrinsic locality sequence.

A distance function gives a single measure of temporal and spatial locality. $D(x,t)$ measures the distance from the current execution point of the process to an object x at time t.

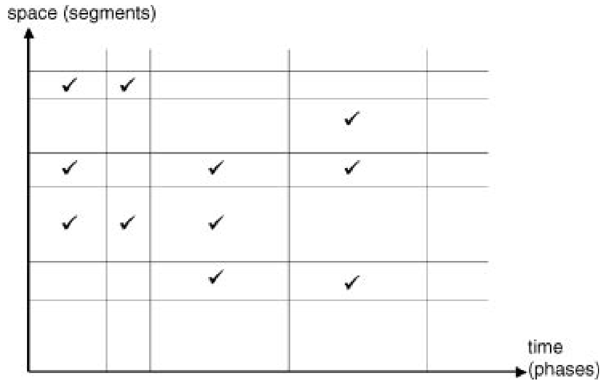

Figure 1. Locality sequence behavior diagrammed by programmer during overlay planning.

Distances can be temporal, such as the time since prior reference or access time within a network; spatial, measuring hops in a network or address separation in a sequence; or cost, which measures any nondecreasing accumulation of cost since prior reference. Object x is in the locality set at time t if the distance is within a threshold: $D(x,t) \leq T$.

By 1980, the locality principle was understood as a package of three ideas (1):

1. Computational processes pass through a sequence of phases.
2. The locality sets of phases can be inferred by applying a distance function to a program's address trace observed during a backward window.
3. Memory management is optimal when it guarantees each program that its locality sets will be present in high-speed memory.

ADOPTION OF LOCALITY PRINCIPLE

The locality principle was adopted almost immediately by operating systems, databases and hardware architects. It was soon adopted into ever-widening circles:

- In virtual memory to organize caches for address translation and to design the replacement algorithms
- In data caches for CPUs, originally as mainframes and now as microchips
- In buffers between main memory and secondary memory devices
- In buffers between computers and networks
- In video boards to accelerate graphics displays
- In modules that implement the information-hiding principle
- In accounting and event logs in that monitor activities within a system
- In alias lists that associate longer names or addresses with short nicknames
- In the "most recently used" object lists of applications
- In Web browsers to hold recent web pages
- In file systems, to organize indexes (e.g., B-trees) for fastest retrieval of file blocks
- In database systems, to manage record-flows between levels of memory
- In search engines to find the most relevant responses to queries
- In classification systems that cluster related data elements into similarity classes
- In spam filters, which infer which categories of e-mail are in the user's locality space and which are not
- In "spread spectrum" video streaming that bypasses network congestion and reduces the apparent distance to the video server
- In "edge servers" to hold recent web pages accessed by anyone in an organization or geographical region
- In the field of computer forensics to infer criminal motives and intent by correlating event records in many caches
- In the field of network science by defining hierarchies of self-similar locality structures within complex power-law networks

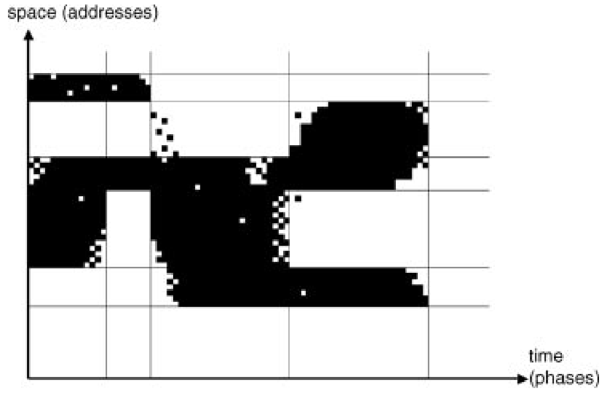

Figure 2. Locality sequence behavior observed by sampling use bits during program execution. Programs exhibit phases and localities naturally, even when overlays are not preplanned.

MODERN MODEL OF LOCALITY: CONTEXT AWARENESS

As the uses of locality expanded into more areas, our understanding of locality has evolved. Locality is the consequence of a more basic principle: Everything we do, we do in a context. Context awareness embraces four key ideas:

- **An observer**
- **Neighborhoods:** One or more sets of objects that are most relevant to the observer at any given time
- **Inference:** A method of identifying the most relevant objects by monitoring the observer's actions and interactions and other information about the observer contained in the environment
- **Optimal actions:** An expectation that the observer will complete work in the shortest time if neighborhood objects are ready accessible in nearby caches

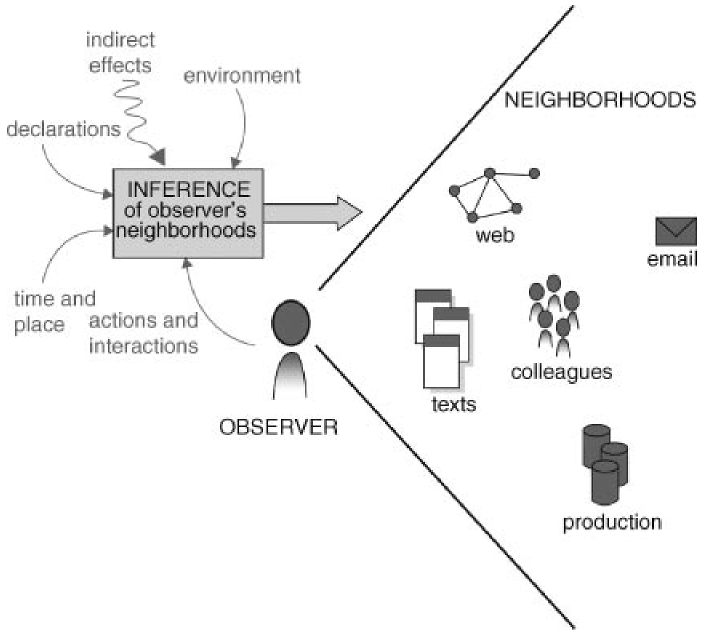

Figure 3. The modern view of locality is a means of inferring the context of an observer using software, so that the software can dynamically adapt its actions to produce optimal behavior for the observer.

These four ideas can be recognized in the original definition. The observer is the execution point of the computational process; the neighborhood is the current locality set; the distance function is the inference mechanism; the optimal action is to guarantee that the current locality is present in a processor's cache. Let us examine the generalizations of these ideas.

The observer is the agent who is trying to accomplish tasks with the help of software, and who places expectations on its function and performance (Fig. 3). In most cases, the observer is the user who interacts with software. In some cases, such as a program that computes a mathematical model, the observer can be built into the software itself.

A neighborhood is a group of objects related to the observer by some metric. Newer examples of neighborhoods include e-mail correspondents, non-spam e-mail, colleagues, teammates, objects used in a project, favorite objects, user's web, items of production, texts, and directories. Some neighborhoods can be known by explicit declarations, for example, a user's file directory, address book, or web pages. But most neighborhoods can only be inferred by monitoring the event sequences of an observer's actions and interactions.

Inference can be any reasonable method that measures the content of neighborhoods. Newer inference methods include Google's counting of incoming hyperlinks to a web page, patterns generated by connectionist networks after being presented with many examples, and Bayesian spam filters.

Optimal actions are performed by the software on behalf of the observer. These actions can come either from inside the software with which the observer is interacting, or from outside that software, in the run-time system.

The matrix below shows four quadrants that correspond to the four combinations of inference data collection and locus of action just mentioned. Examples of software are named in each quadrant and are summarized below. "Inside" and "outside" are relative to the context-aware software.

		Origin of Data for Inference	
		Inside	**Outside**
LOCUS OF ADAPTIVE ACTION	**Inside**	Amazon.com Bayesian spam filter	Semantic web Google
	Outside	Linkers and loaders	Working sets, Ethernet load control

- **Amazon.com, Bayesian spam filters.** Amazon collects data about user purchasing histories and recommends other purchases, by the user or others, that resemble the user's previous purchases. Bayesian spam filters gather data about which e-mails the user considers relevant and then block irrelevant e-mails. (Data collection inside, optimal actions inside.)
- **Semantic web, Google.** Semantic web is a set of declarations of structural relationships that constitute context of objects and their connections. Programs read and act on it. Google gathers data from the Web and uses it to rank pages that seem to be most relevant to a keyword query posed by user. (Data collection outside, optimal actions inside.)
- **Linkers and loaders.** These workhorse systems gather library modules mentioned by a source program and link them together into a self-contained executable module. The libraries are neighborhoods of the source

program. (Data collection inside, optimal action outside.)

- **Working sets, ethernet load controls.** Virtual memory systems measure working sets and guarantee programs enough space to contain them, which thereby prevents thrashing. Ethernet prevents the contention-resolving protocol from getting overloaded by making competing transactions wait longer for retries if load is heavy (10). (Data collection outside, optimal action outside.)

In summary, the modern principle of locality is that observers operate in one or more neighborhoods that can be inferred from dynamic action sequences and static structural declarations. Systems can optimize the observer's productivity by adapting to the observer's neighborhoods, which they can estimate by distance metrics or other inferences.

FUTURE USES OF LOCALITY PRINCIPLE

Locality principles are certain to remain at the forefront of systems design, analysis, and performance, because locality flows from human cognitive and coordinative behavior. The mind focuses on a small part of the sensory field and can work most quickly on the objects of its attention. People organize their social and intellectual systems into neighborhoods of related objects, and they gather the most useful objects of each neighborhood close around them to minimize the time and work of using them. These behaviors are transferred into computational systems they design and into the expectations users have about how their systems should interact with them.

Here are seven modern areas that offer challenging research problems that locality may be instrumental in solving.

Architecture

Computer architects have heavily exploited the locality principle to boost the performance of chips and systems. Putting cache memory near the CPU, either on board the same chip or on a neighboring chip, has enabled modern CPUs to pass the 1-GHz speed mark. Locality within threaded instruction sequences is being exploited by a new generation of multicore processor chips. The "system on a chip" concept places neighboring functions on the same chip to decrease delays of communicating between components significantly. Animated sequences of pictures can be compressed by locality: by detecting the common neighborhood behind a sequence, transmitting it once, and then transmitting the differences for each picture. Architects will continue to examine locality carefully to find new ways to speed up chips, communications, and systems.

Caching

The locality principle is useful wherever there is an advantage in reducing the apparent distance from a process to the objects it can access. Objects in the neighborhood of the process are kept in a local cache with fast access time. The performance acceleration of a cache generally justifies the modest investment in the cache storage. Novel forms of caching have sprung up in the Internet. One prominent example is edge servers that store copies of Web objects near their users. Another example is the clustered databases built by search engines (like Google) to retrieve relevant objects instantly from the same neighborhoods as the asker. Similar capabilities are available in MacOS Windows to speed up finding relevant objects.

Bayesian Inference

A growing number of inference systems exploit Bayes's principle of conditional probability to compute the most likely internal (hidden) states of a system given observable data about the system. Spam filters, for example, use it to infer the e-mail user's mental rules for classifying certain objects as spam. Connectionist networks use it for learning: Their internal states abstract from desired input-output pairs shown to the network; the network gradually acquires a capability for new action. Bayesian inference is an exploitation of locality because it infers a neighborhood given observations of what a user or process is doing.

Forensics

The burgeoning field of computer forensics owes much of its success to the ubiquity of caches. They are literally everywhere in an operating systems and applications. By recovering evidence from these caches, forensics experts can reconstruct (infer) an amazing amount of a criminal's motives and intent (11). Criminals who erase data files are still not safe, because experts use advanced signal-processing methods to recover the faint magnetic traces of the most recent files from the disk (12). Learning to draw valid inferences from data in a computer's caches, and from correlated data in caches in other computers with which the subject has communicated, is a challenging research problem.

Web-Based Business Processes

Web-based business systems allow buyers and sellers to engage in transactions using Web interfaces to sophisticated database systems. Amazon.com illustrates how a system can infer "book interest neighborhoods" of customers and (successfully) recommend additional sales. Many businesses employ customer relationship management systems that infer "customer interest neighborhoods" and allow the company to provide better, more personalized service. Database, network, server, memory, and other caches optimize the performance of these systems (13).

Context-Aware Software

More software designers are coming to believe that most software failures can be traced to the inability of software to be aware of and act on the context in which it operates. More and more modern software uses inferred context to be consistently more reliable, dependable, usable, safe, and secure.

Network Science

Many scientists have begun to apply statistical mechanics to large random networks, typically finding that the distribution of node connections is power law with degree −2 to −3 (14,15). These networks are self-similar, which means that if all neighborhoods (nodes within a maximum distance of each other) are collapsed to single nodes, then the resulting network has the same power distribution as the original (16). The idea that localities are natural in complex systems is not new; in 1976, Madison and Batson (17) reported that program localities have self-similar sublocalities ; in 1977, P. J. Courtois (18) applied it to cluster similar states of complex systems to simplify their performance analyses. The locality principle may offer new understandings of the structure of complex networks.

Researchers looking for challenging problems can find many in these areas and can exploit the principle of locality to solve them.

MARKOV CHAIN MONTE CARLO SIMULATIONS

Markov Chain Monte Carlo (MCMC) simulations are widely used in many branches of science. They are nearly as old as computers themselves, since they started in earnest with a 1953 paper by Nicholas Metropolis, Arianna Rosenbluth, Marshall Rosenbluth, Augusta Teller, and Edward Teller (1) at the Los Alamos National Laboratory, New Mexico.These authors invented what is nowadays called the Metropolis algorithm. Various applications and the history of the basic ideas are reviewed in the proceedings (2) of the 2003 Los Alamos conference, which celebrated the fiftieth anniversary of the Metropolis algorithm.

OVERVIEW

The Monte Carlo method to compute integrals (3) amounts to approximate an integral $\int_\Omega d\mu(X)\mathcal{O}(X)$, inside a volume Ω, where $d\mu(X)$ is some integration measure and $\int_\Omega d\mu(X) < \infty$, by sampling. Without loss of generality, one can assume that $\int_\Omega d\mu(X) = 1$, and consider accordingly $d\mu(X)$ as a probability measure. Drawing independently N_{sample} values of $X \in \Omega$ according to this probability measure, one has

$$\int_\Omega d\mu(X)\mathcal{O}(X) \approx \frac{1}{N_{\text{samples}}} \sum_{s=1}^{N_{\text{samples}}} \mathcal{O}(X_s) \tag{1}$$

where X_s is the s'th random variable drawn. The right hand side of Equation 1 is an unbiased estimator of the integral, namely it is exact in average, for any N_{sample}. It converges toward the correct value when $N_{\text{samples}} \to \infty$, with a $1/\sqrt{N_{\text{samples}}}$ leading correction. This method is of practical use if one can easily draw, in a computer program, random values $X_s \in \Omega$ according to the measure $d\mu(X)$. This is the case in particular if one integrates inside an N- dimensional hypercube with the flat measure $d\mu^{\text{flat}}(X) \propto \prod_{k=1}^{N} dX^{(k)}$, where the $X^{(k)}$'s are the Cartesian components of X, or when the integral reduces to a finite sum. This is not the case in the situation where this simple measure is multiplied by a nontrivial function $\omega(X)$ of the components $X^{(k)}$. If $\omega(X)$ is a smooth function in Ω with a limited range of variations, one can still draw values of X according to the simple measure $d\mu^{\text{flat}}$ and write (assuming without loss of generality that $\int_\Omega d\mu(X) = 1$ and $\int_\Omega d\mu^{\text{flat}}(X) = 1$)

$$\begin{aligned}\int_\Omega d\mu(X)\mathcal{O}(X) &= \int_\Omega d\mu^{\text{flat}}(X)\omega(X)\mathcal{O}(X) \\ &\approx \frac{1}{N_{\text{samples}}} \sum_{s=1}^{N_{\text{sample}}} \omega(X_s)\mathcal{O}(X_s)\end{aligned} \tag{2}$$

If the function $\omega(X)$ has a very large range of variations with one or several sharp peaks, the sum in Equation 2 is dominated by a few rare configurations, and the Monte Carlo method does not work (most samples are drawn in vain). This is the case of the problem considered in Ref. 1, where $\omega(X)$ is a Boltzmann weight, the exponential of N times a function of order one, with N the number of molecules in a box, which is a notoriously large number.

The Markov chain Monte Carlo method allows overcoming this problem by generating a set of random $X \in \Omega$, distributed according to the full measure $d\mu(X)$, using an auxiliary Markov chain. Note that often, in particular in the physics literature, Monte Carlo is used as a short name for Markov chain Monte Carlo (MCMC). MCMC is sometimes called dynamic Monte Carlo, in order to distinguish it from the usual, "static," Monte Carlo. Many probability distributions, which cannot be sampled directly, allow for MCMC sampling. From now on we write a formula for a discrete space Ω with K_{st} states, although the results can be generalized. A Markov chain (4–7) is a sequence of random variables $X_1, \quad X_2, \quad X_3, \ldots$, that can be viewed as the successive states of a system as a function of a discrete time t, with a transition probability $\mathbf{P}(X_{t+1} = r | X_t = s) = W_{r,s}$ that is a function of r and s only. The next future state X_{t+1} is a function of the current state X_t alone. Andrey Markov (8) was the first to analyze these processes. In order to analyze Markov chains, one introduces an ensemble of chains with an initial probability distribution $\mathbf{P}(X_0 = s)$. By multiplying this vector by the transition matrix repeatedly, one obtains $\mathbf{P}(X_1 = s)$, and then $\mathbf{P}(X_2 = s), \ldots$, successively. The natural question is whether this sequence converges. One says that a probability distribution $w = \{w_s\}_{s \in \Omega}$ is an equilibrium distribution of a Markov chain if it is let invariant by the chain, namely if

$$\sum_{s=1}^{K_{st}} W_{r,s}\omega_s = \omega_r \tag{3}$$

This condition is called balance in the physics literature. A Markov chain is said to be ergodic (irreducible and aperiodic in the mathematical literature) if for all states $r, s \in \Omega$ there is a $N_{r,s}$ such that for all $t > N_{r,s}$ the probability $(W^t)_{s,r}$ to go from r to s in t steps is nonzero. If an equilibrium distribution exists and if the chain is irreducible and aperiodic, one can show (4–7) that, starting from any distribution $\mathbf{P}(X_0 = s)$, the distribution after t steps $\mathbf{P}(X_t = s)$ converges when $t \to \infty$ toward the equilibrium configuration ω_s.

The Metropolis algorithm (see the next section) offers a practical way to generate a Markov chain with a desired equilibrium distribution, on a computer using a pseudorandom numbers generator. Starting from an initial configuration X_0, successive configurations are generated. In most cases, the convergence of $\mathbf{P}(X_t = s)$ toward ω_s is exponential in t and one can safely assume that, after some number of steps t_{eq}, "equilibrium is reached" and that the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

configurations $X_{t_{eq}+1}, X_{t_{eq}+2}, \ldots$ are distributed according to $\omega(X)$.

Whereas the random samples used in a conventional Monte Carlo (MC) integration are obviously statistically independent, those used in MCMC are correlated. The effective number of independent events generated by an equilibrated Markov chain is given by the number of steps done divided by a quantity called "integrated autocorrelation time" τ_{int}. In most cases, τ_{int} does not depend on the quantity $\mathcal{O}$ measured, but there are exceptions like, for example the vicinity of a second-order (continuous) phase transition. The algorithm will fail if τ_{int} is too big. In practice it can be quite difficult to estimate τ_{int} reliably and there can also be a residual effect of the starting position. More sophisticated MCMC-based algorithms such as "coupling from the past" (9,10) produce independent samples rigorously but at the cost of additional computation and an unbounded (although finite on average) running time.

The method was originally developed to investigate a statistical physics problem. Suitable applications arise as well in computational biology, chemistry, physics, economics, and other sciences. MCMC calculations have also revolutionized the field of Bayesian statistics.

Most concepts of modern MCMC simulation were originally developed by physicists and chemists, who still seem to be at the cutting edge of new innovative developments into which mathematician, computer scientists, and statisticians have joined. Their interest developed mainly after a paper by Hastings (11), who generalized the accept/reject step of the Metropolis method. Unfortunately a language barrier developed that inhibits cross-fertilization. For instance the "heat bath" algorithm, which may be applied when the conditional distributions can be sampled exactly, was introduced by physicist Refs. (12) and (13). Then it was rediscovered in the context of Bayesian restoration of images under the name "Gibbs sampler" (14). Another example is the "umbrella sampling" algorithm (15) that was invented in chemical physics and later rediscovered and improved by physicists. This is just two of many examples of how different names for the same method emerged. The reader should be aware that this article was written by physicists, so that their notations and views are dominant in this article. The book by Liu (16) tries to some extent to bridge the language barrier. Other textbooks include those by Robert and Casella (17) for the more mathematically minded reader, Landau and Binder (18) for statistical physicists, Berg (19) from a physicist point of view, but also covering statistics and providing extensive computer code (in Fortran). Kendall, et al. (20) edited a book that combines expositions from physicists, statisticians, and computer scientists.

In the following discussion, we will first explain the basic method and illustrate it for a simple statistical physics system, the Ising ferromagnet in two dimensions, followed by a few remarks on autocorrelations and cluster algorithms. An overview of the MCMC updating scheme is subsequently given. The final section of this article focuses on so-called generalized ensemble algorithms.

MCMC AND STATISTICAL PHYSICS

As mentioned, the MCMC algorithm was invented to investigate problems in statistical physics. The aim of statistical physics is to predict the average macroscopic properties of systems made of many constituents, which can be, for example, molecules in a box (as in the original article of Metropolis et al.), magnetic moments (called spins) at fixed locations in a piece of material, or polymer chains, in a solvent. If one considers the so-called canonical ensemble, where the system has a fixed temperature T, one knows that the probability to observe a given microscopic configuration (or micro state) s (defined in the three examples given above by the positions and velocities of all molecules; the orientations of all the spins; and the exact configuration of all the polymer chains, respectively) is proportional to the Boltzmann weight $\exp(-E_s/k_BT) = \exp(-\beta E_s)$, where E_s is the energy of the configuration s, k_B is the Boltzmann constant, and T is the temperature. (In the following discussion, we will use a unit of temperature such that $k_B = 1$). Let $\mathcal{O}_s$ be the value of $\mathcal{O}$ computed in configuration s. The mean value of any macroscopic observable $\mathcal{O}$ (e.g. the energy) is given by the average of $\mathcal{O}_s$ over all possible configurations s, weighted by the Boltzmann weight of the configuration. This sum (or integral if one has continuous variables) is to be normalized by the sum over all configurations of the Boltzmann weight [the so-called partition function $Z(T)$], namely

$$\hat{O} = \hat{O}(T) = \langle O \rangle = Z^{-1}(T) \sum_{s=1}^{K_{st}} O_s e^{-E_s/T} \tag{4}$$

where $Z(T) = \sum_{s=1}^{K_{st}} \exp(-E_s/T)$. The index $s = 1, \ldots, K_{st}$ labels the configuration (states) of the system.

A particularly simple system is the Ising model for which the energy is given by

$$E = \sum_{<ij>} s_i s_j \tag{5}$$

Here the sum is over the nearest-neighbor sites of a hypercubic D-dimensional lattice and the Ising spins take the values $s_i = \pm 1$, $i = 1, \ldots, N$ for a system of $N = \prod_{i=1}^{D} L_i$ spins. Periodic boundary conditions are used in most simulations. The energy per spin is $e = E/N$. The model describes a ferromagnet for which the magnetic moments are simplified to ± 1 spins at the sites of the lattice. In the $N \to \infty$ limit (and for $D > 1$), this model has two phases separated by a phase transition (a singularity) at the critical temperature $T = T_c$. This is a second-order phase transition, which is continuous in the energy, but not in specific heat. This model can be solved analytically when $D = 2$. (This means that one can obtain exact analytical expressions for the thermodynamic quantities, e.g., the energy per spin, as a function of temperature, in the $N \to \infty$ limit.) This makes the two-dimensional (2-D) Ising model an ideal testbed for MCMC algorithms.

The number of configurations of the Ising model is $K_{st} = 2^N$, because each spin can occur in two states (up or down). Already for a moderately sized lattice, say linear dimension $L_1 = L_2 = 100$ in $D = 2$, K_{st} is a tremendously large number. With the exception of very small systems, it is therefore impossible to do the sums in Equation 4 explicitly. Instead, the large value of K_{st} suggests a statistical evaluation.

IMPORTANCE SAMPLING THROUGH MCMC

As explained in the previous section, one needs a procedure that generates configurations s with the Boltzmann probability

$$P_{B,s} = c_B\, w_{B,s} = c_B e^{-\beta E_s} \tag{6}$$

where the constant c_B is determined by the condition $\sum_s P_{B,s} = 1$. The vector $P_B := \{P_{B,s}\}$ is called the Boltzmann state. When configurations are generated with the probability $P_{B,s}$, the expectation values [Equation (4)] are estimated by the arithmetic averages:

$$\langle O \rangle = \lim_{N_{\text{samples}} \to \infty} \frac{1}{N_{\text{samples}}} \sum_{s=1}^{N_{\text{samples}}} O_s \tag{7}$$

With the MCMC algorithm, this is obtained from a Markov chain with the following properties:

1. *Irreducibility and aperiodicity (ergodicity in the physics literature)*: For any two configurations r and s, an integer $N_{r,s}$ exists such that for all $n > N_{r,s}$, the probability $(W^n)_{r,s}$ is nonzero.
2. *Normalization*: $\sum_r W_{r,s} = 1$.
3. *Stationarity of the Boltzmann distribution (balance in the physics literature)*: The Boltzmann state [Equation (6)] is an equilibrium distribution, namely a right eigenvector of the matrix W with eigenvalue one, i.e., $\sum_s W_{r,s} e^{-\beta E_s} = e^{-\beta E_r}$ holds.

There are many ways to construct a Markov process satisfying 1, 2, and 3. In practice, MCMC algorithms are often based on a stronger condition than 3, namely,

3. *Detailed balance*:

$$W_{r,s} e^{-\beta E_s} = W_{s,r} e^{-\beta E_r} \quad \forall\, r, s. \tag{8}$$

METROPOLIS ALGORITHM AND ILLUSTRATION FOR THE ISING MODEL

Detailed balance obviously does not uniquely fix the transition probabilities $W_{r,s}$. The original Metropolis algorithm (1) has remained a popular choice because of its generality (it can be applied straightforwardly to any statistical physics model) and its computational simplicity. The original formulation generates configurations with the Boltzmann weights. It generalizes immediately to arbitrary weights (see the last section of this article). Given a configuration s, the algorithm proposes a new configuration r with a priori probabilities $f(r, s)$. This new configuration r is accepted with probability

$$a^{r,s} = \min\left[1, \frac{P_{B,r}}{P_{B,s}}\right] = \begin{cases} 1 \text{ for } E_r < E_s \\ e^{-\beta(E_r - E_s)} \text{ for } E_r > E_s \end{cases} \tag{9}$$

If the new configuration is rejected, the old configuration is kept and counted again. For such decisions one uses normally a pseudorandom number generator, which delivers uniformly distributed pseudorandom numbers in the range $[0, 1)$; see Refs. (18) and (19) for examples, and Ref. (21) for the mathematics involved. The Metropolis algorithm gives then rise to the transition probabilities

$$W_{r,s} = f(r,s) a_{r,s} \quad r \neq s \tag{10}$$

and

$$W_{s,s} = f(s,s) + \sum_{r \neq s} f(r,s)(1 - a_{r,s}) \tag{11}$$

Therefore, the ratio $W_{r,s}/W_{s,r}$ satisfies the detailed balance condition [Equation (8)] if

$$f(r,s) = f(s,r) \tag{12}$$

holds. This condition can be generalized when also the acceptance probability is changed (11). In particular such "biased" Metropolis algorithms allow for approaching the heat-bath updating scheme (22).

For the Ising model, the new putative configuration differs from the old one by the flip of a single spin. Such a "single spin update" requires a number of operations of order one and leads to a ratio $P_{B,r}/P_{B,s}$ in Equation (9). This is fundamental in order to have an efficient MCMC algorithm. The spin itself may be chosen at random, although some sequential procedure is normally more efficient (19). The latter procedure violates the detailed balance condition but fulfills the balance condition, and thus, it does lead to the probability of states approaching the Boltzmann distribution [Equation (6)]. The unit of Monte Carlo time is usually defined by N single spin updates, aka a lattice sweep or "an update per spin." Many ways to generate initial configurations exist. Two easy to implement choices are as follows:

1. Use random sampling to generate a configuration of ±1 spins.
2. Generate a completely *ordered* configuration, either all spin $+1$ or -1.

Figure 1 shows two Metropolis energy time series (the successive values of the energy as a function of the discrete Monte Carlo time) of 6000 updates per spin for a 2D Ising model on a 100×100 lattice at $\beta = 0.44$, which is close to the (infinite volume) phase transition temperature of this model ($\beta_c = \ln(1 + \sqrt{2})/2 = 0.44068\ldots$). One can compare with the exact value for e (23) on this system size, which is indicated by the straight line in Fig. 1. The time series

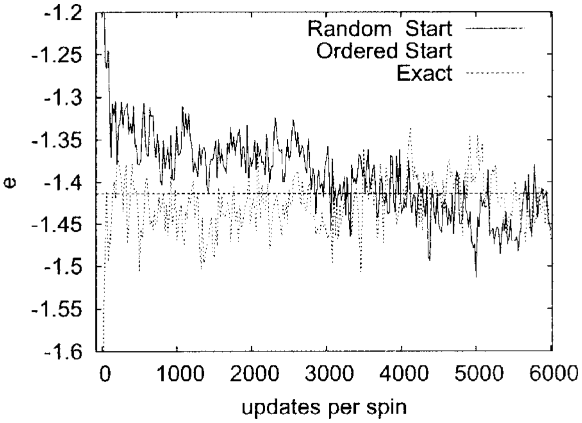

Figure 1. Two-dimensional Ising model: Two initial Metropolis time series for the energy per spin e.

corresponding to the ordered start begins at $e = -2$ and approaches the exact value from below, whereas the other time series begins (up to statistical fluctuation) at $e = 0$ and approaches the exact value from above. It takes a rather long MCMC time of about 3000 to 4000 updates per spin until the two time series start to mix. For estimating equilibrium expectation values, measurements should only be counted from there on. A serious error analysis for the subsequent equilibrium simulation finds an integrated autocorrelation time of $\tau_{\text{int}} \approx 1700$ updates per spin. This long autocorrelation time is related to the proximity of the phase transition (this is the so-called critical slowing down of the dynamics). One can show that, at the transition point, τ_{int} diverges like a power of N.

For this model and a number of other systems with second-order phase transitions, cluster algorithms (24,25) are known, which have much shorter autocorrelation times, in simulations close to the phase transition point. For the simulation of Fig. 1, $\tau_{\text{int}} \approx 5$ updates per spin instead of 1700. Furthermore, for cluster algorithms, τ_{int} grows much slower with the system size N than for the Metropolis algorithm. This happens because these algorithms allow for the instantaneous flip of large clusters of spins (still with order one acceptance probability) in contrast to the local updates of single spins done in the Metropolis and heat-bath-type algorithms. Unfortunately such nonlocal updating algorithms have remained confined to special situations. The interested reader can reproduce these Ising model simulations discussed here using the code that comes with Ref. 19.

UPDATING SCHEMES

We give an overview of MCMC updating schemes that is, because of space limitations, not complete at all.

1. We have already discussed the Metropolis scheme (1) and its generalization by Hastings (7). Variables of the system are locally updated.
2. Within such local schemes, the heat-bath method (12-14) is usually the most efficient. In practice it can be approximated by tabulating Metropolis–Hastings probabilities (22).
3. For simulations at (very) low temperatures, event-driven simulations (26,27), also known as the "N-fold way," are most efficient. They are based on Metropolis or heat-bath schemes.
4. As mentioned before, for a number of models with second order phase transitions the MCMC efficiency is greatly improved by using nonlocal cluster updating (24).
5. Molecular dynamics (MD) moves can be used as proposals in MCMC updating (28,29), a scheme called "hybrid MC", see Ref. (30) for a review of MD simulations.

More examples can be found in the W. Krauth contribution in Ref. (31) and A. D. Sokal in Ref. (32).

GENERALIZED ENSEMBLES FOR MCMC SIMULATIONS

The MCMC method, which we discussed for the Ising model, generates configurations distributed according to the Boltzmann–Gibbs canonical ensemble, with weights $P_{B,s}$. Mean values of physical observables at the temperature chosen are obtained as arithmetic averages of the measurements made [Equation 7]. There are, however, in statistical physics, circumstances where another ensemble (other weights $P_{NB,s}$) can be more convenient. One case is the computation of the partition function $Z(T)$ as a function of temperature. Another is the investigation of configurations of physical interest that are rare in the canonical ensemble. Finally the efficiency of the Markov process, i.e., the computer time needed to obtain a desired accuracy, can depend greatly on the ensemble in which the simulations are performed. This is the case, for example when taking into account the Boltzmann weights, the phase space separates, loosely speaking, into several populated regions separated by mostly vacant regions, creating so-called free energy barriers for the Markov chain.

A first attempt to calculate the partition function by MCMC simulations dates back to a 1959 paper by Salsburg et al. Ref. (33). As noticed by the authors, their method is restricted to very small lattices. The reason is that their approach relies on what is called in the modern language "reweighting." It evaluates results at a given temperature from data taken at another temperature. The reweighting method has a long history. McDonald and Singer (34) were the first to use it to evaluate physical quantities over a range of temperatures from a simulation done at a single temperature. Thereafter dormant, the method was rediscovered in an article (35) focused on calculating complex zeros of the partition function. It remained to Ferrenberg and Swendsen (36), to formulate a crystal clear picture for what the method is particularly good, and for what it is not: The reweighting method allows for focusing on maxima of appropriate observables, but it does not allow for covering a finite temperature range in the infinite volume limit.

To estimate the partition function over a finite energy density range Δe, i.e., $\Delta E \sim N$, one can patch the histograms from simulations at several temperatures. Such multi-histogram methods also have a long tradition. In 1972 Valleau and Card (37) proposed the use of overlapping bridging distributions and called their method "multistage sampling." Free energy and entropy calculations become possible when one can link the temperature region of interest with a range for which exact values of these quantities are known. Modern work (38,39) developed efficient techniques to combine the overlapping distributions into one estimate of the spectral density $\rho(E)$ [with $Z(T) = \int dE\rho(E)\exp(-\beta E)$] and to control the statistical errors of the estimate. However, the patching of histograms from canonical simulations faces several limitations:

1. The number of canonical simulations needed diverges like $\sqrt{N}$ when one wants to cover a finite, noncritical range of the energy density.
2. At a first-order phase transition point, the canonical probability of configurations with an interface decreases exponentially with N.

One can cope with the difficulties of multi-histogram methods by allowing arbitrary sampling distributions instead of just the Boltzmann–Gibbs ensemble. This was first recognized by Torrie and Valleau (15) when they introduced umbrella sampling. However, for the next 13 years, the potentially very broad range of applications of the basic idea remained unrecognized. A major barrier, which prevented researchers from trying such extensions, was certainly the apparent lack of direct and straightforward ways of determining suitable weighting functions $P_{NB,s}$ for problems at hand. In the words of Li and Scheraga (40): *The difficulty of finding such weighting factors has prevented wide applications of the umbrella sampling method to many physical systems*.

This changed with the introduction of the multicanonical ensemble multicanonical ensemble (41), which focuses on well-defined weight functions and offers a variety of methods to find a "working approximation." Here a working approximation is defined as being accurate enough, so that the desired energy range will indeed be covered after the weight factors are fixed. A similar approach can also be constructed for cluster algorithms (42). A typical simulation consists then of three parts:

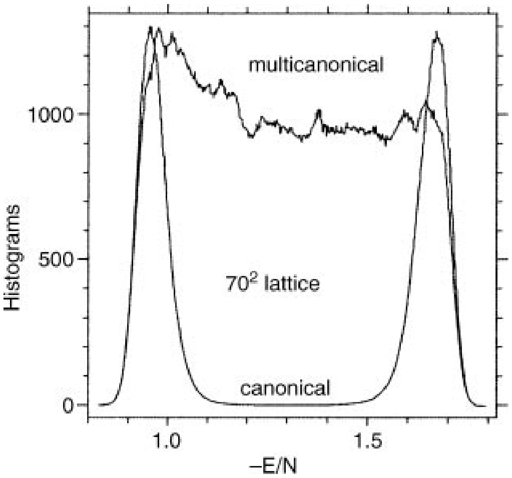

Figure 2. Multicanonical $P_{\text{muca}}(E)$ together with canonical $P(E)$ energy distribution as obtained in Ref. 41 for the $2d$ 10-state Potts model on a 70×70 lattice. In the multicanonical ensemble, the gap between the two peaks present in $P(E)$ is filled up, accelerating considerably the dynamics of the Markov Chain.

1. Construct a working approximation of the weight function P_{muca}. The Wang–Landau recursion (43) is an efficient approach. See Ref. (44) for a comparison with other methods.
2. Perform a conventional MCMC simulation with these weight factors.
3. Reweight the data to the desired ensemble: $\langle \mathcal{O} \rangle = \lim_{N_{\text{samples}} \to \infty} \frac{1}{N_{\text{samples}}} \sum_{s=1}^{N_{\text{samples}}} \mathcal{O}_s P_{B,s}/P_{\text{muca,s}}$ Details can be found in Ref. 19.

Another class of algorithms appeared in a couple of years around 1991 in several papers (45–50), which all aimed at improving MCMC calculations by extending the confines of the canonical ensemble. Practically most important has been the replica exchange method, which is also known under the names parallel tempering and multiple Markov chains. In the context of spin glass simulations, an exchange of partial lattice configurations at different temperatures was proposed by Swendsen and Wang (45). But it was only recognized later (46,50) that the special case for which entire configurations are exchanged is of utmost importance, see Ref. 19 for more details. Closely related is the Jump Walker (J-Walker) approach (51), which feeds replica from a higher temperature into a simulation at a lower temperature instead of exchanging them. But in contrast to the replica exchange method this procedure disturbs equilibrium to some extent. Finally, and perhaps most importantly, from about 1992 on, applications of generalized ensemble methods diversified tremendously as documented in a number of reviews (52–54).

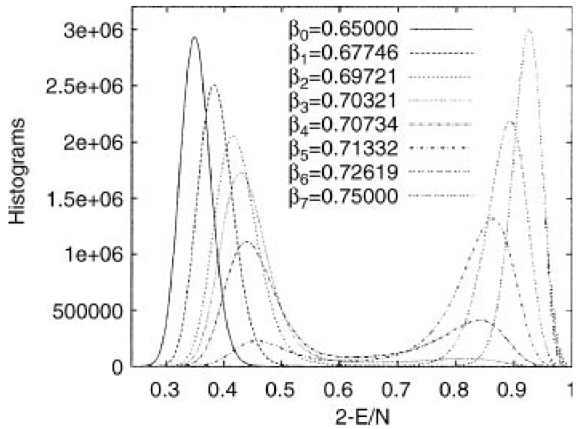

Figure 3. Canonical energy distributions $P(E)$ from a parallel tempering simulation with eight processes for the $2d$ 10-state Potts model on 20×20 lattices (Fig. 6.2 in Ref. 19).

The basic mechanisms for overcoming energy barriers with the multicanonical algorithm are best illustrated for first-order phase transitions (namely a transition with a nonzero latent heat, like the ice–water transition), where one deals with a single barrier. For a finite system the temperature can be fine-tuned to a pseudocritical value, which is defined so that the energy density exhibits two peaks of equal heights. To give an example, Fig. 2 shows for the $2d$ 10-state Potts (55) the canonical energy histogram at a pseudocritical temperature versus the energy histogram of a multicanonical simulation (41). The same barrier can also be overcome by a parallel tempering simulation but in a quite different way. Figure 3 shows the histograms from a parallel tempering simulation with eight processes on 20×20 lattices. The barrier can be "jumped" when there are on both sides temperatures in the ensemble, which are sufficiently close to a pseudocritical temperature for which the two peaks of the histogram are of competitive height. In complex systems with a rugged free energy landscape (spin glasses, biomolecules, . . .), the barriers can no longer be explicitly controlled. Nevertheless it has turned out that switching to the discussed ensembles can greatly enhance the MCMC efficiency (53,54). For a recent discussion of ensemble optimization techniques, see Ref. (56) and references given therein.

MARKOV CHAINS

INTRODUCTION

A Markov chain is, roughly speaking, some collection of random variables with a temporal ordering that have the property that *conditional upon the present, the future does not depend on the past*. This concept, which can be viewed as a form of something known as the *Markov property*, will be made precise below, but the principle point is that such collections lie somewhere between one of *independent* random variables and a completely general collection, which could be extremely complex to deal with.

Andrei Andreivich Markov commenced the analysis of such collections of random variables in 1907, and their analysis remains an active area of research to this day. The study of Markov chains is one of the great achievements of probability theory. In his seminal work (1), Andrei Nikolaevich Kolmogorov remarked, "Historically, the independence of experiments and random variables represents the very mathematical concept that has given probability its peculiar stamp."

However, there are many situations in which it is necessary to consider sequences of random variables that *cannot* be considered to be independent. Kolmogorov went on to observe that "[Markov et al.] frequently fail to assume complete independence, they nevertheless reveal the importance of assuming analogous, weaker conditions, in order to obtain significant results." The aforementioned Markov property, the defining feature of the Markov chain, is such an *analogous, weaker condition* and it has proved both strong enough to allow many, powerful results to be obtained while weak enough to allow it to encompass a great many interesting cases.

Much development in probability theory during the latter part of the last century consisted of the study of sequences of random variables that are not entirely independent. Two weaker, but related conditions proved to be especially useful: the Markov property that defines the Markov chain and the *martingale* property. Loosely speaking, a martingale is a sequence of random variables whose expectation at any point in the future, which is conditional on the past and the present is equal to its current value. A broad and deep literature exists on the subject of martingales, which will not be discussed in this article. A great many people have worked on the theory of Markov chains, as well as their application to problems in a diverse range of areas, over the past century, and it is not possible to enumerate them all here.

There are two principal reasons that Markov chains play such a prominent role in modern probability theory. The first reason is that they provide a powerful yet tractable framework in which to describe, characterize, and analyze a broad class of sequences of random variables that find applications in numerous areas from particle transport through finite state machines and even in the theory of gene expression. The second reason is that a collection of powerful computational algorithms have been developed to provide samples from complicated probability distributions via the simulation of particular Markov chains: These *Markov chain Monte Carlo* methods are now ubiquitous in all fields in which it is necessary to obtain samples from complex probability distributions, and this has driven much of the recent research in the field of Markov chains.

The areas in which Markov chains occur are far too numerous to list here, but here are some typical examples:

- Any collection of independent random variables forms a Markov chain: In this case, given the present, the future is independent of the past *and the present*.
- The celebrated symmetric *random walk* over the integers provides a classic example: The next value taken by the chain is one more or less than the current value with equal probability, regardless of the route by which the current value was reached. Despite its simplicity, this example, and some simple generalizations, can exhibit a great many interesting properties.
- Many popular board games have a Markov chain representation, for example, "Snakes and Ladders," in which there are 100 possible states for each counter (actually, there are somewhat fewer, as it is not possible to end a turn at the top of a snake or the bottom of a ladder), and the next state occupied by any particular counter is one of the six states that can be reached from the current one, each with equal probability. So, the next state is a function of the current state and an external, independent random variable that corresponds to the roll of a die.
- More practically, the current amount of water held in a reservoir can be viewed as a Markov chain: The volume of water stored after a particular time interval will depend only on the volume of water stored now and two random quantities: the amount of water leaving the reservoir and the amount of water entering the reservoir. More sophisticated variants of this model are used in numerous areas, particularly within the field of queueing theory (where water volume is replaced by customers awaiting service).
- The evolution of a finite state machine can be viewed as the evolution of a (usually deterministic) Markov chain.

It is common to think of Markov chains as describing the trajectories of dynamic objects. In some circumstances, a natural dynamic system can be associated with a collection of random variables with the right conditional independence structure—the random walk example discussed previously, for example, can be interpreted as moving from one position to the next, with the nth element of the associated Markov chain corresponding to its position at discrete time index n. As the distribution of each random variable in the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

sequence depends only on the value of the previous element of the sequence, one can endow any such collection (assuming that one can order the elements of the collection, which the definition of a Markov chain employed here ensures is always possible) with a dynamic structure. One simply views the distribution of each element, conditional on the value of the previous one as being the probability of *moving* between those states at that time. This interpretation provides no great insight, but it can allow for simpler interpretations and descriptions of the behavior of collections of random variables of the sort described here. Indeed, it is the image of a chain of states, with each one leading to the next that suggests the term "Markov chain."

STOCHASTIC PROCESSES

To proceed to the formal definition of a Markov chain, it is first necessary to make precise what is meant by a collection of random variables with some temporal ordering. Such a collection of random variables may be best characterized as a stochastic process. An E-valued *process* is a function $X : \mathcal{I} \to E$ that maps values in some index set $\mathcal{I}$ to some other space E. The evolution of the process is described by considering the variation of $X_i := X(i)$ with i. An E-valued *stochastic process* (or *random process*) can be viewed as a process in which, for each $i \in \mathcal{I}$, X_i is a random variable taking values in E.

Although a rich literature on more general situations exists, this article will consider only *discrete time stochastic processes* in which the index set $\mathcal{I}$ is the natural numbers, $\mathbb{N}$ (of course, any index set isomorphic to $\mathbb{N}$ can be used in the same framework by simple relabeling). The notation X_i is used to indicate the value of the process at time i (note that there need be no connection between the index set and *real* time, but this terminology is both convenient and standard). Note that the Markov property may be extended to continuous time processes in which the index set is the positive real numbers, and this leads to a collection of processes known as either *Markov processes* or *continuous time Markov chains*. Such processes are not considered here in more detail, as they are of somewhat lesser importance in computer science and engineering applications. A rich literature on these processes does exist, and many of the results available in the discrete time case have continuous time analog—indeed, some results may be obtained considerably more naturally in the continuous time setting.

At this point, a note on terminology is necessary. Originally, the term "Markov chain" was used to describe any stochastic process with the Markov property and a finite state space. Some references still use this definition today. However, in computer science, engineering, and computational statistics, it has become more usual to use the term to refer to any discrete time stochastic process with the Markov property, regardless of the state space, and this is the definition used here. Continuous time processes with the Markov property will be termed Markov processes, and little reference will be made to them. This usage is motivated by considerations developing from Markov chain Monte Carlo methods and is standard in more recent literature.

Filtrations and Stopping Times

This section consists of some technical details that, although not essential to a basic understanding of the stochastic process or Markov chains in particular, are fundamental and will be encountered in any work dealing with these subjects.

A little more technical structure is generally required to deal with stochastic processes than with simple random variables. Although technical details are avoided as far as possible in this article, the following concept will be needed to understand much of the literature on Markov chains.

To deal with simple random variables, it suffices to consider a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ in which Ω is the set of events, $\mathcal{F}$ is the σ-algebra corresponding to the collection of measurable outcomes (i.e., the collection of subsets of Ω to which it is possible to assign a probability; typically the collection of all subsets of Ω in the discrete case), and $\mathbb{P}$ is the probability *measure*, which tells us the probability that any element of $\mathcal{F}$ contains the event that occurs as follows: $\mathbb{P} : \mathcal{F} \to [0, 1]$. To deal with stochastic processes, it is convenient to define a *filtered probability space*$(\Omega, \mathcal{F}, \{\mathcal{F}_i\}_{i \in \mathbb{N}}, \mathbb{P})$. The collection of sub-$\sigma$-algebras, $\{\mathcal{F}_i\}_{i \in \mathbb{N}}$, which is termed a *filtration*, has a particular structure:

$$\mathcal{F}_1 \subset \mathcal{F}_2 \subset \ldots \subset \mathcal{F}_n \subset \mathcal{F}_{n+1} \subset \ldots \subset \mathcal{F}$$

and its most important property is that, for any n, the collection of variables $X_1, X_2, \ldots, X_n$ must be measurable with respect to $\mathcal{F}_n$. Although much more generality is possible, it is usually sufficient to consider the *natural filtration* of a process: that is the one generated by the process itself. Given any collection of random variables of a common probability space, a smallest σ-algebra exists with respect to which those random variables are jointly measurable. The natural filtration is the filtration generated by setting each $\mathcal{F}_n$ equal to the smallest σ-algebra with respect to which $X_1, \ldots, X_n$ are measurable. Only this filtration will be considered in the current article. An intuitive interpretation of this filtration, which provides increasingly fine subdivisions of the probability space, is that $\mathcal{F}_n$ tells us how much information can be provided by knowledge of the values of the first n random variables: It tells us which events can be be distinguished given knowledge of $X_1, \ldots, X_n$.

It is natural when considering a process of this sort to ask questions about *random times*: Is there anything to stop us from defining additional random variables that have an interpretation as the index, which identifies a particular time in the evolution of the process? In general, some care is required if these random times are to be useful: If the temporal structure is real, then it is necessary for us to be able to determine whether the time which has been reached so far is the time of interest, given some realization of the process up to that time. Informally, one might require that $\{\tau = n\}$ can be ascribed a probability of zero or one, given knowledge of the first n states, for any n. In fact, this is a little stronger than the actual requirement, but it provides a simple interpretation that suffices for many purposes. Formally, if $\tau : \Omega \to \mathcal{I}$ is a random time, and the event $\{\omega : \tau(\omega) = n\} \in \mathcal{F}_n$ for all n, then τ is known as a *stopping time*. Note that this condition amounts to requiring that the event $\{\omega : \tau(\omega) = n\}$ is *independent* of all subsequent states of the chain, $X_{n+1}, X_{n+2}, \ldots$ conditional upon $X_1, \ldots, X_n$. The most common example of a stopping time is the *hitting time*, τ_A, of a set A:

$$\tau_A := \inf\{n : X_n \in A\}$$

which corresponds to the first time that the process enters the set A. Note that the apparently similar

$$\tau_A' = \inf\{n : X_{n+1} \in A\}$$

is *not* a stopping time (in any degree of generality) as the state of the chain at time $n+1$ is not necessarily known in terms of the first n states.

Note that this distinction is not an artificial or frivolous one. Consider the chain produced by setting $X_n = X_{n-1} + W_n$ where $\{W_n\}$ are a collection of independent random variables that correspond to the value of a gambler's winnings, in dollars, in the nth independent game that he plays. If $A = [10,000, \infty)$, then τ_A would correspond to the event of having won \$10,000, and, indeed, it would be possible to stop when this occurred. Conversely, if $A = (-\infty, -10,000]$, then τ_A' would correspond to the last time before that at which \$10,000 have been lost. Although many people would like to be able to stop betting immediately *before* losing money, it is not possible to know that one *will* lose the next one of a sequence of independent games.

Given a stopping time, τ, it is possible to define the *stopped process*, $X_1^\tau, X_2^\tau, \ldots$, associated with the process $X_1, X_2, \ldots$, which has the expected definition; writing $m \wedge n$ for the smaller of m and n, define $X_n^\tau = X_{\tau \wedge n}$. That is, the stopped process corresponds to the process itself at all times up to the random stopping time, after which it takes the value it had at that stopping time: It stops. In the case of τ_A, for example, the stopped process mirrors the original process until it enters A, and then it retains the value it had upon entry to A for all subsequent times.

MARKOV CHAINS ON DISCRETE STATE SPACES

Markov chains that take values in a discrete state space, such as the positive integers or the set of colors with elements red, green, and blue, are relatively easy to define and use. Note that this class of Markov chains includes those whose state space is countably infinite: As is often the case with probability, little additional difficulty is introduced by the transition from finite to countable spaces, but considerably more care is needed to deal rigorously with uncountable spaces.

To specify the distribution a Markov chain on a discrete state space, it is intuitively sufficient to provide an initial distribution, the marginal distribution of its first element, and the conditional distributions of each element given the previous one. To formalize this notion, and precisely what the *Markov property* referred to previously means, it is useful to consider the joint probability distribution of the first n elements of the Markov chain. Using the definition of conditional probability, it is possible to write the joint distribution of n random variables, $X_1, \ldots, X_n$, in the following form, using $X_{1:n}$ to denote the vector $(X_1, \ldots, X_n)$:

$$\mathbb{P}(X_{1:n} = x_{1:n}) = \mathbb{P}(X_1 = x_1) \\ \prod_{i=2}^{n} \mathbb{P}(X_i = x_i | X_{1:i-1} = x_{1:i-1})$$

The probability that each of the first n elements takes particular values can be decomposed recursively as the probability that all but one of those elements takes the appropriate value and the conditional probability that the remaining element takes the specified value given that the other elements take the specified values.

This decomposition could be employed to describe the *finite-dimensional distributions* (that is, the distribution of the random variables associated with finite subsets of $\mathcal{I}$) of any stochastic process. In the case of a Markov chain, the distribution of any element is influenced only by the previous state if the entire history is known: This is what is meant by the statement that "conditional upon the present, the future is independent of the past." This property may be written formally as

$$\mathbb{P}(X_n = x_n | X_{1:n-1} = x_{1:n-1}) = \mathbb{P}(X_n = x_n | X_{n-1} = x_{n-1})$$

and so for any discrete state space Markov chain:

$$\mathbb{P}(X_{1:n} = x_{1:n}) = \mathbb{P}(X_1 = x_1) \prod_{i=2}^{n} \mathbb{P}(X_i = x_i | X_{i-1} = x_{i-1})$$

As an aside, it is worthwhile to notice that Markov chains encompass a much broader class of stochastic processes than is immediately apparent. Given any stochastic process in which for all $n > L$ and $x_{1:n-1}$,

$$\mathbb{P}(X_n = x_n | X_{1:n-1} = x_{1:n-1}) = \mathbb{P}(X_n = x_n | X_{n-L:n-1} = x_{n-L:n-1})$$

it suffices to consider a process Y on the larger space E^L defined as

$$Y_n = (X_{n-L+1}, \ldots, X_n)$$

Note that $(X_{1-L}, \ldots, X_0)$ can be considered arbitrary without affecting the argument. Now, it is straightforward to determine that the distribution of Y_{n+1} depends only on Y_n. In this way, any stochastic process with a finite memory may be cast into the form of a Markov chain on an extended space.

The Markov property, as introduced above, is more correctly known as the *weak Markov property*, and in the case of Markov chains in which the transition probability is not explicitly dependent on the time index, it is normally written in terms of expectations of integrable test function $\xi : E^m \to \mathbb{R}$, where m may be any positive integer. The weak Markov property in fact tells us that the expected value of the integral of any integrable test function over the next m states of a Markov chain depends only on the value of the current state, so for any n and any $x_{1:n}$:

$$\mathbb{E}[\xi(X_{n+1},\ldots,X_{n+m})|X_{1:n}] = \mathbb{E}[\xi(X_{n+1},\ldots,X_{n+m+1})|X_n]$$

It is natural to attempt to generalize this by considering random times rather than deterministic ones. The *strong Markov property* requires that, for any stopping time τ, the following holds:

$$\mathbb{E}[\xi(X_{\tau+1},\ldots,X_{\tau+m})|X_{1:\tau}] = \mathbb{E}[\xi(X_{\tau+1},\ldots,X_{\tau+m+1})|X_\tau]$$

In continuous time settings, these two properties allow us to distinguish between weak and strong Markov processes (the latter is a strict subset of the former, because $\tau = n$ is a stopping time). However, in the discrete time setting, the weak and strong Markov properties are equivalent and are possessed by Markov chains as defined above.

It is conventional to view a Markov chain as describing the path of a dynamic object, which *moves* from one state to another as time passes. Many physical systems that can be described by Markov chains have precisely this property—for example, the motion of a particle in an absorbing medium. The position of the particle, together with an indication as to whether it has been absorbed or not, may be described by a Markov chain whose states contain coordinates and an absorbed/not-absorbed flag. It is then natural to think of the initial state as having a particular distribution, say, $\mu(x_1) = \mathbb{P}(X_1 = x_1)$ and, furthermore, for there to be some *transition kernel* that describes the distribution of moves from a state x_{n-1} to a state x_n at time n, say, $K_n(x_{n-1},x_n) = \mathbb{P}(X_n = x_n|X_{n-1} = x_{n-1})$. This allows us to write the distribution of the first n elements of the chain in the compact form:

$$\mathbb{P}(X_{1:n} = x_{1:n}) = \mu(x_1)\prod\nolimits_{i=2}^{n} K_i(x_{i-1},x_i)$$

Nothing is preventing these transition kernels from being explicitly dependent on the time index; for example, in the reservoir example presented above, one might expect both water usage and rainfall to have a substantial seasonal variation, and so the volume of water stored tomorrow would be influenced by the date as well as by that volume stored today. However, it is not surprising that for a great many systems of interest (and most of those used in computer simulation) that the transition kernel has no dependence on the time. Markov chains that have the same transition kernel at all times are termed *time homogeneous* (or sometimes simply homogeneous) and will be the main focus of this article.

In the time homogeneous context, the n-step transition kernels denoted K^n, which have the property that $\mathbb{P}(X_{m+n} = x_{m+n}|X_m = x_m) = K^n(x_m,x_{m+n})$ may be obtained inductively, as

$$K^n(x_m,x_{m+n}) = \sum_{x_{m+1}} K(x_m,x_{m+1})K^{n-1}(x_{m+1},x_{m+n})$$

for any $n > 1$, whereas $K^1(x_m,x_{m+1}) = K(x_m,x_{m+1})$.

A Matrix Representation

The functional notation above is convenient, as it generalizes to Markov chains on state spaces that are not discrete. However, discrete state space Markov chains exist in abundance in engineering and particularly in computer science. It is convenient to represent probability distributions on finite spaces as a row vector of probability values. To define such a vector μ, simply set $\mu_i = \mathbb{P}(X = i)$ (where X is some random variable distributed according to μ). It is also possible to define a Markov kernel on this space by setting the elements of a matrix K equal to the probability of moving from a state i to a state j; i.e.:

$$K_{ij} = \mathbb{P}(X_n = j|X_{n-1} = i)$$

Although this may appear little more than a notational nicety, it has some properties that make manipulations particularly straightforward; for example, if $X_1 \sim \mu$, then:

$$\begin{aligned}\mathbb{P}(X_2 = j) &= \sum_i \mathbb{P}(X_1 = i)\mathbb{P}(X_2 = j|X_1 = i)\\ &= \sum_i \mu_i K_{ij}\\ &= (\mu K)_j\end{aligned}$$

where μK denotes the usual vector matrix product and $(\mu K)_j$ denotes the jth element of the resulting row vector.In fact, it can be shown inductively that $\mathbb{P}(X_n = j) = (\mu K^{n-1})_j$, where K^{n-1} is the usual matrix power of K. Even more generally, the conditional distributions may be written in terms of the *transition matrix*, K:

$$\mathbb{P}(X_{n+m} = j|X_n = i) = (K^m)_{ij}$$

and so a great many calculations can be performed via simple matrix algebra.

A Graphical Representation

It is common to represent a homogeneous, finite-state space Markov chain graphically. A single directed graph with labeled edges suffices to describe completely the transition matrix of such a Markov chain. Together with the distribution of the initial state, this completely characterizes the Markov chain. The vertices of the graph correspond to the states, and those edges that exist illustrate the moves that it is possible to make. It is usual to label the edges with the probability associated with the move that they represent, unless all possible moves are equally probable.

A simple example, which also shows that the matrix representation can be difficult to interpret, consists of the Markov chain obtained on the space $\{0,1,\ldots,9\}$ in which the next state is obtained by taking the number rolled on an unbiased die and adding it, modulo 10, to the current state *unless a 6 is rolled when the state is 9*, in which case, the chain retains its current value. This has a straightforward, but cumbersome matrix representation, in which:

$$K = \frac{1}{6}\begin{bmatrix} 0 & 1 & 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 \\ 1 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

Figure 1 shows a graphical illustration of the same Markov transition kernel—transition probabilities are omitted in this case, as they are all equal. Although it may initially seem no simpler to interpret than the matrix, on closer inspection, it becomes apparent that one can easily determine from which states it is possible to reach any selected state, which states it is possible to reach from it and those states it is possible to move between in a particular number of moves *without performing any calculations*. It is these properties that this representation makes it very easy to interpret even in the case of Markov chains with large state spaces for which the matrix representation rapidly becomes very difficult to manipulate. Note the *loop* in the graph showing the possibility of remaining in state 9—this is equivalent to the presence of a nonzero diagonal element in the transition matrix.

MARKOV CHAINS ON GENERAL STATE SPACES

In general, more subtle measure theoretic constructions are required to define or study Markov chains on *uncountable* state spaces—such as the real numbers or the points in three-dimensional space. To deal with a fully general state space, a degree of measure theoretic probability beyond that which can be introduced in this article is required. Only Markov chains on some subset of d-dimensional, Euclidean space, $\mathbb{R}^d$ with distributions and transition kernels that admit a density (for definiteness, with respect to Lebesgue measure—that which attributes to any interval mass corresponding to its length—over that space) will be considered here. $K_n(x,y)$ (or $K(x,y)$ in the time homogeneous case) denotes a density with the property that

$$\mathbb{P}(X_n \in A | X_{n-1} = x_{n-1}) = \int_A K_n(x_{n-1},y)dy$$

This approach has the great advantage that many concepts may be written for discrete and continuous state space cases in precisely the same manner, with the understanding that the notation refers to probabilities in the discrete case and densities in the continuous setting. To generalize things, it is necessary to consider Lebesgue integrals with respect to the measures of interest, but essentially, one can replace equalities of densities with those of integrals over any measurable set and the definitions and results presented below will continue to hold. For a rigorous and concise introduction to general state space Markov chains, see Ref. 2. For a much more detailed exposition, Ref. 3 is recommended highly.

STATIONARY DISTRIBUTIONS AND ERGODICITY

The ergodic hypothesis of statistical mechanics claims, loosely, that given a thermal system at equilibrium, the long-term average occurrence of any given system configuration corresponds precisely to the average over an infinite

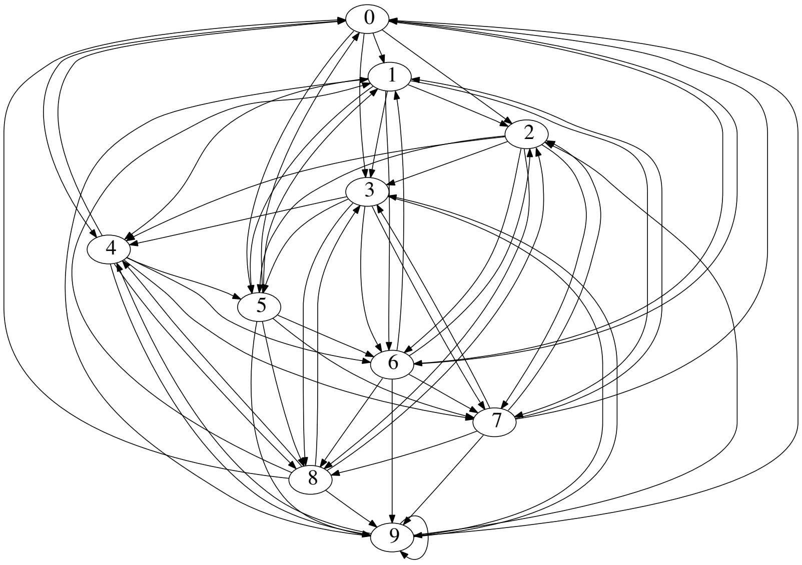

Figure 1. A graphical representation of a Markov chain.

ensemble of identically prepared systems at the same temperature. One area of great interest in the analysis of Markov chains is that of establishing conditions under which a (mathematically refined form of) this assertion can be shown to be true: When are averages obtained by considering those states occupied by a Markov chain over a long period of its evolution close to those that would be obtained by calculating the average under some distribution associated with that chain? Throughout this section, integrals over the state space are used with the understanding that in the discrete case these integrals should be replaced by sums. This process minimizes the amount of duplication required to deal with both discrete and continuous state spaces, which allows the significant differences to be emphasized when they develop.

One of the most important properties of homogeneous Markov chains, particularly within the field of simulation, is that they can admit a *stationary* (or *invariant*) distribution. A transition kernel K is π-stationary if

$$\int \pi(x)K(x,y)dx = \pi(y)$$

That is, given a sample $X = x$ from π, the distribution of a random variable Y, drawn from $K(x,\cdot)$ is the same as that of X, although the two variables are, of course, not independent. In the discrete case, this becomes

$$\sum_i \pi(i)K(i,j) = \pi(j)$$

or, more succinctly, in the matrix representation, $\pi K = \pi$. The last of these reveals a convenient characterization of the stationary distributions, where they exist, of a transition kernel: They are the left eigenvectors (or eigenfunctions in the general state space case) of the transition kernel with an associated eigenvalue of 1. Viewing the transition kernel as an operator on the space of distributions, the same interpretation is valid in the general state space case.

It is often of interest to simulate evolutions of Markov chains with particular stationary distributions. Doing so is the basis of Markov chain Monte Carlo methods and is beyond the scope of this article. However, several theoretical concepts are required to determine when these distributions exist, when they are unique, and when their existence is enough to ensure that a large enough sample path will have similar statistical properties to a collection of independent, identically distributed random variables from the stationary distribution. The remainder of this section is dedicated to the introduction of such concepts and to the presentation of two results that are of great importance in this area.

One property useful in the construction of Markov chains with a particular invariant distributions is that of *reversibility*. A stochastic process is termed reversible if the statistical properties of its time reversal are the same as those of the process itself. To make this concept more formal, it is useful to cast things in terms of certain joint probability distributions. A stationary process is reversible if for any n, m, the following equality holds for all measurable sets $A_n, \ldots, A_{n+m}$:

$$\mathbb{P}(X_n \in A_n, \ldots, X_{n+m} \in A_{n+m}) = \mathbb{P}(X_n \in A_n, \ldots, X_{n-m} \in A_{n+m})$$

It is simple to verify that, in the context of a Markov chain, this is equivalent to the *detailed balance* condition:

$$\mathbb{P}(X_n \in A_n, X_{n+1} \in A_{n+1}) = \mathbb{P}(X_n \in A_{n+1}, X_{n+1} \in A_n)$$

A Markov chain with kernel K is said to satisfy detailed balance for a distribution π if

$$\pi(x)K(x,y) = \pi(y)K(y,x)$$

It is straightforward to verify that, if K is π-reversible, then π is a stationary distribution of K:

$$\begin{aligned} \int \pi(x)K(x,y)dy &= \int \pi(y)K(y,x)dy \\ \pi(x) &= \int \pi(y)K(y,x)dy \end{aligned}$$

This is particularly useful, as the detailed balance condition is straightforward to verify.

Given a Markov chain with a particular stationary distribution, it is important to be able to determine whether, over a long enough period of time, the chain will explore all of the space, which has a positive probability under that distribution. This leads to the concepts of *accessibility, communication structure*, and *irreducibility*.

In the discrete case, a state j is said to be *accessible* from another state i written as $i \rightarrow j$, if for some n, $K^n(i,j) > 0$. That is, a state that is accessible from some starting point is one that can be reached with positive probability in some number of steps. If i is accessible from j and j is accessible from i, then the two states are said to *communicate*, and this is written as $i \leftrightarrow j$. Given the Markov chain on the space $E = \{0,1,2\}$ with transition matrix:

$$K = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{2} & \frac{1}{2} \\ 0 & \frac{1}{2} & \frac{1}{2} \end{bmatrix}$$

it is not difficult to verify that the uniform distribution $\mu = (\frac{1}{3}, \frac{1}{3}, \frac{1}{3})$ is invariant under the action of K. However, if $X_1 = 0$, then $X_n = 0$, for all n: The chain will never reach either of the other states, whereas starting from $X_1 \in \{1,2\}$, the chain will never reach 0. This chain is *reducible*: Some disjoint regions of the state space do not communicate. Furthermore, it has multiple stationary distributions; $(1,0,0)$ and $(0,\frac{1}{2},\frac{1}{2})$ are both invariant under the action of K. In the discrete setting, a chain is *irreducible* if all states communicate: Starting from any point in the state space, any other point may be reached with positive probability in some finite number of steps.

Although these concepts are adequate for dealing with discrete state spaces, a little more subtlety is required in more general settings: As ever, when dealing with probability on continuous spaces, the probability associated with individual states is generally zero and it is necessary to consider integrals over finite regions. The property that is captured by *irreducibility* is that, wherever the chain starts from, a positive probability of it reaches anywhere in the space. To generalize this to continuous state spaces, it suffices to reduce the strength of this statement very slightly: From "most" starting points, the chain has a positive probability of reaching any region of the space that itself has positive probability. To make this precise, a Markov chain of stationary distribution π is said to be π-irreducible if, for all x (except for those lying in a set of exceptional points that has probability 0 under π), and all sets A with the property that $\int_A \pi(x)dx > 0$,

$$\exists n : \int_A K^n(x,y)dy > 0$$

The terms *strongly irreducible* and *strongly* π*-irreducible* are sometimes used when the irreducibility or π-irreducibility condition, respectively, holds for $n = 1$. Notice that any irreducible Markov chain is π-irreducible with respect to any measure π.

These concepts allow us to determine whether a Markov chain has a "joined-up" state space: whether it is possible to move around the entire space (or at least that part of the space that has mass under π). However, it tells us nothing about *when* it is possible to reach these points. Consider the difference between the following two transition matrices on the space $\{0, 1\}$; for example,

$$K = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} \end{bmatrix} \text{and } L = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

Both matrices admit $\pi = (\frac{1}{2}, \frac{1}{2})$ as a stationary distribution, and both are irreducible. However, consider their respective marginal distributions after several iterations:

$$K^n = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} \end{bmatrix}, \text{whereas } L^n = \begin{cases} \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} & n \text{ odd} \\ \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} & n \text{ even} \end{cases}$$

In other words, if $\mu = (\mu_1, \mu_2)$, then the Markov chain associated with K has distribution $\mu K^n = (\frac{1}{2}, \frac{1}{2})$ after n iterations, whereas that associated with L has distribution (μ_2, μ_1) after any odd number of iterations and distribution (μ_1, μ_2) after any even number. L, then, never forgets its initial conditions, and it is *periodic*.

Although this example is contrived, it is clear that such periodic behavior is significant and that a precise characterization is needed. This is straightforward in the case of discrete state space Markov chains. The period of any state, i in the space is defined, using gcd to refer to the greatest common divisor (i.e., the largest common factor), as

$$d = \gcd\{n : K^n(i,i) > 0\}$$

Thus, in the case of L, above, both states have a period $d = 2$. In fact, it can be shown easily, that any pair of states that communicate must have the same period. Thus, irreducible Markov chains have a single period, 2, in the case of L, above and 1, in the case of K. Irreducible Markov chains may be said to have a period themselves, and when this period is 1, they are termed *aperiodic*.

Again, more subtlety is required in the general case. It is clear that something is needed to fill the role that individual states play in the discrete state space case and that individual states are not appropriate in the continuous case. A set of events that is small enough that it is, in some sense, homogeneous and large enough that it has positive probability under the stationary distribution is required. A set C is termed *small* if some integer n, some probability distribution ν, and some $\epsilon > 0$ exist such that the following condition holds:

$$\inf_{x \in C} K^n(x,y) \geq \epsilon \nu(y)$$

This condition tells us that for any point in C, with probability ϵ, the distribution of the next state the chain enters is independent of *where in* C it is. In that sense, C is small, and these sets are precisely what is necessary to extend much of the theory of Markov chains from the discrete state space case to a more general setting. In particular, it is now possible to extend the notion of period from the discrete state space setting to a more general one. Note that in the case of irreducible aperiodic Markov chains on a discrete state space, the entire state space is small.

A Markov chain has a cycle of length d if a small set C exists such that the greatest common divisor of the length of paths from C to a measurable set of positive probability B is d. If the largest cycle possessed by a Markov chain has length 1, then that chain is *aperiodic*. In the case of π-irreducible chains, every state has a common period (except a set of events of probability 0 under π), and the above definition is equivalent to the more intuitive (but more difficult to verify) condition, in which a partition of the state space, E, into d disjoint subsets $E_1, \ldots, E_d$ exists with the property that $\mathbb{P}(X_{n+1} \neq \in E_j | X_n \in E_i) = 0$ if $j = i + 1 \bmod d$.

Thus far, concepts that allow us to characterize those Markov chains that can reach every important part of the space and that exhibit no periodic structure have been introduced. Nothing has been said about *how often* a given region of the space might be visited. This point is particularly important: A qualitative difference exists between chains that have a positive probability of returning to a set infinitely often and those that can only visit it finitely many times. Let η_A denote the number of times that a set A is visited by a Markov chain; that is, $\eta_A = |\{X_n \in A : n \in \mathbb{N}\}|$. A π-irreducible Markov chain is recurrent if $\mathbb{E}[\eta_A] = \infty$ for every A with positive probability under π. Thus, a recurrent Markov chain is one with positive probability of visiting any significant (with respect to π) part of the state space infinitely often: It does not always escape to infinity. A slightly stronger condition is termed *Harris recurrence*; it requires that every significant state *is* visited infinitely often (rather than this event having positive probability); i.e., $\mathbb{P}(\eta_A = \infty) = 1$ for every set A for which $\int_A \pi(x)dx > 0$. A Markov chain that is not recurrent is termed *transient*.

The following example illustrates the problems that can originate if a Markov chain is π-recurrent but *not* Harris recurrent. Consider the Markov chain over the positive integers with the transition kernel defined by

$$K(x,y) = x^{-2}\delta_1(y) + (1 - x^{-2})\delta_{x+1}(y)$$

where for any state, x, δ_x denotes the probability distribution that places all of its mass at x. This kernel is clearly δ_1-recurrent: If the chain is started from 1, it stays there deterministically. However, as the sum

$$\sum_{k=2}^{\infty} \frac{1}{k^2} < \infty$$

the Borel–Cantelli lemma ensures that whenever the chain is started for any x greater than 1, a positive probability exists that the chain will *never* visit state 1—the chain is π-recurrent, but it is not Harris recurrent. Although this example is somewhat contrived, it illustrates an important phenomenon—and one that often cannot be detected easily in more sophisticated situations. It has been suggested that Harris recurrence can be interpreted as a guarantee that no such pathological system trajectories exist: No parts of the space exist from which the chain will escape to infinity rather than returning to the support of the stationary distribution.

It is common to refer to a π-irreducible, aperiodic, recurrent Markov chain as being ergodic and to an ergodic Markov chain that is also Harris recurrent as being *Harris ergodic*. These properties suffice to ensure that the Markov chain will, on average, visit every part of the state space in proportion to its probability under π, that it exhibits no periodic behavior in doing so, and that it might (or will, in the Harris case) visit regions of the state space with positive probability infinitely often. Actually, ergodicity tells us that a Markov chain eventually forgets its initial conditions—after a sufficiently long time has elapsed, the current state provides arbitrarily little information about the initial state. Many stronger forms of ergodicity provide information about the *rate* at which the initial conditions are forgotten; these are covered in great detail by Meyn and Tweedie (3). Intuitively, if a sequence of random variables forgets where it has been, but has some stationary distribution, then one would expect the distribution of sufficiently widely separated samples to approximate that of independent samples from that stationary distribution. This intuition can be made rigorous and is strong enough to tell us a lot about the distribution of large samples obtained by iterative application of the Markov kernel and the sense in which approximations of integrals obtained by using the empirical average obtained by taking samples from the chain might converge to their integral under the stationary measure. This section is concluded with two of the most important results in the theory of Markov chains.

The *ergodic theorem* provides an analog of the law of large numbers for independent random variables: It tells us that under suitable regularity conditions, the averages obtained from the sample path of a Markov chain will converge to the expectation under the stationary distribution of the transition kernel. This mathematically refined, rigorously proved form of the ergodic hypothesis was alluded to at the start of this section. Many variants of this theorem are available; one particularly simple form is the following: If $\{X_n\}$ is a Harris ergodic Markov chain of invariant distribution π, then the following strong law of large numbers holds for any π-integrable function $f : E \to \mathbb{R}$ (convergence is with probability one):

$$\lim_{n\to\infty} \frac{1}{n}\sum_{i=1}^{n} f(X_i) \to \int f(x)\pi(x)dx$$

This is a particular case of Ref. 5 (p. 241, Theorem 6.63), and a proof of the general theorem is given there. The same theorem is also presented with proof in Ref. 3 (p. 433, Theorem 17.3.2).

A *central limit theorem* also exists and tells us something about the rate of convergence of averages under the sample path of the Markov chain. Under technical regularity conditions (see Ref. 4 for a summary of various combinations of conditions), it is possible to obtain a central limit theorem for the ergodic averages of a Harris recurrent, π-invariant Markov chain, and a function that has at least two finite moments, $f : E \to \mathbb{R}$ (with $\mathbb{E}[f] < \infty$ and $\mathbb{E}[f^2] < \infty$).[1]

$$\lim_{n\to\infty} \sqrt{n}\left[\frac{1}{n}\sum_{i=1}^{n} f(X_i) - \int f(x)\pi(x)dx\right] \xrightarrow{d} \mathcal{N}(0, \sigma^2(f))$$

$$\sigma^2(f) = \mathbb{E}[(f(X_1) - \bar{f})^2] + 2\sum_{k=2}^{\infty} \mathbb{E}[(f(X_1) - \bar{f})(f(X_k) - \bar{f})]$$

where $\xrightarrow{d}$ denotes convergence in distribution, $\mathcal{N}(0,\sigma^2)$ is the normal distribution of mean 0, and variance $\sigma^2(f)$ and $\bar{f} = \int f(x)\pi(x)dx$.

A great many refinements of these results exist in the literature. In particular, cases in which conditions may be relaxed or stronger results proved have been studied widely. It is of particular interest in many cases to obtain quantitative bounds on the rate of convergence of ergodic averages to the integral under the stationary distribution. In general, it is very difficult to obtain meaningful bounds of this sort for systems of real practical interest, although some progress has been made in recent years.

SELECTED EXTENSIONS AND RELATED AREAS

It is unsurprising that a field as successful as that of Markov chains has several interesting extensions and related areas. This section briefly describes two of these areas.

So-called *adaptive Markov chains* have received a significant amount of attention in the field of Monte Carlo methodology in recent years. In these systems, the transition kernel used at each iteration is adjusted depending on

[1] Depending on the combination of regularity condition assumed, it may be necessary to have a finite moment of order $2 + \delta$.

the entire history of the system or some statistical summary of that history. Although these adaptive systems are attractive from a practical viewpoint, as they allow for automatic tuning of parameters and promise simpler implementation of Monte Carlo methods in the future, a great deal of care must be taken when analyzing them. It is important to notice that because the transition kernel depends on more than the current state at the time of its application, it does not give rise to a Markov chain.

Feynman–Kac formulas were first studied in the context of describing physical particle motion. They describe a sequence of probability distributions obtained from a collection of Markov transition kernels M_n and a collection of potential functions G_n. Given a distribution η_{n-1} at time $n-1$, the system is *mutated* according to the transition kernel to produce an updated distribution:

$$\hat{\eta}_n(x_n) = \int \eta_{n-1}(x_{n-1}) M_n(x_{n-1}, x_n) dx_{n-1}$$

before weighting the probability of each state/region of the space according to the value of the potential function:

$$\eta_n(x_n) = \frac{\hat{\eta}_n(x_n) G_n(x_n)}{\int \hat{\eta}_n(x) G_n(x) dx}$$

Many convenient ways of interpreting such sequences of distributions exist. One way is that if η_{n-1} describes the distribution of a collection of particles at time $n-1$, which have dynamics described by the Markov kernel M_n in an absorbing medium that is described by the potential function G_n (in the sense that the smaller the value of G_n at a point, the greater the probability that a particle at that location is absorbed), then η_n describes the distribution of those particles that have not been absorbed at time n. These systems have found a great deal of application in the fields of Monte Carlo methodology, particularly sequential and population-based methods, and genetic algorithms. The latter method gives rise to another interpretation: The Markov kernel can be observed as describing the mutation undergone by individuals within a population, and the potential function $G_n(x_n)$ the fitness of an individual with genetic makeup x_n, which governs the success of that individual in a selection step.

Alternatively, one can view the evolution of a Feynman–Kac system as a *nonlinear Markov Chain* in which the distribution of X_n depends on both X_{n-1} and its distribution η_{n-1}. That is, if $X_{n-1} \sim \eta_{n-1}$, then the distribution of X_n is given by

$$\eta_n(\cdot) = \int \eta_{n-1}(x_{n-1}) K_{n,\eta_{n-1}}(x_{n-1}, \cdot) dx_{n-1}$$

where the nonlinear Markov kernel K_{n,η_n} is defined as the composition of selection and mutation steps (numerous such kernels may be associated with any particular Feynman–Kac flow).

An excellent monograph on Feynman–Kac formulas and their mean field approximations has been written recently (6).

MIXED INTEGER PROGRAMMING

INTRODUCTION

A (linear) mixed integer program (MIP) is an optimization problem over a set of integer variables (unknowns) and a set of real-valued (continuous) variables, the constraints are all linear equations or inequalities, and the objective is a linear function to be minimized (or maximized). This can be written mathematically as

$$\begin{aligned}&\min cx + hy\\ &Ax + Gy \geq b\\ &x \in \mathbb{R}^p_+, y \in \mathbb{Z}^n_+\end{aligned}$$

where $\mathbb{R}^p_+$ denotes the space of p-dimensional non-negative real vectors: $\mathbb{Z}^n_+$ denotes the space of n-dimensional non-negative integer vectors: x denotes the p continuous variables: y, denotes the n integer variables; A and G are $m \times p$ and $m \times n$ matrices, respectively; b is an m-vector (the requirements or right-hand side vector) and c and h are p-and n-dimensional row vectors. Often one specifically distinguishes constraints of the form $l \leq x \leq u$ or $l' \leq y \leq u'$, known as lower and upper bound constraints—thus, the problem above is the special case where all the coordinates of l and l' are zero and all the coordinates of u and u' are $+\infty$.

MIPs in which $p = 0$ are called (linear) integer programs (IP): those in which the bounds on the integer variables are all 0 and 1 are called binary or 0–1 MIPs, and those in which $n = 0$ are called linear programs (LP). A problem in which the objective function and/or constraints involve nonlinear functions of the form

$$\min\{c(x,y) : g_i(x,y) \geq b_i \, i = 1,\ldots,m, x \in \mathbb{R}^p_+, y \in \mathbb{Z}^n_+\}$$

is a mixed integer nonlinear program (MINLP).

MIPs in general, are difficult problems ($\mathcal{NP}$—hard in the complexity sense), as are 0–1 MIPs and IPs. However, LPs are easy (polynomially solvable), and linear programming plays a very significant role in both the theory and practical solution of linear MIPs. Readers are referred to the entry "linear programming" for background and some basic terminology.

We now briefly outline what follows. In "The Formulation of various MIPs" section, we present the formulations of three typical optimization problems as mixed integer programs. In the "Basic Properties of MIPs" section, we present some basic properties of MIPs that are used later. In "The Branch-and-Cut Algorithms for MIPs" section, we explain how the majority of MIPs are solved in practice. All the state-of-the-art solvers use a combination of linear programming combined with intelligent enumeration (known as branch-and-bound), preprocessing using simple tests to get a better initial representation of the problem, reformulation with additional constraints (valid inequalities or cutting planes), extended reformulation with additional variables, and heuristics to try to find good feasible solutions quickly.

In the "References and Additional Topics" section, we give references for the basic material described in this article and for more advanced topics, including decomposition algorithms, MIP test instances, MIP modeling and optimization software, and nonlinear MIPs.

THE FORMULATION OF VARIOUS MIPS

MIPs are solved on a regular basis in many areas of business, management, science and engineering. Modeling problems as MIPs is nontrivial. One needs to define first the unknowns (or variables), then a set of linear constraints so as to characterize exactly the set of feasible solutions, and finally a linear objective function to be minimized or maximized. Here we present three simplified problems that exemplify such applications.

A Capacitated Facility Location Problem

Given m clients with demands a_i for i =1,..., m, n potential depots with annual throughput of capacity b_j for j =1,..., n where the annual cost of opening depot j is f_j, suppose that the potential cost of satisfying one unit of demand of client i from depot j is c_{ij}. The problem is to decide which depots to open so as to minimize the total annual cost of opening the depots and satisfying the annual demands of all the clients.

Obviously, one wishes to know which set of depots to open and which clients to serve from each of the open depots. This situation suggests the introduction of the following variables:

y_j =1 if depot j is opened, and y_j=0 otherwise.
x_{ij} is the amount shipped from depot j to client i.

The problem now can be formulated as the following MIP:

$$\min \sum_{j=1}^{n} f_i y_j + \sum_{i=1}^{m}\sum_{j=1}^{n} c_{ij}x_{ij} \tag{1}$$

$$\sum_{j=1}^{n} x_{ij} = a_i \quad \text{for} \quad i = 1,\ldots,m \tag{2}$$

$$\sum_{i=1}^{m} x_{ij} \leq b_j y_j \quad \text{for} \quad j = 1,\ldots,n \tag{3}$$

$$x \in \mathbb{R}^{mn}_+, y \in \{0,1\}^n \tag{4}$$

where the objective function in Equation (1) includes terms for the fixed cost of opening the depots and for the variable shipping costs, the constraints in Equation (2) ensure that

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

the demand of each client is satisfied, the constraints in Equation (3) ensure that, if depot j is closed, nothing is shipped from that depot, and otherwise at most b_j is shipped, and finally Equation (4) indicates the variable types and bounds.

A Multi-Item Production Planning Problem

Given m items to be produced over a time horizon of n periods with known demands d_t^i for $1 \le i \le m, 1 \le t \le n$, all the items have to be processed on a single machine. The capacity of the machine in period t is L_t, and the production costs are as follows: A fixed set-up cost of q_t^i exists if item i is produced in period t, as well as a per unit variable cost p_t^i; a storage cost h_t^i exists for each unit of i in stock at the end of period t. The problem is to satisfy all the demands and minimize the total cost.

Introducing the variables

x_t^i is the amount of item i produced in period t,

s_t^i is the amount of item i in stock at the end of period t,

$y_t^i = 1$ if there is production of item i in period t, and $y_t^i = 0$ otherwise,

a possible MIP formulation of the problem is:

$$\begin{aligned}&\min \sum_{i=1}^{m}\sum_{t=1}^{n}\left(p_t^i x_t^i + q_t^i y_t^i + h_t^i s_t^i\right)\\ &s_{t-1}^i + x_t^i = d_t^i + s_t^i \text{ for } i = 1,\ldots,m, t = 1,\ldots,n\end{aligned} \tag{5}$$

$$x_t^i \le L_t y_t^i \quad \text{for} \quad i = 1,\ldots,m, t = 1,\ldots,n \tag{6}$$

$$\begin{aligned}&\sum_{i=1}^{m} x_t^i \le L_t \quad \text{for} \quad t = 1,\ldots,n\\ &s, x \in \mathbb{R}_+^{mn}, y \in \{0,1\}^{mn}\end{aligned} \tag{7}$$

where constraints in Equation (5) impose conservation of product from one period to the next (namely end-stock of item i in $t-1$ + production of i in t = demand for i in t + end-stock of i in t), Equation (6) forces the set-up variable y_t^i to 1 if there is production ($x_t^i > 0$), and Equation (7) ensures that the total amount produced in period t does not exceed the capacity.

Traveling Salesman Problem with Time Windows

Suppose that a truck (or salesperson) must leave the depot, visit a set of n clients, and then return to the depot. The travel times between clients (including the depot, node 0) are given in an $(n+1) \times (n+1)$ matrix c. Each client i has a time window $[a_i, b_i]$ during which the truck must make its delivery. The delivery time is assumed to be negligible. The goal is to complete the tour and return to the depot as soon as possible while satisfying the time window constraints of each client. Two possible sets of variables are

$y_{ij} = 1$ if the truck travels directly from i to j, $i, j \in \{0, 1 \ldots, n\}$.

t_j is the time of delivery to client j, $j \in \{0,\ldots,n\}$.

τ is the time of return to the depot.

The problem now can be formulated as the following MIP:

$$\min \tau - t_0 \tag{8}$$

$$\sum_{j=0}^{n} y_{ij} = 1, \quad i \in \{0,\ldots,n\} \tag{9}$$

$$\sum_{i=0}^{n} y_{ij} = 1, \quad j \in \{0,\ldots,n\} \tag{10}$$

$$\sum_{i \in S, j \notin S} y_{ij} \ge 1, \quad \phi \subset S \subseteq \{1,\ldots,n\} \tag{11}$$

$$\begin{aligned}&t_j \ge t_i + c_{ij} y_{ij} - M(1 - y_{ij}),\\ &\quad i \in \{0,\ldots,n\}, j \in \{1,\ldots,n\}\end{aligned} \tag{12}$$

$$\tau \ge t_i + c_{i0} y_{i0} - M(1 - y_{i0}), \quad i \in \{1,\ldots,n\} \tag{13}$$

$$\begin{aligned}&a_i \le t_i \le b_i, \quad i \in \{1,\ldots,n\}\\ &\tau \in \mathbb{R}, t \in \mathbb{R}^{n+1}, y \in \{0,1\}^{\frac{(n+1)(n+2)}{2}}\end{aligned} \tag{14}$$

where M is a large value exceeding the total travel time, the objective function in Equation (8) measures the difference between the time of leaving and returning to the depot, Equations (9) and (10) ensure that the truck leaves/arrives once at site i and Equation (11) ensures that the tour of the truck is connected. Constraints in Equations (12) and (13) ensure that if the truck goes from i to j, the arrival time in j is at least the arrival time in i plus the travel time from i to j. Finally, Equation (14) ensures that the time window constraints are satisfied.

BASIC PROPERTIES OF MIPS

Given the MIP

$$z = \min\{cx + hy : Ax + Gy \ge b, x \in \mathbb{R}_+^p, y \in \mathbb{Z}_+^n\}$$

several important properties help us to understand such problems. In particular the linear program obtained by dropping the integrality constraints on the y variables:

$$z_{LP} = \min\{cx + hy : Ax + Gy \ge b, x \in \mathbb{R}_+^p, y \in \mathbb{Z}_+^n\}$$

is called the *linear relaxation* of the original MIP.

Observation 1. *Considering the MIP and its linear relaxation:*

(i) $z_{LP} \le z$, *and*

(ii) *if* (x^*, y^*) *is an optimal solution of LP and* y^* *is integral, then* (x^*, y^*) *is an optimal solution of MIP.*

Definition 2. *A set of the form* $\{x \in \mathbb{R}^n : Ax \ge b\}$ *with* A *an* $m \times n$ *matrix is a polyhedron.*

The convex hull *of a set of points* $X \subseteq \mathbb{R}^n$ *is the smallest convex set containing* X, *denoted* conv(X).

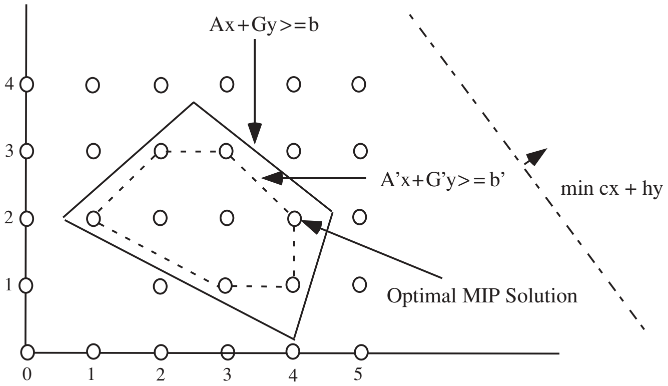

Figure 1. Linear Relaxation and Convex Hull.

Observation 3. *The set* $X_{MIP} = \{(x,y) \in \mathbb{R}^p_+ \times \mathbb{Z}^n_+ : Ax + Gy \geq b\}$*is known as the feasible region of the MIP. When* A, G, b *are rational matrices, then*

(i) $\text{conv}(X_{MIP})$ *is a polyhedron, namely* $\text{conv}(X_{MIP}) = \{(x,y) \in \mathbb{R}^{p+n}_+ : A'x + G'y \geq b'\}$*for some* A', G', b', *and*

(ii) *the linear program* $\min\{cx + hy : (x,y) \in \text{conv}\,(X_{MIP})\}$ *solves MIP. In Fig.1 one sees tha t an optimal vertex of* $\text{conv}(X_{MIP})$ *lies in* X_{MIP}.

The last observation suggests that it it is easy to solve an MIP. Namely, it suffices to find the convex hull of the set of feasible solutions and then solve a linear program. Unfortunately, it is rarely this simple. Finding $\text{conv}(X_{MIP})$ is difficult, and usually an enormous number of inequalities are needed to describe the resulting polyhedron.

Thus, one typically must be less ambitious and examine

(i) whether certain simple classes of MIPs exist for which one can find an exact description of $\text{conv}(X_{\text{MIP}})$, and
(ii) whether one can find a good approximation of $\text{conv}(X_{\text{MIP}})$ by linear inequalities in a reasonable amount of time.

Below, in looking at ways to find such a description of X_{MIP} and in using it in solving an MIP, we often will mix two distinct viewpoints:

(i) Find sets $X^1, \ldots, X^k$ such that

$$X_{\text{MIP}} = \bigcup_{i=1}^{k} X^i$$

where optimizing over X^i is easier than optimizing over X_{MIP} for $i = 1, \ldots, k$, and where possibly good descriptions of the sets $\text{conv}(X^i)$ are known. This decomposition forms the basis of the branch-and-bound approach explained in the next section.

(ii) Find sets $X^1, \ldots, X^k$ such that

$$X_{\text{MIP}} = \bigcap_{i=1}^{k} X^i$$

where a good or exact description of $\text{conv}(X^i)$ is known for $i = 1, \ldots, k$. Then, a potentially effective approximation to $\text{conv}(X_{\text{MIP}})$ is given by the set $\cap_{i=1}^{k}\text{conv}(X^i)$. This decomposition forms the basis of the preprocessing and cut generation steps used in the branch-and-cut approach.

THE BRANCH-AND-CUT ALGORITHM FOR MIPs

Below we will examine the main steps contributing to a branch-and-cut algorithm. The first step is the underlying branch-and-bound algorithm. This algorithm then can be improved by (1) a priori reformulation, (2) preprocessing, (3) heuristics to obtain good feasible solutions quickly, and finally (4) cutting planes or dynamic reformulation in which case we talk of a branch-and-cut algorithm.

Branch-and-Bound

First, we discuss the general ideas, and then we discuss how they typically are implemented. Suppose the MIP to be solved is $z = \min\{cx + hy : (x,y) \in X_{\text{MIP}}\}$ with

$$X_{MIP} = \bigcup_{i=1}^{k} X^i$$

where $X^i = \{(x,y) \in \mathbb{R}^p_+ \times \mathbb{Z}^n_+ : A^i x + G^i y \geq b^i\}$ for $i = 1, \ldots, k$. In addition suppose that we know the value of each linear program

$$z^i_{LP} = \min\{cx + hy : A^i x + G^i y \geq b^i,\ x \in \mathbb{R}^p_+,\ y \in \mathbb{R}^n_+\}$$

and the value $\bar{z}$, of the best known feasible solution $(\bar{x}, \bar{y})$ of MIP found so far, known as the incumbent value.

Observation 4.

(i) $\bar{z} \geq z$ *and* $z \geq \min_i z^i_{LP}$ for $i = 1, \ldots, k$.
(ii) *If* $z^i_{LP} \geq \bar{z}$ *for some i, then no feasible solution with an objective value better than that of the incumbent lies in* X^i. *Thus, the set* X^i *has been enumerated implicitly, and can be ignored (pruned by bound).*
(iii) *If* $z^i_{LP} \geq \bar{z}$ *and the optimal solution of the linear program corresponding to* X^i *has y integer, then using Observation 1, this solution is feasible and optimal in* X^i *and feasible in* X_{MIP}. *Now the incumbent value* $\bar{z}$ *can be improved* $\bar{z} \leftarrow z^i_{LP}$, *and the set* X^i *has been enumerated implicitly and, thus, can be ignored (pruned by optimality).*

Now we outline the steps of the algorithm.

A list L contains a list of unexplored subsets of X_{MIP}, each possibly with some lower bound, as well as an incumbent value $\bar{z}$. Initially, the list just contains X_{MIP} and $\bar{z} = \infty$.

If the list is empty, stop. The best solution found so far is optimal and has value $\bar{z}$.

Otherwise, select and remove a set X^t from the list L.

Solve the corresponding linear program (with optimal solution $(\bar{x}^t, \bar{y}^t)$ and value z^t_{LP}). If it is infeasible, so $X^t = \phi$, or if one of the conditions ii) or iii) of Observation 4 hold, we update the incumbent if appropriate, prune X^t, and return to the list.

If the node is not pruned ($\bar{z} > z^t_{\mathrm{LP}}$ and $\bar{y}^t$ is fractional), we have not succeeded in finding the optimal solution in X^t, so we branch (i.e., break the set X^t into two or more pieces). As the linear programming solution was not integral, some variable y_j takes a fractional value $\bar{y}^t_j$. The simplest and most common branching rule is to replace X^t by two new sets

$$X^t_{\leq} = X^t \cap \{(x,y) : y_j \leq \lfloor \bar{y}^t_j \rfloor\},$$
$$X^t_{\geq} = X^t \cap \{(x,y) : y_j \geq \lceil \bar{y}^t_j \rceil\}$$

whose union is X^t. The two new sets are added to the list L, and the algorithm continues.

Obvious questions that are important in practice are the choice of branching variable and the order of selection/removal of the sets from the list L. "Good" choices of branching variable can reduce significantly the size of the enumeration tree. "Pseudo-costs" or approximate dual variables are used to estimate the costs of different variable choices. "Strong branching" is very effective—this involves selecting a subset of the potential variables and temporarily branching and carrying out a considerable number of dual pivots with each of them to decide which is the most significant variable on which to finally branch. The order in which nodes/subproblems are removed from the list L is a compromise between different goals. At certain moments one may use a depth-first strategy to descend rapidly in the tree so as to find feasible solutions quickly: however, at other moments one may choose the node with the best bound so as not to waste time on nodes that will be cut off anyway once a better feasible solution is found.

The complexity or running time of the branch-and-bound algorithm obviously depends on the number of subsets X^t that have to be examined. In the worst case, one might need to examine 2^n such sets just for a 0–1 MIP. Therefore, it is crucial to improve the formulation so that the value of the linear programming relaxation gives better bounds and more nodes are pruned, and/or to find a good feasible solution as quickly as possible.

Ways to improve the formulation, including preprocessing, cutting planes and a priori reformulation, are discussed in the next three subsections. The first two typically are carried out as part of the algorithm, whereas the MIP formulation given to the algorithm is the responsibility of the user.

Preprocessing

Preprocessing can be carried out on the initial MIP, as well as on each problem X^t taken from the list L. The idea is to improve the formulation of the selected set X^t. This action typically involves *reducing the number of constraints and variables* so that the linear programming relaxation is solved much faster and *tightening the bounds* so as to increase the value of the lower bound z^t_{LP}, thereby increasing the chances of pruning X^t or its descendants.

A variable can be eliminated if its value is fixed. Also, if a variable is unrestricted in value, it can be eliminated by substitution. A constraint can be eliminated if it is shown to be redundant. Also, if a constraint only involves one variable, then it can be replaced by a simple bound constraint. These observations and similar, slightly less trivial observations often allow really dramatic decreases in the size of the formulations.

Now we give four simple examples of the bound tightening and other calculations that are carried out very rapidly in preprocessing:

(i) (Linear Programming) Suppose that one constraint of X^t is $\sum_{j \in N_1} a_j x_j - \sum_{j \in N_2} a_j x_j \geq b, a_j > 0$ for all $j \in N_1 \cup N_2$ and the variables have bounds $l_j \leq x_j \leq u_j$.

If $\sum_{j \in N_1} a_j u_j - \sum_{j \in N_2} a_j l_j < b$, then the MIP is infeasible

If $\sum_{j \in N_1} a_j l_j - \sum_{j \in N_2} a_j u_j \geq b$, then the constraint is redundant and can be dropped.

For a variable $t \in N_1$, we have $a_t x_t \geq b + \sum_{j \in N_2} a_j x_j - \sum_{j \in N_1 \setminus \{t\}} a_j\, x_j \geq b + \sum_{j \in N_2} a_j\, l_j - \sum_{j \in N_1 \setminus \{t\}} a_j u_j$. Thus, we have the possibly improved bound on x_t

$$x_t \geq \max[l_t, \frac{b + \sum_{j \in N_2} a_j l_j - \sum_{j \in N_1 \setminus \{t\}} a_j u_j}{a_t}]$$

One also possibly can improve the upper bounds on x_j for $j \in N_2$ in a similar fashion.

(ii) (Integer Rounding) Suppose that the bounds on an integer variable $l_j \leq y_j \leq u_j$ just have been updated by preprocessing. If $l_j, u_j \notin \mathbb{Z}$, then these bounds can be tightened immediately to

$$\lceil l_j \rceil \leq y_j \leq \lfloor u_j \rfloor$$

(iii) (0-1 Logical Deductions) Suppose that one of the constraints can be put in the form $\sum_{j \in N} a_j y_j \leq b, y_j \in \{0,1\}$ for $j \in N$ with $a_j > 0$ for $j \in N$.

If $b < 0$, then the MIP is infeasible.

If $a_j > b \geq 0$, then one has $y_j = 0$ for all points of X_{MIP}.

If $a_j + a_k > b \geq \max\{a_j, a_k\}$, then one obtains the simple valid inequality $y_j + y_k \leq 1$ for all points of X_{MIP}.

(iv) (Reduced cost fixing) Given an incumbent value $\overline{z}$ from the best feasible solution, and a representation of the objective function in the form $z^t_{LP} + \sum_j \overline{c}_j x_j + \sum_j \tilde{c}^j y_j$ with $\overline{c}_j \geq 0$ and $\tilde{c}_j \geq 0$ obtained by linear programming, any better feasible solution in X^t must satisfy

$$\sum_j \overline{c}_j x_j + \sum_j \tilde{c}_j y_j < \overline{z} - z^t_{LP}$$

Thus, any such solution satisfies the bounds $x_j \leq \frac{\overline{z} - z^t_{LP}}{c_j}$ and $y_j \leq \lfloor \frac{\overline{z} - z^t_{LP}}{c_j} \rfloor$. (Note that reductions such as in item iv) that take into account the objective function actually modify the feasible region X_{MIP}).

Valid Inequalities and Cutting Planes

Definition 5. *An inequality* $\sum_{j=1}^{p} \pi_j x_j + \sum_{j=1}^{n} \mu_j y_j \geq \pi_0$ is a valid inequality (VI) for X$_{MIP}$ if it is satisfied by every point of X_{MIP}.

The inequalities added in preprocessing typically are very simple. Here, we consider all possible valid inequalities, but because infinitely many of them exist, we restrict our attention to the potentially interesting inequalities. In Figure 1, one sees that only a finite number of inequalities (known as facet-defining inequalities) are needed to describe $\text{conv}(X_{MIP})$. Ideally, we would select a facet-defining inequality among those cutting off the present linear programming solution (x^*, y^*) Formally, we need to solve the

Separation Problem: Given X_{MIP} and a point $(x^*, y^*) \in \mathbb{R}^p_+ \times \mathbb{R}^n_+$ either show that $(x^*, y^*) \in \text{conv}(X_{MIP})$, or find a valid inequality $\pi x + \mu y \geq \pi_0$ for X_{MIP} cutting off $(x^*, y^*)(\pi x^* + \mu y^* < \pi_0)$.

Once one has a way of finding a valid inequality cutting off noninteger points, the idea of a cutting plane algorithm is very natural. If the optimal linear programming solution (x^*, y^*) for the initial feasible set X_{MIP} has y^* fractional and a valid inequality cutting off the point is known (for example, given by an algorithm for the Separation Problem), then the inequality is added, the linear program is resolved, and the procedure is repeated until no more cuts are found. Note that this process changes the linear programming representation of the set X_{MIP} and that this new representation must be used from then on.

Below we present several examples of cutting planes.

(i) (Simple Mixed Integer Rounding) Consider the MIP set $X = \{(x, y) \in \mathbb{R}^1_+ \times \mathbb{Z}^1 : y \leq b + x\}$ It can be shown that every point of X satisfies the valid inequality

$$y \leq \lfloor b \rfloor + \frac{x}{1 - f}$$

where $f = b - \lfloor b \rfloor$ is the fractional part of b.

(ii) (Mixed Integer Rounding) Consider an arbitrary row or combination of rows of X_{MIP} of the form:

$$\sum_{j \in P} a_j x_j + \sum_{j \in N} g_j y_j \leq b$$
$$x \in \mathbb{R}^p_+, y \in \mathbb{Z}^n_+$$

Using the inequality from i), it is easy to establish validity of the mixed integer rounding (MIR) inequality:

$$\sum_{j \in P: a_j < 0} \frac{a_j}{1 - f} x_j + \sum_{j \in N} (\lfloor g_j \rfloor + \frac{(f_j - f)^+}{1 - f}) y_j \leq \lfloor b \rfloor$$

where $f = b - \lfloor b \rfloor$ and $f_j = g_j - \lfloor g_j \rfloor$. The Separation Problem for the complete family of MIR inequalities derived from all possible combinations of the initial constraints, namely all single row sets of the form:

$$uAx + uGy \geq ub, x \in \mathbb{R}^p_+, y \in \mathbb{Z}^n_+$$

where $u \geq 0$, is $\mathcal{NP}$-hard.

(iii) (Gomory Mixed Integer Cut) When the linear programming solution $(x*, y*) \notin X_{MIP}$, some row exists from a representation of the optimal solution of the form

$$y_u + \sum_{j \in P_u} a_j x_j + \sum_{j \in N_u} g_j y_j = a_0$$

with $y^*_u = a_0 \notin \mathbb{Z}^1, x^*_j = 0$ for $j \in P_u$,and $y^*_u = 0$ for $j \in N_u$. Applying the MIR inequality and then eliminating the variable y_u by substitution, we obtain the valid inequality

$$\sum_{j \in P^u : a_j > 0} a_j x_j - \sum_{j \in P^u : a_j < 0} \frac{f_0}{1 - f_0} a_j x_j + \sum_{j \in N^u : f_j \leq f_0} f_j y_j$$
$$+ \sum_{j \in N^u : f_j > f_0} \frac{f_0(1 - f_j)}{1 - f_0} y_j \geq f_0$$

called the Gomory mixed integer cut, where $f_j = g_j - \lfloor g_j \rfloor$ *for* $j \in N^u \cup \{0\}$. This inequality cuts off the LP solution (x^*, y^*). Here, the Separation Problem is trivially solved by inspection and finding a cut is guaranteed. However, in practice the cuts may be judged ineffective for a variety of reasons, such as very small violations or very dense constraints that slow down the solution of the LPs.

(iv) (0–1 MIPs and Cover Inequalities) Consider a 0–1 MIP with a constraint of the form

$$\sum_{j \in N} g_j y_j \leq b + x, x \in \mathbb{R}^1_+, y \in \mathbb{Z}^{|N|}_+$$

with $g_j > 0$ for $j \in N$. A set $C \subseteq N$ is a cover if $\sum_{j \in c} g_j = b + \lambda$ with $\lambda > 0$. The MIP cover inequality is

$$\sum_{j \in C} y_j \leq |C| - 1 + \frac{x}{\lambda}$$

Using appropriate multiples of the constraints $y_j \geq 0$ and $y_j \leq 1$, the cover inequality can be obtained as a weakening of an MIR inequality. When $x = 0$, the Separation Problem for such cover inequalities can be shown to be an $\mathcal{NP}$-hard, single row 0–1 integer program.

(v) (Lot Sizing) Consider the single item uncapacitated lot-sizing set

$$\begin{aligned} X^{LS-U} = \quad & \Big\{(x,s,y) \in \mathbb{R}^n_+ \times \mathbb{R}^n_+ \times \{0,1\}^n : \\ & s_{t-1} + x_t = d_t + s_t \; 1 \leq t \leq n \\ & x_t \leq \left(\sum_{u=t}^{n} d_u\right) y_t \; 1 \leq t \leq n \Big\} \end{aligned}$$

Note that the feasible region X^{PP} of the production planning problem formulated in "A Multi-Item Production Planning Problem" section can be written as $X^{\mathrm{PP}} = \cap_{i=1}^{m} X_i^{LS-U} \cap Y$ where $Y \subseteq \{0,1\}^{mn}$ contains the joint machine constraints in Equation (7) and the possibly tighter bound constraints in Equation (6).

Select an interval $[k, k+1, \ldots, l]$ with $1 \leq k \leq l \leq n$ and some subset $T \subseteq \{k, \ldots, l\}$. Note that if $k \leq u \leq l$ and no production exists in any period in $\{k, \ldots, u\} \backslash T$(*i.e.*, $\sum_{j \in \{k,\ldots,u\} \backslash T} y_j = 0$), then the demand d_u in period u must either be part of the stock s_{k-1} or be produced in some period in $T \cap \{k, \ldots, u\}$. This establishes the validity of the inequality

$$s_{k-1} + \sum_{j \in T} x_j \geq \sum_{u=k}^{l} d_u \left(1 - \sum_{j \in \{k,\ldots,u\} \backslash T} y_j\right) \qquad (15)$$

Taking l as above, $L = \{1, \ldots, l\}$, and $S = \{1, \ldots, k-1\} \cup T$,, the above inequality can be rewritten as a so-called (*l,S*)-inequality:

$$\sum_{j \in S} x_j + \sum_{j \in L \backslash S} \left(\sum_{u=j}^{l} d_u\right) y_j \geq \sum_{u=1}^{l} d_u$$

This family of inequalities suffices to describe conv (X^{LS-U})

Now, given a point (x^*, s^*, y^*), the Separation Problem for the (*l,S*) inequalities is solved easily by checking if

$$\sum_{j=1}^{l} \min \left[x_j^*, \left(\sum_{u=j}^{l} d_u\right) y_j^*\right] < \sum_{u=1}^{l} d_u$$

for some l. If it does not, the point lies in conv(X^{LS-U}): otherwise a violated (*l, S*) inequality is found by taking $S = \{j \in \{1, \ldots, l\} : x_j^* < (\sum_{u=j}^{l} d_u) y_j^*\}$.

A Priori Modeling or Reformulation

Below we present four examples of modeling or a priori reformulations in which we add either a small number of constraints or new variables and constraints, called *extended formulations*, with the goal of obtaining tighter linear programming relaxations and, thus, much more effective solution of the corresponding MIPs.

(i) (Capacitated Facility Location—Adding a Redundant Constraint) The constraints in Equations (2) through (4) obviously imply validity of the constraint

$$\sum_{j=1}^{n} b_j y_j \geq \sum_{i=1}^{m} a_i$$

which states that the capacity of the open depots must be at least equal to the sum of all the demands of the clients. As $y \in \{0,1\}^n$, the resulting set is a 0–1 knapsack problem for which cutting planes are derived readily.

(ii) (Lot Sizing—Adding a Few Valid Inequalities) Consider again the single item, uncapacitated lot-sizing set X^{LS-U}. In item v) of the "Valid Inequalities and Cutting Planes" sections, we described the inequalities that give the convex hull. In practice, the most effective inequalities are those that cover a few periods. Thus, a simple a priori strengthening is given by adding the inequalities in Equation (15) with $T = \phi$ and $l \leq k + \kappa$

$$s_{k-1} \geq \sum_{u=k}^{l} d_u \left(1 - \sum_{j=k}^{u} y_j\right)$$

for some small value of κ.

(iii) (Lot Sizing—An Extended Formulation) Consider again the single item, uncapacitated lot-sizing set X^{LS-U}. Define the new variables z_{ut} with $u \leq t$ as the amount of demand for period t produced in period u. Now one obtains the extended formulation

$$\begin{aligned} & \sum_{u=1}^{t} z_{ut} = d_t, 1 \leq t \leq n \\ & z_{ut} \leq d_t y_u, 1 \leq u \leq t \leq n \\ & x_u = \sum_{t=u}^{n} z_{ut}, 1 \leq u \leq n \\ & s_{t-1} + x_t = d_t + s_t, 1 \leq t \leq n \\ & x, s \in \mathbb{R}^n_+, z \in \mathbb{R}^{n(n+1)/2}_+, y \in [0,1]^n \end{aligned}$$

whose (x,s,y) solutions are just the points of conv *(X^{LS-U})*. Thus, the linear program over this set solves the lot-sizing problem, whereas the original description of x^{LS-U} provides a much weaker formulation.

(iv) (Modeling Disjunctive or "Or" Constraints—An Extended Formulation) Numerous problems involve disjunctions,—for instance, given two jobs i, and j to be processed on a machine with processing times p_i, p_j, respectively, suppose that either job i must be completed before job j or vice versa. If t_i, t_j are variables representing the start times, we have the constraint EITHER "job i precedes job j" OR "job j

precedes job i," which can be written more formally as

$$t_i + p_i \leq t_j \, or \, t_j + p_j \leq t_i$$

More generally one often encounters the situation where one must select a point (a solution) from one of k sets or polyhedra (a polyhedron is a set described by a finite number of linear inequalities):

$$x \in \bigcup_{i=1}^{k} P_i \text{ where } P_i = \{x : A^i x \geq b^i\} \subseteq \mathbb{R}^n$$

When each of the sets P_i is nonempty and bounded, the set $\cup_{i=1}^{k} P_i$ can be formulated as the MIP:

$$x = \sum_{i=1}^{k} z^i \tag{16}$$

$$A^i z^i \geq b^i y^i \text{ for } i = 1, \ldots, k \tag{17}$$

$$\sum_{i=1}^{k} y^i = 1 \tag{18}$$

$$x \in \mathbb{R}^n, \quad z \in \mathbb{R}^{nk}, y \in \{0,1\}^k \tag{19}$$

where $y^i = 1$ indicates that the point lies in P_{i}. Given a solution with $y^i = 1$, the constraint in Equation (18) then forces $y^j = 0$ for $j \neq i$ and the constraint in Equation (17) then forces $z^i \in P_i$ and $z^j = 0$ for $j \neq i$. Finally, Equation (16) shows that $x \in P_i$ if and only if $y^i = 1$ as required, and it follows that the MIP models $\cup_{i=1}^{k} P_i$. What is more, it has been shown (6) that the linear programming relaxation of this set describes conv($\cup_{i=1}^{k} P_i$), so this again is an interesting extended formulation.

Extended formulations can be very effective in giving better bounds, and they have the important advantage that they can be added a priori to the MIP problem, which avoids the need to solve a separation problem whenever one wishes to generate cutting planes just involving the original (x, y) variables. The potential disadvantage is that the problem size can increase significantly and, thus, the time to solve the linear programming relaxations also may increase.

Heuristics

In practice, the MIP user often is interested in finding a good feasible solution quickly. In addition, pruning by optimality in branch-and-bound depends crucially on the value of the best known solution value z. We now describe several MIP heuristics that are procedures designed to find feasible, and hopefully, good, solutions quickly.

In general, finding a feasible solution to an MIP is an $\mathcal{NP}$-hard problem, so devising effective heuristics is far from simple. The heuristics we now describe are all based on the solution of one or more MIPs that hopefully are much simpler to solve than the original problem.

We distinguish between *construction heuristics*, in which one attempts to find a (good) feasible solution from scratch, and *improvement heuristics,* which start from a feasible solution and attempt to find a better one. We start with construction heuristics.

Rounding . The first idea that comes to mind is to take the solution of the linear program and to round the values of the integer variables to the nearest integer. Unfortunately, this solution is rarely feasible in $\mathrm{X_{MIP}}$.

A Diving Heuristic. This heuristic solves a series of linear programs. At the tth iteration, one solves

$$\min\{cx + hy : Ax + Gy \geq b, x \in \mathbb{R}_+^p, y \in \mathbb{R}_+^n, y_j = y_j^* \text{ for } j \in N^t\}$$

If this linear program is infeasible, then the heuristic has failed. Otherwise, let $(\overline{x}^t, \overline{y}^t)$ be the linear programming solution.

Now if $\overline{y}^t \in \mathbb{Z}_+^n$, then a diving heuristic solution has been found. Otherwise, if $\overline{y}^t \notin \mathbb{Z}_+^n$, then at least one other variable is fixed at an integer value. Choose $j \in N \backslash N^t$ with $y_j^t \notin \mathbb{Z}^1 \cdot$ Set $N^{t+1} = N^t \cup \{j\}$ and $t \leftarrow t + 1$. For example, one chooses to fix a variable whose LP value is close to an integer, i.e., $j = \operatorname{argmin}_{k: \overline{y}_k^t \notin \mathbb{Z}^1} [\min(\overline{y}_k^t - \lfloor \overline{y}_k^t \rfloor, \lceil \overline{y}_k^t \rceil) - \overline{y}_k^t]$.

A Relax-and-Fix Heuristic. This heuristic works by decomposing the variables into K blocks in natural way, such as by time period, geographical location, or other. Let $N = \{1, \ldots n\} = \cup_{k=1}^{K} I_k$ with intervals $I_k = [s_k, t_k]$ such that $s_1 = 1, t_K = n$, and $s_k = t_{k-1} + 1$ for $k = 2, \ldots, K$.

One solves K MIPs by progressively fixing the integer variables in the sets $I_1, I_2, \ldots, I_K$. Each of these MIPs is much easier because in the k-th problem only the variables in I_k are integer. The k-th MIP is

$$\begin{aligned}
&\min cx + hy \\
&Ax + Gy \geq b \\
&x \in \mathbb{R}_+^p, y_j = \overline{y}_j \text{ for } j \in \cup_{t=1}^{k-1} I_k, \\
&y_j \in \mathbb{Z}_+^1 \text{ for } j \in I_k, y_j \in \mathbb{R}_+^1 \text{ for } j \in \cup_{t=k+1}^{K} I_t
\end{aligned}$$

If $(\tilde{x}, \tilde{y})$ is an optimal solution, then one sets $\overline{y}_j = \tilde{y}_j$ for $j \in I_k$ and $k \leftarrow k + 1$. If the Kth MIP is feasible, then a heuristic solution is found; otherwise, the heuristic fails.

Now we describe three iterative improvement heuristics. For simplicity, we suppose that the integer variables are binary. In each case one solves an easier MIP by restricting the values taken by the integer variables to some neighborhood $N(y^*)$ of the best-known feasible solution (x^*, y^*) and one iterates. Also, let $(x^{\mathrm{LP}}, y^{\mathrm{LP}})$ be the current LP solution. In each case, we solve the MIP

$$\begin{aligned}
&\min cx + hy \\
&Ax + Gy \geq b \\
&x \in \mathbb{R}_+^p, y \in \mathbb{Z}_+^n, y \in N(y^*)
\end{aligned}$$

with a different choice of $N(y^*)$.

The Local Branching Heuristic. This heuristic restricts one to a solution at a (Hamming-) distance at most k from y^*:

$$N(y^*) = \{y \in \{0,1\}^n : |y_j - y_j^*| \leq k\}$$

This neighborhood can be represented by a linear constraint

$$N(y^*) = \{y \in \{0,1\}^n : \sum_{j:y_j^*=0} y_j + \sum_{j:y_j^*=1} (1 - y_j) \leq k\}$$

The Relaxation Induced Neighborhood Search Heuristic (RINS). This heuristic fixes all variables that have the same value in the IP and LP solutions and leaves the others free. Let $A = \{j \in N : y_j^{IP} = y_j^*\}$. Then

$$N(y^*) = \{y : y_j = y_j^* \text{ for } j \in A\}$$

The Exchange Heuristic. This heuristic allows the user to choose the set A of variables that are fixed. As for the Relax-and-Fix heuristic, if a natural ordering of the variables exists then, a possible choice is to fix all the variables except for those in one interval I_k. Now if $A = N \backslash I_k$, the neighborhood can again be taken as

$$N(y^*) = \{y : y_j = y_j^* \text{ for } j \in A\}$$

One possibility then is to iterate over $k = 1,\ldots, K$, and repeat as long as additional improvements are found.

The Branch-and-Cut Algorithm

The branch-and-cut algorithm is the same as the branch-and-bound algorithm except for one major difference. Previously one just selected a subset of solutions X^t from the list L that was described by the initial problem representation $Ax + Gy \geq b, x \in \mathbb{R}_+^p, y \in \mathbb{Z}_+^n$ and the bound constraints on the integer variables added in branching $l^t \leq y \leq u^t$. Now, one retrieves a set X^t from the list, along with a possibly tightened formulation (based on preprocessing and cutting planes)

$$P^t = \{(x,y) \in \mathbb{R}^p + \mathbb{R}_+^n : A^t x + G^t y \geq b^t, l^t \leq y \leq u^t\}$$

where $X^t = P^t \cap (\mathbb{R}^p \times \mathbb{Z}^n)$.

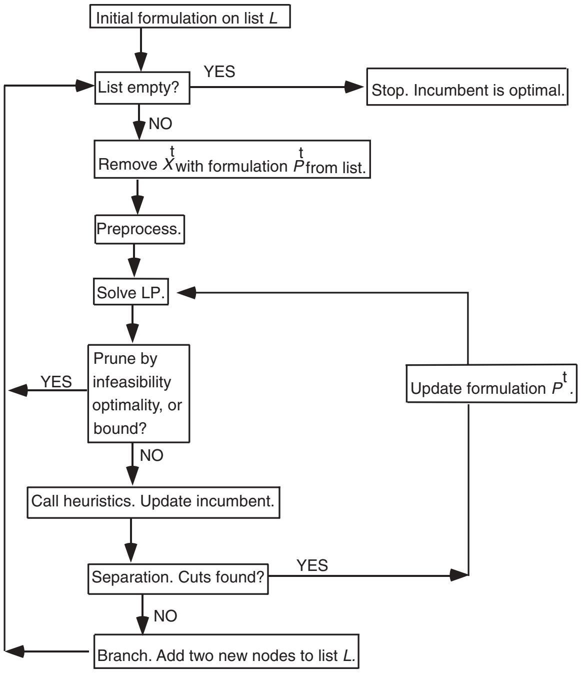
Now the steps, once X^t is taken from the list, L are

(i) Preprocess to tighten the formulation P^t.

(ii) Solve the linear program $z_{LP}^t = \min\{cx + hy : (x,y) \in P^t\}$.

(iii) Prune the node, if possible, as in branch-and-bound.

(iv) Call one or more heuristics. If a better feasible solution is obtained, Then update the incumbent value $\bar{z}$.



Initial formulation on list L
List empty?
YES
Stop. Incumbent is optimal.
NO
Remove X^t with formulation P^t from list.
Preprocess.
Solve LP.
Prune by infeasibility optimality, or bound?
YES
Update formulation P^t.
NO
Call heuristics. Update incumbent.
Separation. Cuts found?
YES
NO
Branch. Add two new nodes to list L.

Figure 2. Branch-and-cut schema.

(v) Look for violated valid inequalities. If one or more satisfactory cuts are found, then add them as cuts, modify P^t, and repeat ii).

(vi) If no more interesting violated inequalities are found, Then branch as in the branch-and-bound algorithm and add the two new sets $X_{\leq}^t$ and $X_{>}^t$ to the list L, along with their latest formulations $P^{\bar{t}}$.

Then one returns to the branch-and-bound step of selecting a new set from the list and so forth.

In practice, preprocessing and cut generation always are carried out on the original set X_{MIP} and then on selected sets drawn from the list (for example, sets obtained after a certain number of branches or every k-th set drawn from the list). Often, the valid inequalities added for set X^t are valid for the original set X_{MIP}, in which case the inequalities can be added to each set P^t. All the major branch-and-cut systems for MIP use preprocessing, and heuristics, such as diving and RINS, and the valid inequalities generated include MIR inequalities, Gomory mixed integer cuts, 0–1 cover inequalities, and path inequalities, generalizing the (l, S) inequalities. A flowchart of a branch-and-cut algorithm is shown in Fig. 2.

REFERENCES AND ADDITIONAL TOPICS

Formulations of Problems as Mixed Integer Programs

Many examples of MIP models from numerous areas, including air and ground transport, telecommunications, cutting and loading, and finance can be found in Heipcke (2) and Williams (3), as well as in the operations research journals such as *Operations Research, Management*

Science, Mathematical Programming, Informs Journal of Computing, *European Journal of Operational Research*, and more specialized journals such as *Transportation Science*, *Networks*, *Journal of Chemical Engineering*, and so forth.

Basic References

Two basic texts on integer and mixed integer programming are Wolsey (4) and part I of Pochet and Wolsey (5). More advanced texts are Schrijver (6) and Nemhauser and Wolsey (7). Recent surveys on integer and mixed integer programming with an emphasis on cutting planes include Marchand et al. (8), Fugenschuh and Martin (9), Cornuejols (10), and Wolsey (11).

Preprocessing is discussed in Savelsbergh (12) and Andersen and Andersen (13), and branching rules are discussed in Achterberg et al. (14). Much fundamental work on cutting planes is due to Gomory (15,16). The related mixed integer rounding inequality appears in chaper II.1 of Nemhauser and Wolsey (7), and cover inequalities for 0–1 knapsack constraints are discussed in Balas (17), Hammer et al. (18), and Wolsey (19). The local branching heuristic appears in Fischetti and Lodi (29): RINS and diving appears in Danna et al. (21).

Decomposition Algorithms

Significant classes of MIP problems cannot be solved directly by the branch-and-cut approach outlined above. At least three important algorithmic approaches use the problem structure to decompose a problem into a sequence of smaller/easier problems. One such class, known as branch-and-price or column generation, see, for instance, Barnhart et al. (22), extends the well-known Dantzig–Wolfe algorithm for linear programming (23) to IPs and MIPs. Essentially, the problem is reformulated with a huge number of columns/variables, then dual variables or prices from linear programming are used to select/generate interesting columns until optimality is reached, and then the whole is embedded into a branch-and-bound approach. Very many problems in the area of airlines, road and rail transport, and staff scheduling are treated in this way. A related approach, Lagrangian relaxation (24), uses the prices to transfer complicating constraints into the objective function. The resulting, easier problem provides a lower bound on the optimal value, and the prices then are optimized to generate as good a lower bound as possible.

An alternative decomposition strategy, known as Benders' decomposition (25), takes a different approach. If the value of the integer variables is fixed, then the remaining problem is a linear program $\phi(y) = \min\{cx : Ax \geq b - Gy, x \in \mathbb{R}^p_+\}$ and the original problem can be rewritten as $\min\{\phi(y) + hy : y \in \mathbb{Z}^n_+\}$. Although $\phi(y)$ is not known explicitly, whenever a linear program is solved for some y^*, a support of the function $\phi(y)$ is obtained and the algorithm works by simultaneously enumerating over the y variables and continually updating the approximation to $\phi(y)$ until an optimal solution is obtained.

MIP Test Problems and Software

An important source for test instances is the MIPLIB library (26). Several commercial branch-and-cut systems are available, of which three of the most well known are Cplex (27), Xpress-MP (28), and Lindo (29). See OR-MS Today for regular surveys of such systems. Among non commercial systems, several MIP codes exist in the Coin library (30), as well as several other research codes, including SCIP (31) and MINTO (32). In addition, modeling languages such as AMPL (33), LINGO (29) and MOSEL (28) that facilitate the modeling and generation of linear and mixed integer programs.

Nonlinear Mixed Integer Programming

The study of algorithms for nonlinear MIPs is, relatively, in its infancy. Portfolio optimization problems with integer variables are being tackled using convex (second order cone) optimization as relaxations: see Ben Tal and Nemirovsky (34). Two approaches for nonconvex MINLPs are generalized Benders' decomposition, see Geoffrion (35), and outer approximation algorithms (36, 37). References include the book of Floudas (38) and the lecture notes of Weismantel (39). Software includes the Dicopt code (40) and the BARON code of Sahinidis and Tawarmalami (41): see also Ref. 42 for recent computational results. SeDuMi (43) is one of the most widely used codes for convex optimization. The Cplex and Xpress-MP systems cited above allow for nonlinear MIPs with quadratic convex objective functions and linear constraints. Heuristics for nonlinear MIPs are presented in Ref. 44, and a test set of nonlinear MIPs is in preparation (45).

MULTIGRID METHODS

INTRODUCTION

Numerical modeling in science and engineering has emerged in recent years as a viable alternative to a more conventional experimental approach, which has some shortfalls, such as the cost, the time consumption, the difficulties with accuracy, or the ethical issues. As computer processing power continues to increase, nowadays it is possible to perform modeling and simulation studies for large-scale problems in important areas, such as continuum mechanics, electromagnetism, quantum physics, and so forth. Modern trends also involve modeling of the complex systems with the constitutive parts from different areas, which are often referred to as *multi-physics systems*. The growing appetite for even larger models requires also a development of sophisticated algorithms and numerical techniques for efficient solution of underlying equations.

Computer-aided modeling represents the space and time continuum by a finite set of properly selected discrete coordinate points. These points typically are connected to form a mesh over the domain of interest. A discrete physical or numerical variable is associated with the mesh points. Such a discrete variable is referred to as the *grid variable*. A set of grid variables, together with the algebraic equations that define their implicit dependencies, represent a *grid problem*. A process of approximating a continuous problem by an appropriate grid problem is called the *discretization*. The most common class of continuous problems that require discretization are differential equations (DEs).

DEs are the mathematical expressions that relate unknown functions and their derivatives in continuous space and time. The local connectivity among the mesh points is used to approximate the derivatives of the unknown function. The order of this approximation determines the order of accuracy of the method itself. The size of the resulting grid problem is proportional to the number of mesh points. Some well-known methods for the discretization of DEs are the *finite difference method* (FDM), the *finite element method* (FEM), and the *finite volume method* (1–3). A common feature of the grid problems obtained by discretization of DEs by these methods is the *local dependence of grid variables*. Namely, a single grid variable depends only on a small set of grid variables in its close neighborhood.

The solution of the grid problems created by the discretization of DEs, which usually take the form of linear or non linear systems of algebraic equations, is obtained by applying a certain solution procedure. Iterative methods start from an initial approximation to the solution, which is improved over a number of iterations until the discrete solution is obtained within the prescribed accuracy. The difference between the initial discrete approximation and the discrete solution represents the *iteration error* that is eliminated during an iterative solution procedure. An optimal iterative solver is the one that scales optimally with the problem size. That is, the computing resources employed by the solver and the execution time should be proportional to the problem size. To achieve an optimal iterative solution procedure, we must ensure that it converges to a prescribed accuracy within a constant, presumably small, number of iterations, regardless of the problem size or any other problem-specific parameters.

Simple iterative methods often fail in fulfilling the optimality condition when applied to discretized DEs. To understand the problem, we shall consider the solution error in the Fourier space, represented as a linear combination of the wave-like components having the shape of sine or cosine functions with different wavelengths (or frequencies). Simple iterative methods are very efficient in eliminating the high-frequency (short wavelength) error components because these require only the information from the closest grid neighbors. This behavior is known as the *smoothing property* of the iterative methods (4, p. 412–419). After this initial phase, when rapid convergence is observed within a few iterations, the simple iterative solvers have to work hard to reduce the remaining error that is now dominated by the low-frequency (long wavelength) error components. The reduction of low-frequency errors requires communication among distant grid variables and takes a much larger number of iterations than in the case of the high-frequency error components. This reason is why the simple iterative procedures become nonoptimal.

The splitting into high-frequency and low-frequency error components is introduced, in principle, relative to the characteristic distance between neighboring mesh points or the *mesh size*. Namely, the wavelengths of the high-frequency solution error components are comparable with the mesh size. Obviously, a part of the low-frequency error components can be regarded as the high-frequency components if the problem is discretized using a coarser mesh. This situation naturally leads to the idea of using a coarser grid problem to improve the convergence and reduce the numerical cost of an iterative solution scheme. But we need to keep in mind that only the fine grid problem approximates the continuous DE with the required accuracy. Therefore, both problems should be combined in a proper way to produce an effective solution algorithm. Moreover, some low-frequency error components still can represent a problem for iterative procedures on the coarser mesh. These components can be reduced by introducing a sequence of additional progressively coarser meshes and corresponding grid problems associated with them. This idea leads to multigrid methods (MG) that employ a hierarchy of discrete grid problems to achieve an optimal solution procedure.

In this section, we present only a high-level description of the MG heuristics. For additional technical details, the reader is referred to the next two sections. After a few steps of a simple iterative procedure at the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

finest grid, the high-frequency error components are eliminated from the initial solution error. This procedure is called the *smoothing*. The remaining low-frequency error then is transferred to the coarser grid by a process called the *restriction*. The same procedure (smoothing and restriction) is repeated on the coarser level. The remaining low-frequency error components at the coarser level are transfered further to a coarser grid, and the smoothing procedure is repeated. This pair of operations (the smoothing and the error transfer to a coarser grid) is repeated until a sufficiently coarse grid, with only a few nodes, is reached. The coarsest grid solution (with the low-frequency errors removed by the application of a direct-solution method) then is used to correct the corresponding discrete solutions on the finer grid levels using *prolongation* or *interpolation*. The prolongation steps often are followed by additional postsmoothing steps to eliminate the remaining high-frequency error components that could be introduced.

The first MG scheme was introduced by Fedorenko in the early 1960s (5). It was presented in the context of the Poisson equation on the unit square domain. However, the full potential of the MG approach was not realized until the work of Brandt in the mid 1970s (6). Since then, a tremendous amount of theory and application related to MG methods has been published, including several monographs (7–15). Over time, MG methods have evolved into an independent field of research, interacting with numerous engineering application areas and having major impact in almost all scientific and engineering disciplines.

A typical application for MG is in the numerical solution of discrete elliptic, self-adjoint, partial differential equations (PDEs), where it can be applied in combination with any of the common discretization techniques. In such cases, MG is among the fastest-known solution techniques. MG also is directly applicable to more complicated, nonsymmetric, and non linear DE problems, systems of DEs, evolution problems, and integral equations. In recent years we have seen an increased development of multi level (ML) solvers for the solution of DE problems in various areas, including aerodynamics (16), atmospheric and oceanic modeling (17), structural mechanics (18), quantum mechanics, statistical physics, (19), semiconductor fabrication (20), and electromagnetism (21–23). In all these applications, MG methods can be used as the building blocks of an overall solver, with an aim of reaching the convergence rate that is nearly independent of the number of unknown grid variables or other problem parameters. Such solvers would be capable of reducing the solution error to the order of the computer truncation error with (nearly) optimal computational cost.

In contrast to other numerical methods, MG represents a computational principle rather than a particular computational technique, and, therefore, it is not restricted by the type of problem, domain, and mesh geometry, or discretization procedure. MG methods even may be applied successfully to algebraic problems that do not involve geometric information and do not even originate from the discretization of DEs. To this end, special techniques are developed to create a required hierarchy that uses only algebraic information available for the "grid" variable dependencies. In addition, a broad range of problems in science and engineering require multi scale modeling and simulation techniques (e.g., oil reservoir modeling). The range of scales involved in such problems induce a prohibitively large number of variables in the classic mono scale modeling approach. MG methods also naturally apply to such cases.

BASIC CONCEPTS

The basic MG ideas are developed more in this section within the context of second-order, elliptic, self-adjoint DE problems. We first introduce the model problem in one spatial dimension. The FDM/FEM discretization of this problem produces a linear system that will serve as an example for studying the efficiency of the basic iterative schemes (fixed-point iterations). Lack of efficiency of simple iterations in this context is the main motivation behind the application of these schemes in a recursive fashion. This naturally leads to MG methods. We describe the main algorithmic components of MG, its arithmetic complexity, and its effectiveness.

Continuous and Discrete Single-Grid Problems

A general, time-dependent, DE in d spatial dimensions can be written as

$$A\left(t,u,\frac{\partial u}{\partial t},\frac{\partial^2 u}{\partial t^2},\ldots,\frac{\partial^k u}{\partial x_1^{k_1}\cdots\partial x_d^{k_d}},\cdots\right)=0 \quad \text{on} \quad \Omega\times T \quad (1)$$

where $\bar{x}=(x_1,\ldots,x_d)\in\Omega\subset\mathbb{R}^d$ and $T=[0,\tau]$. To ensure well-posedness of the solution, an appropriate set of boundary conditions (BCs) and initial conditions (ICs) need to be imposed. By covering the domain of interest Ω by a mesh Ω_h and by applying a suitable spatial discretization procedure, such as the FDM or the FEM, the continuous differential problem becomes a system of differential–algebraic equations:

$$A_h\left(t,u_h,\frac{\partial u_h}{\partial t},\frac{\partial^2 u_h}{\partial t^2},\ldots,\frac{\partial^k u_h}{\partial x_1^{k_1}\cdots\partial x_d^{k_d}},\cdots\right)=0 \quad \text{on} \quad \Omega_h\times T \quad (2)$$

where u_h represents a discrete solution variable of dimension n_h associated with the mesh Ω_h. The BCs are included in the formulation in Equation (2). If the discrete problem is stationary, Equation (2) reduces to a non linear algebraic system

$$A_h(u_h)=0 \qquad \text{on} \qquad \Omega_h \quad (3)$$

Finally, in the case of linear stationary problems, the discrete solution u_h is defined as a linear algebraic system

$$A_h u_h = f_h \qquad \text{on} \qquad \Omega_h \quad (4)$$

where A_h is a coefficient matrix and f_h is the right-hand side vector.

A simple practical example that will serve to introduce the basic MG concepts is the one-dimensional model–problem

$$A(u) = -\frac{d^2u}{dx^2} = f \qquad \text{in} \qquad \Omega = (0,1) \tag{5}$$

subject to the homogeneous Dirichlet BCs

$$u(0) = u(1) = 0 \tag{6}$$

Choosing a mesh Ω_h to be a set of $n_h + 1$ uniformly spaced points $x_i = ih,\ i = 0, \ldots, n_h$ where $h = 1/n_h$, and replacing the second derivative at the mesh points by a central finite-difference approximation (3), we obtain a discrete problem

$$\begin{aligned} A_h u_h = \frac{-u_h(x_{i+1}) + 2u_h(x_i) - u_h(x_{i-1})}{h^2} &= f_h(x_i), \\ i = 1, \ldots, n_h - 1 \end{aligned} \tag{7}$$

with $u_h(x_0) = u_h(x_{n_h+1}) = 0$. The coefficient matrix of the linear system in Equation (7) is a symmetric tridiagonal matrix $A_h = \frac{1}{h^2}\ \text{tridiag}[-1 \quad 2 \ -1]$. Although the linear system in Equation (7), because of its simplicity, can be solved efficiently by a direct method, it is used as an example to explain the main algorithmic features of MG.

The extension of the model–problem in Equations (5) and (6) and MG concepts to two or more spatial dimensions is straightforward. For this purpose, we introduce a natural extension of the model–problem in Equations (5) and (6) to two spatial dimensions, known as the Poisson equation (2, Ch. 1):

$$A(u) = -\left(\frac{\partial^2 u}{\partial x_1^2} + \frac{\partial^2 u}{\partial x_2^2}\right) = f \ \text{ in } \ \Omega = (0,1) \times (0,1) \tag{8}$$

with the homogeneous Dirichlet BCs

$$u = 0 \text{ on } \partial\Omega \tag{9}$$

In Equation (8) we adopted, for simplicity, the unit square domain $\Omega = (0,1) \times (0,1) \subset R^2$. Central finite-difference approximation of the second derivatives in Equation (8), defined on a grid of uniformly spaced points $((x_1)_i, (x_2)_j) = (ih, jh), i, j = 1, \ldots, n_h - 1$, results in a linear system in Equation (4), in which the coefficient matrix A_h can be represented in stencil notation as

$$A_h = \frac{1}{h^2}\begin{bmatrix} & -1 & \\ -1 & 4 & -1 \\ & -1 & \end{bmatrix} \tag{10}$$

We remark that the discretization in Equation (10) of the two-dimensional model problem on a uniform Cartesian grid is obtained as a tensor product of two one-dimensional discretizations in x_1 and x_2 coordinate directions.

The Smoothing Property of Standard Iterative Methods

When an approximate solution $\tilde{u}_h$ of the system in Equation (4) is computed, it is important to know how close it is to the true discrete solution u_h. Two quantitative measures commonly are used in this context. The *error* is defined as $e_h = u_h - \tilde{u}_h$ and the *residual* as $r_h = f_h - A_h\tilde{u}_h$. Note that if the residual is small, this does not imply automatically that the approximation $\tilde{u}_h$ is close to the solution u_h. The error e_h and the residual r_h are connected by the *residual equation*

$$A_h e_h = r_h \tag{11}$$

The importance of Equation (11) can be seen from the fact that if the approximation $\tilde{u}_h$ to the solution u_h of Equation (4) is computed by some iterative scheme, it can be improved as $u_h = \tilde{u}_h + e_h$.

The simplest iterative schemes that can be deployed for the solution of sparse linear systems belong to the class of *splitting iterations* (see Refs 2,4,7,8, and 10 for more details). In algorithmic terms, each splitting iteration starts from the decomposition of the coefficient matrix A_h as $A_h = M_h - N_h$, with M_h being a regular matrix (det $(M_h) \neq 0$), such that the linear systems of the form $M_h u_h = f_h$ are easy to solve. Then, for a suitably chosen initial approximation of the solution $\tilde{u}^{(0)}$ an iteration is formed:

$$\tilde{u}_h^{(k+1)} = M_h^{-1} N_h \tilde{u}^{(k)} + M_h^{-1} f_h, \quad k = 0, 1, \ldots \tag{12}$$

Note that Equation (12) also can be rewritten to include the residual vector $r_h^{(k)} = f_h - A\tilde{u}_h^{(k)}$:

$$\tilde{u}_h^{(k+1)} = \tilde{u}_h^{(k)} + M_h^{-1} r_h^{(k)}, \qquad k = 0, 1, \ldots \tag{13}$$

Some well-known methods that belong to this category are the *fixed-point iterations*, or the *relaxation* methods, such as the Jacobi method, the Gauss-Seidel method, and its generalizations SOR and SSOR (4). To introduce these methods, we start from the splitting of the coefficient matrix A_h in Equation (4) in the form $A_h = D_h - L_h - U_h$, where $D_h = \text{diag}(A_h)$ and $-L_h$ and $-U_h$ are strictly the lower and the upper triangular part of A_h, respectively. In this way, the system in Equation (4) becomes $(D_h - L_h - U_h)u_h = f_h$ and we can form a variety of iterative methods of the form in Equation (12) by taking suitable choices for the matrices M_h and N_h.

In the Jacobi method, the simplest choice for M_h is taken, that is $M_h = D_h$, $N_h = L_h + U_h$ and the iteration can be written as:

$$\tilde{u}_h^{(k+1)} = D_h^{-1}(L_h + U_h)\tilde{u}_h^{(k)} + D_h^{-1} f_h, \quad k = 0, 1, \ldots \tag{14}$$

A slight modification of the original method in Equation (14) is to take the weighted average between $\tilde{u}_h^{(k+1)}$ and $\tilde{u}_h^{(k)}$ to form a new iteration,

$$\begin{aligned} \tilde{u}_h^{(k+1)} &= [(1-\omega)I + \omega D_h^{-1}(L_h + U_h)]\tilde{u}_h^{(k)} + \omega D_h^{-1} f_h, \\ k &= 0, 1, \ldots \end{aligned} \tag{15}$$

where $\omega \in \mathbb{R}$. Equation (15) represents the *weighted* or *damped* Jacobi method. For $\omega = 1$, Equation (15) reduces to the standard Jacobi method in Equation (14).

The Gauss–Seidel method involves the choice $M_h = D_h - L_h, N_h = U_h$ and can be written as

$$\tilde{u}_h^{(k+1)} = (D_h - L_h)^{-1} U_h \tilde{u}_h^{(k)} + (D_h - L_h)^{-1} f_h, \quad k = 0, 1, \ldots \tag{16}$$

The main advantage of the Gauss–Seidel method is that the components of the new approximation $\tilde{u}_h^{(k+1)}$ can be used as soon as they are computed. Several modifications of the standard Gauss–Seidel method were developed with the aim of improving the convergence characteristics or parallelizability of the original algorithm in Equation (16) (symmetric, red-black, etc. see Refs. 4,7, and 8).

When applied to the solution of linear systems in Equation (7) that arise from the discretization of the model–problem in Equations (5) and (6), the convergence of splitting iterations is initially rapid, only to slow down significantly after a few iterations. More careful examination of the convergence characteristics using Fourier analysis (7–10) reveal different speeds of convergence for different Fourier modes. That is, if different Fourier modes (vectors of the form $(v^l)_i = \sin(il\pi/n_h), i = 1, \ldots, n_h - 1$, where l is the wave number) are used as the exact solutions of the residual Equation (11) with a zero initial guess, the convergence speed of the splitting iterations improves with the increasing wave number l. This means that the convergence is faster when l is larger, that is, when the error in the solution u_h contains the high-frequency (highly oscillatory) components. Thus, when a system in Equation (7) with an arbitrary right-hand side is solved using a simple splitting iteration with an arbitrary initial guess $\tilde{u}_h^{(0)}$, the initial fast convergence is because of the rapid elimination of the high-frequency components in the error e_h. A slow decrease in the error at the later stages of iteration indicates the presence of the low-frequency components. We assume that the Fourier modes in the lower half of the discrete spectrum (with the wave numbers $1 \leq l < n_h/2$) are referred to as the low-frequency (smooth) modes, whereas the modes in the upper half of the discrete spectrum (with the wave numbers $n_h/2 \leq l \leq n_h - 1$) are referred to as the high-frequency (oscillatory) modes.

If we rewrite a general splitting iteration in Equation (12) as $\tilde{u}_h^{(k+1)} = G_h \tilde{u}_h^{(k)} + g_h$, then the matrix G_h is referred to as the iteration matrix. The error $e_h^{(k)} = u_h - \tilde{u}_h^{(k)}$ after k iterations satisfies the relation $e_h^{(k)} = G_h^k e_h^{(0)}$. A sufficient and necessary condition for a splitting iteration to converge to the solution $(\{\tilde{u}_h^{(k)}\} \to u_h)$ is that the spectral radius of the iteration matrix G_h is less than 1 (24). The spectral radius is defined as $\rho(G_h) = \max|\lambda_j(G_h)|$, where $\lambda_j(G_h)$ are the eigenvalues of G_h [recall that for a symmetric and positive definite (SPD) matrix, all the eigenvalues are real and positive (24)]. The speed of convergence of a splitting iteration is determined by the asymptotic convergence rate (4)

$$\tau = -\ln\left(\lim_{k \to \infty} \frac{\|e_h^{(k)}\|}{\|e_h^{(0)}\|}\right)^{1/k} \tag{17}$$

For the case of the linear system in Equation (7) obtained from the discretization of the model–problem in Equations (5) and (6), the eigenvalues of the iteration matrix $G_h^J = I - \frac{\omega h^2}{2} A_h$ for the damped Jacobi method are given by $\lambda_j(G_h^J) = 1 - 2\omega \sin^2(\frac{j\pi}{2n_h}),\ j = 1, \ldots, n_h - 1$. Thus, $|\lambda_j\ (G_h^J)| < 1$ for each j if $0 < \omega < 1$, and the method is convergent. However, different choices of the damping parameter ω have a crucial effect on the amount by which different Fourier components of the error are reduced. One particular choice is to find the value of the parameter ω that maximizes the effectiveness of the damped Jacobi method in reducing the oscillatory components of the error (the components with the wave numbers $n_h/2 \leq l \leq n_h - 1$). The optimal value for the linear system in Equation (7) is $\omega = 2/3(7)$, and for this value we have $|\lambda_j| < 1/3$ for $n_h/2 \leq j \leq n_h - 1$. This means that each iteration of the damped Jacobi method reduces the magnitude of the oscillatory components of the error by at least a factor 3. For the linear system obtained from the FEM discretization of the two-dimensional model–problem in Equation (8), the optimal value of ω is 4/5 for the case of linear approximation and $\omega = 8/9$ for bilinear case, (2, p. 100, 4). For the Gauss–Seidel method, the eigenvalues of the iteration matrix for the model-problem in Equation (7) are given by $\lambda_j(G_h^{GS}) = \cos^2(\frac{j\pi}{n_h}),\ j = 1, \ldots, n_h - 1$. As in the case of the damped Jacobi method, the oscillatory modes in the error are reduced rapidly, whereas the smooth modes persist.

The property of the fixed-point iteration schemes to reduce rapidly the high-frequency components in the error is known as the *smoothing* property, and such schemes commonly are known as the *smoothers*. This property is, at the same time, the main factor that impairs the applicability of these methods as stand-alone solvers for linear systems that arise in FDM/FEM discretizations of PDEs.

Two-Grid Correction Method

Having introduced the smoothing property of standard iterative methods, we investigate possible modifications of such iterative procedures that would enable the efficient reduction of all frequency components of the solution error e_h. Again, we study the model–problem in Equations (5) and (6) discretized on the uniform grid $\Omega_h = \{x_i = ih\},\ h = 1/n_h, i = 1, \ldots, n_h - 1$ yielding a linear system in Equation (7). The mesh Ω_h may be regarded as a "fine" mesh obtained by the uniform refinement of a coarse mesh $\Omega_H = \{x_i = iH\},\ H = 2h, i = 1, \ldots, n_H - 1$. The coarse mesh contains only the points of the fine mesh with the even numbers. After applying several steps of a fixed-point method to the h-system in Equation (7), only the smooth components of the error remain. The questions that naturally arise in this setting concern the properties of the smooth error components from the grid Ω_h, when represented on the coarse grid Ω_H. These components seem to be more oscillatory on Ω_H than on Ω_h (see Ref. 7). Notice that on the coarse grid Ω_H, we have only half as many Fourier modes compared with the fine grid $\Omega_h (n_H = \frac{1}{2} n_h)$. The fact that the smooth error components from the fine grid seem less smooth on the coarse grid offers a potential remedy for the situation when a fixed-point iteration loses its effectiveness—we need to move to a coarse grid Ω_H, where a fixed-point iteration will be more effective in reducing the remaining error components. This idea forms the basis of the two-grid method, which is summarized in the Algorithm 1.

Algorithm 1. Two-grid correction scheme.

```
1:  $\tilde{u}_h \leftarrow G_h^{v_1}(\tilde{u}_h^{(0)}, f_h)$
2:  $r_h = f_h - A_h\tilde{u}_h$
3:  $r_H = R_h^H r_h$
4:  Solve approximately $A_H e_H = r_H$
5:  $e_h = P_H^h e_H$
6:  $\tilde{u}_h = \tilde{u}_h + e_h$
7:  $\tilde{u}_h \leftarrow G_h^{v_2}(\tilde{u}_h, f_h)$
```

In Algorithm 1, $G_h^v(\tilde{u}_h, f_h)$ denotes the application of v iterations of a fixed-point iteration method to a linear system in Equation (7) with the initial guess $\tilde{u}_h$. At Step 4 of Algorithm 1, the coarse-grid problem $A_H e_H = r_H$ needs to be solved. The coarse-grid discrete operator A_H can be obtained either by the direct discretization of the continuous problem on a coarse mesh Ω_H or from the fine-grid discrete operator A_h by applying the Galerkin projection $A_h = R_h^H A_h P_H^h$. After solving the coarse grid problem (Step 4), we need to add the correction e_H, defined on the coarse grid Ω_H, to the current approximation of the solution $\tilde{u}_h$, which is defined on the fine grid Ω_h. It is obvious that these two vectors do not match dimensionally. Thus, before the correction, we need to transform the vector e_H to the vector e_h. The numerical procedure that implements the transfer of information from a coarse to a fine grid is referred to as *interpolation* or *prolongation*. The interpolation can be presented in operator form as $v_h = P_H^h v_H$, where $v_H \in \mathbb{R}^{n_H}, v_h \in \mathbb{R}^{n_h}$, and $P_H^h \in \mathbb{R}^{n_h \times n_H}$. Here, n_h denotes the size of a discrete problem on the fine grid and n_H denotes the size of a discrete problem on the coarse grid. Many different strategies exist for doing interpolation when MG is considered in the FDM setting (see Refs. 4,7,8, and 10). The most commonly used is linear or bilinear interpolation. In a FEM setting, the prolongation operator P_H^h is connected naturally with the FE basis functions associated with the coarse grid (see Refs 1,7, and 8). In the case of the one-dimensional problem in Equations (5) and (6), the elements of the interpolation matrix are given by $(P_H^h)_{g(j),g(l)} = \phi_l^H(x_j)$, where $g(l)$ is the global number of the node l on the coarse grid Ω_H and *g(j)* is the global number of the node *j* on the fine grid Ω_h. $\phi_l^H(x_j)$ is the value of the FE basis function associated with the node l from the coarse grid Ω_H at the point j of the fine grid with the coordinate x_j.

Before solving the coarse grid problem $A_H e_H = r_H$, we need to transfer the information about the fine grid residual r_h to the coarse grid Ω_H, thus getting r_H. This operation is the reverse of prolongation and is referred to as *restriction*. The restriction operator can be represented as $v_H = R_h^H v_h$, where $R_h^H \in R^{n_H \times n_h}$. The simplest restriction operator is *injection*, defined in one dimension as $(v_H)_j = (v_h)_{2j}$, $j = 1, \ldots, n_H - 1$, and the coarse grid vector takes the immediate values from the fine grid vector. Some more sophisticated restriction techniques include *half injection* and *full weighting* (see Refs 4,7, and 8). The important property of the full weighting restriction operator in the FDM setting is that it is the transpose of the linear interpolation operator up to the constant that depends on the spatial dimension d, $P_H^h = 2^d(R_h^H)^T$. In the FEM setting, the restriction and the interpolation operators simply are selected as the transpose of each other, $P_H^h = (R_h^H)^T$. The spatial dimension-dependent factor 2^d that appears in the relation between the restriction R_h^H and the interpolation P_H^h is the consequence of the residuals being taken pointwise in the FDM case and being element-weighted in the FEM case.

If the coarse grid problem is solved with sufficient accuracy, the two-grid correction scheme should work efficiently, providing that the interpolation of the error from coarse to fine grid is sufficiently accurate. This happens in cases when the error e_H is smooth. As the fixed-point iteration scheme applied to the coarse-grid problem smooths the error, it forms a complementary pair with the interpolation, and the pair of these numerical procedures work very efficiently.

V-Cycle Multigrid Scheme and Full Multigrid

If the coarse-grid problem $A_H e_H = r_H$ in Algorithm 1 is solved approximately, presumably by using the fixed-point iteration, the question is how to eliminate successfully the outstanding low-frequency modes on Ω_H? The answer lies in the recursive application of the two-grid scheme. Such a scheme would require a sequence of nested grids $\Omega_0 \subset \Omega_1 \subset \cdots \subset \Omega_L$, where Ω_0 is a sufficiently coarse grid (typically consisting of only a few nodes) to allow efficient exact solution of the residual equation, presumably by a direct solver. This scheme defines the V-cycle of MG, which is summarized in Algorithm 2:

Algorithm 2. V-Cycle multigrid (recursive definition): $u_L = \mathrm{MG}(A_L, f_L, \tilde{u}_L^{(0)}, v_1, v_2, L)$.

```
1:  function MG $(A_l, f_l, \tilde{u}_l^{(0)}, v_1, v_2, l)$
2:      $\tilde{u}_l \leftarrow G_h^{v_1}(\tilde{u}_l^{(0)}, f_l)$
3:      $r_l = f_l - A_l\tilde{u}_l$;
4:      $r_{l-1} = R_l^{l-1} r_l$
5:      if $l - 1 = 0$ then
6:          Solve exactly $A_{l-1}e_{l-1} = r_{l-1}$
7:      else
8:          $e_{l-1} = MG(A_{l-1}, r_{l-1}, 0, v_1, v_2, l-1)$
9:          $e_l = P_{l-1}^l e_{l-1}$
10:         $\tilde{u}_l = \tilde{u}_l + e_l$
11:         $\tilde{u}_l \leftarrow G_h^{v_2}(\tilde{u}_l, f_l)$
12:     end if
13:     return $\tilde{u}_l$
14: end function
```

A number of modifications of the basic V-cycle exist. The simplest modification is to vary the number of recursive calls γ of the MG function in Step 8 of the Algorithm 2. For $\gamma = 1$, we have the so-called V-cycle, whereas $\gamma = 2$ produces the so-called W-cycle (7).

Until now, we were assuming that the relaxation on the fine grid is done with an arbitrary initial guess $\tilde{u}_L^{(0)}$, most commonly taken to be the zero vector. A natural question in this context would be if it is possible to obtain an improved initial guess for the relaxation method. Such an approximation can be naturally obtained by applying a recursive procedure referred to as *nested iteration* (7,8,10). Assume that the model–problem in Equation (7) is discretized using a sequence of nested grids $\Omega_0 \subset \Omega_1 \subset \cdots \subset \Omega_L$. Then we can solve the problem on the coarsest level Ω_0 exactly, interpolate the solution to the next finer level, and use this value as the initial guess for the relaxation (i.e., $\tilde{u}_1^{(0)} = P_0^1 \tilde{u}_0$). This procedure can be continued until we reach the finest level L. Under certain assumptions, the error in the initial guess $\tilde{u}_L^{(0)} = P_{L-1}^L \tilde{u}_{L-1}$ on the finest level is of the order of the discretization error and only a small number of MG V-cycles is needed to achieve the desired level of accuracy. The combination of the nested iteration and the MG V-cycle leads to the *full multigrid* (FMG) algorithm, summarized in Algorithm 3:

Algorithm 3. Full multigrid: $\tilde{u}_L = \text{FMG}(A_L, f_L, v_1, v_2, L)$.

```
function $\tilde{u}_L = \text{FMG}(A_L, f_L, v_1, v_2, l)$
    Solve $A_0 \tilde{u}_0 = f_0$ with sufficient accuracy
    for $l$=1, $L$ do
        $\tilde{u}_l^{(0)} = \hat{P}_{l-1}^l \tilde{u}_{l-1}$
        $\tilde{u}_l = \text{MG}(A_l, f_l, \tilde{u}_l^{(0)}, v_1, v_2, l)$   % Algorithm 2
    end for
    return $\tilde{u}_L$
end function
```

The interpolation operator $\hat{P}_{l-1}^l$ in the FMG scheme can be different, in general, from the interpolation operator P_{l-1}^l used in the MG V-cycle. A FMG cycle can be viewed as a sequence of V-cycles on progressively finer grids, where each V-cycle on the grid l is preceeded by a V-cycle on the grid $l - 1$.

Computational Complexity of Multigrid Algorithms

We conclude this section with an analysis of algorithmic complexity for MG, both in terms of the execution time and the storage requirements. For simplicity, we assume that the model problem in d spatial dimensions is discretized on a sequence of uniformly refined grids (in one and two spatial dimensions, the model–problem is given by Equations (5) and (6) and Equations (8) and (9), respectively). Denote the storage required to fit the discrete problem on the finest grid by M_L. The total memory requirement for the MG scheme then is $M_{MG} = \mu M_L$, where μ depends on d but not on L. This cost does not take into account the storage needed for the restriction/prolongation operators, although in some implementations of MG, these operators do not need to be stored explicitly. For the case of uniformly refined grids, the upper bound for the constant μ is 2 in one dimension, and $\frac{4}{3}$ in two dimensions (by virtue of $\mu = \sum_{j=0}^{L} \frac{1}{2^{jd}} < \sum_{j=0}^{\infty} \frac{1}{2^{jd}}$). For non uniformly refined grids, μ is larger but M_{MG} still is a linear function of M_L, with the constant of proportionality independent of L.

Computational complexity of MG usually is expressed in terms of work units (WU). One WU is the arithmetic cost of one step of a splitting iteration applied to a discrete problem on the finest grid. The computational cost of a V(1, 1) cycle of MG (V(1,1) is a V-cycle with one pre smoothing and one post smoothing iteration at each level and is v times larger than WU, with $v = 4$ for $d = 1$, $v = \frac{8}{3}$ for $d = 2$ and $v = \frac{16}{7}$ for $d = 3$ (7). These estimates do not take into account the application of the restriction/interpolation. The arithmetic cost of the FMG algorithm is higher than that of a V-cycle of MG. For the FMG with one relaxation step at each level, we have $v = 8$ for $d = 1$, $v = \frac{7}{2}$ for $d = 2$, and $v = \frac{5}{2}$ for $d = 3$ (7). Now we may ask how many V-cycles of MG or FMG are needed to achieve an iteration error commensurate with the discretization error of the FDM/FEM. To answer this question, one needs to know more about the convergence characteristics of MG. For this, deeper mathematical analysis of spectral properties of the two-grid correction scheme is essential. This analysis falls beyond the scope of our presentation. For further details see Refs 7–10. If a model–problem in d spatial dimensions is discretized by a uniform square grid, the discrete problem has $O(m^d)$ unknowns, where m is the number of grid lines in each spatial dimension. If the $V(v_1, v_2)$ cycle of MG is applied to the solution of the discrete problem with fixed parameters v_1 and v_2, the convergence factor τ in Equation (17) is bounded independently of the discretization parameter h (for a rigorous mathematical proof, see Refs 8–10). For the linear systems obtained from the discretization of the second-order, elliptic, self-adjoint PDEs, the convergence factor τ of a V-cycle typically is of order 0.1. To reduce the error $e_h = u_h - \tilde{u}_h$ to the level of the disretization error, we need to apply $O(\log m)$ V-cycles. This means that the total cost of the V-cycle scheme is $O(m^d \log m)$. In the case of the FMG scheme, the problems discretized on grids $\Omega_l, l = 0, 1, \ldots, L-1$ already are solved to the level of discretization error before proceeding with the solution of the problem on the finest grid Ω_L. In this way, we need to perform only $O(1)$ V-cycles to solve the problem on the finest grid. This process makes the computational cost of the FMG scheme $O(m^d)$, and it is an optimal solution (method).

ADVANCED TOPICS

The basic MG ideas are introduced in the previous section for the case of a linear, scalar and stationary DE with a simple grid hierarchy. This section discusses some important issues when MG is applied to more realistic problems (non linear and/or time-dependent DEs and systems of DEs), with complex grid structures in several spatial dimensions, and when the implementation is done on modern computer architectures.

Non linear Problems

The coarse grid correction step of the MG algorithm is not directly applicable to discrete non linear problems as the superposition principle does not apply in this case. Two basic approaches exist for extending the application of MG methods to non linear problems. In the indirect approach, the MG algorithm is employed to solve a sequence of linear problems that result from certain iterative global linearization procedures, such as *Newton's method*. Alternately, with the slight modification of the grid transfer and coarse grid operators, the MG algorithm can be transformed into the Brandt *Full Approximation Scheme (FAS)* algorithm (6,7), which can be applied directly to the non linear discrete equations.

In the FAS algorithm, the non linear discrete problem defined on a fine grid Ω_h as $A_h(u_h) = f_h$ is replaced by

$$A_h(\tilde{u}_h + e_h) - A_h(\tilde{u}_h) = f_h - A_h(\tilde{u}_h) \qquad (18)$$

The Equation (18) reduces in the linear case to the residual Equation (11). Define a coarse-grid approximation of Equation (18)

$$A_H\left(\hat{R}_h^H \tilde{u}_h + e_H\right) - A_H\left(\hat{R}_h^H \tilde{u}_h\right) = \hat{R}_h^H\left(f^h - A_h(\tilde{u}_h)\right) \quad (19)$$

where $\hat{R}_h^H$ is some restriction operator. Note that if the discrete non linear problem in Equation (3) comes from the FEM approximation, the restriction operators $\hat{R}_h^H$ in Equation (19) should differ by the factor of 2^d, where d is the spatial dimension (see the discussion in the section "Two-Grid Correction Method"). Introducing the approximate coarse grid discrete solution $\tilde{u}_H = \hat{R}_h^H \tilde{u}_h + e_H$ and the *fine-to-coarse correction* $\tau_H^h = A_H(\hat{R}_h^H \tilde{u}_h) - \hat{R}_h^H A_h(\tilde{u}_h)$, the coarse grid problem in the FAS MG algorithm becomes

$$A_H(\tilde{u}_H) = R_h^H f_h + \tau_H^h \qquad (20)$$

Then, the coarse grid correction

$$\tilde{u}_h \leftarrow \tilde{u}_h + \hat{P}_H^h e_H = \tilde{u}_h + \hat{P}_H^h\left(\tilde{u}_H - \hat{R}_h^H \tilde{u}_h\right) \qquad (21)$$

can be applied directly to non linear problems. In Equation (21) $\hat{R}_h^H \tilde{u}_h$ represents the solution of Equation (20) on coarse grid Ω_H. This means that once the solution of the fine grid problem is obtained, the coarse grid correction does not introduce any changes through the interpolation. The fine-to-coarse correction τ_H^h is a measure of how close the approximation properties of the coarse grid equations are to that of the fine grid equations.

When the FAS MG approach is used, the global Newton linearization is not needed, thus avoiding the storage of large Jacobian matrices. However, the linear smoothing algorithms need to be replaced by non linear variants of the relaxation schemes. Within a non linear relaxation method, we need to solve a non linear equation for each component of the solution. To facilitate this, local variants of the Newton method commonly are used. The FAS MG algorithm structure and its implementation are almost the same as the linear case and require only small modifications. For non linear problems, a proper selection of the initial approximation is necessary to guarantee convergence. To this end, it is recommended to use the FMG method described in the Basic Concepts section above.

Systems of Partial Differential Equations

Many complex problems in physics and engineering cannot be described by simple, scalar DEs. These problems, such as DEs with unknown vector fields or multi-physics problems, usually are described by systems of DEs. The solution of systems of DEs is usually a challenging task. Although no fundamental obstacles exist to applying standard MG algorithms to systems of DEs, one needs to construct the grid transfer operators and to create the coarse grid discrete operators. Moreover, the smoothing schemes need to be selected carefully.

Problems in structural and fluid mechanics frequently are discretized using staggered grids (10). In such cases, different physical quantities are associated with different nodal positions within the grid. The main reason for such distribution of variables is the numerical stability of such schemes. However, this approach involves some restrictions and difficulties in the application of standard MG methods. For instance, using the simple injection as a restriction operator may not be possible. An alternative construction of the restriction operator is based on averaging the fine grid values. Moreover, the non matching positions of fine and coarse grid points considerably complicates the interpolation near the domain boundaries. The alternative approach to the staggered grid discretization is to use non structured grids with the same nodal positions for the different types of unknowns. Numerical stabilization techniques are necessary to apply in this context (2,8).

The effectiveness of standard MG methods, when applied to the solution of systems of DEs, is determined to a large extent by the effectiveness of a relaxation procedure. For scalar elliptic problems, it is possible to create nearly optimal relaxation schemes based on standard fixed-point iterations. The straightforward extension of this scalar approach to systems of DEs is to group the discrete equations either with respect to the grid points or with respect to the discrete representations of each DE in the system (the latter corresponds to the blocking of a linear system coefficient matrix). For effective smoothing, the order in which the particular grid points/equations are accessed is very important and should be adjusted for the problem at hand. Two main approaches exist for the decoupling of a system: *global* decoupling, where for each DE all the grid points are accessed simultaneously, and *local* decoupling, where all DEs are accessed for each grid point.

The local splitting naturally leads to *collective* or *block* relaxation schemes, where all the discrete unknowns at a given grid node, or group of nodes, are relaxed simultaneously. The collective relaxation methods are very attractive within the FAS MG framework for non linear problems. Another very general class of smoothing procedures that are applicable in such situations are *distributive relaxations* (20). The idea is to triangulate locally the discrete operator for all discrete equations and variables within the framework of the smoother. The resulting smoothers also are called the *transforming smoothers* (25).

In the section on grid-coarsening techniques, an advanced technique based on the algebraic multigrid (AMG) for the solution of linear systems obtained by the discretization of systems of PDEs will be presented.

Time-Dependent Problems

A common approach in solving time-dependent problems is to separate the discretization of spatial unknowns in the problem from the discretization of time derivatives. Discretization of all spatial variables by some standard numerical procedure results in such cases in a differential-algebraic system (DAE). A number of numerical procedures, such as the method of lines, have been developed for the solution of such problems. Numerical procedures aimed at the solution of algebraic-differential equations usually are some modifications and generalizations of the formal methods developed for the solution of systems of ODEs [e.g., the Runge–Kutta method, the linear multistep methods, and the Newmark method (26,27)]. In a system of DAEs, each degree of freedom within the spatial discretization produces a single ODE in time. All methods for the integration of DAE systems can be classified into two groups: explicit and implicit. Explicit methods are computationally cheap (requiring only the sparse matrix–vector multiplication at each time step) and easy to implement. Their main drawback lies in stability, when the time step size changes (i.e., they are not stable for all step sizes). The region of stability of these methods is linked closely to the mesh size used in spatial discretization (the so-called CFL criterion). However, if a particular application requires the use of small time steps, then the solution algorithms based on explicit time-stepping schemes can be effective. The implicit time-stepping schemes have no restrictions with respect to the time step size, and they are unconditionally stable for all step sizes. The price to pay for this stability is that at each time step one needs to solve a system of linear or non linear equations. If sufficiently small time steps are used with the implicit schemes, standard iterative solvers based on fixed-point iterations or Krylov subspace solvers (4) can be more effective than the use of MG solvers. This particularly applies if the time extrapolation method or an explicit predictor method (within a predictor–corrector scheme) is used to provide a good initial solution for the discrete problem at each time step.

However, if sufficiently large time steps are used in the time-stepping algorithm, the discrete solution will contain a significant proportion of low-frequency errors introduced by the presence of diffusion in the system (20,27). The application of MG in such situations represents a feasible alternative. In this context, one can use the so-called "smart" time-stepping algorithms (for their application in fluid mechanics see Ref. 27). In these algorithms (based on the predictor–corrector schemes), the time step size is adjusted adaptively to the physics of the problem. If a system that needs to be solved within the corrector is non linear, the explicit predictor method is used to provide a good initial guess for the solution, thus reducing the overall computational cost. MG can be used as a building block for an effective solver within the corrector (see the section on preconditioning for the example of such solver in fluid mechanics).

Multigrid with Locally Refined Meshes

Many practically important applications require the resolution of small-scale physical phenomena, which are localized in areas much smaller than the simulation domain. Examples include shocks, singularities, boundary layers, or non smooth boundaries. Using uniformly refined grids with the mesh size adjusted to the small-scale phenomena is costly. This problem is addressed using adaptive mesh refinement, which represents a process of dynamic introduction of local fine grid resolution in response to unresolved error in the solution. Adaptive mesh refinement techniques were introduced first by Brandt (6). The criteria for adaptive grid refinement are provided by a posteriori error estimation (2).

The connectivity among mesh points is generally specified by the small subgroup of nodes that form the mesh cells. Typically, each cell is a simplex (for example, lines in one dimension; triangles or quadrilaterals in two dimensions; and tetrahedra, brick elements, or hexahedra in three dimensions). The refinement of a single grid cell is achieved by placing one or more new points on the surface of, or inside, each grid cell and connecting newly created and existing mesh points to create a new set of finer cells. A union of all refined cells at the given discretization level forms a new, locally refined, grid patch. Because adaptive local refinement and MG both deal with grids of varying mesh size, the two methods naturally fit together. However, it is necessary to perform some adaptations on both sides to make the most effective use of both procedures. To apply MG methods, the local grid refinement should be performed with the possibility of accessing locally refined grids at different levels.

The adaptive mesh refinement (AMR) procedure starts from a basic coarse grid covering the whole computational domain. As the solution phase proceeds, the regions requiring a finer grid resolution are identified by an error estimator, which produces an estimate of the discretization error, one specific example being $e_h = \hat{R}^h u - u_h$(28). Locally refined grid patches are created in these regions. This adaptive solution procedure is repeated recursively until either a maximal number of refinement levels is reached or the estimated error is below the user-specified tolerance. Such a procedure is compatible with the FMG algorithm. Notice that a locally refined coarse grid should contain both the information on the correction of the discrete solution in a part covered by it and the discrete solution, itself, in the remainder of the grid. The simplest and most natural way to achieve this goal is to employ a slightly modified FAS MG algorithm. The main difference between the FAS MG algorithm and the AMR MG algorithm is the additional interpolation that is needed at the interior boundary of each locally refined grid patch. For unstructured grids, it is possible to refine the grid cells close to the interior boundary in such a way to avoid interpolation at the interor boundaries altogether. For structured meshes, the internal boundaries of locally refined patches contain the so-called *hanging nodes* that require the interpolation from the coarse grid to preserve the FE solution continuity across the element boundaries. This interpolation may need to be defined in a recursive fashion if more than one level of refinement is introduced on a grid patch (this procedure resembles the long-range interpolation from the algebraic multigrid). The interpolation operator at the internal boundaries of the locally refined grids could be the same one used in the standard FMG algorithm. Figure 1 shows an example of

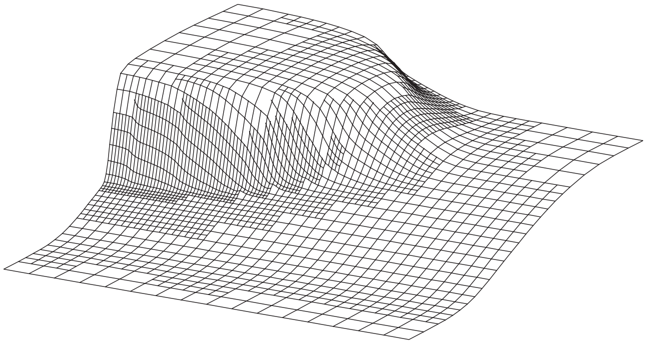

Figure 1. Composite multi level adaptive mesh for the MG solution of a dopant diffusion equation in a semiconductor fabrication.

the adaptive grid structure comprising several locally refined grid patches dynamically created in the simulation of dopant redistribution during semiconductor fabrication (20). Other possibilities exist in the context of the FAS MG scheme, for example, one could allow the existence of hanging nodes and project the non conforming solution at each stage of the FAS to the space where the solution values at the hanging nodes are the interpolants of their coarse grid parent values (29).

Various error estimators have been proposed to support the process of the local grid refinement. The multi level locally refined grid structure and the MG algorithm provide additional reliable and numerically effective evaluation of discretization errors. Namely, the grid correction operator τ_H^h [introduced in Equation (20)] represents the local discretization error at the coarse grid level Ω_H (up to a factor that depends on the ratio H/h). It is the information inherent to the FAS MG scheme and can be used directly as a part of the local grid refinement process. The other possibility for error estimation is to compare discrete solutions obtained on different grid levels of FMG algorithms to extrapolate the global discretization error. In this case, the actual discrete solutions are used, rather than those obtained after fine-to-coarse correction.

Another class of adaptive multi level algorithms are the fast adaptive composite-grid (FAC) methods developed in the 1980s (30). The main strength of the FAC is the use of the existing single-grid solvers defined on uniform meshes to solve different refinement levels. Another important advantage of the FAC is that the discrete systems on locally refined grids are given in the conservative form. The FAC allows concurrent processing of grids at given refinement levels, and its convergence rate is bounded independently of the number of refinement levels. One potential pitfall of both AMR MG and the FAC is in the multiplicative way various refinement levels are treated, thus implying sequential processing of these levels.

Grid-Coarsening Techniques and Algebraic Multigrid (AMG)

A multi level grid hierarchy can be created in a straightforward way by successively adding finer discretization levels to an initial coarse grid. To this end, nested global and local mesh refinement as well as non-nested global mesh generation steps can be employed. However, many practical problems are defined in domains with complex geometries. In such cases, an unstructured mesh or a set of composite block-structured meshes are required to resolve all the geometric features of the domain. The resulting grid could contain a large number of nodes to be used as the coarsest grid level in the MG algorithms. To take full advantage of MG methods in such circumstances, a variety of techniques have been developed to provide multi level grid hierarchy and generate intergrid transfer operators by coarsening a given fine grid.

The first task in the grid-coarsening procedure is to choose the coarse-level variables. In practice, the quality of the selected coarse-level variables is based on heuristic principles (see Refs. 4,7, and 8). The aim is to achieve both the quality of interpolation and a significant reduction in the dimension of a discrete problem on the coarse grids. These two requirements are contradictory, and in practice some tradeoffs are needed to meet them as closely as possible. The coarse-level variables commonly are identified as a subset of the fine grid variables based on the mesh connectivity and algebraic dependencies. The mesh connectivity can be employed in a graph-based approach, by selecting coarse-level variables at the fine mesh points to form the *maximal independent set* (MIS) of the fine mesh points. For the construction of effective coarse grids and intergrid transfer operators, it often is necessary to include the algebraic information in the coarse nodes selection procedure. One basic algebraic principle is to select coarse-level variables with a *strong connection* to the neighboring fine-level variables (strength of dependence principle) (31). This approach leads to a class of MG methods referred to as *algebraic multigrid (AMG)* methods. Whereas geometric MG methods operate on a sequence of nested grids, AMG operates on a hierarchy of progressively smaller linear systems, which are constructed in an automatic coarsening process, based on the algebraic information contained in the coefficient matrix.

Another class of methods identifies a coarse grid variable as a combination of several fine-grid variables. It typically is used in combination with a finite-volume discretization method (10), where the grid variables are associated with the corresponding mesh control volumes. The *volume agglomeration method* simply aggregates the fine control volumes into larger agglomerates to form the coarse grid space. The agglomeration can be performed by a *greedy algorithm*. Alternatively, the fine grid variables can be clustered directly (aggregated) into coarse-level variables based on the algebraic principle of strongly or weakly coupled neighborhoods. The *aggregation method* is introduced in Ref. 32, and some similar methods can be found in Refs. 33 and 34. The agglomeration method works also in the finite element setting (35).

The most common approach in creating the intergrid transfer operators within the grid-coarsening procedure is to formulate first the prolongation operator P_H^h and to use $R_h^H = (P_H^h)^T$ as a restriction operator. One way of constructing the prolongation operator from a subset of fine grid variables is to apply the *Delauney triangulation procedure* to the selected coarse mesh points. A certain finite element space associated to this triangulation can be used to create the interpolation operator P_H^h. The prolongation operators for the agglomeration and aggregation methods are defined in the way that each fine grid variable is represented by a single (agglomerated or aggregated) variable of the coarse grid.

The interpolation operator also can be derived using purely algebraic information. We start from a linear discrete problem in Equation (4) and introduce a concept of *algebraically smooth error* e_h. Algebraically smooth error is the error that cannot be reduced effectively by a fixed-point iteration. Note that the graph of an algebraically smooth error may not necessarily be a smooth function (7). The smooth errors are characterized by small residuals, for example, componentwise $|r_i| \ll a_{ii}|e_i|$. This condition can be interpreted broadly as

$$Ae \approx 0 \tag{22}$$

For the cases of model–problems in Equations (5) and (6) and Equations (8) and (9), where the coefficient matrices are characterized by zero row sums, Equation (22) means that we have component-wise

$$a_{ii}e_i \approx -\sum_{j \neq i} a_{ij}e_j \tag{23}$$

The relation in Equation (23) means that the smooth error can be approximated efficiently at a particular point if one knows its values at the neighboring points. This fact is the starting point for the development of the interpolation operator P_H^h for AMG. Another important feature in constructing the AMG interpolation is the fact that the smooth error varies slowly along the strong connections (associated with large negative off-diagonal elements in the coefficient matrix). Each equation in the Galerkin system describes the dependence between the neighboring unknowns. The i-th equation in the system determines which unknowns u_j affect the unknown u_i the most. If the value u_i needs to be interpolated accurately, the best choice would be to adopt the interpolation points u_j with large coefficients a_{ij} in the Galerkin matrix. Such points u_j are, in turn, good candidates for coarse grid points. The quantitative expression that u_i depends strongly on u_j is given by

$$-a_{ij} \geq \theta \max_{1 \leq k \leq n} \{-a_{ik}\}, \qquad 0 < \theta \leq 1 \tag{24}$$

Assume that we have partitioned the grid points into the subset of coarse grid points C and fine grid points F. For each fine grid point i, its neighboring points, defined by the nonzero off-diagonal entries in the i-th equation, can be subdivided into three different categories, with respect to the strength of dependence: coarse grid points with strong influence on $i(C_i)$, fine grid points with strong influence on $i(F_i^s)$, and the points (both coarse and fine) that weakly influence $i(D_i)$. Then, the relation in Equation (23) for algebraically smooth error becomes (for more details, see Ref. 31)

$$a_{ii}e_i \approx -\sum_{j \in C_i} a_{ij}e_j - \sum_{j \in F_i^s} a_{ij}e_j - \sum_{j \in D_i} a_{ij}e_j \tag{25}$$

The sum over weakly connected points D_i can be lumped with the diagonal terms, as a_{ij} is relatively small compared with a_{ii}. Also, the nodes $j \in F_i^s$ should be distributed to the nodes in the set C_i. In deriving this relation, we must ensure that the resulting interpolation formula works correctly for the constant functions. The action of the interpolation operator P_H^h obtained in this way can be represented as

$$(P_H^h e)_i = \begin{cases} e_i & i \in C \\ \sum\limits_{j \in C_i} \omega_{ij}e_j & i \in F \end{cases} \tag{26}$$

where

$$\omega_{ij} = -\frac{a_{ij} + \sum\limits_{k \in F_i^s} \dfrac{a_{ik}a_{kj}}{\sum\limits_{l \in C_i} a_{kl}}}{a_{ii} + \sum\limits_{m \in D_i} a_{im}} \tag{27}$$

Finally, the coarse grid discrete equations should be determined. The volume agglomeration methods allow us, in some cases, to combine the fine grid discretization equations in the formulation of the coarse grid ones. However, in most cases, the explicit discretization procedure is not possible and coarse grid equations should be constructed algebraically. An efficient and popular method to obtain a coarse-level operator is through the Galerkin form

$$A_H = R_h^H A_h P_H^h \tag{28}$$

For other, more sophisticated methods based on constrained optimization schemes see Ref. 36.

The AMG approach that was introduced previously is suitable for the approximate solution of linear algebraic systems that arise in discretizations of scalar elliptic PDEs. The most robust performance of AMG is observed for linear systems with coefficient matrices being SPD and M-matrices (the example being the discrete Laplace operator) (24). A reasonably good performance also can be expected for the discrete systems obtained from the discretizations of the perturbations of elliptic operators (such as the convection–diffusion–reaction equation). However, when the AMG solver, based on the standard coarsening approach, is applied to the linear systems obtained from the discretization of non scalar PDEs or systems of PDEs (where the coefficient matrices are substantially different from the SPD M-matrices), its performance usually deteriorates significantly (if converging at all). The reason for this is that the classical AMG uses the *variable-based approach*. This approach treats all the unknowns in the system equally. Thus, such approach cannot work effectively for systems of PDEs, unless a very weak coupling exists between the different unknowns. If the different types of unknowns in a PDE system are coupled tightly, some modifications and extensions of the classical approach are needed to improve the AMG convergence characteristics and robustness (see Ref. 37).

An initial idea of generalizing the AMG concept to systems of PDEs resulted in the *unknown-based approach*. In this approach, different types of unknowns are treated separately. Then, the coarsening of the set of variables that corresponds to each of the unknowns in a PDE system is based on the connectivity structure of the submatrix that corresponds to these variables (the diagonal block of the overall coefficient matrix, assuming that the variables corresponding to each of the unknowns are enumerated consecutively), and interpolation is based on the matrix entries in each submatrix separately. In contrast, the coarse-level Galerkin matrices are assembled using the whole fine level matrices. The unknown-based approach is the simplest way of generalizing the AMG for systems of PDEs. The additional information that is needed for the unknown-based approach (compared with the classical approach) is the correspondence between the variables and the unknowns. The best performance of AMG with the unknown-based approach is expected if the diagonal submatrices that corrspond to all the unknowns are close to M-matrices. This approach is proved to be effective for the systems involving non scalar PDEs [such as linear elasticity (38)]. However, this approach loses its effectiveness if different unknowns in the system are coupled tightly.

The latest development in generalizations of AMG for the PDE systems is referred to as the *point-based approach*. In this approach, the coarsening is based on a set of points, and all the unknowns share the same "grid" hierarchy. In a PDE setting, points can be regarded as the physical grid points in space, but they also can be considered in an abstract setting. The coarsening process is based on an auxiliary matrix, referred to as the *primary matrix*. This matrix should be defined to be the representative of the connectivity patterns for all the unknowns in the system, as the same coarse levels are associated to all the unknowns. The primary matrix is defined frequently based on the distances between the grid points. Then, the associated coarsening procedure is similar to that of geometric MG. The interpolation procedure can be defined as block interpolation (by approximating the block equations), or one can use the variable-based approaches, which are the same (s-interpolation) or different (u-interpolation) for each unknown. The interpolation weights are computed based on the coefficients in the Galerkin matrix, the coefficients of the primary matrix, or the distances and positions of the points. The interpolation schemes deployed in classical AMG [such as direct, standard, or multi pass interpolation (8)] generalize to the point-based AMG concept.

Although great progress has been made in developing AMG for systems of PDEs, no unique technique works well for all systems of PDEs. Concrete instances of this concept are found to work well for certain important applications, such as CFD (segregated approaches in solving the Navier–Stokes equations), multiphase flow in porous media (39), structural mechanics, semiconductor process and device simulation (40,41), and so further. Finally, it should be pointed out that the code SAMG (42), based on the point approach, was developed at Fraunhofer Institute in Germany.

Multigrid as a Preconditioner

In the Basic Concepts section, the fixed-point iteration methods were introduced. Their ineffectiveness when dealing with the low-frequency error components motivated the design of MG techniques. Fixed-point iterations are just one member of the broad class of methods for the solution of sparse linear systems, which are based on projection. A projection process enables the extraction of an approximate solution of a linear system from a given vector subspace. The simplest case of the projection methods are one-dimensional projection schemes, where the search space is spanned by a single vector. The representatives of one-dimensional projection schemes are the steepest descent algorithm and the minimum residual iteration (4).

One way of improving the convergence characteristics of the projection methods is to increase the dimension of the vector subspace. Such approach is adopted in the Krylov subspace methods (2,4). Krylov methods are based on the projection process onto the Krylov subspace defined as

$$K_m(A,y) = \mathrm{span}\,(y, Ay, \ldots, A^{m-1}y) \tag{29}$$

In Equation (29), A is the coefficient matrix and the vector y usually is taken to be the initial residual $r^{[0]} = f - Ax^{[0]}$. The main property of the Krylov subspaces is that their dimension increases by 1 at each iteration. From the definition in Equation (29) of the Krylov subspace, it follows that the solution of a linear system $Ax = f$ is approximated by $x = A^{-1} f \approx q_{m-1}(A) r^{[0]}$, where $q_{m-1}(A)$ is the matrix polynomial of degree $m - 1$. All Krylov subspace methods work on the same principle of polynomial approximation. Different types of Krylov methods are obtained from different types of orthogonality constraints imposed to extract the approximate solution from the Krylov subspace (4). The well-known representative of the Krylov methods aimed for the linear systems with SPD coefficient matrices is the conjugate gradient (CG) algorithm.

The convergence characteristics of Krylov iterative solvers depend crucially on the spectral properties of the coefficient matrix. In the case of the CG algorithm, the error norm reduction at the k-th iteration can be represented as (2,4)

$$\frac{\|e^{[k]}\|_A}{\|e^{[0]}\|_A} \le \min_{q_{k-1} \in P^0_{k-1}} \max_j |q_{k-1}(\lambda_j)| \tag{30}$$

where q_{k-1} is the polynomial of degree $k - 1$ such that $q_{k-1}(0) = 1$ and $\| \cdot \|_A^2 = (A\cdot, \cdot)$. The estimate in Equation (30) implies that the contraction rate of the CG algorithm at the iteration k is determined by the maximum value of the characteristic polynomial q_{k-1} evaluated at the eigenvalues λ_j of the coefficient matrix. This implies that the rapid convergence of the CG algorithm requires the construction of the characteristic polynomial q of relatively low degree, which has small value at all eigenvalues of A. This construction is possible if the eigenvalues of A are clustered tightly together. Unfortunately, the coefficient matrices that arise in various discretizations of PDEs have the eigenvalues spread over the large areas of the real axis (or the complex plane). Moreover, the spectra of such coefficient matrices change when the discretization parameter or other problem parameters vary. The prerequisite for rapid and robust convergence of Krylov solvers is the redistribution of the coefficient matrix eigenvalues. Ideally, the eigenvalues of the transformed coefficient matrix should be clustered tightly, and the bounds of the clusters should be independent on any problem or discretization parameters. As a consequence, the Krylov solver should converge to a prescribed tolerance within a small, fixed number of iterations. The numerical technique that transforms the original linear system $Ax = f$ to an equivalent system, with the same solution but a new coefficient matrix that has more favorable spectral properties (such as a tightly clustered spectrum), is referred to as *preconditioning* (2,4). Designing sophisticated preconditioners is problem-dependent and represents a tradeoff between accuracy and efficiency.

Preconditioning assumes the transformation of the original linear system $Ax = f$ to an equivalent linear system $M^{-1}Ax = M^{-1}f$. In practice, the preconditioning matrix (or the preconditioner) M is selected to be spectrally close to the matrix A. The application of a preconditioner requires at each iteration of a Krylov solver that one solves (exactly or approximately) a linear system $Mz = r$, where r is the current residual. This operation potentially can represent a considerable computational overhead. This overhead is the main reason why the design of a good preconditioner assumes the construction of such matrix M that can be assembled and computed the action of its inverse to a vector at optimal cost. Moreover, for preconditioning to be effective, the overall reduction in number of iterations of the preconditioned Krylov solver and, more importantly, the reduction in the execution time should be considerable, when compared with a non preconditioned Krylov solver (43). To design a (nearly) optimal Krylov solver for a particular application, the preconditioner needs to take into account the specific structure and spectral properties of the coefficient matrix.

In previous sections, we established MG as the optimal iterative solver for the linear systems that arise in discretizations of second-order, elliptic, PDEs. As an alternative to using MG as a solver, one may consider using it as a preconditioner for Krylov subspace solvers. When MG is used as a preconditioner, one applies a small number (typically 1 to 2) of V-cycles, with a small number of pre- and post smoothing iterations, at each Krylov iteration to approximate the action of M^{-1} to a residual vector. This approach works well for SPD linear systems arising from the discretization of second-order, elliptic PDEs. A number of similar MG-based approaches work well in the same context.

One group of MG-based preconditioners creates explicitly the transformed system matrix $M_L^{-1}AM_R^{-1}$, where M_L and M_R are the left and the right preconditioning matrices, respectively. A typical representative is the hierarchical basis MG (HBMG) method (44). The HBMG method is introduced in the framework of the FE approximations based on nodal basis. In the HBMG method, the right preconditioning matrix M_R is constructed in such a way that the solution x is contained in the space of hierarchical basis functions. Such space is obtained by replacing, in a recursive fashion, the basis functions associated with the fine grid nodes that also exist at the coarser grid level, by the corresponding coarse grid nodal basis functions. The process is presented in Fig. 2, where the fine grid basis functions that are replaced by the coarse grid basis functions are plotted with the dashed lines. The HBMG may be interpreted as the standard MG method, with the smoother at each level applied to the unknowns existing only at this level (and not present at coarser levels). The common choice $M_L = M_R^t$ extends the important properties of the original coefficient matrix, such as symmetry and positive definitness, to the preconditioned matrix. The HBMG method is suitable for implementation on adaptive, locally refined grids. Good results are obtained for the HBMG in two dimensions (with uniformly/locally refined meshes), but the efficiency deteriorates in 3-D.

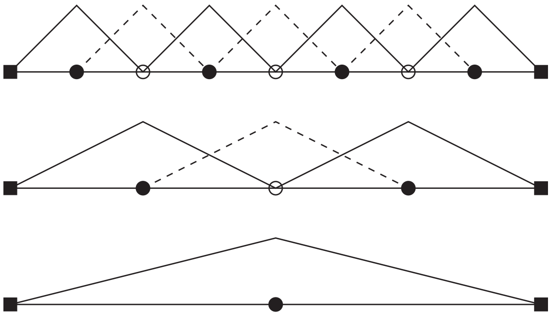

Figure 2. The principles of creating hierarchical basis in HBMG methods.

Another important MG-like preconditioning method is the so-called BPX preconditioner (45). It belongs to a class of parallel multi level preconditioners targeted for the linear systems arising in discretizations of second-order, elliptic PDEs. The main feature of this preconditioner is that it is expressed as a sum of independent operators defined on a sequence of nested subspaces of the finest approximation space. The nested subspaces are associated with the sequence of uniformly or adaptively refined triangulations and are spanned by the standard FEM basis sets associated with them. Given a sequence of nested subspaces $S_1^h \subset S_2^h \subset \cdots S_L^h$ with $S_l^h = \mathrm{span}\{\phi_k^l\}_{k=1}^{N_l}$, the action of the BPX preconditioner to a vector can be represented by

$$P^{-1}v = \sum_{l=1}^{L}\sum_{k=1}^{N_l}(v, \phi_k^l)\phi_k^l \tag{31}$$

The condition number of the preconditioned discrete operator $P^{-1}A$ is at most $O(L^2)$, and this result is independent on the spatial dimension and holds for both quasi-uniform and adaptively refined grids. The preconditioner in Equation (31) also can be represented in the operator form as

$$P^{-1} = \sum_{l=1}^{L} R_l Q_l \tag{32}$$

where R_l is an SPD operator $S_l^h \mapsto S_l^h$ and $Q_l : S_L^h \mapsto S_l^h$ is the projection operator defined by $(Q_l u, v) = (u, v)$ for $u \in S_L^h$ and $v \in S_l^h$ [$(\cdot,\cdot)$ denotes the l_2-inner product]. The cost of applying the preconditioner P will depend on the choice of R_l. The preconditioner in Equation (32) is linked closely to the MG V-cycle. The operator R_l has the role of a smoother; however, in BPX, preconditioner smoothing at every level is applied to a fine grid residual (which can be done concurrently). In MG, smoothing of the residual at a given level cannot proceed until the residual on that level is formed using the information from the previous grids. This process also involves an extra computational overhead in the MG algorithm. Parallelization issues associated with the BPX preconditioner will be discussed in the final section.

Many important problems in fundamental areas, such as structural mechanics, fluid mechanics, and electromagnetics, do not belong to the class of scalar, elliptic PDEs. Some problems are given in so-called mixed forms (2) or as the systems of PDEs. The latter is the regular case when multiphysics and multiscale processes and phenomena are modeled. When the systems of PDEs or PDEs with unknown vector fields are solved, the resulting discrete operators (coefficient matrices) have spectral properties that are not similar to the spectral properties of discrete elliptic, self-adjoint problems, for which MG is particularly suited. Thus, direct application of standard MG as a preconditioner in such complex cases is not effective. In such cases, it is possible to construct the block preconditioners—an approach that proved efficient in many important cases (2). A coefficient matrix is subdivided into blocks that correspond to different PDEs/unknowns in the PDE system (similarly to the unknown-based approach in the AMG for systems of PDEs). If some main diagonal blocks represent the discrete second-order, elliptic PDEs (or their perturbations), they are suitable candidates to be approximated by the standard MG/AMG with simple relaxation methods. The action of the inverse of the whole preconditioner is achieved by the block back-substitution. Successful block preconditioners have been developed for important problems in structural mechanics (46), fluid mechanics (2,47), and electromagnetics (48). In the following list, a brief review of some of these techniques is given.

1. Mixed formulation of second-order elliptic problems. The boundary value problem is given by

$$\begin{aligned} A^{-1}\vec{u} - \nabla p &= 0 \\ \nabla \cdot \vec{u} &= -f \end{aligned} \tag{33}$$

in $\Omega \subset \mathbb{R}^d$, subject to suitable BCs. In Equation (33) $A : \mathbb{R} \mapsto \mathbb{R}^{d\times d}$ is a symmetric and uniformly positive definite matrix function, p is the pressure, and $\vec{u} = A^{-1}p$ is the velocity. Problems of this type arise in modeling of fluid flow through porous media. The primal variable formulation of Equation (33) is $-\nabla \cdot A\nabla p = f$, but if $\vec{u}$ is the quantity of interest, a numerical solution of the mixed form in Equation (33) is preferable. Discretization of Equation (33) using Raviart–Thomas FEM leads to a linear system with an indefinite coeffiient matrix

$$\begin{bmatrix} M_A & B^t \\ B & 0 \end{bmatrix} \begin{bmatrix} u \\ p \end{bmatrix} = \begin{bmatrix} g \\ f \end{bmatrix} \tag{34}$$

with $(M_A)_{ij} = (A\vec{\varphi}_i, \vec{\varphi}_j), i, j = 1, \ldots, m$. For details, see Ref. 47. The optimal preconditioner for the linear system in Equation (34) is given by

$$M = \begin{bmatrix} M_A & 0 \\ 0 & BM_A^{-1}B^t \end{bmatrix} \tag{35}$$

The exact implementation of this preconditioner requires the factorization of the dense Schur complement matrix $S = BM_A^{-1}B^t$). The matrix S can be approximated without significant loss of efficiency by the matrix $S_D = B\mathrm{diag}\,(M_A^{-1})B^t$, which is a sparse matrix. The action of S_D^{-1} to a vector can be approximated further by a small number of AMG V-cycles (47).

2. Lame's equations of linear elasticity. This problem is a fundamental problem in structural mechanics. It also occurs in the design of integrated electronic components (microfabrication). The equations by Lamé represent a displacement formulation of linear elasticity:

$$\rho\frac{\partial^2\vec{u}}{\partial t^2} - \mu\Delta\vec{u} + (\lambda + \mu)\nabla(\nabla \cdot \vec{u}) = \vec{f} \tag{36}$$

subject to a suitable combination of Dirichlet and Neumann BCs. Equation (36) is a special case of non linear equations of visco-elasticity. In Equation (36), ρ denotes density of a continuous material body, $\vec{u}$ is the displacement of the continuum from the equilibrium position under the combination of external forces $\vec{f}$, and λ and μ are the Lamé constants (see Ref. 49 for more details). After the discretization of Equation (36) by the FEM, a linear system $A_e u = f$ is obtained, with $A_e \in \mathbb{R}^{nd\times nd}, u$, and $f \in \mathbb{R}^{nd}$, where n is the number of unconstrained nodes and d is the spatial dimension. If the degrees of freedom are enumerated in such a way that the displacements along one Cartesian direction (unknowns that correspond to the same displacement component) are grouped together, the PDE system in Equation (36) consists of d scalar equations and can be preconditioned effectively by a block-diagonal preconditioner. For this problem, effective solvers/preconditioners based on the variable and the point approach in AMG also are developed. However, the block-diagonal preconditioner, developed in (46) uses classical (unknown-based) AMG. From Equation (36) it can be seen that each scalar PDE represents a pertur- bation of the standard Laplacian operator. Thus, the effectiveness of MG applied in this context depends on the relative size of the perturbation term. For compressible materials (λ away from ∞), the block-diagonal preconditioner (46) is very effective. For nearly incompressible cases ($\lambda \to \infty$), an alternative formulation of the linear elasticity problem in Equation (36) is needed (see the Stokes problem).

3. The biharmonic equation. The biharmonic problem $\Delta^2 u = f$ arises in structural and fluid mechanics (2,49). FEM discretization of the original formulation of the biharmonic problem requires the use of Hermitian elements that result in a system with SPD coefficient matrix, which is not an M-matrix. Consequently, direct application of the standard GMG/AMG preconditioners will not be effective.

An alternative approach is to reformulate the biharmonic problem as the system of two Poisson equations:

$$\begin{aligned} -\Delta u &= v \\ -\Delta v &= f \end{aligned} \tag{37}$$

subject to suitable BCs (2). Discretization of Equation (37) can be done using the standard Lagrangian FEM, producing an indefinite linear system

$$\begin{bmatrix} M_B & A^t \\ A & 0 \end{bmatrix} \begin{bmatrix} v \\ u \end{bmatrix} = \begin{bmatrix} f \\ 0 \end{bmatrix} \tag{38}$$

with $(M_B)_{ij} = (\phi_i, \phi_j), i, j = 1, \ldots, m,$ and $(A)_{ij} = (\nabla\phi_j, \nabla\phi_i), i = 1, \ldots, n, j = 1, \ldots, m$. In Ref. 50, the application of a modified MG method to the Schur complement system obtained from Equation (38) is discussed. Another nearly optimal preconditioner for the system in Equation (38) can be obtained by decoupling the free and constrained nodes in the first equation of Equation (37). This decoupling introduces a 3×3 block splitting of the coefficient matrix, and the preconditioner is given by (see Ref. 51)

$$M = \begin{bmatrix} 0 & 0 & A_I^t \\ 0 & M_B & A_B^t \\ A_I & A_B & 0 \end{bmatrix} \tag{39}$$

In Equation (39), the matrix block $A_I \in \mathbb{R}^{n \times n}$ corresponds to a discrete Dirichlet Laplacian operator and it can be approximated readily by a small fixed number of GMG/AMG V-cycles.

The Stokes Problem. The Stokes equations represent a system of PDEs that model visous flow:

$$\begin{aligned} -\Delta \vec{u} + \nabla p &= \vec{0} \\ \nabla \cdot \vec{u} &= 0 \end{aligned} \tag{40}$$

subject to a suitable set of BCs (see Ref. 2). The variable $\vec{u}$ is a vector function representing the velocity, wheras the scalar function p is the pressure. A host of suitable pairs of FE spaces can be used to discretize Equation (40). Some combinations are stable, and some require the stabilization (2,27). If a stable discretization is applied (see Ref. 2 for more discussion), the following linear system is obtained

$$\begin{bmatrix} A & B^t \\ B & 0 \end{bmatrix} \begin{bmatrix} u \\ p \end{bmatrix} = \begin{bmatrix} f \\ g \end{bmatrix} \tag{41}$$

In Equation (41), $A \in \mathbb{R}^{m \times m}$ represents the vector Laplacian matrix (a block-diagonal matrix consisting of d scalar discrete Laplacians where d is the spatial dimension), and $B \in \mathbb{R}^{n \times m}$ is the discrete divergence matrix. The unknown vectors u and p are the discrete velocity and pressure solutions, respectively.

Optimal preconditioners for the discrete Stokes problem in Equation (41) are of the form:

$$M = \begin{bmatrix} A & 0 \\ 0 & M_p \end{bmatrix} \tag{42}$$

where M_p is the pressure mass matrix, which is spectrally equivalent to the Schur complement matrix $BA^{-1}B^t$. The vector Laplacian matrix A can be approximated componentwise by a small number of V-cycles of GMG/AMG (2).

The Navier–Stokes Problem. The Navier–Stokes equations have similar block structure as the Stokes equations, with the vector Laplacian operator replaced by the vector convection-diffusion operator. The steady-state Navier–Stokes system is given by

$$\begin{aligned} -v\nabla^2 \vec{u} + \vec{u} \cdot \nabla \vec{u} + \nabla p &= \vec{f} \\ \nabla \cdot \vec{u} &= 0 \end{aligned} \tag{43}$$

In Equation (43), $\vec{u}$ and p are the velocity and pressure and $v > 0$ is kinematic viscosity. The Navier–Stokes equations represent a model of fluid flow of an incompressible Newtonian fluid. The system in Equation (43) is non linear. The use of mixed FEM for the discretization of Equation (43) leads to a non linear system of algebraic equations. Such systems need to be solved iteratively, either by the Picard method or the Newton method. If a stable discretization method is used in conjuction with the Picard linearization, we obtain the *discrete Oseen problem*(2):

$$\begin{bmatrix} F & B^t \\ B & 0 \end{bmatrix} \begin{bmatrix} \Delta u \\ \Delta p \end{bmatrix} = \begin{bmatrix} f \\ g \end{bmatrix} \tag{44}$$

In Equation (44), $F = vA + C$ is the discrete vetor convection-diffusion operator and B is, as before, the divergence matrix. The ideal preconditioning of the system in Equation (44) an be achieved by the blocks-triangular matrix (2)

$$M = \begin{bmatrix} M_F & B_t \\ 0 & -M_S \end{bmatrix} \tag{45}$$

In Equation (45), M_F is the spectrally equivalent approximation of the matrix F. This approximation can be achieved by a small number of V-cycles of GMG/AMG with appropriate smoothing [line, ILU(0)] applied to each component of F (2). The optimal choice for the block M_S would be $BF^{-1}B^t$ (the Schur complement). As the Schur complement is a dense matrix, some effective approximations are needed. One such choice leads to the pressure convection-diffusion preconditioner (2) with

$$BF^{-1}B^t \approx BM_u^{-1}B^tF_p^{-1}M_u \tag{46}$$

In Equation (46), M_u is the velocity mass matrix and F_p is the discretization of the convection-diffusion equation on the pressure space. Another effective choice for the Schur complement matrix approximation is to take (2)

$$BF^{-1}B^t \approx (BM_u^{-1}B^t)(BM_u^{-1}FM_u^{-1}B^t)^{-1}(BM_u^{-1}B^t) \quad (47)$$

Parallel Multigrid Methods

The MG methods commonly are applied to large-scale computational problems that involve millions of unknowns, which frequently are non linear and/or time-dependent, for which the use of modern parallel computers is essential. To benefit from MG in such cases, various techniques to parallelize MG algorithms have been developed.

The simplest and most commonly used approach of implementing MG algorithms in parallel is to employ the *grid partitioning technique* (52,53). This technique involves no real change to the basic MG algorithm. Namely, the finest grid level, level Ω_h, can be partitioned in a non overlapping set of subgrids

$$\Omega_h = \bigcup_{i=1}^{P} \Omega_h^{(i)} \quad (48)$$

and each of the resulting subgrids $\Omega_h^{(i)}$ can be assigned to one of P parallel processors. The partition on the finest grid induces, naturally, a similar partitioning of the coarser levels. The partitioning in Equation (48) should be performed in such a way that the resulting subgrids have approximately the same number of nodes. This requirement is necessary for good load balancing of the computations. In addition, the grid partitioning should introduce a small number of grid lines between the neighboring subdomains. It also is beneficial that the grid lines stretching between the neighboring subdomains define the weak connections between the unknowns. The former requirement is related to the minimization of the communication overhead between the neighboring processors, whereas the latter affects the efficiency and the convergence characteristics of the parallel MG algorithm. For structured grids defined on regular geometries, the partitioning in Equation (48) can be done fairly simply. However, this problem becomes progressively more complicated for non trivial geometries (possibly with the internal boundaries) on which a problem is discretized by unstructured or adaptively refined grids. In such cases, general-purpose algorithms for graph partitioning, such as METIS (54), provide the required balanced grid subdivision.

Two strategies of combining MG and domain decomposition for parallel computers exist. The simpler choice is to apply a serial MG algorithm on each of the subdomain problems, communicating the solution among the processors only at the finest level. This method is particularly effective if the subdomains are connected along physically narrow areas that actually are not visible on coarse levels. A more complex choice is to extend the communication to the coarse grid levels.

In some parallel MG algorithms based on the grid decomposition, different grid levels still are processed sequentially. When the number of grid variables at the coarse grid levels falls below a certain threshold, some processors could become idle. This effect can be particularly pronounced in applications with the local grid refinement. In some extreme cases, no single level, may exist with enough grid points to keep all the processors busy. Moreover, the number of grid levels obtained by the coarsening could be limited by the number of partitions in the domain decomposition. Therefore, the grid decomposition based parallelization of MG methods make sense only if the total number of unknowns in the multi level grid structure is significantly larger than the number of available processors.

The problem of sequential processing of different grid levels in standard MG algorithm can potentially represent a serious bottleneck for large-scale applications. The solution to this problem is to use a class of multi level (ML) methods known as the additive ML methods. In these methods, the solution (or the preconditioning) procedure is defined as a sum of independent operators. It should be emphasised that this type of parallelism is completely independent of the parallelism induced by the grid partitioning. As a result, the two techniques can be combined together, giving a powerful parallel solver/preconditioner for elliptic problems. An example of a parallel ML preconditioner, in which different grid levels can be processed simultaneously, is the BPX preconditioner (45) introduced in the previous section. The smoothing operator R_k in Equation (32) applies to the fine grid residual for all levels k. This application allows the smoothing operation to be performed concurrently for all levels. Another example of additive ML method can be derived from the FAC method introduced in the section on MG with locally refined meshes. The original FAC algorithm is inherently sequential in the sense that, although different grid levels can be processed asynchronously, the various refinement levels are treated in a multiplicative way (i.e., the action of the FAC solver/preconditioner is obtained as a product of the actions from different refinement levels). To overcome this obstacle, an asynchronous version of the FAC algorithm, referred to as AFAC, was developed (55). The AFAC has the convergence rate independent of the number of refinement levels and allows the use of uniform grid solvers on locally refined grid patches. However, these uniform grid solvers are, themselves, MG-based, which can lead potentially to a substantial computational overhead. A new version, AFACx (56), is designed to use the simple fixed-point iterations at different refinement levels without significant deterioration of the convergence characteristics when compared with the previous versions.

In this article, AMG was introduced as a prototype of a black-box solver and a preconditioner for elliptic PDEs and some other class of problems where the coefficient matrix has the properties that resemble the M-matrix. Because of its robustness and ease of use, AMG has become an obvious candidate as a solver for a variety of large-scale scientific applications. In such cases, the performance characteristics of the sequential AMG may not be sufficient. This reason is why a considerable research effort was devoted to the parallelization of AMG.

The application of AMG to the solution of a linear system consists of two phases: the coarsening and the solve phase (which implements the MG V-cycle). The parallelization of AMG is done using the domain decomposition approach based on the grid decomposition in Equation (48). In the solve phase, parallelization is restricted to fixed-point iterations. In this context, instead of the standard versions, some modifications are needed. The most common approach is the CF Gauss–Seidel method, which is performed independently on each subdomain using the frozen values in the boundary areas. The values in these areas are refreshed by the data communication between the neighboring subdomains.

In most of the application areas, the coarsening phase is the most time-consuming part of the algorithm. Thus, the efficient parallelization of AMG coarsening will have a major impact on AMG parallel performance. The problem is that the previously introduced classical coarsening algorithm, which also is referred to as the Ruge–Stüben (RS) coarsening, is inherently sequential. To perform the subdivision of a set of variables at each "grid" level into coarse (C) and fine (F) variables, based on the strength of dependence principle, one needs to start from an arbitrary variable and visit all the remaining variables in succession. To parallelize this process, a combination of the domain decomposition methodology and the RS coarsening was proposed. To facilitate this approach, a partitioning of the graph associated with the coefficient matrix is performed. In this context, it is desirable that the partitioning cuts only (or mostly) the weak connections in the graph. Moreover, it is necessary to mark the unknowns that have some of their connections cut, as these unknowns belong to the boundary layer between the neighboring subdomains and will be involved subsequently in the interprocessor communication. Most of the parallel coarsening schemes are based on the application of the standard RS coarsening scheme applied concurrently on each of the subdomains, employing some kind of special treatment of the points in the boundary layers. Two main reasons exist for this special treatment; the standard coarsening scheme usually creates an unnecessarily high concentration of the C points close to the processor boundaries, and possible coarsening inconsistencies may appear. The latter are manifested in strong F–F couplings across the subdomain boundaries, where both F points do not have a common C point. Several different modifications have been proposed to alleviate such problems. In the sequel, a brief review of some well-known modifications of the classical coarsening scheme is given.

Minimum Subdomain Blocking (MSB). This approach was the first used to parallelize the AMG coarsening phase (57). In this approach, the coarsening process in each subdomain is decoupled into the coarsening of the variables in the boundary layer (done by the classical RS coarsening scheme, taking into account only the connections within the layer) and the coarsening of the remainder of the subdomain (again, done by the classical RS algorithm). Such heuristics ensures that each of the F-points in the boundary layer has at least one connection to a C-point within the boundary layer. The main drawback of this approach is that the strong couplings across the subdomain boundaries are not taken into account. When MSB is used, the assembly of the interpolation operators is local for each subdomain (requiring no communication). The assembly of the coarse grid discrete operators does require some communication; however, it is restricted to the unknowns in the boundary layers of the neighboring subdomains.

Third-Pass Coarsening (RS3). This coarsening is an alternative approach to correct the problem of F–F dependencies across the subdomain boundaries that do not have a common C-point (58). In this approach, a two-pass standard RS coarsening is performed on each subdomain concurrently, before the third pass is performed on the points within the boundary layers. This method requires the communication between the neighboring subdomains. In the RS3 coarsening, additional coarse grid points can be created in each of the subdomains on demand from its neighboring subdomains. This fact may lead potentially to the load imbalance between the subdomains. One drawback of the RS3 coarsening is the concentration of the coarse points near the subdomain boundaries. Another problem is that the introduction of a large number of subdomains will make the coarsest grid problem unacceptably large (as each of the subdomains cannot be coarsened beyond a single grid point).

The CLJP Coarsening. This procedure is based on parallel graph-partitioning algorithms and is introduced in Ref. 59. In this approach, a directed weighted graph is defined with the vertices corresponding to the problem unknowns and the edges corresponding to the strong couplings. A weight is associated with each vertex, being equal to the number of strong couplings of the neighboring vertices to this vertex plus a random number. Random numbers are used to break ties between the unknowns with the same number of strong influences (and thus to enable parallelization of the coarsening procedure). The coarsening process proceeds iteratively, where at each iteration an independent set is chosen from the vertices of the directed graph. A point i is selected to be in an independent set if its weight is larger than the weights of all neighboring vertices. Then, the points in the independent set are declared as C-points. The main advantage of the CLJP coarsening is that it is entirely parallel and it always selects the same coarse grid points, regardless of the number of subdomains (this is not the case with the RS and the RS3 coarsenings). A drawback is that the CLJP coarsening process selects the coarse grids with more points than necessary. This action, in turn, increases the memory requirements and the complexity of the solution phase. A recent modification of the CLJP scheme that addresses these issues is proposed in [Ref. 60]. The interpolation operators and the coarse grid discrete operators are assembled in a usual way.

The Falgout Coarsening. This hybrid scheme involves both the classical RS and the CLJP coarsening, designed with the aim of reducing the drawbacks that each of these two schemes introduce. The Falgout coarsening (58) uses the RS coarsening in the interior of the subdomains and the CLJP coarsening near the subdomain boundaries.

Parallel AMG as a Preconditioner for 3-D Applications. When traditional coarsening schemes are applied to large-scale problems obtained from the discretizations of 3-D PDEs, the computational complexity and the memory requirements increase considerably, diminishing the optimal scalability of AMG. If AMG is used as a preconditioner in this context, the two coarsening schemes, based on the maximal independent set algorithm, referred to as the *parallel modified independent set* (PMIS) and the *hybrid modified independent set* (HIMS) (introduced in Ref. 61), can reduce the complexity issues significantly.

FINAL REMARKS

MG methods have been a subject of considerable research interest over the past three decades. Research groups at many institutions are involved in ongoing projects related to both theoretical and practical aspects of MG. It is virtually impossible to cover all the aspects of this versatile area of research and to cite all the relevant references within the limited space of this review. A comprehensive reference list with over 3500 units on MG can be found at [Ref. 62], together with some publicly available MG software (63). The ongoing interest of the scientific community in MG methods is reflected in two long-running regular conference series on MG methods (64,65), which attract an ever-increasing number of participants. Some additional relevant monographs, that were not previously mentioned in this presentation, include Refs. 11–15 and Ref. 66.

P

POSETS AND LATTICES

PARTIALLY ORDERED SETS

In this section, we introduce the reader to the basic notion of partially ordered sets according to the following definition.

Definition 1. *A* partially ordered set *(poset, for short) is a structure $\langle \mathcal{P}, \leq \rangle$ where $\mathcal{P}$ is a nonempty set and $\leq$ is a* partial order relation *on $\mathcal{P}$,* i.e., *a binary relation such that for arbitrary a, b, c $\in \mathcal{P}$ the following conditions hold:*

(or1) $a \leq a$ (reflexive)
(or2) $a \leq b$ and $b \leq a$ imply $a = b$ (antisymmetric)
(or3) $a \leq b$ and $b \leq c$ imply $a \leq c$ (transitive)

If $a \leq b$, then we say that a is less than or equal to b, or that b is greater than or equal to a, also written in this case as $b \geq a$. Some other terminology frequently adopted in this case is that a precedes *or is* smaller *than b and that b* follows *or* dominates *or is* larger *than a.*

Example 1. Let us denote by $\mathcal{P}(X)$ the power set of a set (also universe) X, i.e., the collection of all subsets of X. The usual set theoretic inclusion on pairs A, B of subsets of X defined as "$A \subseteq B$ iff every element of A is also an element of B" (formally, "$a \in A$ implies a $\in B$") is a partial order relation on $\mathcal{P}(X)$. Thus $\langle \mathcal{P}(X), \subseteq \rangle$ is a poset.

Example 2. Let 2^X denote the collection of all Boolean-valued functionals defined on the set X, i.e., the collection of all mappings $\chi : X \mapsto \{0, 1\}$. For any pair of such mappings $\chi_1, \chi_2 \in 2^X$, the binary relation defined as follows:

$$\chi_1 \leq \chi_2 \quad \text{iff} \quad \forall x \in X, \chi_1(x) \leq \chi_2(x) \tag{1}$$

is a partial order relation for 2^X, also called the pointwise order relation. Thus, $\langle 2^X, \leq \rangle$ is a poset.

Let us introduce some notions that can be derived in any poset structure. First of all, in a poset $\langle \mathcal{P}, \leq \rangle$ we can distinguish a *strict* partial ordering, written $<$, which means "x precedes y and x does not coincide with y"; formally, $x < y$ iff $x \leq y$ and $x \neq y$. For example, if $\leq$ is the set inclusion $\subseteq$, then $A < B$ means that A is a proper subset of B (there exists an element b in B that does not belong to A), i.e., $A \subset B$. Moreover, we say that *z covers y* iff $y < z$ and $y \leq x \leq z$ implies either $x = y$ or $x = z$ ($x < y$ and there is no element between x and y).

It is possible to give a graphical representation of a poset with a finite number of elements representing the fact that *x covers y* by drawing y below x and connecting them by a line segment according to the following figure:

The global figure so obtained is called the *Hasse diagram* of the finite poset.

Example 3. The Hasse diagram of a poset with five elements is presented in Fig. 1.

By the property of transitivity of a partial ordering, we read right from the diagram that $a \leq d$ because there exists the path $a \leq c$ and $c \leq d$ that moves steadily upward from a to d. Note that, in general, transitive relation can be run together without causing confusion: $x \leq y \leq z$ means $x \leq y$ and $y \leq z$, from which $x \leq z$.

Two elements a, b from a poset are called *comparable* iff one of the two cases, either $a \leq b$ or $b \leq a$, holds; two elements c, d that are not comparable are said to be *incomparable*. For example, in Fig. 1, the elements a and c are comparable, whereas a and b are not.

A poset $\mathcal{P}$ is a *totally* (or *linearly*) *ordered poset* iff $\forall\, x, y \in \mathcal{P}$ either $x \leq y$ or $y \leq x$, that is, iff any two elements a, b from the poset $\mathcal{P}$ are comparable. A totally ordered poset is also called *chain*. Examples of totally ordered posets are the set of all natural numbers $\mathbb{N} = \{0, 1, 2, 3, 4, 5 \ldots\}$ with the standard ordering, the set of all real numbers $\mathbb{R}$ and the unit interval $[0, 1] := \{x \in \mathbb{R} : 0 \leq x \leq 1\}$ with the usual order on real numbers, this latter being a bounded chain.

It is possible to define special elements in a poset $\mathcal{P}$ and so to introduce operations in such a structure. First, an element $0 \in \mathcal{P}$ is said to be the *least* (1) (or *minimum, first*, or *zero*) element in $\mathcal{P}$ iff $0 \leq a$ for every $a \in \mathcal{P}$; if the least element 0 exists, then it is unique. Similarly, if a poset contains an element $1 \in \mathcal{P}$ such that $a \leq 1$ for every element a in the poset, then this element is uniquely determined and will be called the *greatest* (1) (or *maximum, last*, or *unit*) element. The poset S5 of Fig. 1 has neither least nor greatest element.

Definition 2. *A partially ordered set with a minimum and a maximum element (also called* bounded poset*) is a*

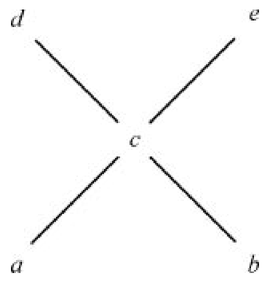

Figure 1. The poset S5.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

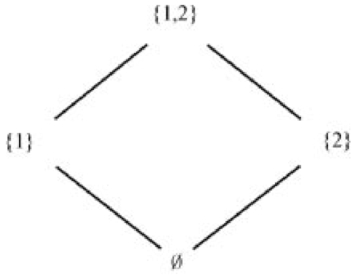

Figure 2. The atomic lattice 2^2 of all subsets of the universe {1,2}.

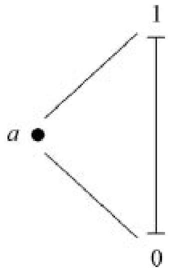

Figure 3. The nonatomic real unit interval plus an atom a.

structure $\langle \mathcal{P}, \leq, 0, 1\rangle$, *where* $\leq$ *is a partial order relation on* $\mathcal{P}$ *such that* 0 *and* 1 *are the* least (minimum) *and the* greatest (maximum) *element with respect to* $\leq$, *respectively. In other words, for all* $b \in \mathcal{P} : 0 \leq b \leq 1$.

In a poset with the least element $\langle \mathcal{P}, \leq, 0\rangle$, every element that covers the 0 element is called *atom*. We say that $\mathcal{P}$ is *atomic* iff for every $x \neq 0$ at least one atom a in $\mathcal{P}$ exists such that $a \leq x$ holds.

Example 4. The power set $\mathcal{P}(X)$ of a universe X is atomic; every singlet set $\{a\}$ for $a \in X$ is an atom of the poset. For instance, in the lattice 2^2 of all subsets of the universe that consist of two elements $X = \{1,2\}$, the singletons {1} and {2} are atoms (see Fig. 2).

Example 5. An example of poset without atoms is the real unit interval [0,1] endowed with the usual order on numbers. If to [0,1] we add an element $0 < a < 1$ such that a is incomparable with all elements in (0,1) (see the Hasse diagram of Fig. 3), we obtain a poset with an atom a that is nonatomic.

Let A be a subset of a poset $\langle \mathcal{P}, \leq\rangle$. Then the ordering $\leq$ of $\mathcal{P}$ induces an order on A in the following way: If $a, b \in A$, then $a \leq b$ as elements of A iff $a \leq b$ as elements of $\mathcal{P}$. In this case, we shall say that the pair $\langle A, \leq\rangle$ is a subposet of $\langle \mathcal{P}, \leq\rangle$. Note that a subposet of a poset $\mathcal{P}$ may be totally ordered, also if $\mathcal{P}$ is not. For instance, in the nonlinear poset represented by the diagram of Fig. 1, the two subposets {*b, c, e*} and {*a, d*} are totally ordered, i.e., chains, whereas the subposet {*a, b, c*} is not. Any way, a subposet of a chain is always a chain.

Definition 3. *Let* $\mathcal{S} \neq \emptyset$ *be a nonempty set, subset of the poset* $\mathcal{P}$.

i) An element $x \in \mathcal{P}$ *is said to be the* least upper bound *(l.u.b.) of* $\mathcal{S}$, *written* $x = sup(\mathcal{S})$(also $x = \vee \mathcal{S}$), *iff:*

a) $\forall\ s \in \mathcal{S}, s \leq x$

b) if $c \in \mathcal{P}$ satisfies $s \leq c$ for any $s \in S$, then $x \leq c$

If only condition i) holds, then the element s is said to be an upper bound *of S*.

ii) An element $y \in \mathcal{P}$ *is said to be the* greatest lower bound *(g.l.b.) of S, written* $y = in\ f(S)$ *(also* $y = \wedge S$*), iff:*

a) $\forall\ s \in S; y \leq s$

b) if $d \in \mathcal{P}$ satisfies $d \leq s$ for any $s \in S$, then $d \leq y$

If only condition i) holds, the element s is said to be a lower bound of $\mathcal{S}$.

Hence, an upper bound lies “above” every element of the set $\mathcal{S}$, whereas a lower bound lies “below” each element with respect to the involved partial ordering. The l.u.b. and the g.l.b. are the “smallest” upper bound and the “largest” lower bound of the set, respectively. If $\mathcal{S}$ is a finite set, say $\mathcal{S} = \{a_1, \ldots, a_n\}$, it is customary to write (if they exist) $\wedge_{i=1}^{n} a_i$ or $a_1 \wedge \ldots \wedge a_n$ and $\vee_{i=1}^{n} a_i$ or $a_1 \vee \ldots \vee a_n$ instead of $\wedge \mathcal{S}$ and $\vee \mathcal{S}$. In particular, we denote by $a \vee b$ and $a \wedge b$, if they exist, the l.u.b. and the g.l.b. of the pair $a, b \in \mathcal{P}$ respectively. Let us note that in the case of a bounded poset $\mathcal{P}$ we have that $x \vee 0 = x, x \wedge 0 = 0$ and $x \wedge 1 = x, x \wedge 1 = x$ for any element $x \in \mathcal{P}$.

Example 6. In Fig. 1, the set {*d, e*} has no l.u.b., whereas its g.l.b. is $c = d \wedge e$; the set {*a, b*} has g.l.b. $c = a \vee b$, but the l.u.b. of this set does not exist. Moreover, the whole poset has neither the minimum element 0 nor the maximum element 1.

Example 7. In the set of all integer numbers $\mathbb{Z}$, with the standard partial ordering, number 8 is an upper bound of the two subsets $\mathcal{S} = \{-2,0,1,3,4\}$ and $Q = \{-4,-1,2,4,8\}$, which is the l.u.b of Q but not of $\mathcal{S}$. Similarly, -4 is a lower bound of both $\mathcal{S}$ and Q, which is the g.l.b of Q.

In the poset of all real numbers $\mathbb{R}$, number 8 is an upper bound of the open intervals (–2,6) and (6,8) and also of the closed intervals $[-5, -2]$ and $[-1,8]$. Moreover, it is the l.u.b of both (6, 8) and $[-1,8]$; in this second case, 8 belongs to the interval, contrary to the former one. In an analogous way, -5 is a lower bound of all these intervals, which is the g.l.b. of $[-5,-2]$.

There cannot be a number $\underline{\vee}$(resp., $\overline{\wedge}$) that is an upper (resp., lower) bound of the whole set $\mathbb{Z}$ of all integer numbers, or of all real numbers $\mathbb{R}$ for that matter, Because $\underline{\vee}$ (resp., $\overline{\wedge}$) is evidently strictly less (resp., great) than the number $\underline{\vee} + 1$ (resp., $\overline{\wedge} - 1$).

In the following proposition, for a pair of subsets Y_1 and Y_2 of a poset $\mathcal{P}$ we adopt the convention to denote by $Y_1 \leq Y_2$ the fact that $y_1 \leq y_2$ for every $y_1 \in Y_1$ and every $y_2 \in Y_2$.

Proposition 1. *Let* $\langle \mathcal{P}, \leq\rangle$ *be a poset.*

1) Let Y be a subset of $\mathcal{P}$; *then the elements* sup(Y) *and* inf(Y), *if they exist, are unique.*

2) Let Y_1 *and* Y_2 *be subsets of* $\mathcal{P}$ *such that* $Y_1 \leq Y_2$ *and both* $\inf(Y_1)$ *and* $\sup(Y_2)$ *exist; then* $\inf(Y_1) \leq \sup(Y_2)$.

3) $x \leq y$ iff $x \wedge y = x$ and $x \vee y = y$

Proof 1. Let $x_1 = \sup(Y)$ and $x_2 = \sup(Y)$. Then from (i-b) of Definition 3 applied to x_1, we have in particular that $y \le h$ for any $y \in Y$ implies $x_1 \le h$. On the other hand, from (i-a) of the same definition applied to x_2, we have that $y \le x_2$ for any $y \in Y$; hence $x_1 \le x_2$. Reversing the role of these two elements, we arrive at the result that $x_2 \le x_1$ and so $x_1 = x_1$.

A similar proof can be given in the case of inf(Y). The proofs of points 2 and 3 are trivial.

Proposition 2. *A poset $\mathcal{P}$ that has the l.u.b. $\vee\mathcal{P}$ and the g.l.b. $\wedge\mathcal{P}$ is* bounded; *indeed*, $\wedge\mathcal{P} \le x \le \vee\mathcal{P}$ *for every* $x \in \mathcal{P}$.

Given the poset $\langle \mathcal{P}, \le \rangle$, it is possible to construct the binary relation $\le_c$ on $\mathcal{P}$ defined as $x \le_c y$ iff $y \le x$, which trivially is itself a partial ordering on $\mathcal{P}$ called the *converse* of $\le$.

Other interesting notions involving posets are the following.

Definition 4. *A* meet *(resp., join)-semilattice is a poset for which the g.l.b.* $a \wedge b$ *(resp., l.u.b.* $a \vee b$*)exists for any pair a, b of elements from the poset.*

Example 8. Let us consider a finite set $\mathcal{A} = \{a_1, a_2. \ldots, a_n\}$, the *alphabet* of this example, whose elements a_i are symbols, also called *letters*. A *word* of the alphabet $\mathcal{A}$ is any finite sequence (also called *string*) of elements from $\mathcal{A}$, whose collection will be denoted by $\mathcal{A}^*$. The string with no letters at all, denoted by $\in$, is a special word of $\mathcal{A}^*$ called the *empty* or *null word*. The length of a word $w \in \mathcal{A}^*$, denoted by $|w|$, is the number of letters forming w, counting each appearance of a letter; in particular $|\in| = 0$. For instance, in the case of a Boolean alphabet $\mathcal{A} = \{0,1\}$, the finite sequence 0010101 is a word, i.e., an element from $\{0,1\}^*$, of length 7.

A standard inner operation on $\mathcal{A}^*$ is the so-called *concatenation* (also *juxtaposition*): Let $u = u_1u_2 \ldots u_h$ and $w = w_1w_2 \ldots w_k$ be two words in $\mathcal{A}^*$ (of length h and k, respectively); then one can construct the new word $uw = u_1u_2 \ldots u_hw_1w_2 \ldots w_k$, which is another element of $\mathcal{A}^*$ (of length $h + k$). Concatenation with the empty word leaves the word unchanged: $w\epsilon = \epsilon w =$ w whatever be $w \in \mathcal{A}^*$. In the case of a nontrivial alphabet (i.e., containing two or more letters), this operation is not commutative; for instance, in $\{0,1\}^*$ the two words $u = 00$ and $w = 100$ are such that $uw = 00100$ and $wu = 10000$, which are different: $uw \ne wu$.

On $\mathcal{A}^*$, the binary relation $u \le w$ means that the word $u \in \mathcal{A}^*$ is the initial segment of the word $w \in \mathcal{A}^*$, formally that there exists a word $v \in \mathcal{A}^*$ such that $uv = w$; in this case, u is said to be a *prefix* of w. For instance, in the case of the Boolean alphabet, the two words 010 and 010011 are comparable, with $010 \le 010011$, because there exists the word 011 such that 010011 = (010)(011). The poset $\{0,1\}^*$ has the empty word $\in$ as its minimum element; indeed, for any word $w \in \mathcal{A}^*$ the property $\in w = w$ means that $\in \le w$. Moreover, it is a meet-semilattice; for instance, with respect to the meet, we have $110 \wedge 10 = 1$, $010 \wedge 1 = \in$, but the join of the words 10 and 01 does not exists because there is no upper bound w such that $10 \le w$ and $01 \le w$, i.e., two words u_1 and u_2 such that $10u_1 = 01u_2 = w$.

From the computational point of view, strings of an alphabet, for instance, the Boolean one, "may be thought of as information encoded in binary form: the longer the string the greater the information content. Further, given any string v, we may think of elements u with $u < v$ as providing approximations to v" 2. Extending in an obvious way these considerations to the collection $\mathcal{A}^{**}$ of all finite and infinite sequences of letters from the alphabet $\mathcal{A}$, "any infinite string is, in an [intuitive] sense, the limit of its finite initial substrings" (2).

LATTICES

In the following, if they exist, we shall denote by $\vee a_j$ and $\wedge a_j$ the l.u.b. and the g.l.b. of any family $\{a_j : j \in J\}$ of elements from a poset $\mathcal{P}$, respectively.

Definition 5. *A* lattice *is a poset* $\langle \mathcal{L}, \le \rangle$ *such that both* $x \wedge y := in\ f\{x,y\}$ *(the lattice* meet *or* conjunction*)* $andx \vee y := sup\{x,y\}$ *(the lattice* join *or* disjunction*) exist for every pair of elements x, y* $\in \mathcal{L}$. *To be precise, the lattice meet satisfies the conditions*

$$\begin{array}{lll} \text{(LM1)} & a \wedge b \le \{a,b\} & \\ \text{(LM2)} & x \le \{a,b\} & \text{implies} \quad x \le a \wedge b \end{array}$$

whereas the lattice join satisfies the conditions

$$\begin{array}{lll} \text{(LJ1)} & \{a,b\} \le a \vee b & \\ \text{(LJ2)} & \{a,b\} \le x & \text{implies} \quad a \vee b \le x \end{array}$$

Example 9. Let $\mathcal{P}(X)$ be the poset of all subsets of a given universe X with respect to the usual set theoretic inclusion relation $\subseteq$. A subset A of the universe X can be defined by a property $P(x)$ characterizing just the elements of the universe that satisfies this property, and, in this case, we write $A = \{x \in X : P(x)\}$ where the symbol ":" has the meaning of *such that*. If the element x belongs to the set A, then we write $x \in A$.

If the universe is finite, then a set can be given by listing all its elements: $A = \{x_1, x_2, \ldots, x_n\}$. For instance, in the universe $[0, 10]_{\mathbb{N}}$ that consist of all integer numbers between 0 and 10, the set of even numbers less than 10 can be specified as $\{x$: x is integer, $x < 10$, $x \bmod 2 = 0\}$ or equivalently as {2, 4, 6, 8}.

A special set is the *empty set*, which is a set with no elements, denoted by the symbol $\emptyset$. On the opposite site is the *universe* X, which is the set of all the elements of a given domain of interest. With respect to the poset $\langle \mathcal{P}(X), \subseteq \rangle$ of all subsets of a universe X, the set $\emptyset$ is the least element and X the greatest one:

$$\forall A \in \mathcal{P}(X) : \emptyset \subseteq A \subseteq X$$

Given two subsets $A = \{a \in X : P(a)\}$ and $B = \{b \in X : Q(b)\}$ of X defined by the properties P and Q, respectively, their set intersection and union are given by:

$$\begin{array}{c} A \cap B = \{x \in X : P(x) \text{ and } Q(x)\} = \{x \in X : x \in A \text{ and } x \in B\} \\ A \cup B = \{y \in X : P(y) \text{ or } Q(y)\} = \{y \in X : y \in A \text{ or } y \in B\} \end{array}$$

It is easy to verify that the poset $\langle \mathcal{P}(X), \subseteq \emptyset, X\rangle$ is a lattice because inf{*A, B*} and sup{*A, B*} coincide with their set intersection and union, respectively:

$$A \wedge B = A \cap B \quad \text{and} \quad A \vee B = A \cup B \tag{2}$$

Indeed, the set union $A \cup B$ contains both A and B; hence, it is an upper bound of A and B. However, every subset C of X that contains both A and B (that is, every upper bound of A and B) contains their union too; thus, $A \cup B$ is the smallest upper bound of A and B. We apply the same procedure to the intersection.

To stress the set operations of intersection $\cap$ and union $\cup$ as lattice meet and join, respectively, the power set-bounded lattice based on the universe X will be denoted in the sequel as the system $\langle \mathcal{P}(X), \cap, \cup, \emptyset, X\rangle$.

Remark 1. The formal definition of set union (resp., intersection) of two elements A and B of $\mathcal{P}(X)$ [as collection of all points from X that belong to at least (resp., both) the sets A and B] is very different from the formal definition of least upper (resp., greatest lower) bound of the same elements according to Definition 3. We have just proved that these two formal definitions coincide on $\mathcal{P}(X)$ in the sense that they produce the same subsets of X.

Example 10. The poset 2^X of all Boolean-valued functionals on X is a lattice where the meet and join of any pair of such functionals χ_1, χ_2 are defined for every point $x \in X$ as follows:

$$(\chi_1 \wedge \chi_2)(x) = \inf\{\chi_1(x), \chi_2(x)\} \quad \text{and} \quad (\chi_1 \vee \chi_2)(x) = \sup\{\chi_1(x), \chi_2(x)\} \tag{3}$$

Now, the following result is very important because it assures that the operators of meet $\wedge$ and join $\vee$ of a lattice $\mathcal{L}$ are interchangeable, i.e., it validates the dualization of all theorems with respect to $\mathcal{L}$ in the sense that the join may be replaced by the meet, and conversely.

Proposition 3 (Duality Principle). *Let us consider a lattice* $\langle \mathcal{L}, \leq\rangle$, *with associated converse lattice* $\langle \mathcal{L}, \leq_c\rangle$. Then, for any pair *x,y* $\in \mathcal{L}$ *the following holds:*

(ia) If $x \wedge y$ is the lattice meet of the pair x, y with respect to the ordering $\leq$, then $x \wedge y$ is the lattice join of the same pair with respect to the converse *ordering $\leq_c$; formally, $x \vee_c y$ exists and $x \vee_c y = x \wedge y$.*

(ib) If $x \vee y$ is the lattice join of the pair x, y with respect to the ordering $\leq$, then $x \vee y$ is the lattice meet of the same pair with respect to the converse *ordering $\leq_c$; formally, $x \wedge_c y$ exists and $x \wedge_c y = x \vee y$.*

(iia) If $x \wedge_c y$ is the lattice meet of the pair x,y with respect to the ordering $\leq_c$, then $x \wedge_c y$ is the lattice join of the same pair with respect to the converse *ordering $\leq$; formally, $x \vee y$ exists and $x \vee y = x \wedge_c y$.*

(iib) If $x \wedge_c y$ is the lattice join of the pair x, y with respect to the ordering $\leq_c$, then $x \vee_c y$ is the lattice meet of the same pair with respect to the converse *ordering $\leq$; formally, $x \wedge y$ exists and $x \wedge y = x \wedge_c y$.*

The results (ia) and (iib) can be summarized in the unique formulation:

$$x \wedge y \quad \text{under} \quad \leq \quad \text{iff} \quad x \vee y \quad \text{under} \quad \leq_c$$

Similarly, the results (ib) and (iia) can be summarized in the unique formulation:

$$x \vee y \quad \text{under} \quad \leq \quad \text{iff} \quad x \wedge y \quad \text{under} \quad \leq_c$$

Proof. Let us set $h = x \wedge y$. Then, the condition $h \leq \{x, y\}$ (lower bound of the pair *x, y*) translates in the "converse" condition $\{x, y\} \leq_c h$ (upper bound of the same pair). Moreover, the fact that $d \leq \{x,y\}$ implies $d \leq h$ (l.u.b. of *x, y*) leads to the fact that $\{x, y\} \leq_c d$ implies $h \leq_c d$. So we have proved that if $x \wedge y$ is the lattice meet of the pair *x, y* with respect to the ordering $\leq$, then the same element $x \wedge y$ is the lattice join of the same pair with respect to the ordering $\leq_c$; formally, $x \vee_c y$ exists and $x \vee_c y = x \wedge y$.

The case of the join (ib), and the corresponding dual, can be proved likewise.

Definition 6. *An* σ*-lattice is a poset for which the* sup *and* inf *exist for any countable collection of its elements.*

Example 11. Let us recall that a *measurable space* is a pair $(X, \mathcal{A}(X))$ consisting of a nonempty set X and a family $\mathcal{A}(X)$ of its subsets, called *measurable sets*, that satisfy the following conditions:

(M1) The empty set is measurable: $\emptyset \in \mathcal{A}(x)$.

(M2) The set union of countable measurable sets is measurable: Let $M_n \in \mathcal{A}(x)$: $n \in \mathbb{N}$, then $\cup_{n \in \mathbb{N}} M_n \in \mathcal{A}(x)$.

(M3) The set complement of a measurable set is measurable: $M^c \in \mathcal{A}(X)$ for every $M \in \mathcal{A}(X)$.

The σ-algebra $(\mathcal{A}(X), \subseteq)$ equipped with the set inclusion is an σ-lattice, bounded by the least element $\emptyset \in \mathcal{A}(X)$ and the greatest one $X = \emptyset^c \in \mathcal{A}(X)$. Indeed, for any countable family of measurable sets, from (M2) $\vee M_n = \cup M_n$ follows, and because $\cap M_n = (\cup (M_n)^c)^c \in \mathcal{A}(X)$ from (M2) and (M3), also $\wedge M_n = \cap M_n$. Note that in this example, the meet is the set intersection and the join the set union.

Definition 7. *A lattice $\mathcal{L}$ is* complete *iff both* inf(*S*) *and* sup(*S*) *exist for every nonempty subset, i.e., any $S \subseteq \mathcal{L}$ with $S \neq \emptyset$.*

Every finite lattice is obviously complete. Every complete lattice $\mathcal{L}$ is bounded because 0:= inf($\mathcal{L}$) is the least element and 1 := sup($\mathcal{L}$) is the greatest one.

Example 12. Given a universe X, the two lattices $\mathcal{P}(X)$ (of all subsets of X) and 2^X (of all Boolean-valued functionals defined on X) are complete lattices because the operations introduced in Equations (2) and (3) can be extended to arbitrary families.

Example 13. Let us recall that a *topological space* is a pair *(X,C(X))* that consists of a set X and a family *C(X)* of its subsets, called *closed sets*, which satisfies the following conditions:

(T1) The empty set and the whole space X are closed $\emptyset, X \in$ *C(X)*.

(T2) The set intersection of *any* family of closed sets is closed: Let $C_i \in C(X)$, with i running on an arbitrary index set I, then $\cap_{i \in I} C_i \in C(X)$.

(T3) The *finite* union of closed sets is closed: $\cup_{j=1,\dots k} C_k \in C(X)$ for any finite collection $C_1, \dots, C_k$ of closed sets.

Then *(C(X)*, $\subseteq$), being $\subseteq$ the usual set inclusion, is a complete lattice in which the meet is the set intersection $(\wedge C_i = \cap_i C_i)$, whereas the join is the closure of the set union $[\vee C_j = \overline{\cup_j C_j}$, obtained as the set intersection of all closed sets containing $\cup C_j$, formally $\vee C_j = \cap \{K \in C(X) : \cup C_j \subseteq K\}$, which is closed owing to (T2)]. Therefore, if we exclude the case of a finite number of closed sets, then the join is, in general, different from the set union.

For instance, if one considers the real line $\mathbb{R}$. with the standard Euclidean topology, then the sequence of closed sets $I_n = [-\frac{1}{n}, 1 + \frac{1}{n}]$ (for $n \in \mathbb{N}$) has the set union

$$\bigcup_{n \in N} I_n = (0,1)$$

which is an open set whose closure is the interval [0,1], the intersection of all closed sets containing the union $\cup I_n =$ (0,1):

$$\bigvee_{n \in \mathbb{N}} I_n = [0,1] \neq (0,1) = \bigcup_{n \in \mathbb{N}} I_n$$

This is not the unique situation in which some lattice operation does not coincide with the set theoretic ones.

Example 14. Let $\mathcal{V}(X) = \langle X, +, \mathbb{K} \rangle$ be a *linear space*, i.e., a nonempty set of *vectors* containing a privileged element $\underline{0}$ and equipped with a binary operation of sum $+ : X \times X \to X$ (of abelian group with $\underline{0}$ as the zero vector) and an external operation:$\mathbb{K} \times X \to X$ of multiplication of *scalars* from a field $\mathbb{K}$ (usually $\mathbb{K} = \mathbb{R}$ or $\mathbb{K} = \mathbb{C}$) with vectors from X to produce a new vector in X.

A *linear subspace*, simply subspace in the following, is a nonempty subset M of X (in general $\underline{0} \in M$), which is closed with respect to the inner sum (for any pair of vectors *x, y* $\in$ *M*, it is $x+y \in M$) and the external product of scalars with vectors ($\alpha \in \mathbb{K}$ and $x \in M$ imply $\alpha \cdot x \in M$). The collection of all subspaces of X will be denoted by $\mathcal{M}(X)$, which is a poset with respect to the set inclusion, bounded by the least element $\{\underline{0}\}$, the subspace consisting of the unique zero vector, and the greatest element X, the whole space; formally, for any subspace $M \in \mathcal{M}(X)$, it is $\{\underline{0}\} \subseteq M \subseteq X$ with both $\{\underline{0}\}, X \in \mathcal{M}(X)$. Then it is easy to show that the set intersection of *any* family of subspaces is a subspace too:

$$\bigcap_{i \in I} M_i \in \mathcal{M}(X) \quad \text{for any family of subspaces} \quad M_i \in \mathcal{M}(X)$$

In this way, the lattice meet of any family of subspaces is their set intersection:

$$\bigwedge_{i \in I} M_i = \bigcap_{i \in I} M_i$$

whereas, the lattice join of the same family is the subspace *generated* by the set union, which is the intersection of all subspaces that contain the union $\cup M_i$:

$$\bigvee_{i \in I} M_i = \bigcap \{H \in \mathcal{M}(X) : \bigcup_{i \in I} M_i \subseteq H\}$$

For instance, in the linear space $\mathbb{R}^2$, the two subspaces $M_x = \{(x,0) \in \mathbb{R}^2 : x \in \mathbb{R}\}$ and $M_{\pi/4} = \{(x,x) \in \mathbb{R}^2 : x \in \mathbb{R}\}$ are both (one-dimensional) subspaces for which $M_x \wedge M_{\pi/4} = M_x \cap M_{\pi/4} = \{\underline{0}\}$ and $M_x \vee M_{\pi/4} = \mathbb{R}^2$ (because $\mathbb{R}^2$ is the unique subspace that contains both M_x and $M_{\pi/4}$), this latter being strictly greater than the set union of these two subspaces.

If one represents any one-dimensional subspace of $\mathbb{R}^2$ by the angle $\alpha \in [0, \pi)$ between this subspace and the x-axis, written as M_α, then the complete lattice $\mathcal{M}(\mathbb{R}^2)$ can be represented by the Hasse diagram of the right side of Fig. 4, where it is clear that for any pair of different one-dimensional subspaces M_α and M_β, it is $M_\alpha \wedge M_\beta = \{\underline{0}\}$ and $M_\alpha \vee M_\beta = \mathbb{R}^2$.

Note that in this lattice, the distributivity conditions of the two lattice meet and join operations do not hold. For instance, if one considers two different one-dimensional subspaces $\alpha \neq \beta$, which are both different from the x-axis, too, then $M_\alpha \wedge (M_\beta \vee M_x) = M_\alpha \wedge \mathbb{R}^2 = M_\alpha$, whereas $(M_\alpha \wedge M_\beta) \vee (M_\alpha \wedge M_x) = \{\underline{0}\} \vee \{\underline{0}\} = \{\underline{0}\}$. Similarly, $M_\alpha \vee (M_\beta \wedge M_x) = M_\alpha \vee \{\underline{0}\} = M_\alpha$, whereas $(M_\alpha \vee M_\beta) \wedge (M_\alpha \vee M_x) = \mathbb{R}^2 \wedge \mathbb{R}^2 = \mathbb{R}^2$.

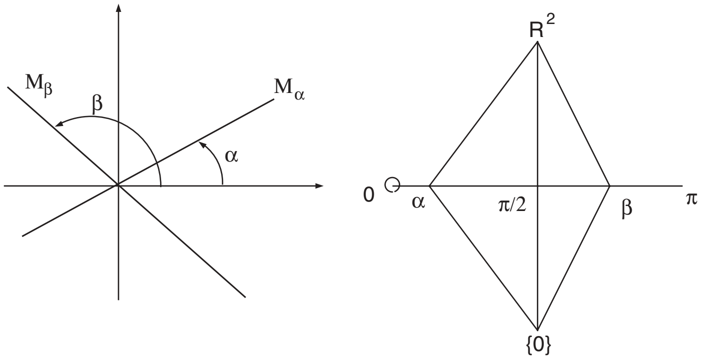

Figure 4. The two-dimensional linear space $\mathbb{R}^2$ with two one-dimensional subspaces M_α, M_β (left) and the corresponding Hasse diagram representation of the (non-distributive) lattice (right).

Lattices and Related Algebras

As we have seen before, a partially ordered set $\langle \mathcal{L}, \leq \rangle$ is a lattice iff both the g.l.b. and the l.u.b exist for every pair of elements x, $y \in \mathcal{L}$ [and are unique according to point 1 of Proposition 1 applied to the subset $Y = \{x,y\}$]. Because of their properties of existence and uniqueness, we can think of inf(x, y) and sup(x, y), with x and y running on the lattice $\mathcal{L}$, as the results of two binary operations on $\mathcal{L}$. In this way, a lattice can be considered as a particular algebraic structure $\langle \mathcal{L}, \wedge, \vee \rangle$, based on a set $\mathcal{L}$ equipped with two inner composition laws.

$$\wedge : \mathcal{L} \times \mathcal{L} \mapsto \mathcal{L}, (x,y) \to x \wedge y := \inf\{x,y\} \qquad (4)$$

$$\vee : \mathcal{L} \times \mathcal{L} \mapsto \mathcal{L}, (x,y) \to x \vee y := \sup\{x,y\} \qquad (5)$$

It is possible to make a link between the lattice $\langle \mathcal{L}, \leq \rangle$ and the algebra $\langle \mathcal{L}, \wedge, \vee \rangle$, whose proof can be found in Ref. 1 on page 8.

Theorem 1. *Let$\langle \mathcal{L}, \leq \rangle$be a lattice. Then, the algebraic structure$\langle \mathcal{L}, \wedge, \vee \rangle$, where $\wedge$ and $\vee$ are the binary operations on $\mathcal{L}$ of meet in Equation*(4) *and join in Equation*(5), *satisfies the following laws for every x, y, z* $\in \mathcal{L}$:

$(L1)$ $x \wedge x = x,$ and $x \vee x = x$ (idempotence)

$(L2)$ $x \wedge y = y \wedge x$ and $x \vee y = y \vee x$ (commutativity)

$(L3)$ $x \wedge (y \wedge z) = (x \wedge y) \wedge z$ and $x \vee (y \vee z)$
$= (x \vee y) \vee z$ (associativity)

$(L4)$ $x \wedge (x \vee y) = x$ and $x \vee (x \wedge y) = x$ (absorpton)

Moreover the two consistence properties hold:

$(L5a)$ $x \leq y$ is equivalent to $x = x \wedge y$

$(L5b)$ $x \leq y$ is equivalent to $y = x \vee y$

Let us notice that according to this result, the algebraic version $\langle \mathcal{L}, \wedge, \vee \rangle$ of the lattice is defined in an entirely *equational* way. Moreover, the peculiar form of the properties (L1)–(L4) gives a corroboration of the duality principle expressed in Proposition 3 because if we consider one of the properties that defines a lattice and we replace each symbol $\wedge$ by $\vee$ and each $\vee$ with $\wedge$, then we obtain the dual property. Thus, it follows that any theorem, result, or identity that holds for a lattice will remain true if we dualize it, that is, if we replace each $\wedge$ by $\vee$ and each $\vee$ by $\wedge$.

We recall the following result whose proof can be found in Ref. 1 on page 22.

Theorem 2. *Postulates (L2)–(L4) for lattices imply (L1), but the six identities of (L2)–(L4) are independent.*

Properties (L2)–(L4) characterize lattices completely, in a sense expressed by the following theorem.

Theorem 3. *Let* $\langle \mathcal{L}, \wedge, \vee \rangle$ *be an algebraic structure where:*

i) $\mathcal{L}$ *is a nonempty set,*

ii) $\wedge$ *and* $\vee$ *are two binary operations on* $\mathcal{L}$ *satisfying properties (L2)–(L4).*

If we define the following binary relation on $\mathcal{L}$:

$$x \leq y \quad \text{iff} \quad y = x \vee y \quad (\text{equivalently, iff} \quad x = x \wedge y) \qquad (6)$$

then $\langle \mathcal{L}, \leq \rangle$ *is a lattice such that*

$$x \vee y = \sup\{x,y\} \quad \text{and} \quad x \wedge y = \inf\{x,y\}$$

Moreover, the following result assures the "categorical equivalence" between the two versions of the lattice notions, the poset one and the algebraic one.

Proposition 4. *Starting with a poset version of a lattice* $\langle \mathcal{L}, \leq \rangle$, *forming its algebraic version* $\langle \mathcal{L}, \wedge, \vee \rangle$, *and then forming its corresponding poset version, denoted by* $\langle \mathcal{L}, \preceq \rangle$, *then this latter gives us back our original poset structure, i.e.,* $\preceq$ *is the partial order* $\leq$ *we started with.*

Vice versa, starting from an algebraic version of a lattice $\langle \mathcal{L}, \wedge, \vee \rangle$, *forming its poset version* $\langle \mathcal{L}, \leq \rangle$, *and then forming its corresponding algebraic version, denoted by* $\langle \mathcal{L}, \sqcap, \vee \rangle$, *then one obtains the original algebraic structure, i.e.,* $\wedge = \sqcap$ *and* $\vee = \sqcup$.

Until now we have considered *inf* and *sup* as two binary operations holding between two generic elements of a set. It is time for us to ask if we can find neutral elements for these operations.

Proposition 5. *Let*$\langle \mathcal{L}, \wedge, \vee \rangle$*be the algebraic formulation of a lattice.*

i) If a neutral element exists for the binary operation $\vee$, *called the algebraic* zero, *then this element is unique and turns out to be the minimum element* 0 *with respect to partial ordering in Equation* (6) *induced from the algebra.*

ii) If the neutral element exists for the binary operation $\wedge$, *called the algebraic* unity, *then this element is unique and turns out to be the maximum element* 1 *with respect to partial ordering in Equation* (6) *induced from the algebra.*

Proof. By definition of $\vee$–neutral element we have that $\forall x \in \mathcal{L} : x \vee 0 = x$, that is, $0 \leq x$ for every element x, according to Equation (6). This result means that if the zero element exists in the algebraic version of a lattice $\langle \mathcal{L}, \wedge, \vee \rangle$, then it is the minimum element relative to the induced poset $\langle \mathcal{L}, \leq \rangle$, and it is unique at the same time.

On the other side, always according to Equation (6), $x \wedge 1 = x$ for every $x \in \mathcal{L}$ is equivalent to $x \leq 1$; so if the algebraic unity 1 exists in $\mathcal{L}$, then this unity is unique and is the maximum element in the induced poset structure $\langle \mathcal{L}, \leq \rangle$.

The case of a bounded lattice has an interesting peculiar algebraic characterization, at least in terms of the join operation.

Proposition 6. *Let* $\langle \mathcal{L}, \leq, 0 \rangle$ *be a bounded lattice; then, the binary operation of join* $\vee$ *satisfies the equations for all x, y, and z*:

$(L1)$ $x \vee x = x$ (idempotence)
$(L2)$ $x \vee y = y \vee x$ (commutativity)
$(L3)$ $x \vee (y \vee z) = (x \vee y) \vee z$ (associativity)
$(L0)$ $x \vee 0 = x$ (unit element)

Briefly, the structure $\langle \mathcal{L}, \vee, 0 \rangle$ *is a* commutative monoid *(semigroup with unity) in which any element is idempotent.*

Conversely, we have that if $\langle \mathcal{L}, \vee, 0 \rangle$ *is a commutative monoid in which every element is idempotent, then there exists a unique partial ordering on* $\mathcal{L}$ *such that* $x \vee y$ *is the lattice join of any pair x and y, and* 0 *is the least element.*

This situation means that this structure is a join-semilattice, and so a semilattice can be defined either in terms of the order relation or in terms of join operation.

Definition 8. *Two lattices* $\mathcal{L}_1$ *and* $\mathcal{L}_2$ *are said to be* isomorphic *if there exists a bijective mapping of* $\mathcal{L}_1$ *into* $\mathcal{L}_2$, *say* ϕ: $\mathcal{L}_1 \mapsto \mathcal{L}_2$, such that for arbitrary $x, y \in \mathcal{L}_1$

$$\phi(x \wedge y) = \phi(x) \wedge \phi(y) \quad \text{and} \quad \phi(x \vee y) = \phi(x) \vee \phi(y) \qquad (7)$$

Of course, if $\phi : \mathcal{L}_1 \mapsto \mathcal{L}_2$ is a lattice isomorphism, then its inverse $\phi^{-1} : \mathcal{L}_2 \mapsto \mathcal{L}_1$ is a lattice isomorphism, too. Trivially, a lattice isomorphism preserves the ordering, i.e., it is a poset isomorphism:

$$\begin{array}{lll} x \leq y & \text{implies} & \phi(x) \leq \phi(y) \\ \phi(x) \leq \phi(y) & \text{implies} & x \leq y \end{array}$$

Indeed, $x \leq y$ is equivalent to $x = a \wedge y$, and so $\phi(x) = \phi(x) \wedge \phi(y)$, which means that $\phi(x) \leq \phi(y)$. The second condition can be proved in a similar, if a little bit complicated, way.

Proposition 7. *If two bounded lattices are* isomorphic, *then the additional conditions are satisfied*:

$$\phi(0) = 0 \quad \text{and} \quad \phi(1) = 1$$

Proof. If we apply the first part of Equation (7) to the particular case $y = 0$, then we obtain that for every x it is $\phi(0) = \phi(x) \wedge \phi(0)$, i.e., $\phi(0) \leq \phi(x)$. Because this inequality holds for every element x of the lattice $\mathcal{L}_1$, let us denote by $x_0 = \phi^{-1}(0)$ the inverse imagine of the $0 \in \mathcal{L}_2$; then, we have that $\phi(0) \leq 0$, i.e., $\phi(0) = 0$. The second statement can be proved analogously.

Example 15. Let us consider the two bounded lattices $\mathcal{P}(X)$ and 2^X of Examples 1 and 2, respectively. The lattice structure of the power lattice $\mathcal{P}(X)$ of the universe X has been widely discussed in Example 9. Now, let us consider the mapping

$$\chi : \mathcal{P}(X) \mapsto 2^X$$

associating with any subset A of X its characteristic functional $\chi_A : X \mapsto \{0, 1\}$, i.e., the Boolean-valued functional defined as $\chi_A(x) = 1$ if $x \in A$ and $= 0$ otherwise.

This mapping is a bijection because *(1)* it is injective: $A \neq B$ trivially implies that $\chi_A \neq \chi_B$, and *(2)* it is surjective because for any $\psi : X \mapsto \{0, 1\}$ in 2^X, constructed the subset $A(\psi) := \{x \in X : \psi(x) = 1\}$, the corresponding characteristic functional is such that $\chi_{A(\psi)} = \psi$.

With respect to the meet and join operations, recalling that the lattice meet and join of two characteristic functionals $\chi_A, \chi_B \in 2^X$ with respect to the partial ordering in Equation (1) both exist (Example 10), we have the following correspondences whatever be A, $B \in \mathcal{P}(X)$:

$$\begin{array}{l} A \cap B \xrightarrow{\chi} \chi_{A \cap B} = \chi_A \wedge \chi_B \\ A \cup B \xrightarrow{\chi} \chi_{A \cup B} = \chi_A \vee \chi_B \end{array}$$

i.e., χ is a lattice isomorphism, which allows one to identify the subset A of the universe X with its characteristic functional χ_A. Let us note that if one interprets the Boolean values 0 and 1 as two *membership degrees*, with 1 (resp., 0) the membership certainty (resp., impossibility), in fuzzy set theory the characteristic functional χ_A is considered as the *crisp* representation of the set A (see Refs. 3 and 4. In this context, $\chi_\emptyset$ is the identical zero function, also denoted by 0, that assigns to any x the value 0; similarly, χ_X is the identical one function, also denoted by 1, that assigns to any x the value 1. Of course, the lattice 2^X is bounded because for any $\chi \in 2^X$, it is $0 \leq \chi \leq 1$.

DISTRIBUTIVE AND MODULAR LATTICES

In the context of lattices, we can distinguish at least two different classes: *distributive lattices* and *modular lattices*.

Definition 9. *A lattice* $\mathcal{L}$ *is said to be* distributive *if and only if the following equalities hold:*

(d1) for every $x, y, z \in \mathcal{L}, x \vee (y \wedge z) = (x \vee y) \wedge (x \vee z)$
(d2) for every $x, y, z \in \mathcal{L}, x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$

Remark 2. As remarked in Ref. 1 on page 11, conditions (d1) and (d2) are mutually equivalent, and so only one of these equalities is enough to define a distributive lattice [either (d1) or (d2)]. Notice that in the proof of this equivalence property, a determinant role is played by the universal quantifier in the sense that these two conditions are equivalent if they hold for *any* triple of elements from the lattice $(\forall x, y, z \in \mathcal{L})$.

If the lattice is not distributive, then there might be particular triples of individual elements $(\exists x_0, y_0, z_0 \in \mathcal{L})$ such that $x_0 \vee (y_0 \wedge z_0) = (x_0 \vee y_0) \wedge (x_0 \vee z_0)$, but with respect to which $x_0 \wedge (y_0 \vee z_0) \neq (x_0 \wedge y_0) \vee (x_0 \wedge z_0)$, and vice versa.

Example 16. The lattice N5 shown in Fig. 5 is not distributive.

Indeed, one has that $b \wedge (a \vee c) = (b \wedge a) \vee (b \wedge c) = b$, i.e., the (ordered) triple *(b, a, c)* is (d2)-distributive, but $b \vee (a \wedge c) = b \neq a = (b \vee a) \wedge (b \vee c)$, i.e., this triple is not (d1)-distributive.

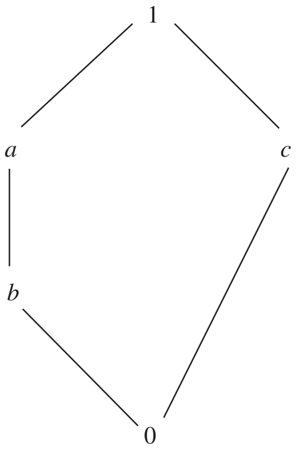

Figure 5. The nondistributive lattice N5.

In Ref. 5, one can find the following result, which is the distributive analogous of Theorem 3 that links lattices and algebraic structures.

Theorem 4. *Let $\langle \mathcal{L}, \wedge, \vee \rangle$ be an algebraic structure where:*

1) *$\mathcal{L}$ is a nonempty set, and*
2) *$\wedge$ and $\vee$ are two binary operations on $\mathcal{L}$ satisfying properties:*
   (DL1) $x = x \wedge (x \vee y)$
   (DL2) $x \wedge (y \vee z) = (z \wedge x) \vee (y \wedge x)$

Then, $\mathcal{L}$ is a distributive lattice.

Definition 10. *A lattice $\mathcal{L}$ is said to be* modular *if and only if the following equality holds:*

(m1) for every *x,y,z* $\in \mathcal{L}$, $x \leq z$ implies $x \vee (y \wedge z) = (x \vee y) \wedge z$

Remark 3. As (d1) and (d2) are dual forms, one is suggested to consider the dual of (m1) whose form is

(m2) $z \leq x$ implies $x \wedge (y \vee z) = (x \wedge y) \vee z$

However, if one makes the substitutions $\hat{x} := z$ and $\hat{z} := x$, then the (m2) assumes the form

(m2) $\hat{x} \leq \hat{z}$ implies $\hat{z} \wedge (y \vee \hat{x}) = (\hat{z} \wedge y) \vee \hat{x}$

which is nothing else than the original (m1).

From Definitions 9 and 10, it is straightforward to prove that every distributive lattice is modular too; indeed, from (d1) $x \vee (y \wedge z) = (x \vee y) \wedge (x \vee z)$ the condition $x \leq z$, i.e., $z = x \vee z$, leads to (m1). The vice versa is in general not true because it is possible to find modular lattices that are not distributive.

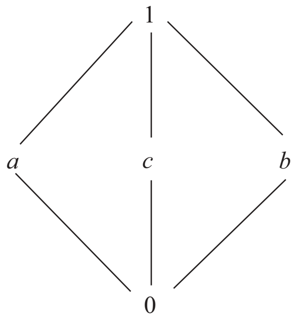

Figure 6. The modular lattice M5.

Example 17. This situation is exactly the case of the finite lattice M5 which has its Hasse diagram represented in Fig. 6.

Indeed, we have $a \wedge (b \vee c) = a \wedge 1 = a$ and $(a \wedge b) \vee (a \wedge c) = 0 \vee 0 = 0$, from which it follows that $a \wedge (b \vee c) \neq (a \wedge b) \vee (a \wedge c)$, i.e., this lattice is not distributive.

We prove now that this lattice is modular. Let $x \leq z$ be two nontrivial ($\neq$ 0,1) elements in M5; then, from the particular structure of M5 it follows that $x \vee (y \wedge z) = x \vee (y \wedge x) = x$ and $(y \vee z) \wedge z = (x \vee y) \wedge x = x$, by absorption (this latter does not hold in the lattice of 5 where, for instance, $b \leq a$, but $(b \vee c) \wedge a \neq (b \vee c) \wedge b$). In the nontrivial cases, we have to consider two subcases $0 < a$ and $a < 1$ by symmetry; in the first, we obtain $0 \vee (y \wedge a) = y \wedge a$ and $(0 \vee y) \wedge a = y \wedge a$, whereas in the latter, we have $a \vee (y \wedge 1) = a \vee y$ and $(a \vee y) \wedge 1 = a \vee y$.

As a concrete example of this behavior, let us consider the complete lattice $\mathcal{M}(\mathbb{R}^2)$ of all subspaces of the two-dimensional linear space $\mathbb{R}^2$. Then, if one set $0 := \{\underline{0}\}$ (the subspace consisting of the zero vector) and $1 = \mathbb{R}^2$, the following subspaces realize the Hasse diagram of Fig. 6:

$$a := M_x = \{(x,0) : x \in \mathbb{R}\} \quad b := M_y\{(0,y) : y \in \mathcal{R}\}$$
$$c := M_{\pi/4} = \{(x,x) : x \in \mathcal{R}\}$$

In general, it can be proved that

> any *finite dimensional* (real or complex) linear space is such that the complete lattice of all its subspaces is modular: "In particular, set–products and straight linear sums are known to satisfy the so-called modular identity" 6.

This result is very simple to prove in the two-dimensional case, whereas the proof of the general finite-dimensional case can be found in Ref. 6 (Footnote 23 of section 11).

Example 18. The lattice $\mathcal{M}(\mathbb{R}^2)$ of all subspaces of the real vector space $\mathbb{R}^2$ has been represented by the Hasse diagram in the right side of Fig. 4. To verify the condition (m1) of Definition 10, we first consider the trivial case of $\alpha = \gamma$. Because for any β it is $\alpha \leq \beta \vee \alpha$, we have $\alpha = \alpha \wedge (\beta \vee \alpha)$. If β represents any subspace different from α and $\mathbb{R}^2$, then $\beta \wedge \alpha = \{\underline{0}\}$, and so $\alpha = \alpha \vee \{\underline{0}\} = \alpha \vee (\beta \wedge \alpha)$: if $\beta = \mathbb{R}^2$, then $\alpha = \mathbb{R}^2 \wedge \alpha$, and so $\alpha = \alpha \vee \alpha = \alpha \vee (\mathbb{R}^2 \wedge \alpha)$. Thus, we have obtained that when α = γ, it is $\alpha \wedge (\beta \vee \alpha) = \alpha = \alpha \vee (\beta \wedge \alpha)$.

Let us now consider the strict ordering $\alpha < \gamma$. It is obvious that this condition implies that $\alpha = \{\underline{0}\}$ or $\gamma = \mathbb{R}^2$. But, if $\alpha = \{\underline{0}\}$, then $\{\underline{0}\} \vee (\gamma \wedge \beta) = \gamma \wedge \beta = (\{\underline{0}\} \vee \gamma) \wedge \beta$, and if $\beta = \mathbb{R}^2$, then it is $\alpha \vee (\gamma \wedge \mathbb{R}^2) = \alpha \vee \gamma = (\alpha \vee \gamma) \wedge \mathbb{R}^2$.

Lastly, we have lattices like the one shown in Fig. 5, which does not belong to the class of modular lattices. Indeed, for this lattice $b \leq a$, but $b \vee (c \wedge a) = b \vee 0 = b$ and $(b \vee c) \wedge a = 1 \wedge a = a$; from $a \neq b$ we can deduce $b \vee (c \wedge a) \neq (b \vee c) \wedge a$.

BOOLEAN LATTICES AND ALGEBRAS

The concept of complement has a great importance in lattice theory.

Definition 11. *Let $\mathcal{L}$ be a bounded lattice. We identify the element $y \in \mathcal{L}$ as the* complement *of a given element $x \in \mathcal{L}$ if it is such that*

$$x \vee y = 1 \quad \text{and} \quad x \wedge y = 0$$

It is easy to see that if y is the x complement, then x is the y complement, as well. However, the following relations $0 \vee 1 = 1$ and $0 \wedge 1 = 0$ imply that these two elements are complements of each other. Moreover, it is easy to prove the following result.

Proposition 8. *If in a distributive lattice $\mathcal{L}$ the complement of a given element exists, then it is unique.*

Proof. Suppose that $\mathcal{L}$ is a distributive lattice and that a is an element with two complements a_1 and a_2. Then, from $a \vee a_2 = 1$ and $a \wedge a_1 = 0$ it follows that

$$a_1 = a_1 \wedge (a \vee a_2) = \text{distributivity} = (a_1 \wedge a) \vee (a_1 \wedge a_2)$$
$$= a_1 \wedge a_2 \leq a_2$$

Similarly, $a_2 \leq a_1$, so $a_1 = a_2$.

In a nondistributive lattice, this uniqueness property, in general, does not hold.

Example 19. In the modular lattice M5 of Fig. 6, both c and b are complements of the element a because $a \wedge c = a \wedge b = 0$ and $a \vee c = a \vee b = 1$. In general, for any $x \in \{a, b, c\}$, the two elements $y \in \{a, b, c\}$ such that $y \neq x$ are both complements of x.

But, there could exist distributive bounded lattice in which only the elements 0 and 1 have the complement (which is 1 and 0, respectively).

Example 20. Let $\mathcal{L}$ be a totally ordered bounded lattice that contain more than two elements. Then it is easy to see that this lattice is distributive, but no other element than 0 and 1 can have a complement.

Definition 12. *We have a* complementable *bounded lattice when every element of the lattice has* at least *one complement. We have a bounded* complemented *lattice when every element a of the lattice has just one complement, denoted by a'.*

A *Boolean lattice $\mathcal{B}$* is a distributive bounded lattice equipped with a *complementation* unary mapping, i.e., every element x has a well-defined (unique) complement, denoted by x'. The operation of assigning the complement x' to every element x of the lattice defines a unary operation $'$ from $\mathcal{B}$ onto itself, called *complementation*. These very important structures were introduced by George Boole in 1854. At that time, Boole was trying to define a logical calculus that could coincide with the propositional (enunciative) calculus. Later on, it was possible to recognize as another important concrete Boolean lattice class, the power set $\mathcal{P}(X)$ of a *universe* X equipped with the set theoretic union and intersection, and the set theoretic complementation operations. Formally, a Boolean lattice is defined in the following way:

Definition 13. *A* Boolean lattice *is a structure$\langle \mathcal{B}, \wedge, \vee, \prime, 0, 1\rangle$where*

- *(b1) $\mathcal{B}$ is a set that contains two distinct elements* 0 *and* 1,
- *(b2) $\wedge$ and $\vee$ are two binary operations on$\mathcal{B}$ with respect to which the structure$\langle \mathcal{B}, \wedge, \vee, 0, 1\rangle$is a distributive lattice bounded by the least element* 0 *and the greatest element 1: $\forall x \in B, 0 \leq x \leq 1$,* and
- *(b3) For everyx $\in$ $\mathcal{B}$there existsx$'$ $\in$ $\mathcal{B}$such thatx $\wedge$ x$'$* = 0 *andx $\vee$ x$'$ = 1; x$'$ is the complement of x.*

The following are very important examples of Boolean lattice:

Example 21. Let $\langle\{0, 1\}, \leq\rangle$ be the set consisting of the two elements 0,1 equipped with the usual order relation $0 \leq 1$. This poset is a Boolean lattice with respect to the operations presented in the tables below (at the left the lattice operations and at the right the complementation):

a	b	$a \wedge b$	$a \vee b$
0	0	0	0
0	1	0	1
1	0	0	1
1	1	1	1

x	x'
0	1
1	0

This part is usually known as the *two-valued* or *two-elements Boolean lattice*, denoted by $\mathbb{B} = \langle\{0, 1\}, \wedge, \vee, \prime, 0, 1\rangle$.

Example 22. The power set $P(X)$ of a universe X discussed in Example 9 is a Boolean lattice if we choose the set theoretic complement $A^c = X \backslash A := \{x \in X : x \in X \text{ and } x \notin A\}$ as the complement of a given set A in the universe X. Such a Boolean lattice is $\mathcal{P} = \langle \mathcal{P}(X), \cap, \cup, ^c, \emptyset, X\rangle$.

Example 23. The collection 2^X of all two-valued functionals on the universe X introduced in Example 10 is a Boolean lattice if we choose the functional $\chi' := 1 - \chi$ as the complement of a given functional χ. Such a lattice is $\mathbb{E} = \langle 2^X, \wedge, \vee, ', \underline{0}, \underline{1}\rangle$.

Example 24. In example 14, we have investigated the lattice of all closed sets of a topological space X. Taking inspiration from usual set theory, a natural way to introduce a complement of a generic closed set K could be its set complement K^c. The problem is that in general this latter is not a closed set. For instance, in the usual topology of $\mathbb{R}$ by closed sets, the closed interval $[a,b] := \{x, \in \mathbb{R} : a \leq x \leq b\}$ (for $a \leq b$) has set complement $[a,b]^c = (-\infty, a) \cup (b, +\infty)$ that is not closed.

In general, if $\mathcal{C}(X)$ is the collection of all closed sets (as primitive notion of a topology), then the collection of all set complement of closed sets determines (as derived notion in this context) the family $\mathcal{O}(X)$ of all *open* sets; formally, $O \in \mathcal{O}(X)$ iff there exists a closed set $K \in \mathcal{C}(X)$ such that $O = K^c$. On the basis of this definition and the properties (T1)–(T3) of Example 13, it is easy to prove that the family $\mathcal{O}(X)$ satisfies the following conditions:

(O1) The empty set and the whole space X are open $\emptyset, X \in \mathcal{O}(X)$.
(O2) The set union of *any* family of open sets is open, and
(O3) The *finite* intersection of open sets is open.

Now if one considers the collection $\mathcal{CO}(X)$ of all subsets of X that are both closed and open (the so-called *clopen* sets), then according to (T2) and (O2), the induced partial order structure is the one of complete lattice; moreover, for any clopen set U, its set complement U^c is obviously clopen, too, and so one obtains that $\langle \mathcal{CO}(X), \cap, \cup, ^c, \emptyset, X \rangle$ is a Boolean algebra.

In the topological space $\mathbb{R}$, the unique clopen sets are the trivial ones $\emptyset$ and $\mathbb{R}$, a very poor collection. A canonical way to obtain a sufficiently rich topology of clopen is the following one. Let us consider a *partition space* (X,π), which consists of a nonempty universe X equipped with a partition π, i.e., a collection of nonempty subsets of X that are pairwise disjoint and whose set union covers the universe. Let us denote by $\mathcal{CO}(X,\pi)$ the collection of all subsets of X that are union of equivalence classes from π (i.e., $E \in \mathcal{CO}(X,\pi)$ iff there exists a family $\{A_i\} \subseteq \pi$ such that $E = \cup A_i$) plus the empty set. Trivially, for any pair of sets, $E, F \in \mathcal{CO}(X,\pi)$, also, $E \cup F \in \mathcal{CO}(X,\pi)$ and $E \cap F \in \mathcal{CO}(X,\pi)$; moreover, if $E \in \mathcal{CO}(X,\pi)$, then its set complement $E^c \in \mathcal{CO}(X,\pi)$, too (it is also a set union of equivalence classes from π). Then, the structure $\langle \mathcal{CO}(X,\pi), \cap, \cup, ^c, \emptyset, X \rangle$ is the Boolean lattice induced from the partition π of X that, from the topological point of view, is a topological space of clopen sets.

This Boolean lattice is the basic structure of the so-called approach to *rough sets* as introduced by Pawlak in Ref. 7 (see Ref. 8 for the abstract approach to this argument). In this framework, one considers an information system formalized as a mapping $F : X \times Att \mapsto val$ defined on pairs $(x, a) \in X \times Att$ consisting of an object x and an attribute a, and furnishing the value $F(x, a) \in val$ assumed by the object x relatively to the attribute a. For any family of attributes $\mathcal{A} \subseteq Att$, it is possible to introduce the equivalence relation of *indistinguishability* on objects: $x(\text{Ind})_{\mathcal{A}}y$ iff for any $a \in \mathcal{A} : F(x,a) = F(y,a)$, i.e., two objects are equivalent if they cannot be distinguished relatively to the knowledge supported by all the attributes of $\mathcal{A}$.

Example 25. Let $D = \{1, 2, 5, 7, 10, 14, 35, 70\}$ be the set of all divisors of 70. Once defined $x \wedge y = \text{mcd}(x, y)$ $(5 \wedge 14 = 1,$ $10 \wedge 35 = 5)$, $x \vee y = \text{mcm}(x, y)$ $(5 \vee 14 = 70,\ 10 \vee 35 = 70)$ and $x' = \frac{70}{x}(5' = 14)$, the structure $\langle D, \wedge, \vee, ', 1, 70 \rangle$ is a Boolean lattice.

Summarizing, a Boolean lattice is a distributive, complementable lattice. But, we have seen that in a distributive lattice, the uniqueness property of the complement of each element holds, and so in a complementable distributive lattice $\mathcal{B}$, we can introduce a unary operation$'$: $\mathcal{B} \mapsto \mathcal{B}, x \to x'$, the *complementation*, which associates with each element x its unique complement x'. In this way, we can have the following equivalent, but equational, algebraic definition.

Definition 14. *A* Boolean algebra *is a sextuple* $\langle \mathcal{B}, \wedge, \vee, ', 0, 1 \rangle$, *where:*

i) *$\mathcal{B}$ is a set that contains two distinct elements,* 0 *and* 1,
ii) *$\wedge$ and $\vee$ are binary operations on $\mathcal{B}$*, and
(iii) *$' : \mathcal{B} \mapsto \mathcal{B}$ is a unary operation from $\mathcal{B}$ onto $\mathcal{B}$,*

such that for every x,y,z $\in \mathcal{B}$, *the following axioms hold:*

1) $x \wedge y = y \wedge x$ and $x \vee y = y \vee x$
2) $x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z)$ and $x \vee (y \wedge z) = (x \vee y) \wedge (x \vee z)$
3) $x \vee 0 = x$ and $x \wedge 1 = x$
4) $x \vee x' = 1$ and $x \wedge x' = 0$

An alternative system of axioms for Boolean algebras is presented in Ref. 1.

Definition 15. *A structure* $\langle \mathcal{B}, \wedge, \vee, ', 0, 1 \rangle$ *with* $\wedge$ *and* $\vee$ *binary operations on*$\mathcal{B}$*and*$'$ *a unary operation on the same set is a Boolean algebra iff the following properties are satisfied for all* $a, b \in \mathcal{B}$:

(B1) $a \wedge b = (a' \vee b')'$
(B2) $a \vee b = b \vee a$
(B3) $a \vee (b \vee c) = (a \vee b) \vee c$
(B4) $(a \wedge b) \vee (a \wedge b') = a$

In this case, axioms (B1)–(B4) are independent, that is, no one of them can be derived from the other; if one's eliminates then the structure $\langle \mathcal{B}, \wedge, \vee, ', 0, 1 \rangle$ is no more a Boolean algebra. Independence is an important property of an algebra, because it enables us to determine which are the necessary properties to define it. Given a set of axioms, it is possible to prove the independence of one of them by finding a model (a concrete example) of the structure that satisfies all the axioms but this chosen one.

Example 26. Let us consider axioms (B1)–(B4). We show that (B2) is independent from the others. To do this, we give a structure, that satisfies (B1), (B3), (B4) and not (B2). The structure is the following: $\langle\{0,1\}, \wedge, \wedge, i\rangle$ (this means that $\vee := \wedge$), where $i(x) = x$ and $0 \wedge x = 0, 1 \wedge x = 1$. As can be easily seen, (B2) is not satisfied: $0 \vee 1 = 0 \neq 1 = 1 \vee 0$.

Proposition 9. 1. *In any Boolean algebra, it is possible to prove that the following properties hold:*

1) The lattice conditions

$$\begin{array}{ll} a \vee a =, a \wedge a = a & \text{(idempotency)} \\ a \vee b = b \vee a, a \wedge b = b \wedge a & \text{(commutativity)} \\ a \vee (b \vee c) = (a \vee b) \vee c & (\vee \text{ associativity}) \\ a \wedge (b \wedge c) = (a \wedge b) \wedge c & (\wedge \text{ associativity}) \\ a \vee (a \wedge b) = a, a \wedge (a \vee b) = a & \text{(absorption)} \end{array}$$

2) The distributivity conditions

$$\begin{array}{ll} a \vee (b \wedge c) = (a \vee b) \wedge (a \vee c) & (\vee \text{ distributivity}) \\ a \wedge (b \vee c) = (a \wedge b) \vee (a \wedge c) & (\wedge \text{ distributivity}) \end{array}$$

3) The lattice zero and unit elements

$$\begin{array}{ll} a \vee 0 = a, a \vee 1 = 1 & (\vee \text{ boundry conditions}) \\ a \wedge 0 = 0, a \wedge 1 = a & (\wedge \text{ boundry conditions}) \end{array}$$

4) The orthocomplementation conditions

$$\begin{array}{ll} (a')' = a & \text{(involution)} \\ (a \wedge b)' = a' \vee b' & (\vee \text{ de Morgan law}) \\ (a \vee b)' = a' \wedge b' & (\wedge \text{ de Morgan law}) \\ a \vee a' = 1 & \text{(excluded middle law)} \\ a \wedge a' = 0 & \text{(noncontradiction law)} \end{array}$$

Also, for the case of Boolean lattices, in Ref. 5 it is possible to find a result that represents the analog of Theorem 3 (for lattices) and Theorem 4 (for distributive lattices).

Theorem 5. *Let $\langle \mathcal{B}, \wedge, \vee \rangle$ be an algebraic structure where:*

1) $\mathcal{L}$ is a nonempty set, and

2) $\wedge$ and $\vee$ are two binary operations on $\mathcal{L}$ satisfying properties:

(DL1) $x = x \wedge (x \vee y)$

(DL2) $x \wedge (y \vee z) = (z \wedge x) \vee (y \wedge x)$

(BL) to each y there corresponds some y' such that

$$x \wedge (y \vee y') = x \vee (y \wedge y')$$

Then, $\mathcal{L}$ is a Boolean lattice.

Now we can extend the notion of lattice isomorphism to the case of Boolean algebras.

Definition 16. *Two Boolean algebras $\mathcal{B}_1$ and $\mathcal{B}_2$ are said to be* isomorphic *iff there exists a lattice isomorphism $\phi : \mathcal{B}_1 \mapsto \mathcal{B}_2$ that preserves the complementation,*

$$\forall x \in \mathcal{B}_1, \quad \phi(x') = \phi(x)'$$

Example 27. The lattice isomorphism seen in Example 15 between the power set $\mathcal{P}(X)$ of a universe X and the collection 2^X of all the Boolean–valued functionals on $X, \chi : \mathcal{P}(X) \mapsto 2^X, A \in \mathcal{P}(X) \to \chi_A \in 2^X$, is, indeed, a Boolean lattice isomorphism because trivially for any subset A of X

$$\chi_{A^c} = 1 - \chi_A$$

As we have seen in Example 22, the collection of all subsets of a universe X is a Boolean algebra under set inclusion (with associated set union and intersection) and set complementation. The following is an interesting *representation theorem* of finite Boolean algebras.

Theorem 6 (Stone's Representation Theorem). *Every finite Boolean algebra $\mathcal{B}$ is isomorphic to the algebra of parts of the set of its atoms.*

The preceding theorem causes the following important consequences:

1) The cardinality of every finite Boolean algebra is a power of 2.

2) Two finite Boolean algebras with the same cardinality are isomorphic to each other.

Let us explain this procedure with one example.

Example 28. In Fig. 7, the left side is the Hasse diagram of the (finite) Boolean lattice B8, whose atoms are the elements

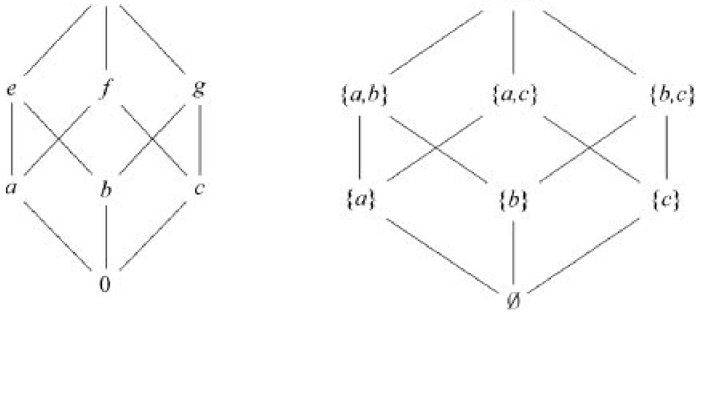

Figure 7. The finite Boolean lattice B8 with its Stone representation 2^3 of all subsets of the universe $\{a, b, n\}$.

a, b, and *c*. If one then considers the universe $X = \{a,\ b,\ c\}$ formed by all atoms of B8, the power set 2^3 of this universe ordered with the standard set theoretic ordering (the right side of the figure) is the Stone representation of B8.

The general procedure is the following one. Let $\mathcal{B}$ be a finite Boolean lattice, and let us denote by $A(\mathcal{B})$ the collection of all its atoms, assumed as the universe of the Stone representation of $\mathcal{B}$. Then, let us construct the mapping $\phi : \mathcal{B} \mapsto \mathcal{P}(A(B))$ that assigns to any element $x \in \mathcal{B}$ of the Boolean lattice the subset $\phi(x) = \{a \in A(\mathcal{B})) : a \leq x\}$, element of the power set $\mathcal{P}(A(\mathcal{B}))$ obtained as the collection of all atoms a that precede x. For instance, in the example below, $\phi(e) = \{a,\ b\}$ because a and b are the two atoms that precede e. Trivially, the mapping ϕ is a Boolean lattice isomorphism. For instance, $\phi(e \vee g) = \phi(1) = \{a,b,c\} = \{a,b\} \cup \{b,c\} = \phi(e) \vee \phi(g)$.

The extension of this representation procedure to the case of an infinite Boolean lattice presents some problems because it is easy to give examples either of nonatomic or of noncomplete Boolean algebras and any Boolean algebra $\mathcal{P}(X)$ of all subsets of a universe X has both these properties. The best results of this situation are given by the following.

Proposition 10. *Let $\mathcal{B}$ be an abstract Boolean algebra, and let $A(\mathcal{B})$ denote the set of all its atoms. Then, the mapping $\phi : \mathcal{B} \mapsto \mathcal{P}(A(\mathcal{B}))$ associating with any element $x \in \mathcal{B}$ the subset of atoms $\phi(x) := \{a \in A(\mathcal{B}) : a \leq x\}$ is a homomorphism of Boolean lattices, i.e., both conditions in Equation* (7) *of Definition 8 are satisfied by the mapping ϕ without the certainty that the bijective condition is assured. Moreover,*

i) if $\mathcal{B}$ is atomic, then the mapping ϕ is injective, and
ii) if $\mathcal{B}$ is complete, then the mapping ϕ is surjective.

Proof. The fact that ϕ is a Boolean algebras homomorphism follows from the remark that an atom a satisfies the condition $a \leq x \vee y$ iff either $a \leq x$ or $a \leq y$. Analogously, an atom a satisfies the condition $a \leq x \wedge y$ iff both $a \leq x$ and $a \leq y$.

If $\mathcal{B}$ is atomic, then for any pair of its elements $x \neq y$, their symmetric difference $x\Delta y := (x \wedge y') \vee (y \wedge x')$ admits an atom $a \leq (x\Delta y)$; this implies that either $a \leq x \wedge y'$ or $a \leq y \wedge x'$ but not both (otherwise, for instance, $a \leq x \wedge x' = 0$). Hence, a will be in just one, and only one, of $\phi(x)$ and $\phi(y)$.

If $\mathcal{B}$ is complete, then for any subset Y of $A(\mathcal{B})$ there exists the element $z = \vee\{y : y \in Y\}$ in $\mathcal{B}$ such that $\phi(z) = Y$.

As an immediate consequence, we have:

Theorem 7. *A Boolean algebra $\mathcal{B}$ is isomorphic to the algebra $\mathcal{P}(X)$of all subsets of some universe X iff it is atomic and complete.*

This result states the problem of what happens in all the other cases of Boolean algebras for which at least one of the above conditions does not hold. In Example 24, we have seen that given a topological space X, the clopen subsets of X are closed under intersection, union, and complementation forming a Boolean algebra. Note that, in general, the topology of clopen set $\mathcal{CO}(X)$ of a space X is contained in the power set of this latter, $\mathcal{CO}(X) \subseteq \mathcal{P}(X)$, in other words, it is a subBoolean algebra of the power set. A well-known theorem of Stone 9 asserts that *every* Boolean algebra is represented isomorphically by one of such and that if one requires the topological space to be compact Hausdorff as well as totally disconnected (what is now called *Stone space*, whereas Stone originally called these spaces with the name of *Boolean spaces*), then this representation is essentially uniquely determined by the Boolean algebra. The meaning of this isomorphism is that any algebraic fact about Boolean algebras could be translated into a topological fact about Stone spaces, and vice versa.

Ortholattices

Point 4 of Proposition 9 lists the conditions that are satisfied by the complement of a Boolean algebra. Relative to this point, and as the consequence of the uniqueness of the complement a' of a given element a from the Boolean algebra $\mathcal{B}$, it is possible to introduce a unary operation $' : \mathcal{B} \mapsto \mathcal{B}, a \to a'$ that satisfies the condition of involution, both the de Morgan laws, the excluded middle, and the noncontradiction laws. We can formalize this situation in the following way:

Definition 17. *An orthocomplemented lattice*, ortholattice *for short, is a structure $\langle \mathcal{L}, \wedge, \vee, ', 0\rangle$ of lower-bounded lattice $\langle \mathcal{L}, \wedge, \vee, 0\rangle$ equipped with an ortho-complementation mapping$' : \mathcal{L} \mapsto \mathcal{L}$that satisfies the equational conditions:*

$$\begin{array}{lll}
\text{(oc1)} & x = x'' & \text{(double negation)} \\
\text{(oc2a)} & x' \wedge y' = (x \vee y)' & \text{(de Morgan)} \\
\text{(oc3a)} & x \wedge x' = 0 & \text{(noncontradiction)}
\end{array}$$

With respect to the properties listed in point 4 of Proposition 9, in the now-introduced definition, it involves only one de Morgan property. Also, the two properties of point 3 in the same proposition are simplified by the unique (oc3). But the following results hold:

Proposition 11. *In any lattice, under condition (oc1), the following are equivalent:*

$$\begin{array}{lll}
\text{(oc2a)} & x' \wedge y' = (a \vee y)' & \text{(first de Morgan law)} \\
\text{(oc2b)} & x' \vee y' = (a \wedge y)' & \text{(second de Morgan law)} \\
\text{(oc2c)} & x \leq y \text{ implies } y' \leq x' & \text{(contraposition law)} \\
\text{(oc2d)} & x' \leq y' \text{ implies } y \leq x & \text{(dual contraposition law)}
\end{array}$$

In a similar way, in any bounded lattice under conditions (oc1) and (oc2), the following two are equivalent:

$$\begin{array}{lll}
\text{(oc3a)} & x \wedge x' = 0 & \text{(noncontradiction law)} \\
\text{(oc3b)} & x \vee y' = 1 & \text{(excluded middle law)}
\end{array}$$

Let us stress that the just-introduced notion of ortholattice can be applied to lattice that are not necessarily distributive, but with the loss of the uniqueness of the orthocomplementation mapping that characterizes Boolean

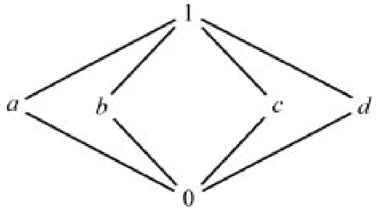

Figure 8. The six elements modular lattice M6.

algebras. In this way, the complementation mapping assumes an important role, outside the "restricted" class of Boolean algebras. We clarify this fact with an example from the larger class of modular lattices.

Example 29. Let us consider the (six-elements) modular lattice M6 represented by the Hasse diagram of Fig. 8.

Then, any nontrivial element $x \neq 0{,}1$ has three complements, precisely every nontrivial $y \neq 0{,}1$ such that $y \neq x$. So, this lattice is complementable, but it is possible to assign more than one orthocomplementation mapping, two of which are represented by the diagrams drawn in Fig. 9.

Example 30. Let us consider the two-dimensional linear space $\mathbb{R}^2$. We have seen in Example 14 that the collection $\mathcal{M}(\mathbb{R}^2)$ of all its subspaces is a modular (nondistributive) lattice, bounded by the minimum subspace $0 = \{\underline{0}\}$ and the maximum subspace $1 = \mathbb{R}^2$. In this lattice any one-dimensional subspace α–has an infinite collection of complements, i.e., any one-dimensional subspace $\beta \neq \alpha$ is a complement of α. At a first glance, it seems that there could be no intuitive criterium to select for each α one of these infinite subspaces, say α', as its *unique* orthocomplement.

But, $\mathbb{R}^2$ can be equipped with the inner product defined for any pair of its vectors $\underline{x} = (x_1, x_2)$ and $\underline{y} = (y_1, y_2)$ as the real number

$$\langle \underline{x} | \underline{y} \rangle := x_1 y_1 + x_2 y_2$$

The standard notion of *orthogonality* is the following one:

$$\underline{x} \perp \underline{y} \quad \text{iff} \quad \langle \underline{x} | \underline{y} \rangle = 0$$

Now, for any subspace M of $\mathbb{R}^2$ (i.e., the trivial subspaces $\{\underline{0}\}$ and $\mathbb{R}^2$, and all one-dimensional subspaces) one can define its complement, denoted by $M^\perp$ as the subspace that is orthogonal to M. Formally,

$$M^\perp := \{\underline{h} \in \mathbb{R}^2 : \forall \underline{m} \in M, \langle \underline{h} | \underline{m} \rangle = 0\}$$

This is a subspace, and the mapping $\perp : \mathcal{M}(\mathbb{R}^2) \mapsto \mathcal{M}(\mathbb{R}^2), M \mapsto M^\perp$ is an orthocomplementation acting on a modular lattice. Probably, this example has been the cause of the term *ortho*complementation given to any mapping that satisfies the above conditions (oc1)–(oc3).

For instance, if one considers the subspace $M_{\pi/4} = \{(x,x) \in \mathbb{R}^2; x \in \mathbb{R}\}$ then its orthocomplement is $(M_{\pi/4})^\perp = \{(h,-h) \in \mathbb{R}^2 : h \in \mathbb{R}\} = M_{(3/4)\pi}$ because a fixed generic vector $(h_0, -h_0) \in (M_{\pi/4})^\perp$ is such that for any $(x,x) \in M_{\pi/4}$ the orthogonality condition $\langle (h_0, -h_0) | (x,x) \rangle = 0$ holds. However, $M_x = \{(x,0) : x \in \mathbb{R}\}$ and $M_y = \{(0,y) : y \in \mathbb{R}\}$ are such that trivially $(M_x)^\perp = M_y$ and $(M_y)^\perp = M_x$. If one considers the modular sublattice of $\mathcal{M}(\mathbb{R}^2)$ consisting of the six subspaces $\{\{\underline{0}\}, M_x, M_{\pi/2}, M_y, M_{(3/4)\pi}, \mathbb{R}^2\}$, then the corresponding Hasse diagram has the form of the one depicted in the right side of Fig. 9 by the identifications $a = M_x, b = M_{\pi/2}, c = M_y$ and $d = M_{(3/4)\pi}$.

Let us make now a brief discussion about the semantical interpretation of the algebraic operations of an orthocomplemented lattice with respect to the ordinary propositional logic, the so–called *algebraic semantic* of a logic. First of all, let us stress that "when interpreting [lattice] structures from the viewpoint of logic, it is customary to interpret the lattice elements [a, b,. . .] as *propositions,* the meet operation [$\wedge$] as *conjunction* [logical And], the join operation [$\vee$] as *disjunction* [logical Or], and the orthocomplement [$\neg$] as *negation* [logical Not]" (10). Hence, from the point of view of *algebraic semantic,* "clearly L1–L4 [of a lattice, according to Theorem 1] are well-known properties of And and Or in ordinary logic. This gives an algebraic reason for admitting as a *postulate* (if necessary) the statement that a given calculus of proposition is a lattice" 6. In this lattice context, "it is generally agreed that the partial ordering $\leq$ of a lattice [. . .] can be logically interpreted as a *relation* of implication, more specifically *semantic entailment"*(6), which must not be confused with an implication logical *connective* that, like conjunction and disjunction, forms propositions out of propositions remaining at the same linguistic level.

In particular, Boolean algebras have a significant role in classical logic. Indeed, once interpreted the elements of the algebra "as representing [. . .] *propositions* or *statements* or *sentences"* (11), then all the postulates (axioms) of a Boolean algebra represent axioms of Boolean logic.

However, the modular distributive lattice of all subspaces of a finite-dimensional (complex) linear space (or, better, the orthomodular version of any infinite-dimensional complex separable Hilbert space) has a significant role in the so–called quantum logic or logic of quantum mechanics, as described by Birkhoff and von Neumann in their seminal paper about this subject 6. Quoting from the latter: "The object of the present paper is to discover what

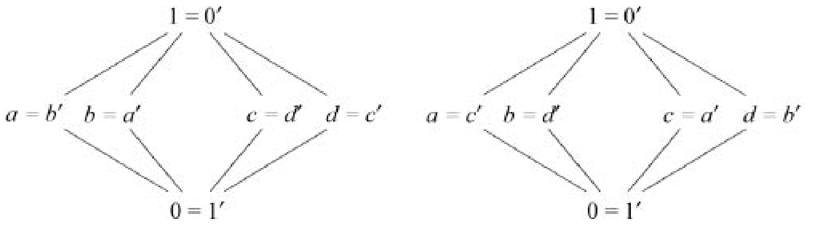

Figure 9. Two different orthocomplementations of the modular lattice M6 of Fig. 8.

logical structure one may hope to find in physical theories which, like quantum mechanics, do not conform to classical logic. Our main conclusion ... is that one can reasonably expected to find a calculus of propositions which is formally indistinguishable from the calculus of linear subspaces with respect to *set products* [i.e., intersection], *linear sums* [i.e., linear subspace generated by the set union], and *orthogonal complements* – and resembles the usual calculus of propositions with respect to *and*, *or*, and *not*."

Coming back to the general situation of an orthocomplementation in a generic lattice, condition (oc1) is the algebraic counterpart of the *strong double negation law* of a negation. Conditions (oc2a,b) are the *de Morgan* laws, whereas (oc2c) is the *contraposition* law and (oc2d) its dual. Finally, condition (oc3a) is the lattice realization of the *noncontradiction* law and (oc3b) of the *excluded middle* law.

Let us stress that conditions (oc3a) and (oc3b) define the mapping $'$ as a *complementation*, whereas conditions (oc1) and (oc2a–d) define $'$ as an *orthogonality* operator because one can introduce the *orthogonality* binary relation $a \perp b$ iff $a \leq b'$ or equivalently $b \leq a'$. For these reasons, the mapping $'$ has been called an *orthocomplementation*. Sometimes, for the sake of simplicity, we shall also name this mapping as *complementation* and the lattice as *complemented lattice,* if no confusion is likely.

CHARACTERISTIC FUNCTIONS ON A UNIVERSE AS SHARP SETS

As we have seen in Example 15, in the power set $\mathcal{P}(X)$ based on a universe X, any subset A of X can be represented by the corresponding *characteristic functional*$\chi_A : X \mapsto \{0,1\}$, which is the *crisp* (or *exact*, also *sharp*) realization of the set A, i.e., a mapping defined as follows:

$$\chi_A(x) := \begin{cases} 1, & \text{iff} \quad x \in A \\ 0, & \text{iff} \quad x \notin A \end{cases}$$

In this way, the set $\varepsilon(X) := \{0,1\}^X$ of all characteristic functionals on X has the structure $\langle \varepsilon(X), \leq, \prime, 0, 1\rangle$ of Boolean complete lattice ($0 = \chi_\emptyset$ and $1 = \chi_X$ being the characteristic functionals of the empty set and of the whole space respectively) with respect to the usual pointwise ordering:

$$\text{(or)} \quad \chi_A \leq \chi_B \quad \text{iff} \quad \text{for all} \quad x \in X, \quad \chi_A(x) \leq \chi_B(x)$$

The lattice meet of any two sharp sets $\chi_A, \chi_B \in \varepsilon(X)$ is the sharp set $\chi_A \wedge \chi_B \in \varepsilon(X)$ defined $\forall x \in X$ in the following way:

$$(\chi_A \wedge \chi_B)(x) = \min\{\chi_A(x), \chi_B(x)\} \tag{8a}$$

$$= \max\{0, \chi_A(x) + \chi_B(x) - 1\} \tag{8b}$$

$$= \chi_A(x) \cdot \chi_B(x) \tag{8c}$$

The lattice join of any two sharp sets $\chi_A, \chi_B \in \varepsilon(X)$ is the sharp set $\chi_A \vee \chi_B \in \varepsilon(X)$ defined $\forall x \in X$ by the law

$$(\chi_A \vee \chi_B)(x) = \max\{\chi_A(x), \chi_B(x)\} \tag{9a}$$

$$= \min\{1, \chi_A(x) + \chi_B(x)\} \tag{9b}$$

$$= \chi_A(x) + \chi_B(x) - \chi_A(x) \cdot \chi_B(x) \tag{9c}$$

The orthocomplementation mapping associates to any characteristic functional χ_A the characteristic functional

$$(\chi_A)'(x) = (1 - \chi_A)(x) \tag{10a}$$

$$= \begin{cases} 1, & \text{iff} \quad \chi_A(x) = 0 \\ 0, & \text{iff} \quad \chi_A(x) = 1 \end{cases} \tag{10b}$$

Of course, the mapping $\chi : \mathcal{P}(X) \mapsto \varepsilon(X), A \mapsto \chi_A$ is an isomorphism between the two Boolean lattice structures $\langle \mathcal{P}(X), \cap, \cup, {}^c, \emptyset, X\rangle$ and $\langle \varepsilon(X), \wedge, \vee, \prime, 0, 1\rangle$ because besides the identities $\chi_{A \cap B} = \chi_A \wedge \chi_B$ and $\chi_{A \cup B} = \chi_A \vee \chi_B$, one has that $\chi_{A^c} = (\chi_A)' = 1 - \chi_A$. This isomorphism preserves also the partial ordering:

$$A \subseteq B \quad \text{iff} \quad \chi_A \leq \chi_B$$

According to the classic logic approach, the implication connective is algebraically realized by the characteristic function of the set $A \to B := A^c \cup B$

$$\chi_{A \to B} = \chi_{A^c \cup B} = \max\{1 - \chi_A, \chi_B\} \tag{11}$$

from which trivially the minimal implication condition $\chi_{A \to B} = 1 \quad \text{iff} \quad A \subseteq B$ follows.

GENERALIZED CHARACTERISTIC FUNCTIONS AS FUZZY (UNSHARP) SETS

The more natural generalization of the notion of characteristic (or, equivalently, Boolean-valued) functional on the reference space X is the notion of *generalized characteristic functional* or *fuzzy set*, which is defined as a functional $f : X \mapsto [0,1]$ whose range may assume all the real values of the interval [0,1], not only the extreme ones, either 0 or 1. Let us stress that in fuzzy theory, any value $f(x) \in [0,1]$ is not interpreted as a possible probability value assumed by the object $x \in X$ but, on the contrary, as a *degree of membership* of this object relative to the fuzzy set f under consideration.

Example 31. Let us define the fuzzy set of *tall* people. So, we have that x is a man/woman belonging to a certain universe X, and *h(x)* is a real positive number, which

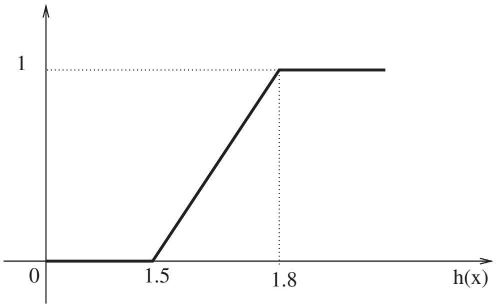

Figure 10. Fuzzy set of tall people.

represents the height of x in meters (see Fig. 10). The tall fuzzy set is defined as:

$$t(x) := \begin{cases} 1 & h(x) \geq 1.80 \\ \dfrac{h(x) - 1.50}{0.30} & 1.50 < h(x) < 1.80 \\ 0 & h(x) \leq 1.50 \end{cases}$$

The set $\mathcal{F}(X) := [0,1]^X$ of all generalized characteristic functionals is a partially ordered set with respect to the ordering

$$(\text{or} - \text{F}) \quad f_1 \leq f_2 \quad \text{iff} \quad f_1(x) \leq f_2(x), \quad \text{for all} \quad x \in X$$

which is an extension of the ordering (or) previously introduced on the set $\varepsilon(X)$ of all crisp characteristic functionals. With respect to this ordering, $\mathcal{F}(X)$ turns out to be a distributive complete lattice. In particular, we have that the g.l.b. $f \wedge g$ and the l.u.b. $f \vee g$ of two fuzzy sets with respect to this ordering are given, for any $x \in X$, respectively as

$$(f \wedge g)(x) = \min\{f(x), g(x)\} = f(x) \wedge g(x) \qquad (12)$$

$$(f \vee g)(x) = \max\{f(x), g(x)\} = f(x) \vee g(x) \qquad (13)$$

These operations are just the operation of intersection and union that are customarily introduced in the usual theory of fuzzy set (see Ref. 3).

Example 32. Let us define the fuzzy set of short people, s for all $x \in X$, as

$$s(x) := \begin{cases} 1 & h(x) \leq 1.45 \\ \dfrac{1.70 - h(x)}{0.25} & 1.45 < h(x) < 1.70 \\ 0 & h(x) \geq 1.70 \end{cases}$$

Considering also the fuzzy set of tall people defined in Example 31, the set of tall *or* short people, i.e., $t \vee s$ is defined $\forall x \in X$ as

$$(t \vee s)(x) := \begin{cases} 1 & h(x) \leq 1.45 \text{ or } h(x) \geq 1.80 \\ \dfrac{1.70 - h(x)}{0.25} & 1.45 < h(x) < 1.61 \\ \dfrac{h(x) - 1.50}{0.30} & 1.61 \leq h(x) < 1.70 \end{cases}$$

The set of tall *and* short people i.e., $t \wedge s$, is defined for all x

$$(t \wedge s)(x) := \begin{cases} 0 & h(x) \leq 1.50 \text{ or } h(x) \geq 1.70 \\ \dfrac{h(x) - 1.50}{0.30} & 1.50 < h(x) < 1.61 \\ \dfrac{1.70 - h(x)}{0.25} & 1.61 \leq h(x) < 1.80 \end{cases}$$

In Fig. 11, both fuzzy set intersection $t \wedge s$ and union $t \vee s$ of tall and short people are drawn.

Let us remark that a person can be at the same time and with a certain degree tall and short. Let us consider for example that x is a person who has an eighth of $h(x) = 1.55$ meters. Then, x is “tall *and* short” with a degree $\{t \wedge s)(x) = 0.17$.

Negations in Fuzzy Set Theory

The generalization of the orthocomplement of a fuzzy set f, starting from the equivalent forms in Equation (10) of the crisp case, presents some trouble because it is not so univocal as it could seem, and, moreover, all the here-analyzed

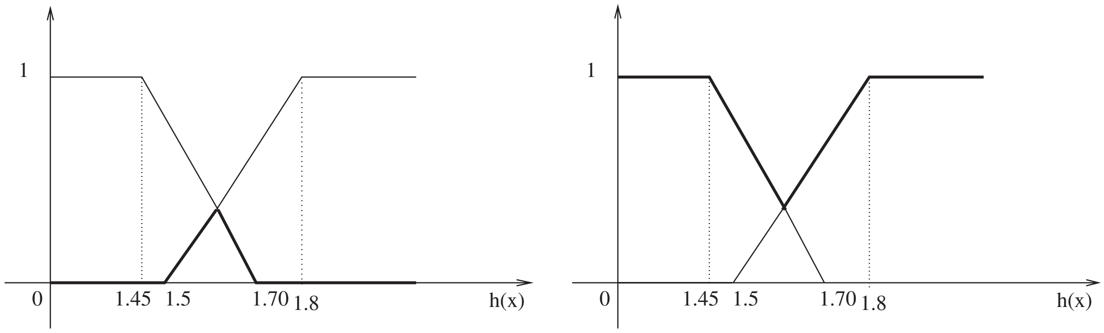

Figure 11. Fuzzy set of intersection (at left) and union (at right) of tall and short people.

versions present some pathological behavior with respect to the standard properties that characterize the standard version of negation (i.e., orthocomplementation) as introduced in Definition 17, with the Proposition 11. First of all, we can have at least these three distinct possibilities of fuzzy negation:

1) The *diametrical* orthocomplement

$$f'(x) := (1 - f)(x) \tag{14a}$$

which is an extension of Equation (10a), and the following, which are two different extensions of Equation (10b)

2) The *intuitionistic* orthocomplement

$$f^{\sim}(x) := \begin{cases} 1, & \text{if} \quad f(x) = 0 \\ 0, & \text{if} \quad f(x) \neq 0 \end{cases} \tag{14ba}$$

3) The *anti-intuitionistic* orthocomplement

$$f^{\flat}(x) := \begin{cases} 1, & \text{if} \quad f(x) \neq 1 \\ 0, & \text{if} \quad f(x) = 1 \end{cases} \tag{14ca}$$

Remark 4. If one introduces the subset of the universe

$$A_0(f) := \{x \in X : f(x) = 0\}$$

collection of all objects from the universe X in which the fuzzy set f is *impossible* (the membership degree is 0), called the *certainly not* or *impossibility domain* of f, then $f^{\sim}$ is the crisp set $f^{\sim} = \chi A_0(f)$. Similarly, if one defines as *contingency domain* of f the subset

$$A_c(f) := \{x \in X : f(x) \neq 1\}$$

collection of all objects in which the membership degree of f is not certain, then f^b is the crisp set $f^b = \chi A_c(f)$.

Trivially, for the ordering point of view

$$f^{\sim} \leq f' \leq f^b$$

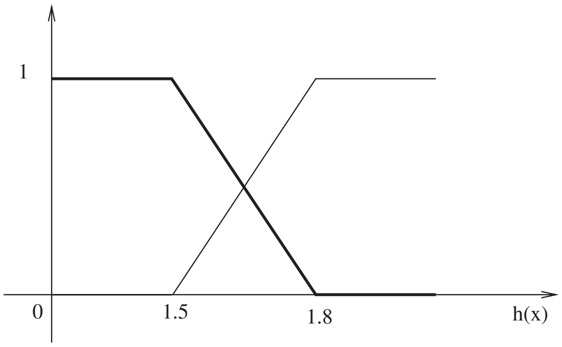

Figure 12. Fuzzy set of not tall people with respect to diametrical complementation.

Example 33. Let us consider the fuzzy set of tall people. Using the diametrical negation (see Fig. 12), the set of *not tall* people is thus defined as:

$$(t')(x) = \begin{cases} 0 & h(x) \geq 1.80 \\ \dfrac{1.80 - h(x)}{0.30} & 1.50 \quad < h(x) \quad < 1.80 \\ 1 & h(x) \leq 1.50 \end{cases}$$

The *impossible tall* people with respect to the intuitionistic negation is:

$$(t^{\sim})(x) = \begin{cases} 1 & \text{if} \quad h(x) \leq 1.50 \\ 0 & \text{otherwise} \end{cases}$$

Finally, using the anti–intuitionistic negation (see Fig. 13) we obtain that the *contingent tall* people is:

$$(t^b)(x) = \begin{cases} 1 & \text{if} \quad h(x) \leq 1.80 \\ 0 & \text{otherwise} \end{cases}$$

Hence, if we consider a person whose height is $h(x) = 1.70$, we have that he/she is not tall with values: $(t')(1.70) = \frac{1}{3}$, $(t^{\sim})(1.70) = 0$, and $(t^b)(1.70) = 1$.

Diametrical Complementation

The diametrical complementation allows one to introduce the mapping $' : \mathcal{F}(X) \to \mathcal{F}(X)$, $f \to f'$, which is a unusual

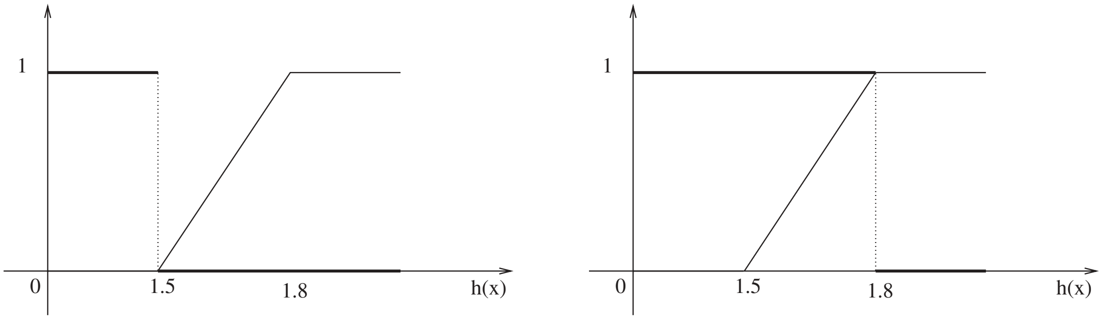

Figure 13. Fuzzy set of not tall people with respect to intuitonistic (at left) and anti-intuitionistic (at right) complementation.

orthocomplementation because it satisfies only the following conditions:

$$\text{(ocl)}\quad f'' = f, \text{for all } f \in \mathcal{F}(X)$$

$$\begin{array}{ll} \text{(oc2a)} & \text{Let } f, g \in \mathcal{F}(X), \text{ then } f' \wedge g' = (f \vee g)' \\ \text{(oc2b)} & \text{Let } f, g \in \mathcal{F}(X), \text{ then } f' \vee g' = (f \wedge g)' \\ \text{(oc2c)} & \text{Let } f, g \in \mathcal{F}(X), \text{ then } f \leq g \text{ implies } g' \leq f' \\ \text{(oc2d)} & \text{Let } f, g \in \mathcal{F}(X), \text{ then } f' \leq g' \text{ implies } g \leq f \end{array}$$

Moreover, the diametrical orthocomplementation satisfies the following *Kleene* condition:

$$\text{(KL)}\quad \text{for every } f, g \in \mathcal{F}(X),\ f \wedge f' \leq g \vee g'$$

Remark 5. As stressed before, under condition (oc1), all the conditions (oc2a–d) are mutually equivalent among them.

Let us denote by $\mathbf{k}$, for any fixed $k \in [0, 1]$, the fuzzy set $\forall x \in X, \mathrm{k}(x) = k$. We observe that the fuzzy set $\mathbf{1/2}$, called the *half* fuzzy set, satisfies $\mathbf{1/2} = \mathbf{(1/2)}'$. Making use of the half fuzzy set, condition (KL) can be strengthened more in the form:

$$\text{(KLa)}\quad \text{For every } f, g \in \mathcal{F}(X),\ f \wedge f' \leq 1/2 \leq g \vee g'$$

The unusual behavior of this weak form of negation with respect to the standard orthocomplementation is that the *contradiction* law $'\forall\ f,\ f \wedge f' = \mathbf{0}'$, and the *excluded middle* law $'\forall\ f,\ f \vee f' = \mathbf{1}'$, in general, do not hold for the diametrical orthocomplementation. In particular, we have that

$$(\mathbf{1/2}) \wedge (\mathbf{1/2})' = (\mathbf{1/2}) \vee (\mathbf{1/2})' = (\mathbf{1/2}) \neq \mathbf{0}, \mathbf{1}$$

The Intuitionistic Complementation

The intuitionistic complementation allows one to introduce the mapping $^{\sim} : \mathcal{F}(X) \to \mathcal{F}(X),\ f \to f^{\sim}$, which also, in this case, turns out to be an unusual orthocomplementation because the following conditions are fulfilled:

$$\text{(woc1)}\quad f \leq f^{\sim\sim}, \text{ for all } f.$$

$$\begin{array}{ll} \text{(woc2a)} & \text{Let } f, g \in \mathcal{F}(X); \text{ then } f^{\sim} \wedge g^{\sim} = (f \vee g)^{\sim}. \\ \text{(woc2b)} & \text{Let } f, g \in \mathcal{F}(X); \text{ then } f \leq g \text{ implies } g^{\sim} \leq f^{\sim}. \end{array}$$

$$\text{(woc3)}\quad f \wedge f^{\sim} = \mathbf{0}, \text{ for all f.}$$

The anti-intuitionistic complementation can be derived from the other two complementations according to the formula:

$$f^{b} = f'^{\sim\prime}$$

Remark 6. From the general point of view, in an abstract lattice, the condition (woc1) implies only the equivalence between (woc2a) and (woc2b); the de Morgan law "dual" of (woc2a) $f^{\sim} \vee g^{\sim} = (f \wedge g)^{\sim}$ in general is not true.

A dual behavior can be stated for the anti–intuitionistic complementation. For these reasons the following result is quite important because it shows a behavior that is peculiar of classic fuzzy set theory.

Proposition 12. *The distributive complete lattice of all fuzzy sets on the universe X satisfies the "dual" de Morgan laws:*

$$\begin{array}{ll} (woc2c) & \text{Let } f, g \in \mathcal{F}(X); \text{ then } f^{\sim} \vee g^{\sim} = (f \wedge g)^{\sim}. \\ (aoc2c) & \text{Let } f, g \in \mathcal{F}(X); \text{ then } f^{b} \wedge g^{b} = (f \vee g)^{b}. \end{array}$$

Proof. For any fixed point $x \in X$, without losing in generality, we can assume that $f(x) \leq g(x)$. Then, owing to (woc2b), $g^{\sim}(x) \leq f^{\sim}(x)$, from which we get $f^{\sim}(x) \vee g^{\sim}(x) = f^{\sim}(x)$. However $(f \wedge g)(x) = f(x)$, and so $(f \wedge g)^{\sim}(x) = f^{\sim}(x)$. Therefore, $\forall x \in X, (f^{\sim} \vee g^{\sim})(x) = (f \wedge g)^{\sim}(x)$.

The anti-intuitionistic case can be proved in a similar way.

The intuitionistic-like orthocomplementation satisfies the *weak double negation* law (woc1), which algebraically expresses the fact that any proposition f "implies" its double negation $f^{\sim\sim}$, but, in general, the vice versa does not hold. In particular, $(\mathbf{1/2})^{\sim} = \mathbf{0}$, from which it follows that $(\mathbf{1/2})^{\sim\sim} = \mathbf{0}^{\sim} = \mathbf{1}$, concluding that $(\mathbf{1/2}) < (\mathbf{1/2})^{\sim\sim}$, with $(\mathbf{1/2}) \neq (\mathbf{1/2})^{\sim\sim}$.

The *excluded middle* law for the intuitionistic-like orthocomplementation $'\forall\ f,\ f \vee f^{\sim} = \mathbf{1}'$, does not hold. Indeed, as a simple example, we have that $(\mathbf{1/2}) \vee (\mathbf{1/2})^{\sim} = (\mathbf{1/2}) \vee \mathbf{0} = (\mathbf{1/2}) \neq \mathbf{1}$. As another, less-trivial example, let us consider the fuzzy set on the universe $X = \mathbb{R}$

$$f(x) = \begin{cases} 1 & \text{if } x \in [0, 1] \\ 1/2 & \text{if } x \in (1, +\infty) \\ 0 & \text{otherwise} \end{cases} \text{then } f^{\sim}(x) = \begin{cases} 1 & \text{if } x \in (-\infty, 0) \\ 0 & \text{otherwise} \end{cases}$$

from which we have

$$(f \vee f^{\sim})(x) = \begin{cases} 1 & \text{if } x \in (-\infty, 0) \\ 1/2 & \text{otherwise} \end{cases}$$

and so $f \vee f^{\sim} \neq \mathbf{1}$.

Summarizing, both the intuitionistic-like and the fuzzy-like orthocomplementation do not satisfy the "excluded middle" law. Moreover, the intuitionistic-like negation does not satisfy the strong "double negation" law, and the "contradiction" law, too, which are substituted by the weaker Kleene condition (K). Indeed, if for a certain fuzzy set $f \wedge f' = \mathbf{0}$ and $f \vee f' = \mathbf{1}$, then trivially $f \wedge f' \leq f \vee f'$. For a complete discussion of the role of negation in intuitionistic logic or better, in its algebraic semantic, let us refer to Ref. 12.

Let us note that the negations of impossibility (i.e., the *possibility*) and contingency (i.e., the *necessity*) assume the form:

$$(4a)\quad ((f)(x) := f^{\sim\prime}(x) = \begin{cases} 1, & \text{if} \quad f(x) \neq 0 \\ 0, & \text{if} \quad f(x) = 0 \end{cases}$$

$$(4b)\quad \square(f)(x) := f^{b'}(x) = \begin{cases} 1, & \text{if} \quad f(x) = 1 \\ 0, & \text{if} \quad f(x) \neq 1 \end{cases}$$

Remark 7. If one associates with any fuzzy set f the *possibility* domain $A_p(f) := \{x \in X : f(x) \neq 0\}$ and the *necessity* domain $A_1(f) := \{x \in X : f(x) = 1\}$, then, as in the two cases of Remark 5, we have to do with two crisp sets:

$$\Box(f) = \chi A_1(f) \quad \text{and} \quad ((f) = \chi A_p(f)$$

The Lattice of Ordered-Pairs of Crisp Sets (OCS)

Note that the necessity $\Box(f)$ (resp., possibility $((f)$) is the best crisp approximation of the fuzzy set f from the bottom (resp., top): $\Box(f) \leq f \leq \ ((f)$. For this reason, in the application of roughness theory to fuzzy sets (see Ref. 12), the *rough approximation* of the fuzzy set f by crisp sets is defined as the pair of crisp sets

$$r(f) := \Box((f),((f)) = (\chi A_1(f), \chi A_p(f)) \quad \text{with} \quad \chi A_1(f) \leq \chi A_p(f)$$

This rough approximation can be identified with the pair $r(f) = (A_1(f), A_p(f))$ by the bijective correspondence $r : f \in \mathcal{F}(X) \to r(f) = (A_1(f), A_p(f)) \in \mathcal{P}(X) \times \mathcal{P}(X)$, with $A_1(f) \subseteq A_p(f)$.

These considerations lead one to treat as interesting the so-called *ordered pairs of crisp sets* (OCS) defined as pair (A_1, A_p) of subsets of the universe X under the condition that $A_1 \subseteq A_p$ whose collection will be denoted by $OC(X)$. To the best of our knowledge, the concept of OCS was introduced for the first time by M. Yves Gentilhomme in Ref. 13. (see also Ref. 14). Let us now investigate the lattice behavior of an OCS. First of all, let us introduce on $OC(X)$ the following Gentilhomme binary operations:

$$\begin{aligned}(A_1, A_p) \sqcap (B_1, B_p) &= (A_1 \cap B_1, A_p \cap B_p)\\ (A_1, A_p) \sqcup (B_1, B_p) &= (A_1 \cup B_1, A_p \cup B_p)\end{aligned}$$

Now, the structure $\langle OC(X), \sqcap, \sqcup \rangle$ is a distributive lattice whose induced partial order relation is

$$(A_1, A_p) \sqsubseteq (B_1, B_p) \quad \text{iff} \quad A_1 \subseteq B_1 \,\text{and}\, A_p \subseteq B_p$$

This lattice is bounded by the least element $\mathbf{0} = (\theta, \theta)$ and the greatest element $\mathbf{1} = (X, X)$.

As to the negation, we have the two cases

$$\begin{aligned}-(A_1, A_p) &= ((A_p)^c, (A_1)^c)\\ \sim (A_1, A_p) &= ((A_p)^c, (A_p)^c)\end{aligned}$$

The operation – is a Kleene complementation because (oc1) $-(-(A_1, A_p)) = (A_1, A_p)$; (oc2c) $(A_1, A_p) \sqsubseteq (B_1, B_p)$ implies $-(B_1, B_p) = ((B_p)^c, (B_1)^c) \sqsubseteq ((A_p)^c, (A_1)^c) = -(A_1, A_p)$. Moreover, this lattice admits the half element $\frac{1}{2} = (\emptyset, X)$ with respect to the negation —, because $-\frac{1}{2} = -(\emptyset, X) = \frac{1}{2}$. As a consequence, with respect to this complement, the lattice $OC(X)$ is not Boolean. As to the Kleene condition, let us observe that $(A_1, A_p) \sqcap -(A_1, A_p) = (\emptyset, (A_1)^c \cap A_p)$ (with $(A_1)^c \cap A_p$ the *boundary* of the OCS (A_1, A_p)), $(B_1, B_p) \sqcup -(B_1, B_p) = (B_1 \cup (B_p)^c, X)$, and so

$$(A_1, A_0) \sqcap -(A_1, A_0) \sqsubseteq (\theta, X) \sqsubseteq (B_1, B_0) \sqcup -(B_1, B_0).$$

In a similar way, it is easy to prove that the operation $\sim$ is an intuitionistic complementation, i.e., conditions (woc1)-(woc3) are all satisfied.

PROBABILITY AND STATISTICS

As an introductory definition, we consider probability to be a collection of concepts, methods, and interpretations that facilitate the investigation of nondeterministic phenomena. Although more mathematically precise definitions will appear in due course, this broadly inclusive description certainly captures the nonspecialist's meaning of probability, and it aligns closely with the intuitive appreciation shared by engineering and computer science professionals. That is, probability is concerned with chance. In a general context, probability represents a systematic attempt to cope with fluctuations of the stock market, winning and losing streaks at the gaming table, and trends announced by economists, sociologists, and weather forecasters. In more scientific contexts, these examples extend to traffic flow patterns on computer networks, request queue lengths at a database server, and charge distributions near a semiconductor junction.

Modern life, despite the predictability afforded by scientific advances and technological accomplishments, offers frequent exposure to chance happenings. It is a safe conclusion that this situation has been part of human existence from prehistoric times. Indeed, despite the associated anxiety, it seems that humans actively seek chance encounters and that they have done so from earliest times. For example, archeological evidence confirms that gambling, typically in the form of dice games, has been with us for thousands of years. Given this long history, we might expect some accumulation of knowledge, at least at the level of folklore, that purports to improve the outcomes of chance encounters. In Europe, however, no evidence of a science of gambling appears before the fifteenth century, and it is only in the middle of the seventeenth century that such knowledge starts to encompass chance phenomena outside the gaming sphere.

A science of chance in this context means a set of concepts and methods that quantifies the unpredictability of random events. For example, frequency of occurrence provides a useful guideline when betting on a roll of the dice. Suppose your science tells you, from observation or calculation, that a seven occurs about once in every 6 throws and a two occurs about once in every 36 throws. You would then demand a greater payoff for correctly predicting the next throw to be a two than for predicting a seven. Although the dice rolls may be random, a pattern applies to repeated rolls. That pattern governs the relative abundance of sevens and twos among the outcomes.

Probability as a science of chance originated in efforts to quantify such patterns and to construct interpretations useful to the gambler. Many historians associate the birth of probability with a particular event in mid-seventeenth-century France. In 1654, the Chevalier de Mère, a gambler, asked Blaise Pascal and Pierre Fermat, leading mathematicians of the time, to calculate a fair disposition of stakes when a game suffers a premature termination. They reasoned that it was unfair to award all stakes to the party who was leading at the point of interruption. Rather, they computed the outcomes for all possible continuations of the game. Each party is allocated that fraction of the outcomes that result in a win for him. This fraction constitutes the probability that the party would win if the game were completed. Hence, the party's "expectation" is that same fraction of the stakes and such should be his fair allocation in the event of an interrupted game. We note that this resolution accords with the intuition that the party who is ahead at the time of interruption should receive a larger share of the stakes. Indeed, he is "ahead" precisely because the fraction of game continuations in his favor is noticeably larger than that of his opponent.

For his role in gambling problems, such as the one described above, and for his concept of dominating strategies in decision theory, Pascal is sometimes called the father of probability theory. The title is contested, however, as there are earlier contributers. In the 1560s, Girolamo Cardano wrote a book on games of chance, and Fra Luca Paciuoli described the division of stakes problem in 1494. In any case, it is not realistic to attribute such a broad subject to a single parental figure. The mid-seventeenth-century date of birth, however, is appropriate. Earlier investigations are frequently erroneous and tend to be anecdotal collections, whereas Pascal's work is correct by modern standards and marks the beginning of a systematic study that quickly attracted other talented contributors.

In 1657, Christian Huygens introduced the concept of expectation in the first printed probability textbook. About the same time John Wallis published an algebra text that featured a discussion of combinatorics. Appearing posthumously in 1713, Jacques Bernoulli's *Ars Conjectandi* (The Art of Conjecture) presented the first limit theorem, which is today known as the Weak Law of Large Numbers. Soon thereafter, Abraham de Moivre demonstrated the normal distribution as the limiting form of binomial distributions, a special case of the Central Limit Theorem. In marked contrast with its earlier focus on gambling, the new science now found application in a variety of fields. In the 1660s, John Hudde and John de Witt provided an actuarial foundation for the annuities used by Dutch towns to finance public works. In 1662, John Graunt published the first set of statistical inferences from mortality records, a subject of morbid interest in those times when the plague was devastating London. Around 1665, Gottfried Leibniz brought probability to the law as he attempted to assess the credibility of judicial evidence.

Excepting Leibniz's concern with the credibility of evidence, all concepts and applications discussed to this point have involved patterns that appear over repeated trials of some nondeterministic process. This is the frequency-of-occurrence interpretation of probability, and it presents some dificulty when contemplating a single trial. Suppose a medical test reveals that there is a 44% chance of your having a particular disease. The frequency-of-occurrence

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

interpretation is that 44% of a large number of persons with the same test results have actually had the disease. What does this information tell you? At best, it seems to be a rough guideline. If the number were low, say 0.01%, then you might conclude that you have no medical problem. If it were high, say 99.9%, then you would likely conclude that you should undergo treatment. There is a rather large gap between the two extremes for which it is dificult to reach any conclusion. Even more tenuous are statements such as "There is a 30% chance of war if country X acquires nuclear weapons." In this case, we cannot even envision the "large number of trials" that might underlie a frequency-of-occurrence interpretation. These philosophical issues have long contributed to the uneasiness associated with probabilistic solutions. Fortunately for engineering and computer science, these questions do not typically arise. That is, probability applications in these disciplines normally admit a frequency-of-occurrence interpretation. If, for example, we use probability concepts to model query arrivals at a database input queue, we envision an operating environment in which a large number of such queries are generated with random time spacings between them. We want to design the system to accommodate most of the queries in an economic manner, and we wish to limit the consequences of the relatively rare decision to reject a request.

In any case, as probability developed a sophisticated mathematical foundation, the mathematics community took the opportunity to sidestep the entire issue of interpretations. A movement, led primarily by Andrei Kolmogorov, developed *axiomatic* probability theory. This theory defines the elements of interest, such as probability spaces, random variables, and distributions and their transforms, as abstract mathematical objects. In this setting, the theorems have specific meanings, and their proofs are the timeless proofs of general mathematics. The theorems easily admit frequency-of-occurrence interpretations, and other interpretations are simply left to the observer without further comment. Modern probability theory, meaning probability as understood by mathematicians since the first third of the twentieth century, is grounded in this approach, and it is along this path that we now begin a technical overview of the subject.

PROBABILITY SPACES

Formally, a probability space is a triple $(\Omega, \mathcal{F}, \mathcal{P})$. The first component Ω is simply a set of outcomes. Examples are $\Omega = \{\text{heads, tails}\}$ for a coin-flipping scenario, $\Omega = \{1, 2, 3, 4, 5, 6\}$ for a single-die experiment, or $\Omega = \{x : 0 \leq x < 1\}$ for a spinning pointer that comes to rest at some fraction of a full circle. The members of Ω are the occurrences over which we wish to observe quantifiable patterns. That is, we envision that the various members will appear nondeterministically over the course of many trials, but that the relative frequencies of these appearances will tend to have established values. These are values assigned by the function P to outcomes or to collections of outcomes. These values are known as *probabilities*. In the single-die experiment, for example, we might speak of $P(3) = 1/6$ as the probability of obtaining a three on a single roll. A composite outcome, such as three or four on a single roll, is the probability $P\{3, 4\} = 1/3$.

How are these values determined? In axiomatic probability theory, probabilities are externally specified. For example, in a coin-tossing context, we might know from external considerations that heads appears with relative frequency 0.55. We then simply declare $P(\text{heads}) = 0.55$ as the probability of heads. The probability of tails is then $1.0 - 0.55 = 0.45$. In axiomatic probability theory, these values are assigned by the function P, the third component of the probability space triple. That is, the theory develops under the assumption that the assignments are arbitrary (within certain constraints to be discussed shortly), and therefore any derived results are immediately applicable to any situation where the user can place meaningful frequency assignments on the outcomes.

There is, however, one intervening technical dificulty. The function P does not assign probabilities directly to the outcomes. Rather, it assigns probabilities to *events*, which are subsets of Ω. These events constitute $\mathcal{F}$, the second element of the probability triple. In the frequency-of-occurrence interpretation, the probability of an event is the fraction of trials that produces an outcome in the event. A subset in $\mathcal{F}$ may contain a single outcome from Ω, in which case this outcome receives a specific probability assignment. However, some outcomes may not occur as singleton subsets in $\mathcal{F}$. Such an outcome appears only within subsets (events) that receive overall probability assignments. Also, all outcomes of an event $E \in \mathcal{F}$ may constitute singleton events, each with probability assignment zero, whereas E itself receives a nonzero assignment. Countability considerations, to be discussed shortly, force these subtleties in the general case to avoid internal contradictions. In simple cases where Ω is a finite set, such as the outcomes of a dice roll, we can take $\mathcal{F}$ to be all subsets of Ω, including the singletons. In this case, the probability assignment to an event must be the sum of the assignments to its constituent outcomes.

Here are the official rules for constructing a probability space $(\Omega, \mathcal{F}, P)$. First, Ω may be any set whatsoever. For engineering and computer science applications, the most convenient choice is often the real numbers, but any set will do. $\mathcal{F}$ is a collection of subsets chosen from Ω. $\mathcal{F}$ must constitute a σ-*field*, which is a collection containing ϕ, the empty subset, and closed under the operations of complement and countable union. That is,

- $\phi \in \mathcal{F}$.
- $A \in \mathcal{F}$ forces $\overline{A} = \Omega - A \in \mathcal{F}$.
- $A_n \in \mathcal{F}$ for $n = 1, 2, \ldots$ forces $\cup_{n=1}^{\infty} A_n \in \mathcal{F}$.

Finally, the function P maps subsets in $\mathcal{F}$ to real numbers in the range zero to one in a countably additive manner. That is,

- $P : \mathcal{F} \rightarrow [0, 1]$.
- $P(\phi) = 0$.
- $P(\Omega) = 1$.
- $P(\cup_{n=1}^{\infty} A_n) = \sum_{n=1}^{\infty} P(A_n)$ for pairwise disjoint subsets $A_1, A_2, \ldots$.

The events in $\mathcal{F}$ are called *measurable* sets because the function P specifies their sizes as probability allotments. You might well wonder about the necessity of the σ-field $\mathcal{F}$. As noted, when Ω is a finite outcome set, $\mathcal{F}$ is normally taken to be the collection of all subsets of Ω. This maximal collection clearly satisfies the requirements. It contains all singleton outcomes as well as all possible groupings. Moreover, the rule that P must be countably additive forces the probability of any subset to be the sum of the probabilities of its members. This happy circumstance occurs in experiments with dice, coins, and cards, and subsequent sections will investigate some typical probability assignments in those cases.

A countable set is one that can be placed in one-to-one correspondence with the positive integers. The expedient introduced for finite Ω extends to include outcome spaces that are countable. That is, we can still choose $\mathcal{F}$ to be all subsets of the countably infinite Ω. The probability of a subset remains the sum of the probabilities of its members, although this sum now contains countably many terms. However, the appropriate Ω for many scientific purposes is the set of real numbers. In the nineteenth century, Georg Cantor proved that the real numbers are uncountable, as is any nonempty interval of real numbers.

When Ω is an uncountable set, set-theoretic conundrums beyond the scope of this article force $\mathcal{F}$ to be smaller than the collection of all subsets. In particular, the countable additivity requirement on the function P cannot always be achieved if $\mathcal{F}$ is the collection of all subsets of Ω. On most occasions associated with engineering or computer science applications, the uncountable Ω is the real numbers or some restricted span of real numbers. In this case, we take $\mathcal{F}$ to be the *Borel* sets, which is the smallest σ-field containing all open intervals of the form (a, b).

Consider again the example where our outcomes are interarrival times between requests in a database input queue. These outcomes can be any positive real numbers, but our instrumentation cannot measure them in infinite detail. Consequently, our interest normally lies with events of the form (a, b). The probability assigned to this interval should reflect the relative frequency with which the interarrival time falls between a and b. Hence, we do not need all subsets of the positive real numbers among our measurable sets. We need the intervals and interval combinations achieved through intersections and unions. Because $\mathcal{F}$ must be a σ-field, we must therefore take some σ-field containing the intervals and their combinations. By definition the collection of Borel sets satisfies this condition, and this choice has happy consequences in the later development of random variables.

Although not specified explicitly in the defining constraints, closure under countable intersections is also a property of a σ-field. Moreover, we may interpret countable as either finite or countably infinite. Thus, every σ-field is closed under finite unions and finite intersections. From set-theoretic arguments, we obtain the following properties of the probability assignment function P:

- $P(\overline{A}) = 1 - P(A)$.
- $P(\cup_{n=1}^{\infty} A_n) \leq \sum_{n=1}^{\infty} P(A_n)$, without regard to disjointness among the A_n.
- If $A \subseteq B$, then $P(A) \leq P(B)$.
- If $A_1 \subseteq A_2 \subseteq \ldots$, then $P(\cup_{n=1}^{\infty} A_n) = \lim_{n\to\infty} P(A_n)$.
- If $A_1 \supseteq A_2 \supseteq \ldots$, then $P(\cap_{n=1}^{\infty} A_n) = \lim_{n\to\infty} P(A_n)$.

The final two entries above are collectively known as the Continuity of Measure Theorem. A more precise continuity of measure result is possible with more refined limits. For a sequence $a_1, a_2, \ldots$ of real numbers and a sequence $A_1, A_2, \ldots$ of elements from $\mathcal{F}$, we define the limit supremum and the limit infimum as follows:

$$\begin{aligned}
\operatorname*{limsup}_{n\to\infty} a_n &= \operatorname*{limsup}_{k\to\infty n\geq k} a_n \\
\operatorname*{limsup}_{n\to\infty} A_n &= \cap_{k=1}^{\infty} \cup_{n=k}^{\infty} A_n \\
\operatorname*{liminf}_{n\to\infty} a_n &= \operatorname*{liminf}_{k\to\infty n\geq k} a_n \\
\operatorname*{liminf}_{n\to\infty} A_n &= \cup_{k=1}^{\infty} \cap_{n=k}^{\infty} A_n
\end{aligned}$$

We adopt the term extended limits for the limit supremum and the limit infimum. Although a sequence of bounded real numbers, such as probabilities, may oscillate indefinitely and therefore fail to achieve a well-defined limiting value, every such sequence nevertheless achieves extended limits. We find that $\operatorname{liminf} a_n \leq \operatorname{limsup} a_n$ in all cases, and if the sequence converges, then $\operatorname{liminf} a_n = \lim a_n = \operatorname{limsup} a_n$. For a sequence of subsets in $\mathcal{F}$, we adopt equality of the extended limits as the definition of convergence. That is, $\lim A_n = A$ if $\operatorname{liminf} A_n = \operatorname{limsup} A_n = A$.

When applied to subsets, we find $\operatorname{liminf} A_n \subseteq \operatorname{limsup} A_n$. Also, for increasing sequences, $A_1 \subseteq A_2 \subseteq \ldots$, or decreasing sequences, $A_1 \supseteq A_2 \supseteq \ldots$, it is evident that the sequences converge to the countable union and countable intersection, respectively. Consequently, the Continuity of Measure Theorem above is actually a statement about convergent sequences of sets: $P(\lim A_n) = \lim P(A_n)$. However, even if the sequence does not converge, we can derive a relationship among the probabilities: $P(\operatorname{liminf} A_n) \leq \operatorname{liminf} P(A_n) \leq \operatorname{limsup} P(A_n) \leq P(\operatorname{limsup} A_n)$.

We conclude this section with two more advanced results that are useful in analyzing sequences of events. Suppose A_n, for $n = 1, 2, \ldots$, is a sequence of events in $\mathcal{F}$ for which $\sum_{n=1}^{\infty} P(A_n) < \infty$. The Borel Lemma states that, under these circumstances, $P(\operatorname{liminf} A_n) = P(\operatorname{limsup} A_n) = 0$.

The second result is the Borel–Cantelli Lemma, for which we need the definition of independent subsets. Two subsets A, B in $\mathcal{F}$ are *independent* if $P(A \cap B) = P(A)P(B)$. Now suppose that A_i and A_j are independent for any two distinct subsets in the sequence. Then the lemma asserts that if $\sum_{n=1}^{\infty} P(A_n) = \infty$, then $P(\operatorname{limsup} A_n) = 1$. A more general result, the Kochen–Stone Lemma, provides a lower bound on $P(\operatorname{limsup} A_n)$ under slightly more relaxed conditions.

COMBINATORICS

Suppose a probability space $(\Omega, \mathcal{F}, P)$ features a finite outcome set Ω. If we use the notation $|A|$ to denote the number of elements in a set A, then this condition is $|\Omega| = n$

for some positive integer n. In this case, we take $\mathcal{F}$ to be the collection of all subsets of Ω. We find that $|\mathcal{F}| = 2^n$, and a feasible probability assignment allots probability $1/n$ to each event containing a singleton outcome. The countable additivity constraint then forces each composite event to receive probability equal to the sum of the probabilities of its constituents, which amounts to the size of the event divided by n. In this context, combinatorics refers to methods for calculating the size of Ω and for determining the number of constituents in a composite event.

In the simplest cases, this computation is mere enumeration. If Ω contains the six possible outcomes from the roll of a single die, then $\Omega = 1, 2, 3, 4, 5, 6$. We observe that $n = 6$. If an event E is described as "the outcome is odd or it is greater than 4," then we note that outcomes 1, 3, 5, 6 conform to the description, and we calculate $P(E) = 4/6$. In more complicated circumstances, neither n nor the size of E is so easily available. For example, suppose we receive 5 cards from a shuffled deck of 52 standard playing cards. What is the probability that we receive five cards of the same suit with consecutive numerical values (a straight flush)? How many possible hands exist? How many of those constitute a straight flush?

A systematic approach to such problems considers sequences or subsets obtained by choosing from a common pool of candidates. A further distinction appears when we consider two choice protocols: choosing with replacement and choosing without replacement. Two sequences differ if they differ in any position. For example, the sequence 1, 2, 3 is different from the sequence 2, 1, 3. However, two sets differ if one contains an element that is not in the other. Consequently, the sets 1, 2, 3 and 2, 1, 3 are the same set.

Suppose we are choosing k items from a pool of n without replacement. That is, each choice reduces that size of the pool available for subsequent choices. This constraint forces $k \leq n$. Let $P_{k,n}$ be the number of distincts sequences that might be chosen, and let $C_{k,n}$ denote the number of possible sets. We have

$$P_{k,n} = (n)_k^{\downarrow} \equiv n(n-1)(n-2)\cdots(n-k+1) = \frac{n!}{k!}$$
$$C_{k,n} = \binom{n}{k} \equiv \frac{n!}{k!(n-k)!}$$

Consider again the scenario mentioned above in which we receive five cards from a shuffled deck. We receive one of $(52)_5^{\downarrow} = 311875200$ sequences. To determine whether we have received a straight flush, however, we are allowed to reorder the cards in our hand. Consequently, the size of the outcome space is the number of possible sets, rather than the number of sequences. As there are $\binom{52}{5} = 2598960$ such sets, we conclude that the size of the outcome space is $n = 2598960$. Now, how many of these possible hands constitute a straight flush?

For this calculation, it is convenient to introduce another useful counting tool. If we can undertake a choice as a succession of subchoices, then the number of candidate choices is the product of the number available at each stage. A straight flush, for example, results from choosing one of four suits and then one of nine low cards to anchor the ascending numerical values. That is, the first subchoice has candidates: clubs, diamonds, hearts, spades. The second subchoice has candidates: 2, 3,. . ., 10. The number of candidate hands for a straight flush and the corresponding probability of a straight flush are then

$$\begin{aligned} N(\text{straight flush}) &= \binom{4}{1}\binom{9}{1} = 36 \\ P(\text{straight flush}) &= \frac{36}{2598960} = 0.0000138517 \end{aligned}$$

The multiplicative approach that determines the number of straight flush hands amounts to laying out the hands in four columns, one for each suit, and nine rows, one for each low card anchor value. That is, each candidate from the first subchoice admits the same number of subsequent choices, nine in this example. If the number of subsequent subchoices is not uniform, we resort to summing the values. For example, how many hands exhibit either one or two aces? One-ace hands involve a choice of suit for the ace, followed by a choice of any 4 cards from the 48 non-aces. Two-ace hands require a choice of two suits for the aces, followed by a selection of any 3 cards from the 48 non-aces. The computation is

$$\begin{aligned} N(\text{one or two aces}) &= \binom{4}{1}\binom{48}{4} + \binom{4}{2}\binom{48}{3} = 882096 \\ P(\text{one or two aces}) &= \frac{882096}{2598960} = 0.3394 \end{aligned}$$

When the selections are performed with replacement, the resulting sequences or sets may contain duplicate entries. In this case, a set is more accurately described as a multiset, which is a set that admits duplicate members. Moreover, the size of the selection k may be larger than the size of the candidate pool n. If we let $\overline{P}_{k,n}$ and $\overline{C}_{k,n}$ denote the number of sequences and multisets, respectively, we obtain

$$\begin{aligned} \overline{P}_{k,n} &= n^k \\ \overline{C}_{k,n} &= \binom{n+k-1}{k} \end{aligned}$$

These formulas are useful in occupancy problems. For example, suppose we have n bins into which we must distribute k balls. As we place each ball, we choose one of the n bins for it. The chosen bin remains available for subsequent balls, so we are choosing with replacement. A generic outcome is $(n_1, n_2,\ldots, n_k)$, where n_i denotes the bin selected for ball i. There are n^k such outcomes corresponding to the number of such sequences.

If we collect birthdays from a group of 10 persons, we obtain a sequence $n_1, n_2,\ldots, n_{10}$, in which each entry is an integer in the range 1 to 365. As each such sequence represents one choice from a field of $\overline{P}_{365,10} = 365^{10}$, we can calculate the probability that there will be at least one repetition among the birthdays by computing the number of such sequences with at least one repetition and dividing by the size of the field. We can construct a sequence with *no* repetitions by selecting, without replacement, 10 integers from the range 1 to 365. There are $P_{365,10}$ such sequences, and the remaining sequences must all correspond to least one repeated birthday among the 10 people. The probability of a repeated birthday is then

$$\begin{aligned} P(\text{repeated birthday}) &= \frac{365^{10} - P_{365,10}}{365^{10}} \\ &= 1 - \frac{(365)(364)\ldots(365)}{365^{10}} = 0.117 \end{aligned}$$

As we consider larger groups, the probability of a repeated birthday rises, although many people are surprised by how quickly it becomes larger than 0.5. For example, if we redo the above calculation with 23 persons, we obtain 0.5073 for the probability of a repeated birthday.

Multisets differ from sequences in that a multiset is not concerned with the order of its elements. In the bin-choosing experiment above, a generic multiset outcome is $k_1, k_2, \ldots, k_n$, where k_i counts the number of times bin i was chosen to receive a ball. That is, k_i is the number of occurrences of i in the generic sequence outcome $n_1, n_2, \ldots, n_k$, with a zero entered when a bin does not appear at all. In the birthday example, there are $\overline{C}_{365,10}$ such day-count vectors, but we would not consider them equally likely outcomes. Doing so would imply that the probability of all 10 birthdays coinciding is the same as the probability of them dispersing across several days, a conclusion that does not accord with experience.

As an example of where the collection of multisets correctly specifies the equally likely outcomes, consider the ways of writing the positive integer k as a sum of n nonnegative integers. A particular sum $k_1 + k_2 + \ldots + k_n = k$ is called a *partition* of k into nonnegative components. We can construct such a sum by tossing k ones at n bins. The first bin accumulates summand k_1, which is equal to the number of times that bin is hit by an incoming one. The second bin plays a similar role for the summand k_2 and so forth. There are $\overline{C}_{3,4} = 15$ ways to partition 4 into 3 components:

$$\begin{array}{lllll} 0+0+4 & 0+1+3 & 0+2+2 & 0+3+1 & 0+4+0 \\ 1+0+3 & 1+1+2 & 1+2+1 & 1+3+0 & \\ 2+0+2 & 2+1+1 & 2+2+0 & & \\ 3+0+1 & 3+1+0 & & & \\ 4+0+0 & & & & \end{array}$$

We can turn the set of partitions into a probability space by assigning probability 1/15 to each partition. We would then speak of a random partition as 1 of these 15 equally likely decompositions.

When the bin-choosing experiment is performed with distinguishable balls, then it is possible to observe the outcome $n_1, n_2, \ldots, n_k$, where n_i is the bin chosen for ball i. There are $\overline{P}_{n,k}$ such observable vectors. If the balls are not distinguishable, the outcome will not contain enough information for us to know the numbers n_i. After the experiment, we cannot locate ball i, and hence, we cannot specify its bin. In this case, we know only the multiset outcome $k_1, k_2, \ldots, k_n$, where k_i is the number of balls in bin i. There are only $\overline{C}_{n,k}$observable vectors of this latter type. In certain physics contexts, probability models with $\overline{P}_{n,k}$ equally likely outcomes accurately describe experiments with distinguishable particles across a range of energy levels (bins). These systems are said to obey *Maxwell–Boltzmann* statistics. On the other hand, if the experiment involves indistinguishable particles, the more realistic model use $\overline{C}_{n,k}$ outcomes, and the system is said to obey *Bose–Einstein* statistics.

The discussion above presents only an introduction to the vast literature of counting methods and their interrelationships that is known as combinatorics. For our purposes, we take these methods as one approach to establishing a probability space over a finite collection of outcomes.

RANDOM VARIABLES AND THEIR DISTRIBUTIONS

A random variable is a function that maps a probability space into the real numbers $\mathcal{R}$. There is a subtle constraint. Suppose $(\Omega, \mathcal{F}, P)$ is a probability space. Then $X : \Omega \to \mathcal{R}$ is a random variable if $X^{-1}(B) \in \mathcal{F}$ for all Borel sets $B \subset \mathcal{R}$. This constraint ensures that all events of the form $\{\omega \in \Omega | a < X(\omega) < b\}$ do indeed receive a probability assignment. Such events are typically abbreviated $(a < X \quad < b)$ and are interpreted to mean that the random variable (for the implicit outcome ω) lies in the interval (a, b). The laws of σ-fields then guarantee that related events, those obtained by unions, intersections, and complements from the open intervals, also receive probability assignments. In other words, X constitutes a *measurable* function from $(\Omega, \mathcal{F})$ to $\mathcal{R}$.

If the probability space is the real numbers, then the identity function is a random variable. However, for any probability space, we can use a random variable to transfer probability to the Borel sets $\mathcal{B}$ via the prescription $P'(B) = P(\{\omega \in \Omega | X(\omega) \in B\})$ and thereby obtain a new probability space $(\mathcal{R}, \mathcal{B}, P')$. Frequently, all subsequent analysis takes place in the real number setting, and the underlying outcome space plays no further role.

For any $x \in \mathcal{R}$, the function $F_X(x) = P'(X \leq x)$ is called the *cumulative distribution* of random variable X. It is frequently written $F(x)$ when the underlying random variable is clear from context. Distribution functions have the following properties:

- $F(x)$ is monotone nondecreasing.
- $\lim_{x \to -\infty} F(x) = 0$; $\lim_{x \to +\infty} F(x) = 1$.
- At each point x, F is continuous from the right and possesses a limit from the left. That is, $\lim_{y \to x^-} F(y) \leq F(x) = \lim_{y \to x^+} F(y)$.
- The set of discontinuities of F is countable.

Indeed, any function F with these properties is the distribution of some random variable over some probability space. If a nonnegative function f exists such that $F(x) = \int_{-\infty}^{x} f(t)dt$, then f is called the *density* of the underlying random variable X. Of course, there are actually many densities, if there is one, because f can be changed arbitrarily at isolated points without disturbing the integral.

Random variables and their distributions provide the opening wedge into a broad spectrum of analytical results because at this point the concepts have been quantified. In working with distributions, we are working with real-valued functions. The first step is to enumerate some distributions that prove useful in computer science and engineering applications. In each case, the underlying probability space is scarcely mentioned. After transfering probability to the Borel sets within the real numbers, all analysis takes place in a real-number setting. When the random variable takes on only a countable number of discrete values, it is traditionally described by giving the probability assigned to each of these values. When the random variable assumes a continuum of values, it is described by its density or distribution.

The *Bernoulli* random variable models experiments with two outcomes. It is an abstraction of the coin-tossing experiment, and it carries a parameter that denotes the probability of “heads.” Formally, a Bernoulli random variable X takes on only two values: 0 or 1. We say that X is a Bernoulli random variable with parameter p if $P(X = 1) = p$ and (necessarily) $P(X = 0) = 1 - p$.

The *expected value* of a discrete random variable X, denoted $E[X]$, is

$$E[X] \quad = \quad \sum_{n=1}^{\infty} t_n \cdot P(X = t_n)$$

where t_1, t_2,... enumerates the discrete values that X may assume. The expected value represents a weighted average across the possible outcomes. The *variance* of a discrete random variable is

$$\mathrm{Var}[X] = \sum_{n=1}^{\infty} (t_n - E[X])^2$$

The variance provides a summary measure of the dispersion of the X values about the expected value with low variance corresponding to a tighter clustering. For a Bernoulli random variable X with parameter p, we have $E[X] = p$ and $\mathrm{Var}[X] = p(1 - p)$.

An *indicator* random variable is a Bernoulli random variable that takes on the value 1 precisely when some other random variable falls in a prescribed set. For example, suppose we have a random variable X that measures the service time (seconds) of a customer with a bank teller. We might be particularly interested in lengthy service times, say those that exceed 120 seconds. The indicator

$$I_{(120,\infty)} = \begin{cases} 1, X > 120 \\ 0, X \leq 120 \end{cases}$$

is a Bernoulli random variable with parameter $p = P(X > 120)$.

Random variables X_1, X_2,..., X_n are *independent* if, for any Borel sets B_1, B_2,..., B_n, the probability that all n random variables lie in their respective sets is the product of the individual occupancy probabilities. That is,

$$P\left(\bigcap_{i=1}^{n} (X_i \in B_i)\right) = \prod_{i=1}^{n} P(X_i \in B_i)$$

This definition is a restatement of the concept of independent events introduced earlier; the events are now expressed in terms of the random variables. Because the Borel sets constitute a σ-field, it suffices to check the above condition on Borel sets of the form $(X \leq t)$. That is, X_1, X_2,..., X_n are independent if, for any n-tuple of real numbers t_1, t_2,...,t_n, we have

$$P\left(\bigcap_{i=1}^{n} (X_i \leq t_i)\right) = \prod_{i=1}^{n} P(X_i \leq t_i) = \prod_{i=1}^{n} F_X(t_i)$$

The sum of n independent Bernoulli random variables, each with parameter p, exhibits a *binomial* distribution. That is, if X_1, X_2,..., X_n are Bernoulli with parameter p and $Y = \sum_{i=1}^{n} X_i$, then

$$P(Y = i) \quad = \quad \binom{n}{i} p^i (1 - p)^{n-i}$$

for $i = 0, 1, 2, \ldots, n$. This random variable models, for example, the number of heads in n tosses of a coin for which the probability of a head on any given toss is p. For linear combinations of independent random variables, expected values and variances are simple functions of the component values.

$$\begin{aligned} E[a_1X_1 + a_2X_2 + \ldots] &= a_1E[X_1] + a_2E[X_2] + \ldots \\ \mathrm{Var}[a_1X_1 + a_2X_2 + \ldots] &= a_1^2\mathrm{Var}[X_1] + a_2^2\mathrm{Var}[X_2] + \ldots \end{aligned}$$

For the binomial random variable Y above, therefore, we have $E[Y] = np$ and $\mathrm{Var}[Y] = np(1 - p)$.

A *Poisson* random variable X with parameter λ has $P(X = k) = e^{-\lambda}\lambda^k/k!$. This random variable assumes all nonnegative integer values, and it is useful for modeling the number of events occurring in a specified interval when it is plausible to assume that the count is proportional to the interval width in the limit of very small widths. Specifically, the following context gives rise to a Poisson random variable X with parameter λ. Suppose, as time progresses, some random process is generating events. Let $X_{t,\Delta}$ count the number of events that occur during the time interval $[t, t + \Delta]$. Now, suppose further that the generating process obeys three assumptions. The first is a homogeneity constraint:

- $P(X_{t_1,\,\Delta} = k) = P(X_{t_2,\,\Delta} = k)$ for all integers $k \geq 0$

That is, the probabilities associated with an interval of width do not depend on the location of the interval. This constraint allows a notational simplification, and we can now speak of X_Δ because the various random variables associated with different anchor positions t all have the same distribution. The remaining assumptions are as follows:

- $P(X_\Delta = 1) = \lambda\Delta + o_1(\Delta)$
- $P(X_\Delta > 1) = o_2(\Delta)$

where the $o_i(\Delta)$ denote anonymous functions with the property that $o_i(\Delta)/\Delta \rightarrow 0$ as $\Delta \rightarrow 0$. Then the assignment $P(X = k) = \lim_{\Delta\rightarrow 0} P(X_\Delta = k)$ produces a Poisson random variable.

This model accurately describes such diverse phenomena as particles emitted in radioactive decay, customer arrivals at an input queue, flaws in magnetic recording media, airline accidents, and spectator coughing during a concert. The expected value and variance are both λ. If we consider a sequence of binomial random variables $B_{n,p}$, where the parameters n and p are constrained such that $n \rightarrow \infty$ and $p \rightarrow 0$ in a manner that allows $np \rightarrow \lambda > 0$, then the distributions approach that of a Poisson random variable Y with parameter λ. That is, $P(B_{n,p} = k) \rightarrow P(Y = k) = e^{-\lambda}\lambda^k/k!$.

A *geometric* random variable X with parameter p exhibits $P(X = k) = p(1-p)^k$ for $k = 0, 1, 2, \ldots$. It models, for example, the number of tails before the first head in repeated tosses of a coin for which the probability of heads is p. We have $E[X] = (1-p)/p$ and $\mathrm{Var}[X] = (1-p)/p^2$. Suppose, for example, that we have a hash table in which j of the N addresses are unoccupied. If we generate random address probes in search of an unoccupied slot, the probability of success is j/N for each probe. The number of failures prior to the first success then follows a geometric distribution with parameter j/N.

The sum of n independent geometric random variables displays a *negative binomial* distribution. That is, if X_1, $X_2, \ldots, X_n$ are all geometric with parameter p, then $Y = X_1 + X_2 + \ldots + X_n$ is negative binomial with parameters (n, p). We have

$$P(Y = k) = C_{n+k-1,k}\, p^n (1-p)^k$$

$$E[Y] = \frac{n(1-p)}{p}$$

$$\mathrm{Var}[Y] = \frac{n(1-p)}{p^2}$$

where $C_{n+k-1,k}$ is the number of distinct multisets available when choosing k from a field of n with replacement. This random variable models, for example, the number of tails before the nth head in repeated coin tosses, the number of successful fights prior to the nth accident in an airline history, or the number of defective parts chosen (with replacement) from a bin prior to the nth functional one. For the hash table example above, if we are trying to fill n unoccupied slots, the number of unsuccessful probes in the process will follow a negative binomial distribution with parameters $n, j/N$. In this example, we assume that n is significantly smaller than N, so that insertions do not materially change the probability j/N of success for each address probe.

Moving on to random variables that assume a continuum of values, we describe each by giving its density function. The summation formulas for the expected value and variance become integrals involving this density. That is, if random variable X has density f, then

$$E[X] = \int_{-\infty}^{\infty} t\, f(t)dt$$

$$\mathrm{Var}[X] = \int_{-\infty}^{\infty} [t - E[X]]^2\, f(t)dt$$

In truth, precise work in mathematical probability uses a generalization of the familiar Riemann integral known as a *measure-theoretic* integral. The separate formulas, summation for discrete random variables and Riemann integration against a density for continuous random variables, are then subsumed under a common notation. This more general integral also enables computations in cases where a density does not exist. When the measure in question corresponds to the traditional notion of length on the real line, the measure-theoretic integral is known as the *Lebesgue* integral. In other cases, it corresponds to a notion of length accorded by the probability distribution: $P(a < X < t)$ for real a and b. In most instances of interest in engineering and computer science, the form involving ordinary integration against a density suffices.

The *uniform* random variable U on [0, 1] is described by the constant density $f(t) = 1$ for $0 \leq t \leq 1$. The probability that U falls in a subinterval (a, b) within [0, 1] is simply $b - a$, the length of that subinterval. We have

$$E[U] = \int_0^1 t dt = \frac{1}{2}$$

$$\mathrm{Var}[U] = \int_0^1 \left(t - \frac{1}{2}\right)^2 dt = \frac{1}{12}$$

The uniform distribution is the continuous analog of the equally likely outcomes discussed in the combinatorics section above. It assumes that any outcome in the interval [0, 1] is equally likely to the extent possible under the constraint that probability must now be assigned to Borel sets. In this case, all individual outcomes receive zero probability, but intervals receive probability in proportion to their lengths. This random variable models situations such as the final resting position of a spinning pointer, where no particular location has any apparent advantage.

The most famous continuous random variable is the *Gaussian* or *normal* random variable $Z_{\mu,\sigma}$. It is characterized by two parameters, μ and σ, and has density, expected value, and variance as follows:

$$f_{z_{\mu,\sigma}}(t) = \frac{1}{\sigma\sqrt{2\pi}} e^{(t-\mu)^2/2\sigma^2}$$

$$E[Z_{\mu,\sigma}] = \mu$$

$$\mathrm{Var}[\mathrm{Z}_{\mu,\sigma}] = \sigma^2$$

The well-known *Central Limit Theorem* states that the average of a large number of independent observations behaves like a Gaussian random variable. Specifically, if $X_1, X_2, \ldots$ are independent random variables with identical finite-variance distributions, say $E[X_i] = a$ and $\mathrm{Var}[X_i] = c^2$, then for any t,

$$\lim_{n\to\infty} P\left(\frac{1}{\sqrt{nc^2}}\sum_{i=1}^{n}(X_i - a) \le t\right) = P(Z_{0,1} \le t)$$

For example, if we toss a fair coin 100 times, what is the probability that we will see 40 or fewer heads? To use the Central Limit Theorem, we let $X_i = 1$ if heads occurs on the ith toss and zero otherwise. With this definition, we have $E[X_i] = 0.5$ and $\mathrm{Var}[X_i] = 0.25$, which yields

$$P\left(\sum_{i=1}^{100} X_i \le 40\right) = P\left(\frac{1}{\sqrt{100(0.25)}}\sum_{i=1}^{100}(X_i - 0.5) \le \frac{40 - 100(0.5)}{\sqrt{100(0.25)}}\right)$$
$$\approx P(Z_{0,1} \le -2) = 0.0288$$

The last equality was obtained from a tabulation of such values for the *standard* normal random variable with expected value 0 and variance 1.

Because it represents a common limiting distribution for an average of independent observations, the Gaussian random variable is heavily used to calculate *confidence intervals* that describe the chance of correctly estimating a parameter from multiple trials. We will return to this matter in a subsequent section.

The *Gamma* function is $\Gamma(t) = \int_0^\infty x^{t-1}e^{-x}dx$, defined for $t < 0$. The Gamma random variable X with parameters (γ, λ) (both positive) is described by the density

$$f(x) = \begin{cases} \lambda^\gamma x^{\gamma-1}e^{-\lambda x}/\Gamma(\gamma), & \text{for } x \ge 0 \\ 0, & \text{for } x < 0 \end{cases}$$

It has $E[X] = \gamma/\lambda$ and $\mathrm{Var}[X] = \gamma/\lambda^2$. For certain specific values of γ, the random variable is known by other names. If $\gamma = 1$, the density reduces to $f(x) = \lambda e^{-\lambda x}$ for $x \le 0$, and X is then called an *exponential* random variable. The exponential random variable models the interarrival times associated with events such as radioactive decay and customer queues, which were discussed in connnection with Poisson random variables above. Specifically, if a Poisson random variable with parameter λT models the number of events in interval T, then an exponential random variable with parameter λ models their interarrival times. Consequently, the exponential random variable features prominently in queueing theory.

Exponential random variables possess a remarkable feature; they are *memoryless*. To understand this concept, we must first define the notion of *conditional probability*. We will use the exponential random variable as an example, although the discussion applies equally well to random variables in general. Notationally, we have a probability space $(\Omega, \mathcal{F}, P)$ and a random variable X, for which

$$P\{\omega \in \Omega : X(\omega) > t\} = \int_t^\infty \lambda e^{-\lambda x}dx = e^{-\lambda t}$$

for $t \le 0$. Let t_1 be a fixed positive real number, and consider a related probability space $(\hat{\Omega}, \hat{\mathcal{F}}, \hat{P})$, obtained as follows:

$$\hat{\Omega} = \{\omega \in \Omega : X(\omega) > t_1\}$$
$$\hat{\mathcal{F}} = \{A \cap \hat{\Omega} : A \in \mathcal{F}\}$$
$$\hat{P}(B) = P(B)/P(\hat{\Omega}), \text{ for all } \quad B \in \hat{\mathcal{F}}$$

By restricting its domain, we can consider X to be a random variable on $\hat{\Omega}$. For any $\omega \in \hat{\Omega}$, we have $X(\omega) > t_1$, but we can legitimately ask the probability, using the new measure $\hat{P}$, that $X(\omega)$ exceeds t_1 by more than t.

$$\begin{aligned}\hat{P}(X > t_1 + t) &= \frac{P(X > t_1 + t_2)}{P(X > t_1)} = \frac{e^{-\lambda(t_1+t)}}{e^{-\lambda t_1}} \\ &= e^{-\lambda t} = P(X > t)\end{aligned}$$

The probability $\hat{P}(B)$ is known as the *conditional probability* of B, given $\hat{\Omega}$. From the calculation above, we see that the conditional probability that X exceeds t_1 by t or more, given that $X > t_1$ is equal to the unconditional probability that $X > t$. This is the memoryless property. If X is an exponential random variable representing the time between query arrivals to a database input queue, then the probability that 6 microseconds or more elapses before the next arrival is the same as the probability that an additional 6 microseconds or more elapses before the next arrival, given that we have already waited in vain for 10 microseconds.

In general, we can renormalize our probability assignments by restricting the outcome space to some particular event, such as the $\hat{\Omega}$ in the example. The more general notation is $P(B \mid A)$ for the conditional probability of B given A. Also, we normally allow B to be any event in the original $\mathcal{F}$ with the understanding that only that part of B that intersects A carries nonzero probability under the new measure. The definition requires that the conditioning event A have nonzero probability. In that case,

$$P(B|A) = \frac{P(B \cap A)}{P(A)}$$

specifies the revised probabilities for all events B. Note that

$$P(B|A) = \frac{P(A \cap B)}{P(A)} = \frac{P(A \cap B)}{P(A \cap B) + P(A \cap \overline{B})}$$
$$= \frac{P(A|B)P(B)}{P(A|B)P(B) + P(A|\overline{B})P(\overline{B})}$$

This formula, a simple form of *Bayes' Law*, relates the conditional probability of B given A to that of A given B. It finds frequent use in updating probability assignments to reflect new information. Specifically, suppose we know $P(B)$ and therefore $P(\overline{B}) = 1 - P(B)$. Such probabilities are called *prior* probabilities because they reflect the chances of a B occurrence in the absence of further knowledge about the underlying random process. If the actual outcome remains unknown to us, but we are told that event A has occurred, we may want to update our probability assignment to reflect more accurately the chances that B has also occurred. That is, we are interested in the *posterior* probability $P(B\,|\,A)$. Bayes' Law allows us to compute this new value, provided we also have the reverse conditional probabilities.

For example, suppose a medical test for a specific disease is applied to a large population of persons known to have the disease. In 99% of the cases, the disease is detected. This is a conditional probability. If we let S be the event "person is sick" and "+" be the event "medical test was positive," we have $P(+|S) = 0.99$ as an empirical estimate. Applying the test to a population of persons known not to have the disease might reveal $P(+|\overline{S}) = 0.01$ as a false alarm rate. Suppose further that the fraction $P(S) = 0.001$ of the general population is sick with the disease. Now, if you take the test with positive results, what is the chance that you have the disease? That is, what is $P(S|+)$? Applying Bayes' Law, we have

$$\begin{aligned} P(S|+) &= \frac{P(+|S)P(S)}{P(+|S)P(S) + P(+|\overline{S})P(\overline{S})} \\ &= \frac{0.99(0.001)}{0.99(0.001) + 0.01(0.99)} = 0.0909 \end{aligned}$$

You have only a 9% chance of being sick, despite having scored positive on a test with an apparent 1% error rate. Nevertheless, your chance of being sick has risen from a prior value of 0.001 to a posterior value of 0.0909. This is nearly a hundredfold increase, which is commensurate with the error rate of the test.

The full form of Bayes' Law uses an arbitrary partition of the outcome space, rather than a simple two-event decomposition, such as "sick" and "not sick." Suppose the event collection $\{A_i : 1 \leq i \leq n\}$ is a partition of the outcome space Ω. That is, the A_i are disjoint, each has nonzero probability, and their union comprises all of Ω. We are interested in which A_i has occurred, given knowledge of another event B. If we know the reverse conditional probabilities, that is if we know the probability of B given each A_i, then Bayes' Law enables the computation

$$P(A_i|B) = \frac{P(B|A_i)P(A_i)}{\sum_{j=1}^{n} P(B|A_j)P(A_j)}.$$

Returning to the Gamma random variable with parameters (γ, λ), we can distinguish additional special cases. If $\gamma = n$, a positive integer, then the corresponding distribution is called an *Erlang* distribution. It models the time necessary to accumulate n events in a process that follows a Poisson distribution for the number of events in a specified interval. An Erlang distribution, for example, describes the time span covering the next n calls arriving at a telephone exchange.

If $\gamma = n/2$ for a positive integer n and $\lambda = 1/2$, then the corresponding Gamma random variable is called a chi-square random variable. It exhibits the distribution of the sum of n independent squares, $Y = \sum_{i=1}^{n} Z_i^2$, where each Z_i is a Gaussian random variable with $(\mu, \sigma^2) = (0, 1)$. These distributions are useful in computing confidence intervals for statistical estimates.

Gamma distributions are the limiting forms of negative binomial random variables in the same manner that the Poisson distribution is the limit of binomials. That is, suppose we have a sequence C_n of negative binomial random variables. The parameters of C_n are (m, p_n). As $n \to \infty$, we assume that $p_n \to 0$ in a manner that allows $n p_n \to \lambda > 0$. Then the limiting distribution of C_n/n is the Gamma (Erlang) distribution with parameters (m, γ). In particular, if $m = 1$, the C_n are geometric and the limit is exponential.

Figure 1 summarizes the relationships among the random variables discussed in this section.

The *renewal count* arrow from exponential to Poisson refers to the fact that a phenomenon in which the event interarrival time is exponential (λ) will accumulate events in an interval T according to a Poisson distribution with parameter λT . That is, if the sequence X_1, X_2,... of random variables measures time between successive events, then the random variable

$$N_T = \max\left\{ k | \sum_{i=1}^{k} X_i \leq T \right\}$$

is called a renewal count for the sequence. If the X_i are independent exponentials with parameter λ, then N_T has a Poisson distribution with parameter λT.

A similar relationship holds between a sequence $G_1 + 1$, $G_2 + 1$,... of geometric random variables with a common parameter p. The difference is that the observation interval T is now a positive integer. The renewal count N_T then exhibits a binomial distribution with parameters (T, p).

CONVERGENCE MODES

For a sequence of real numbers, there is a single mode of convergence: A tail of the sequence must enter and remain within any given neighborhood of the limit. This property either holds for some (possibly infinite) limiting value or it does not. Sequences of random variables exhibit more variety in this respect. There are three modes of convergence.

A sequence X_1, X_2,... of random variables converges *pointwise* to a random variable Y if $X_n(\omega) \to Y(\omega)$ as a sequence of real numbers for every point ω in the underlying probability space. We may also have pointwise convergence on sets smaller than the full probability space. If pointwise convergence occurs on a set of probability one, then we say that the sequence converges *almost surely*. In this case, we use the notation $X_n \to Ya.s.$

The sequence converges *in probability* if, for every positive ϵ, the measure of the misbehaving sets approaches zero. That is, as $n \to \infty$,

$$P(\{\omega : |X_n(\omega) - Y(\omega)| > \epsilon\}) \to 0$$

If $X_n \to Y$ *a.s*, then it also converges in probability. However, it is possible for a sequence to converge in probability and at the same time have no pointwise limits.

The final convergence mode concerns distribution functions. The sequence converges *in distribution* if the corresponding cumulative distribution functions of the X_n converge pointwise to the distribution function of Y at all points where the cumulative distribution function of Y is continuous.

The *Weak Law of Large Numbers* states that the average of a large number of independent, identically distributed random variables tends in probability to a constant, the expected value of the common distribution. That is, if X_1, X_2,... is an independent sequence with a common distribution such that $E[X_n] = \mu$ and $\mathrm{Var}[X_n] = \sigma^2 < \infty$, then for every positive ϵ,

$$P\left(\left\{\omega : \left|\frac{\sum_{i=1}^{n} X_i}{n} - \mu\right| > \epsilon\right\}\right) \to 0$$

as $n \to \infty$.

Suppose, for example, that a random variable T measures the time between query requests arriving at a database server. This random variable is likely to exhibit an exponential distribution, as described in the previous section, with some rate parameter λ. The expected value and variance are $1/\lambda$ and $1/\lambda^2$, respectively. We take n observations of T and label them T_1, T_2,... , T_n. The weak law suggests that the number $\sum_{i=1}^{n} T_i/n$ will be close to $1/\lambda$. The precise meaning is more subtle. As an exponential random variable can assume any nonnegative value, we can imagine a sequence of observations that are all larger than, say, twice the expected value. In that case, the average would also be much larger than $1/\lambda$. It is then clear that not all sequences of observations will produce averages close to $1/\lambda$. The weak law states that the set of sequences that misbehave in this fashion is not large, when measured in terms of probability.

We envision an infinite sequence of independent database servers, each with its separate network of clients. Our probability space now consists of outcomes of the form $\omega = (t_1, t_2, \ldots)$, which occurs when server 1 waits t_1 seconds for its next arrival, server 2 waits t_2 seconds, and so forth. Any event of the form $(t_1 \le x_1, t_2 \le x_2, \ldots, t_p \le x_p)$ has probability equal to the product of the factors $P(t_1 \le x_i)$, which are in turn determined by the common exponential distribution of the T_i. By taking unions, complements, and intersections of events of this type, we arrive at a σ-field that supports the probability measure. The random variables $\sum_{i=1}^{n} T_i/n$ are well defined on this new probability space, and the weak law asserts that, for large n, the set of sequences $(t_1, t_2, \ldots)$ with misbehaving prefixes $(t_1, t_2, \ldots, t_n)$ has small probability.

A given sequence can drift into and out of the misbehaving set as n increases. Suppose the average of the first 100 entries is close to $1/\lambda$, but the next 1000 entries are all larger than twice $1/\lambda$. The sequence is then excluded from the misbehaving set at $n = 100$ but enters that set before $n = 1100$. Subsequent patterns of good and bad behavior can migrate the sequence into and out of the exceptional set. With this additional insight, we can interpret more precisely the meaning of the weak law.

Suppose $1/\lambda = 0.4$. We can choose $\epsilon = 0.04$ and let $Y_n = \sum_{i=1}^{n} T_i/n$. The weak law asserts that $P(|Y_n - 0.4| > 0.04) \to 0$, which is the same as $P(0.36 \le Y_n \le 0.44) \to 1$. Although the law does not inform us about the actual size of n required, it does say that eventually this latter probability exceeds 0.99. Intuitively, this means that if we choose a large n, there is a scant 1% chance that our average will fail to fall close to 0.4. Moreover, as we choose larger and larger values for n, that chance decreases.

The *Strong Law of Large Numbers* states that the average converges pointwise to the common expected value, except perhaps on a set of probability zero. specifically, if X_1, X_2,... is is an independent sequence with a common distribution such that $E[X_n] = \mu$ (possibly infinite), then

$$\frac{\sum_{i=1}^{n} X_i}{n} \to \mu \quad a.s.$$

as $n \to \infty$.

Applied in the above example, the strong law asserts that essentially all outcome sequences exhibit averages that draw closer and closer to the expected value as n increases. The issue of a given sequence forever drifting into and out of the misbehaving set is placed in a pleasant perspective. Such sequences must belong to the set with probability measure zero. This reassurance does not mean that the exceptional set is empty, because individual outcomes $(t_1, t_2, \ldots)$ have zero probability. It does mean that we can expect, with virtual certainty, that our average of n observations of the arrival time will draw ever closer to the expected $1/\lambda$.

Although the above convergence results can be obtained with set-theoretic arguments, further progress is greatly facilitated with the concept of characteristic functions, which are essentially Fourier transforms in a probability space setting. For a random variable X, the *characteristic function* of X is the complex-valued function $\beta_X(u) = E[e^{iuX}]$. The exceptional utility of this device follows because there is a one-to-one relationship between characteristic functions and their generating random variables (distributions). For example, X is Gaussian with parameters $\mu = 0$ and $\sigma^2 = 1$ if and only if $\beta_X(u) = e^{u^2/2}$. X is Poisson with parameter λ if and only if $\beta_X(u) = \exp(-\lambda(1 - e^{iu}))$.

If X has a density $f(t)$, the computation of β_X is a common integration: $\beta_X(u) = \int_{-\infty}^{\infty} e^{iut} f(t)\mathrm{d}t$. Conversely, if β_X is absolutely integrable, then X has a density, which can be recovered by an inversion formula. That is, if $\int_{-\infty}^{\infty} |\beta(u)|\, du < \infty$, then the density of X is

$$f_X(t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-iut} \beta(u) du$$

These remarks have parallel versions if X is integer-valued. The calculation of β_X is a sum: $\beta_X(u) = \sum_{n=-\infty}^{\infty} e^{iun}P(X = n)$. Also, if β_X is periodic with period 2π, then the corresponding X is integer-valued and the point probabilities are recovered with a similar inversion formula:

$$P(X = n) \quad = \quad \frac{1}{2\pi}\int_{-\pi}^{\pi} e^{-iun}\beta(u)du$$

In more general cases, the β_X computation requires the measure-theoretic integral referenced earlier, and the recovery of the distribution of X requires more complex operations on β_X. Nevertheless, it is theoretically possible to translate in both directions between distributions and their characteristic functions.

Some useful properties of characteristic functions are as follows:

- (Linear combinations) If $Y = aX + b$, then $\beta_Y(u) = e^{iub}\beta_X(au)$.
- (Independent sums) If $Y = X_1 + X_2 + \ldots + X_n$, where the X_i are independent, then $\beta_Y(u) = \prod_{i=1}^{n} \beta_{X_i}(u)$.
- (Continuity Theorem) A sequence of random variables $X_1, X_2, \ldots$ converges in distribution to a random variable X if and only if the corresponding characteristic functions converge pointwise to a function that is continuous at zero; in which case, the limiting function is the characteristic function of X.
- (Moment Theorem) If $E[|X|^n] < \infty$, then β_X has derivatives through order n and $E[X^n] = (-i)^n \beta_X^{(n)}(0)$, where $\beta_X^{(n)}(u)$ is the n^{th} derivative of β_X.

These features allow us to study convergence in distribution of random variables by investigating the more tractable pointwise convergence of their characteristic functions. In the case of independent, identically distributed random variables with finite variance, this method leads quickly to the Central Limit Theorem cited earlier.

For a nonnegative random variable X, the *moment generating function* $\phi_X(u)$ is less difficult to manipulate. Here $\phi_X(u) = E[e^{-uX}]$. For a random variable X that assumes only nonnegative integer values, the *probability generating function* $\rho_X(u)$ is another appropriate transform. It is defined by $\rho_X(u) = \sum_{n=0}^{\infty} P(X = n)u^n$. Both moment and probability generating functions admit versions of the moment theorem and the continuity theorem and are therefore useful for studying convergence in the special cases where they apply.

COMPUTER SIMULATIONS

In various programming contexts, particularly with simulations, the need arises to generate samples from some particular distribution. For example, if we know that $P(X = 1) = 0.4$ and $P(X = 0) = 0.6$, we may want to *realize* this random variable as a sequence of numbers $x_1, x_2, \ldots$. This sequence should exhibit the same variability as would the original X if outcomes were directly observed. That is, we expect a thorough mixing of ones and zeros, with about 40% ones. Notice that we can readily achieve this result if we have a method for generating samples from a uniform distribution U on [0, 1]. In particular, each time we need a new sample of X, we generate an observation U and report $X = 1$ if $U \leq 0.4$ and $X = 0$ otherwise.

This argument generalizes in various ways, but the gist of the extension is that essentially any random variable can be sampled by first sampling a uniform random variable and then resorting to some calculations on the observed value. Although this reduction simplifies the problem, the necessity remains of simulating observations from a uniform distribution on [0, 1]. Here we encounter two dificulties. First, the computer operates with a finite register length, say 32 bits, which means that the values returned are patterns from the 2^{32} possible arrangements of 32 bits. Second, a computer is a deterministic device.

To circumvent the first problem, we put a binary point at the left end of each such pattern, obtaining 2^{32} evenly spaced numbers in the range [0, 1). The most uniform probability assignment allots probability $1/2^{32}$ to each such point. Let U be the random variable that operates on this probability space as the identity function. If we calculate $P(a < U < b)$ for subintervals (a, b) that are appreciably wider than $1/2^{32}$, we discover that these probabilities are nearly $b - a$, which is the value required for a true uniform random variable. The second dificulty is overcome by arranging that the values returned on successive calls exhaust, or very nearly exhaust, the full range of patterns before repeating. In this manner, any deterministic behavior is not observable under normal use. Some modern supercomputer computations may involve more than 2^{32} random samples, an escalation that has forced the use of 64-bit registers to maintain the appearance of nondeterminism.

After accepting an approximation based on 2^{32} (or more) closely spaced numbers in [0, 1), we still face the problem of simulating a discrete probability distribution on this finite set. This problem remains an area of active research today. One popular approach is the *linear congruential* method. We start with a seed sample x_0, which is typically obtained in some nonreproducible manner, such as extracting a 32-bit string from the computer real-time clock. Subsequent samples are obtained with the recurrence $x_{n+1} = (ax_n + b) \bmod c$, where the parameters a, b, c are chosen to optimize the criteria of a long period before repetition and a fast computer implementation. For example, c is frequently chosen to be 2^{32} because the $(ax_n + b) \bmod 2^{32}$ operation involves retaining only the least significant 32 bits of $(ax_n + b)$. Knuth (1) discusses the mathematics involved in choosing these parameters.

On many systems, the resulting generator is called rand(). A program assignment statement, such as $x = \mathrm{rand}()$, places a new sample in the variable x. From this point, we manipulate the returned value to simulate samples from other distributions. As noted, if we wish to sample B, a Bernoulli random variable with parameter p, we continue by setting $B = 1$ if $x \leq p$ and $B = 0$ otherwise. If we need an random variable $U_{a,b}$, uniform on the interval $[a, b]$, we calculate $U_{a,b} = a + (b - a)x$.

If the desired distribution has a continuous cumulative distribution function, a general technique, called distribution inversion, provides a simple computation of samples. Suppose X is a random variable for which the cumulative distribution $F(t) = P(X \leq t)$ is continuous and strictly increasing. The inverse $F^{-1}(u)$ then exists for $0 < u < 1$, and it can be shown that the derived random variable $Y = F(X)$ has a uniform distribution on (0, 1). It follows that the distribution of $F^{-1}(U)$ is the same as that of X, where U is the uniform random variable approximated by rand(). To obtain samples from X, we sample U instead and return the values $F^{-1}(U)$.

For example, the exponential random variable X with parameter λ has the cumulative distribution function $F(t) = 1 - e^{-\lambda t}$, for $t \geq 0$, which satisfies the required conditions. The inverse is $\mathcal{F}^{-1}(u) = -[\log(1-u)]/\lambda$. If U is uniformly distributed, so is $1 - U$. Therefore, the samples obtained from successive $-[\log(\text{rand}())]/\lambda$ values exhibit the desired exponential distribution.

A variation is necessary to accommodate discrete random variables, such as those that assume integer values. Suppose we have a random variable X that assumes nonnegative integer values n with probabilities p_n. Because the cumulative distribution now exhibits a discrete jump at each integer, it no longer possesses an inverse. Nevertheless, we can salvage the idea by acquiring a rand() sample, say x, and then summing the p_n until the accumulation exceeds x. We return the largest n such that $\sum_{i=0}^{n} p_i \leq x$. A moment's reflection will show that this is precisely the method we used to obtain samples from a Bernoulli random variable above.

For certain cases, we can solve for the required n. For example, suppose X is a geometric random variable with parameter p. In this case, $p_n = p(1-p)^n$. Therefore if x is the value obtained from rand(), we find

$$\max\left\{ n : \sum_{k=0}^{n} p_k \leq x \right\} = \left\lfloor \frac{\log_x}{\log(1-p)} \right\rfloor$$

For more irregular cases, we may need to perform the summation. Suppose we want to sample a Poisson random variable X with parameter λ. In this case, we have $p_n = e^{-\lambda}\lambda^n/n!$, and the following pseudocode illustrates the technique. We exploit the fact that $p_0 = e^{-\lambda}$ and $p_{n+1} = p_n\lambda/(n+1)$.

```
$x$ = rand();
$p = \exp(-\lambda)$;
cum = $p$;
$n = 0$;
while ($x >$ cum){
    $n = n + 1$;
    $p = p * \lambda/(n + 1)$;
    cum = cum + $p$;}
return $n$;
```

Various enhancements are available to reduce the number of iterations necessary to locate the desired n to return. In the above example, we could start the search near $n = \lfloor \lambda \rfloor$, because values near this expected value are most frequently returned.

Another method for dealing with irregular discrete distributions is the *rejection filter*. If we have an algorithm to simulate distribution X, we can, under certain conditions, systematically withhold some of the returns to simulate a related distribution Y. Suppose X assumes nonnegative integer values with probabilities $p_0, p_1, \ldots$, Y assumes the same values but with different probabilities $q_0, q_1, \ldots$. The required condition is that a positive K exists such that $q_n \leq K p_n$ for all n. The following pseudocode shows how to reject just the right number of X returns so as to correctly adjust the return distribution to that of Y. Here the routine X() refers to the existing algorithm that returns nonnegative integers according to the X distribution. We also require that the p_n be nonzero.

```
while (true) {
    $n$ = X();
    $x$ = rand();
    if ($x < q_n/(K * p_n)$)
        return $n$;}
```

STATISTICAL INFERENCE

Suppose we have several random variables $X, Y, \ldots$ of interest. For example, X might be the systolic blood pressure of a person who has taken a certain drug, whereas Y is the blood pressure of an individual who has not taken it. In this case, X and Y are defined on different probability spaces. Each probability space is a collection of persons who either have or have not used the drug in question. X and Y then have distributions in a certain range, say [50, 250], but it is not feasible to measure X or Y at each outcome (person) to determine the detailed distributions. Consequently, we resort to samples. That is, we observe X for various outcomes by measuring blood pressure for a subset of the X population. We call the observations $X_1, X_2, \ldots, X_n$. We follow a similar procedure for Y if we are interested in comparing the two distributions. Here, we concentrate on samples from a single distribution.

A sample from a random variable X is actually another random variable. Of course, after taking the sample, we observe that it is a specific number, which hardly seems to merit the status of a random variable. However, we can envision that our choice is just one of many parallel observations that deliver a range of results. We can then speak of events such as $P(X_1 \leq t)$ as they relate to the disparate values obtained across the many parallel experiments as they make their first observations. We refer to the distribution of X as the *population* distribution and to that of X_n as the nth *sample* distribution. Of course, $P(X_n \leq t) = P(X \leq t)$ for all n and t, but the term sample typically carries the implicit understanding that the various X_n are independent. That is, $P(X_n \leq t_1, \ldots, X_n \leq t_n) = \prod_{i=1}^{n} P(X_i \leq t_i)$. In this case, we say that the sample is a *random* sample.

With a random sample, the X_n are independent, identically distributed random variables. Indeed, each has the same distribution as the underlying population X. In practice, this property is assured by taking precautions to avoid any selection bias during the sampling. In the blood pressure application, for example, we attempt to choose persons in a manner that gives every individual the same chance of being observed.

Armed with a random sample, we now attempt to infer features of the unknown distribution for the population X. Ideally, we want the cumulative distribution of $F_X(t)$, which announces the fraction of the population with blood pressures less than or equal to t. Less complete, but still valuable, information lies with certain summary features, such as the expected value and variance of X.

A *statistic* is simply a function of a sample. Given the sample $X_1, X_2, \ldots, X_n$,, the new random variables

$$\overline{X} = \frac{1}{n}\sum_{k=1}^{n} X_k$$

$$S^2 = \frac{1}{n-1}\sum_{k=1}^{n}(X_k - \overline{X})^2$$

are statistics known as the *sample mean* and *sample variance* respectively. If the population has $E[X] = \mu$ and $\mathrm{Var}[X] = \sigma^2$, then $E[\overline{X}] = \mu$ and $E[S^2] = \sigma^2$. The expected value and variance are called*parameters* of the population, and a central problem in statistical inference is to estimate such unknown parameters through calculations on samples. At any point we can declare a particular statistic to be an *estimator* of some parameter. Typically we only do so when the value realized through samples is indeed an accurate estimate.

Suppose θ is some parameter of a population distribution X. We say that a statistic Y is an *unbiased* estimator of θ if $E[Y] = \theta$. We then have that the sample mean and sample variance are unbiased estimators of the population mean and variance. The quantity

$$\hat{S}^2 = \frac{1}{n}\sum_{k=1}^{n}(X_k - \overline{X})^2$$

is also called the sample variance, but it is a *biased* estimator of the population variance σ^2. If context is not clear, we need to refer to the biased or unbiased sample variance. In particular $E[\hat{S}^2] = \sigma^2(1 - 1/n)$, which introduces a bias of $b = -\sigma^2/n$. Evidently, the bias decays to zero with increasing sample size n. A sequence of biased estimators with this property is termed *asymptotically unbiased*.

A statistic can be a vector-valued quantity. Consequently, the entire sample $(X_1, X_2, \ldots, X_n)$ is a statistic. For any given t, we can compute the fraction of the sample values that is less than or equal to t. For a given set of t values, these computation produce a *sample distribution function*:

$$F_{n}(t) = \frac{\#\{k : X_k \le t\}}{n}$$

Here we use #{. . .} to denote the size of a set. For each t, the Glivenko–Cantelli Theorem states that the $F_n(t)$ constitute an asymptotically unbiased sequence of estimators for $F(t) = P(X \le t)$.

Suppose $X_1, X_2, \ldots, X_n$ is a random sample of the population random variable X, which has $E[X] = \mu$ and $\mathrm{Var}[X] = \sigma^2 < \infty$. The Central Limit Theorem gives the limiting distribution for $\sqrt{n}(\overline{X} - \mu)/\sigma$ as the standard Gaussian $Z_{0,1}$. Let us assume (unrealistically) for the moment that we know σ^2. Then, we can announce $\overline{X}$ as our estimate of μ, and we can provide some credibility for this estimate in the form of a *confidence interval*. Suppose we want a 90% confidence interval. From tables for the standard Gaussian, we discover that $P(|Z_{0,1}| \le 1.645) = 0.9$. For large n, we have

$$\begin{aligned} 0.9 &= P(|Z_{0,1}| \le 1.645) \approx P\left(\left|\frac{\sqrt{n}(\overline{X} - \mu)}{\sigma}\right| \le 1.645\right) \\ &= P\left(|\overline{X} - \mu| \le \frac{1.645\sigma}{\sqrt{n}}\right) \end{aligned}$$

If we let $\delta = 1.645\sigma/\sqrt{n}$, we can assert that, for large n, there is a 90% chance that the estimate $\overline{X}$ will lie within δ of the population parameter μ. We can further manipulate the equation above to obtain $P(\overline{X} - \delta \le \mu \le \overline{X} + \delta) \approx 0.9$. The specific interval obtained by substituting the observed value of $\overline{X}$ into the generic form $[\overline{X} - \delta, \overline{X} + \delta]$ is known as the (90%) confidence interval. It must be properly interpreted. The parameter μ is an unknown constant, not a random variable. Consequently, either μ lies in the specified confidence interval or it does not. The random variable is the interval itself, which changes endpoints when new values of $\overline{X}$ are observed. The width of the interval remains constant at δ. The proper interpretation is that 90% of these nondeterministic intervals will bracket the parameter μ.

Under more realistic conditions, neither the mean μ nor the variance σ^2 of the population is known. In this case, we can make further progress if we assume that the individual X_i samples are normal random variables. Various devices, such as composing each X_i as a sum of a subset of the samples, render this assumption more viable. In any case, under this constraint, we can show that $n(\overline{X} - \mu)^2/\sigma^2$ and $(n-1)\mathcal{S}^2/\sigma^2$ are independent random variables with known distributions. These random variables have chi-squared distributions.

A *chi-squared* random variable with m *degrees of freedom* is the sum of the squares of m independent standard normal random variables. It is actually a special case of the gamma distributions discussed previously; it occurs when the parameters are $\gamma = m$ and $\lambda = 1/2$. If Y_1 is chi-squared with m_1 degrees of freedom and Y_2 is chi-squared with m_2 degrees of freedom, then the ratio $m_2Y_1/(m_1Y_2)$ has an F distribution with (n,m) degree of freedom. A symmetric random variable is said to follow a t distribution with m_2 degrees of freedom if its square has an F distribution with $(1,m_2)$ degrees of freedom. For a given random variable R and a given value p in the range $(0, 1)$, the point r_p for which $P(R \le r_p) = p$ is called the pth *percentile* of the random variable. Percentiles for F and t distributions are available in tables.

Returning to our sample $X_1, X_2, \ldots, X_n$, we find that under the normal inference constraint, the two statistics mentioned above have independent chi-squared distributions with 1 and $n-1$ degrees of freedom, respectively. Therefore the quantity $\sqrt{n}|\overline{X} - \mu|/\sqrt{S^2}$ has a t distribution with $n-1$ degrees of freedom. Given a confidence level, say

90%, we consult a table of percentiles for the t distribution with $n-1$ degrees of freedom. We obtain a symmetric interval $[-r, r]$ such that

$$0.9 = P\left(\frac{\sqrt{n}|\overline{X}-\mu|}{\sqrt{S}^2} \le r\right) = P\left(|\overline{X}-\mu| \le \frac{r\sqrt{S}^2}{\sqrt{n}}\right)$$

Letting $\delta = r\sqrt{S}^2/\sqrt{n}$, we obtain the 90% confidence interval $[\overline{X}-\delta, \overline{X}+\delta]$ for our estimate $\overline{X}$ of the population parameter μ. The interpretation of this interval remains as discussed above.

This discussion above is an exceedingly abbreviated introduction to a vast literature on statistical inference. The references below provide a starting point for further study.

P

PROOFS OF CORRECTNESS IN MATHEMATICS AND INDUSTRY

THE QUALITY PROBLEM

Buying a product from a craftsman requires some care. For example, in the Stone Age, an arrow, used for hunting and hence for survival, needed to be inspected for its sharpness and proper fixation of the stone head to the wood. Complex products of more modern times cannot be checked in such a simple way and the idea of warranty was born: A nonsatisfactory product will be repaired or replaced, or else you get your money back. This puts the responsibility for quality on the shoulders of the manufacturer, who has to test the product before selling. In contemporary IT products, however, testing for proper functioning in general becomes impossible. If we have an array of 17×17 switches in a device, the number of possible positions is $2^{17^2} = 2^{289} \sim 10^{87}$, more than the estimated number of elementary particles in the universe. Modern chips have billions of switches on them, hence, a state space of a size that is truly dwarfing astronomical numbers. Therefore, in most cases, simple-minded testing is out of the question because the required time would surpass by far the lifetime expectancy of the universe. As these chips are used in strategic applications, like airplanes, medical equipment, and banking systems, there is a problem with how to warrant correct functioning.

Therefore, the need for special attention to the quality of complex products is obvious, both from a user's point of view and that of a producer. This concern is not just academic. In 1994 the computational number theorist T. R. Nicely discovered by chance a bug[1] in a widely distributed Pentium chip. After an initial denial, the manufacturer eventually had to publicly announce a recall, replacement, and destruction of the flawed chip with a budgeted cost of US $475 million.

Fortunately, mathematics has found a way to handle within a finite amount of time a supra-astronomical number of cases, in fact, an infinity of them. The notion of proof provides a way to handle all possible cases with certainty. The notion of mathematical induction is one proof method that can deal with an infinity of cases: If a property P is valid for the first natural number 0 (or if you prefer 1) and if validity of P for n implies that for $n+1$, then P is valid for all natural numbers. For example, for all n one has

$$\sum_{k=0}^{n} k^2 = \frac{1}{6} n(n+1)(2n+1). \qquad P(n)$$

This can be proved by showing it for $n = 0$; and then showing that if $P(n)$ holds, then also $p(n+1)$. Indeed $P(0)$ holds: $\sum_{k=0}^{0} k^2 = 0$. If $P(n)$ holds, then

$$\begin{aligned} \sum_{k=0}^{n+1} k^2 &= \left(\sum_{k=0}^{n} k^2\right) + (n+1)^2 \\ &= \frac{1}{6} n(n+1)(2n+1) + (n+1)^2 \\ &= \frac{1}{6}(n+1)(n+2)(2n+3), \end{aligned}$$

hence $P(n+1)$. Therefore $P(n)$ holds for all natural numbers n.

Another method to prove statements valid for an infinite number of instances is to use symbolic rewriting: From the usual properties of addition and multiplication over the natural numbers (proved by induction), one can derive equationally that $(x+1)(x-1) = x^2 - 1$, for all instances of x.

Proofs have been for more than two millennia the essence of mathematics. For more than two decades, proofs have become essential for warranting quality of complex IT products. Moreover, by the end of the twentieth century, proofs in mathematics have become highly complex. Three results deserve mention: the Four Color Theorem, the Classification of the Finite Simple Groups, and the correctness of the Kepler Conjecture (about optimal packing of equal three-dimensional spheres). Part of the complexity of these proofs is that they rely on large computations by a computer (involving up to a billion cases). A new technology for showing correctness has emerged: automated verification of large proofs.

Two methodological problems arise (1). How do proofs in mathematics relate to the physical world of processors and other products? (2) How can we be sure that complex proofs are correct? The first question will be addressed in the next section, and the second in the following section. Finally, the technology is predicted to have a major impact on the way mathematics will be done in the future.

SPECIFICATION, DESIGN, AND PROOFS OF CORRECTNESS

The Rationality Square

The ideas in this section come from Ref. 2 and make explicit what is known intuitively by designers of systems that use proofs. The first thing to realize is that if we want quality of a product, then we need to specify what we want as its behavior. Both the product and its (desired) behavior are in "reality", whereas the specification is written in some precise language. Then we make a design with the intention to realize it as the intended product. Also the design is a formal (mathematical) object. If one can prove that the designed object satisfies the formal specification, then it is expected that the realization has the desired behavior

[1] It took Dr. Nicely several months to realize that the inconsistency he noted in some of his output was not due to his algorithms, but caused by the (microcode on the) chip. See Ref. 1 for a description of the mathematics behind the error.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

$$\begin{tikzcd}
\text{Design} \arrow[r, dash, "\text{proof}"] \arrow[d, "\text{realization}"'] & \text{Specification} \\
\text{Product} \arrow[r, dash, "\text{warranty}"'] & \text{Behavior} \arrow[u, "\text{requirement}"']
\end{tikzcd}$$

Figure 1. Wupper's rationality square.

(see Fig. 1). For this it is necessary that the informal (desired) behavior and the specification are close to each other and can be inspected in a clearly understandable way. The same holds for the design and realization. Then the role of proofs is in its place: They do not apply to an object and desired behavior in reality but to a mathematical descriptions of these.

In this setup, the specification language should be close enough to the informal specification of the desired behavior. Similarly, the technology of realization should also be reliable. The latter again may depend on tools that are constructed component wise and realize some design (e.g., silicon compilers that take as input the design of a chip and have as output the instructions to realize them). Hence, the rationality square may have to be used in an earlier phase.

This raises, however, two questions. Proofs should be based on some axioms. Which ones? Moreover, how do we know that provability of a formal (mathematical) property implies that we get what we want? The answers to these questions come together. The proofs are based on some axioms that hold for the objects of which the product is composed. Based on the empirical facts that the axioms hold, the quality of the realized product will follow.

Products as Chinese Boxes of Components

Now we need to enter some of the details of how the languages for the design and specification of the products should look. The intuitive idea is that a complex product consists of components $b_1, \ldots, b_k$ put together in a specific way yielding $F^{(k)}(b_1, \ldots, b_k)$. The superscript "$(k)$" indicates the number of arguments that F needs. The components are constructed in a similar way, until one hits the basic components $O_0, O_1, \ldots$ that no longer are composed. Think of a playing music installation B. It consists of a CD, CD-player, amplifier, boxes, wires and an electric outlet, all put together in the right way. So

$$B = F^{(6)}(\text{CD}, \text{CD-player, amplifyer, boxes, wires, outlet}),$$

where $F^{(6)}$ is the action that makes the right connections. Similarly the amplifier and other components can be described as a composition of their parts. A convenient way to depict this idea in general is the so-called *Chinese box* (see Fig. 2). This is a box with a lid. After opening the lid one finds a (finite) set of "neatly arranged" boxes that either are open and contain a basic object or are again other Chinese boxes (with lid). Eventually one will find something in a decreasing chain of boxes. This corresponds to the component-wise construction of anything, in particular of hardware, but also of software[2]. It is easy to construct a grammar for expressions denoting these Chinese boxes. The basic objects are denoted by $o_0, o_1, \ldots$. Then there are "constructors" that turn expressions into new expressions. Each constructor has an "arity" that indicates how many arguments it has. There may be unary, binary, ternary, and so on constructors. Such constructors are denoted by

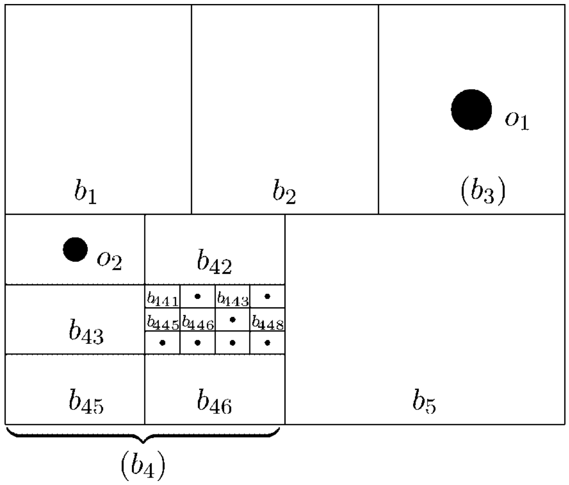

Figure 2. Partially opened Chinese box.

$$f_0^{(k)}, f_1^{(k)}, \ldots,$$

where k denotes the arity of the constructor. If $b_1, \ldots, b_k$ are expressions and $f_i^{(k)}$ is a constructor of arity k, then

$$f_i^{(k)}(b_1, \ldots, b_k)$$

is an expression. A precise grammar for such expressions is as follows.

Definition

1. Consider the following alphabet:

$$\sum = \{o_i | i \in \mathbb{N}\} \cup \{f_i^k | i, k \in \mathbb{N}\} \cup \{,, (,)\}.$$

2. Expressions $\mathcal{E}$ form the smallest set of words over Σ satisfying

$$o_i \in \mathcal{E};$$

$$b_1, \ldots, b_k \in \mathcal{E} \Rightarrow f_i^{(k)} \ (b_1, \ldots, b_k) \in \mathcal{E}.$$

An example of a fully specified expression is

$$f_1^{(2)}(o_0, f_3^1(o_1, o_2, o_0)).$$

[2] In order that the sketched design method works well for software, it is preferable to have *declarative* software, i.e., in the *functional* or *logic* programming style, in particular without side effects.

The partially opened Chinese box in Fig. 2 can be denoted by

$$f_1^{(5)}(b_1, b_2, o_1, b_4, b_5),$$

where

$$\begin{aligned} b_4 &= f_2^{(6)}(o_2, b_{4,2}, b_{4,3}, b_{4,4}, b_{4,5}, b_{4,6}),\\ b_{4,4} &= f_4^{(12)}(b_{4,4,1}, o_3, b_{4,4,3}, o_4, b_{4,3,5}, b_{4,4,6}, o_5,\\ &\quad b_{4,4,8}, o_6, o_7, o_8, o_9), \end{aligned}$$

and the other b_k still have to be specified.

Definition. A *design* is an expression $b \in \mathcal{E}$.

Specification and Correctness of Design

Following the rationality square, one now can explain the role of mathematical proofs in industrial design.

Some mathematical language is needed to state in a precise way the requirements of the products. We suppose that we have such a specification language $\mathcal{L}$, in which the expressions in $\mathcal{E}$ are terms. We will not enter into the details of such a language, but we will mention that for IT products, it often is convenient to be able to express relationships between the states before and after the execution of a command or to express temporal relationships. Temporal statements include "eventually the machine halts" or "there will be always a later moment in which the system receives input". See Refs. 3–6 for possible specification languages, notably for reactive systems, and Ref. 7 for a general introduction to the syntax and semantics of logical languages used in computer science.

Definition. A *specification* is a unary formula[3] $S(\cdot)$ in $\mathcal{L}$.

Suppose we have the specification S and a candidate design b as given. The task is to prove in a mathematical way $S(b)$, i.e., that S holds of b. We did not yet discuss any axioms, or a way to warrant that the proved property is relevant. For this we need the following.

Definition. A *valid interpretation* for $\mathcal{L}$ consists of the following.

1. For basic component expressions o, there is an interpretation O in the "reality" of products.
2. For constructors $f^{(k)}$, there is a way to put together k products $p_1, \ldots, p_k$ to form $F^{(k)}(p_1, \ldots, p_k)$.
3. By (1) and (2), all designs have a realization. For example, the design $f_1^{(2)}(o_0, f_3^{(1)}(o_1, o_2, o_0))$ is interpreted as $F_1^{(2)}(O_0, F_3^{(1)}(O_1, O_2, O_0))$.
4. (4) There are axioms of the form

$$P(c)$$
$$\forall x_1 \ldots x_k [Q(x_1, \ldots, x_k) \Rightarrow R(f^{(k)}(x_1, \ldots, x_k))].$$

   Here P, Q, and R are formulas (formal statements) about designs: P and R about one design and Q about k designs.
5. The formulas of $\mathcal{L}$ have a physical interpretation.
6. By the laws of physics, it is known that the interpretation given by (5) of the axioms holds for the interpretation described in the basic components and constructors. The soundness of logic then implies that statements proved from the axioms will also hold after interpretation.

This all may sound a bit complex, but the idea is simple and can be found in any book on predicate logic and its semantics (see Refs. 7 and 8). Proving starts from the axioms using logical steps; validity of the axioms and soundness of logic implies that the proved formulas are also valid.

The industrial task of constructing a product with a desired behavior can be fulfilled as follows.

Design Method (I)

1. *Find a language $\mathcal{L}$ with a valid interpretation.*
2. *Formulate a specification S, such that the desired behavior becomes the interpretation of S.*
3. *Construct an expression b, intended to solve the task.*
4. *Prove S(b) from the axioms of the interpretation mentioned in (1).*
5. *The realization of b is the required product.*

Of course the last step of realizing designs may be nontrivial. For example, transforming a chip design to an actual chip is an industry by itself. But that is not the concern now. Moreover, such a realization process can be performed by a tool that is the outcome of a similar specification-design-proof procedure.

The needed proofs have to be given from the axioms in the interpretation. Design method I builds up products from "scratch". In order not to reinvent the wheel all the time, one can base new products on previously designed ones.

Design Method (II). *Suppose one wants to construct b satisfying S.*

1. *Find subspecifications $S_1, \ldots, S_k$ and a constructor $f^{(k)}$ such that*

$$S_1(x_i) \;\&\; \ldots \;\&\; S_k(x_k) \Rightarrow S(f^{(k)}(x_1, \ldots, x_k)).$$

2. *Find (on-the-shelf) designs $b_1, \ldots, b_k$ such that for $1 \le i \le k$, one has*

$$S_i(b_i).$$

3. Then the design $b = f^{(k)}(b_1, \ldots, b_k)$ solves the task.

Again this is done in a context of a language $\mathcal{L}$ with a valid interpretation and the proofs are from the axioms in the interpretation.

[3] Better: A formula $S = S(x) = S(\cdot)$ with one free variable x in S.

After having explained proofs of correctness, the correctness of proofs becomes an issue. In an actual nontrivial industrial design, a software system controlling metro-trains in Paris without a driver, one needed to prove about 25,000 propositions in order to get reliability. These proofs were provided by a theorem prover. Derivation rules were added to enhance the proving power of the system. It turned out that if no care was taken, 2% to 5% of these added derivation rules were flawed and led to incorrect statements; see Ref. 9. The next section deals with the problem of getting proofs right.

CORRECTNESS OF PROOFS

Methodology

Both in computer science and in mathematics proofs can become large. In computer science, this is the case because the proofs that products satisfy certain specifications, as explained earlier, may depend on a large number of cases that need to be analyzed. In mathematics, large proofs occur as well, in this case because of the depth of the subject. The example of the Four Color Theorem in which billions of cases need to be checked is well known. Then there is the proof of the classification theorem for simple finite groups needing thousands of pages (in the usual style of informal rigor).

That there are long proofs of short statements is not an accident, but a consequence of a famous undecidability result.

Theorem (Turing). *Provability in predicate logic is undecidable.*

Proof. See, for example, Ref. 10. ■

Corollary. *For predicate logic, there is a number n and a theorem of length n, with the smallest proof of length at least $n^{n!}$.*

Proof. Suppose that for every n theorems of length at least n, a proof of length $< n^{n!}$ exists. Then checking all possible proofs of such length provides a decision method for theoremhood, contradicting the undecidablity result. ■

Of course this does not imply that there are *interesting* theorems with essentially long proofs.

The question now arises, how one can verify long proofs and large numbers of shorter ones? This question is both of importance for pure mathematics and for the industrial applications mentioned before.

The answer is that the state of the foundations of mathematics is such that proofs can be written in full detail, making it possible for a computer to check their correctness. Currently, it still requires considerable effort to make such "formalizations" of proofs, but there is good hope that in the future this will become easier. Anyway, industrial design, as explained earlier, already has proved the viability and value of formal proofs. For example, the Itanium, a successor of the Pentium chip, has a provably correct arithmetical unit; see Ref. 11.

Still one may wonder how one can assure the correctness of mathematical proofs via machine verification, if such proofs need to assure the correctness of machines. It seems that there is here a vicious circle of the chicken-and-the-egg type. The principal founder of machine verification of formalized proofs is the Dutch mathematician N. G. de Bruijn[4]; see Ref. 13. He emphasized the following criterion for reliable automated proof-checkers: Their programs must be small, so small that a human can (easily) verify the code by hand. In the next subsection, we will explain why it is possible to satisfy this so-called de Bruijn criterion.

Foundations of Mathematics

The reason that fully formalized proofs are possible is that for all mathematical activities, there is a solid foundation that has been laid in a precise formal system. The reason that automated proof-checkers exist that satisfy the de Bruijn criterion is that these formal systems are simple enough, allowing a logician to write them down from memory in a couple of pages.

Mathematics is created by three mental activities: structuring, computing, and reasoning. It is an art and craftsmanship "with a power, precision and certainty, that is unequalled elsewhere in life[5]." The three activities, respectively, provide definitions and structures, algorithms and computations, and proofs and theorems. These activities are taken as a subject of study by themselves, yielding ontology (consisting either of set, type, or category theory), computability theory, and logic.

Activity	Tools	Results	Meta study
Structuring	Axioms Definitions	Structures	Ontology
Computing	Algorithms	Answers	Computability[6]
Reasoning	Proofs	Theorems	Logic

Figure 3. Mathematical activity: tools, results, and meta study.

During the history of mathematics these activities enjoyed attention in different degrees. Mathematics started with the structures of the numbers and planar geometry. Babylonian–Chinese–Egyptian mathematics, was mainly occupied with computing. In ancient Greek mathematics, reasoning was introduced. These two activities came together in the work of Archimedes, al-Kwarizmi, and Newton. For a long time only occasional extensions of the number systems was all that was done as structuring activity. The art of defining more and more structures started in the ninteenth century with the introduction of groups by Galois and non-Euclidean spaces by Lobachevsky and Bolyai. Then mathematics flourished as never before.

[4] McCarthy described machine proof-checking some years earlier (see, Ref. 12), but did not come up with a formal system that had a sufficiently powerful and convenient implementation.

[5] From: *The man without qualities*, R. Musil, Rohwolt.

[6] Formerly called "Recursion Theory".

Logic. The quest for finding a foundation for the three activities started with Aristotle. This search for "foundation" does not imply that one was uncertain how to prove theorems. Plato had already emphasized that any human being of normal intelligence had the capacity to reason that was required for mathematics. What Aristotle wanted was a survey and an understanding of that capacity. He started the quest for logic. At the same time Aristotle introduced the "synthetic way" of introducing new structures: the axiomatic method. Mathematics consists of concepts and of valid statements. Concepts can be defined from other concepts. Valid statements can be proved from other such statements. To prevent an infinite regress, one had to start somewhere. For concepts one starts with the primitive notions and for valid statements with the axioms. Not long after this description, Euclid described geometry using the axiomatic method in a way that was only improved by Hilbert, more than 2000 years later. Also Hilbert gave the right view on the axiomatic method: The axioms form an implicit definition of the primitive notions.

Frege completed the quest of Aristotle by giving a precise description of predicate logic. Gödel proved that his system was complete, i.e., sufficiently strong to derive all valid statements within a given axiomatic system. Brouwer and Heyting refined predicate logic into the so-called *intuitionistic* version. In their system, one can make a distinction between a weak existence ("there exists a solution, but it is not clear how to find it") and a constructive one ("there exists a solution and from the proof of this fact one can construct it") (see Ref. 14).

Ontology. An early contribution to ontology came from Descartes, who introduced what is now called Cartesian products (pairs or more generally tuples of entities), thereby relating geometrical structures to arithmetical (in the sense of algebraic) ones. When in the nineteenth century, there was a need for systematic ontology, Cantor introduced set theory in which sets are the fundamental building-blocks of mathematics. His system turned out to be inconsistent, but Zermelo and Fraenkel removed the inconsistency and improved the theory so that it could act as an ontological foundation for large parts of mathematics, (see Ref 15).

Computability. As soon as the set of consequences of an axiom system had become a precise mathematical object, results about this collection started to appear. From the work of Gödel, it followed that the axioms of arithmetic are essentially incomplete (for any consistent extension of arithmetic, there is an independent statement A that is neither provable nor refutable). An important part of the reasoning of Gödel was that the notion "p is a proof of A" is after coding a computable relation. Turing showed that predicate logic is undecidable (it cannot be predicted by machine whether a given statement can be derived or not). To prove undecidability results, the notion of computation needed to be formalized. To this end, Church came with a system of lambda-calculus (see Ref. 16), later leading to the notion of functional programming with languages such as Lisp, ML, and Haskell. Turing came with the notion of the Turing machine, later leading to imperative programming with languages such as Fortran and C and showed that it gave the same notion of computability as Church's. If we assume the so-called Church–Turing thesis that humans and machines can compute the same class of mathematical functions, something that most logicians and computer scientists are willing to do, then it follows that provability in predicate logic is also undecidable by humans.

Mechanical Proof Verification

As soon as logic was fully described, one started to formalize mathematics. In this endeavor, Frege was unfortunate enough to base mathematics on the inconsistent version of Cantorian set theory. Then Russell and Whitehead came with an alternative ontology, type theory, and started to formalize very elementary parts of mathematics. In type theory, that currently exists in various forms, functions are the basic elements of mathematics and the types form a way to classify these. The formal development of mathematics, initiated by Russell and Whitehead, lay at the basis of the theoretical results of Gödel and Turing. On the other hand, for practical applications, the formal proofs become so elaborate that it is almost undoable for a human to produce them, let alone to check that they are correct.

It was realized by J. McCarthy and independently by N. G. de Bruijn that this verification should not be done by humans but by machines. The formal systems describing logic, ontology, and computability have an amazingly small number of axioms and rules. This makes it possible to construct relatively small mathematical assistants. These computer systems help the mathematician to verify whether the definitions and proofs provided by the human are well founded and correct.

Based on an extended form of type theory, de Bruijn introduced the system AUTOMATH (see Ref. 17), in which this idea was first realized, although somewhat painfully, because of the level of detail in which the proofs needed to be presented. Nevertheless, proof-checking by mathematical assistants based on type theory is feasible and promising. For some modern versions of type theory and assistants based on these, see Refs. 17–21.

Soon after the introduction of AUTOMATH, other mathematical assistants were developed, based on different foundational systems. There is the system MIZAR based on set theory; the system HOL(-light) based on higher order logic; and ACL_2 based on the computational model "primitive recursive arithmetic." See Ref. 22 for an introduction and references and Ref. 23 for resulting differences of views in the philosophy of mathematics. To obtain a feel of the different styles of formalization, see Ref. 24.

In Ref. 25, an impressive full development of the Four Color Theorem is described. Tom Hales of the University of Pittsburgh, assisted by a group of computer scientists, specializing in formalized proof-verification, is well on his way to verifying his proof of the Kepler conjecture (26); see Ref. 27. The *Annals of Mathematics* published that proof and considered adding—but finally did not do so– a proviso, that the referees became exhausted (after 5 years) from checking all of the details by hand; therefore, the full correctness depends on a (perhaps not so reliable) computer computation. If Hales and his group succeed in formalizing and verifying the entire proof, then that will be of a reliability higher than most mathematical proofs, one third of which is estimated to contain real errors, not just typos.[7]

The possibility of formalizing mathematics is not in contradiction with Gödel's theorem, which only states the limitations of the axiomatic method, informal or formal alike. The proof of Gödel's incompleteness theorem does in fact heavily rely on the fact that proof-checking is decidable and uses this by reflecting over the notion of provability (the Gödel sentence states: "This sentence is not provable").

One particular technology to verify that statements are valid is the use of model-checking. In IT applications the request "statement A can be proved from assumptions Γ (the 'situation')" often boils down to "A is valid in a model $\mathcal{A} = \mathcal{A}_\Gamma$ depending on Γ". (In logical notation

$$\Gamma \vdash A \Leftrightarrow \mathcal{A}_\Gamma \models A.$$

This is so because of the completeness theorem of logic and because of the fact that the IT situation is related to models of digital hardware that are finite by its nature.) Now, despite the usual huge size of the model, using some cleverness the validity in several models in some industrially relevant cases is decidable within a feasible ammount of time. One of these methods uses the so-called *binary decision diagrams* (BDDs). Another ingredient is that universal properties are checked via some rewriting rules, like $(x+1)(x-1) = x^2 - 1$.

For an introduction to model-checkers, see Ref. 20. For successful applications, see Ref. 29. The method of model-checking is often somewhat ad hoc, but nevertheless important. Using "automated abstraction" that works in many cases (see Refs. 30 and 31), the method becomes more streamlined.

SCALING-UP THROUGH REFLECTION

As to the question of whether fully formalized proofs are practically possible, the opinions have been divided. Indeed, it seems too much work to work out intuitive steps in full detail. Because of industrial pressure, however, full developments have been given for correctness of hardware and frequently used protocols. Formalizations of substantial parts of mathematics have been lagging behind.

There is a method that helps in tackling larger proofs. Suppose we want to prove statement A. Then it helps if we can write $A \leftrightarrow B(f(t))$, where t belongs to some collection X of objects, and we also can see that the truth of this is independent of t; i.e., one has a proof $\forall x \in X.B(f(x))$. Then $B(f(t))$, hence A.

An easy example of this was conveyed to me by A. Mostowski in 1968. Consider the following formula as proof obligation in propositional logic:

$$A = p \leftrightarrow (p \leftrightarrow (p \leftrightarrow (p \leftrightarrow (p \leftrightarrow (p \leftrightarrow (p \leftrightarrow (p \leftrightarrow (p \leftrightarrow (p \leftrightarrow (p \leftrightarrow)))))))))).$$

Then $A \leftrightarrow B(12)$, with $B(1) = p, B(n+1) = (p \leftrightarrow B(n))$. By induction on n one can show that for all natural numbers $n \geq 1$, one has $B(2 \times n)$. Therefore, B(12) and hence A, because $2 \times 6 = 12$. A direct proof from the axioms of propositonal logic would be long. Much more sophisticated examples exist, but this is the essence of the method of reflection. It needs some form of computational reasoning inside proofs. Therefore, the modern mathematical assistants contain a model of computation for which equalities like $2 \times 6 = 12$ and much more complex ones become provable. There are two ways to do this. One possibility is that there is a deduction rule of the form

$$\frac{A(s)}{A(t)}\ s \twoheadrightarrow_R t.$$

This so-called *Poincaré Principle* should be interpreted as follows: From the assumption $A(s)$ and the side condition that s computationally reduces in several steps to t according to the rewrite system R, it follows that $A(t)$. The alternative is that the transition from $A(s)$ to $A(t)$ is only allowed if $s = t$ has been proved first. These two ways of dealing with proving computational statements can be compared with the styles of, respectively, functional and logical programming. In the first style, one obtains proofs that can be recorded as *proof-objects*. In the second style, these full proofs become too large to record as one object, because computations may take giga steps. Nevertheless the proof exists, but appearing line by line over time, and one speaks about an *ephemeral* proof-object.

In the technology of proof-verification, general statements are about mathematical objects *and* algorithms, proofs show the correctness of statements *and* computations, and computations are dealing with objects *and* proofs.

RESULTS

The state-of-the-art of computer-verified proofs is as follows. To formalize one page of informal mathematics, one needs four pages in a fully formalized style and it takes about five working days to produce these four pages (see Ref. 22). It is expected that both numbers will go down. There have been formalized several nontrivial statements, like the fundamental theorem of algebra (also in a constructive fashion; it states that every non-constant polynomial over the complex numbers has a root), the prime number theorem (giving an asymptotic estimation of the number of primes below a given number), and the Jordan curve theorem (every closed curve divides the plane into two regions that cannot be reached without crossing this curve; on the torus surface, this is not true). One of the great success stories is the full formalization of the Four Color Theorem by Gonthier (see Ref. 25). The original proof of

[7] It is interesting to note that, although informal mathematics often contains bugs, the intuition of mathematicians is strong enough that most of these bugs usually can be repaired.

this result was not completely trustable for its correctness, as a large number of cases needed to be examined by computer. Gonthier's proof still needs a computer-aided computation, but all steps have been formally verified by an assistant satisfying the de Bruijn principle.

REGRESSION ANALYSIS

In statistics, regression is the study of *dependence*. The goal of regression is to study how the distribution of a response variable changes as values of one or more predictors are changed. For example, regression can be used to study changes in automobile stopping distance as speed is varied. In another example, the response could be the total profitability of a product as characteristics of it like selling price, advertising budget, placement in stores, and so on, are varied. Key uses for regression methods include prediction of future values and assessing dependence of one variable on another.

The study of conditional distributions dates at least to the beginning of the nineteenth century and the work of A. Legendre and C. F. Gauss. The use of the term *regression* is somewhat newer, dating to the work of F. Galton at the end of the nineteenth century; see Ref. 1 for more history.

GENERAL SETUP

For the general univariate regression problem, we use the symbol Y for a response variable, which is sometimes called the dependent variable. The response can be a continuous variable like a distance or a profit, or it could be discrete, like success or failure, or some other categorical outcome. The predictors, also called independent variables, carriers, or features, can also be continuous or categorical; in the latter case they are often called *factors* or *class variables*. For now, we assume only one predictor and use the symbol X for it, but we will generalize to many predictors shortly. The goal is to learn about the conditional distribution of Y given that X has a particular value x, written symbolically as $F(Y|X = x)$.

For example, Fig. 1 displays the heights of $n = 1375$ mother–daughter pairs, with $X =$ mother's height on the horizontal axis and $Y =$ daughter's height on the vertical axis, in inches. The conditional distributions $F(Y|X = x)$ correspond to the vertical spread of points in strips in this plot. In Fig. 1, three of these conditional distributions are highlighted, corresponding to mother's heights of 58, 61, and 65 inches. The conditional distributions almost certainly differ in mean, with shorter mothers on average having shorter daughters than do taller mothers, but there is substantial overlap between the distributions.

Most regression problems center on the study of the *mean function*, to learn about the average value of Y given $X = x$. We write the most general mean function as $\mu(Y|X = x)$, the mean of Y when $X = x$. The mean function for the heights data would be a smooth curve, with $\mu(Y|X = x)$ increasing as x increases. Other characteristics of the conditional distributions, such as conditional variances $\mathrm{var}(Y|X = x)$ may well be constant across the range of values for mother's height, but in general the variance or indeed any other moment or percentile function can depend on X.

Most regression models are *parametric*, so the mean function $\mu(Y|X = x)$ depends only on a few unknown parameters collected into a vector β. We write $\mu(Y|X = x) = g(x, \beta)$, where g is completely known apart from the unknown value of β.

In the heights data described above, data are generated obtaining a sample of units, here mother–daughter pairs, and measuring the values of height for each of the pairs. Study of the conditional distribution of daughter's height given the mother's height makes more sense than the study of the mother's height given the daughter's height because the mother precedes the daughter, but in principle either conditional distribution could be studied via regression. In other problems, the values of the predictor or the predictors may be set by an experimenter. For example, in a laboratory setting, samples of homogeneous material could be assigned to get different levels of stress, and then a response variable is measured with the goal of determining the effect of stress on the outcome. This latter scenario will usually include random assignment of units to levels of predictors and can lead to more meaningful inferences. Considerations for allocating levels of treatments to experimental units are part of the *design of experiments*; see Ref. 3. Both cases of predictors determined by the experimenter and predictors measured on a sample of units can often be analyzed using regression analysis.

SIMPLE LINEAR REGRESSION

Model

Linear regression is the most familiar and widely used method for regression analysis; see, for example, Ref. 4 for book-length treatment of simple and multiple regression. This method concentrates almost exclusively on the mean function. Data consist of n independent pairs $(x_1, y_1), \ldots, (x_n, y_n)$ as with the heights data in Fig. 1. The independence assumption might be violated if, for example, a mother were included several times in the data, each with a different daughter, or if the mothers formed several groups of sisters.

The simple linear regression model requires the following mean and variance functions:

$$\begin{aligned} \mu(Y|X = x) = g(x, \boldsymbol{\beta}) &= \beta_0 + \beta_1 x \\ \mathrm{Var}(Y|X = x) &= \sigma^2 \end{aligned} \tag{1}$$

so for this model $\beta = (\beta_0, \beta_1)'$. β_1 is *slope*, which is the expected change in Y when X is increased by one unit. The intercept β_0 is the mean value of Y when $X = 0$, although that interpretation may not make sense if X cannot equal zero. The line shown on Fig. 1 is an estimate of the simple regression mean function, computed using least squares, to be described below. For the heights data, the simple regression mean function seems plausible, as it matches the data in the graph.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

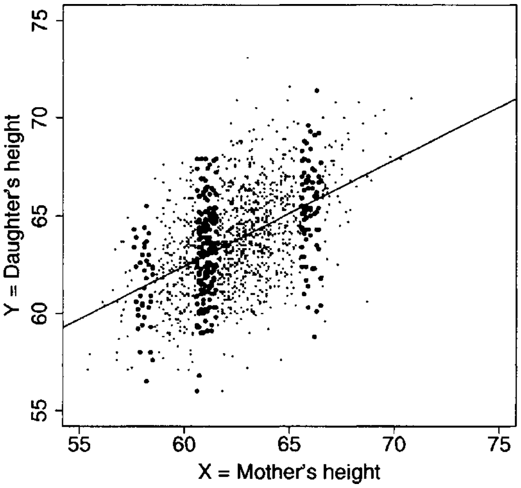

Figure 1. Heights of a sample of $n = 1375$ mothers and daughters as reported by Ref. 2. The line shown on the plot is the *ordinary least-squares* regression line, assuming a simple linear regression model. The darker points display all pairs with mother's height that would round to 58, 61, or 65 inches.

The simple regression model also assumes a constant variance function, with $\sigma^2 > 0$ generally unknown. This assumption is not a prerequisite for all regression models, but it is a feature of the simple regression model.

Estimation

We can obtain estimates of the unknown parameters, and thus of the mean and the variance functions, without any further assumptions. The most common method of estimation is via *least squares*, which chooses the estimates $\mathbf{b} = (b_0, b_1)'$ of $\beta = (\beta_0, \beta_1)'$ via a minimization problem:

$$b = \arg\min_{b^*} \sum_{i=1}^{n} \{y_i - g(x, b^*)\}^2 \qquad (2)$$

A generic notation is used in Equation (2) because this same objective function can be used for other parametric mean functions.

The solution to this minimization problem is easily found by differentiating Equation (2) with respect to each element of b* and setting the resulting equations to zero, and solving. If we write m_x and m_y as the sample means of the x_i and the y_i respectively, SD_x and SD_y as the sample standard deviations, and r_{xy} as the sample correlation, then

$$b_1 = r_{xy}\frac{\mathrm{SD}_y}{\mathrm{SD}_x} \qquad b_0 = m_y - b_1 m_x \qquad (3)$$

These are *linear* estimators because both m_y and r_{xy} are linear combinations of the y_i. They are also unbiased, $\mathrm{E}(b_0) = \beta_0$ and $\mathrm{E}(b_1) = \beta_1$. According to the Gauss-Markov theorem, the least-squares estimates have minimum variance among all possible linear unbiased estimates. Details are given in Refs. 4 and 5, the latter reference at a higher mathematical level.

As σ^2 is the mean-squared difference between each data point and its mean, it should be no surprise that the estimate of σ^2 is similar to the average of the squared fitting errors. Let d be the *degrees of freedom* for error, which in linear regression is the number of observations minus the number of parameters in the mean function, or $n - 2$ in simple regression. Then

$$s^2 = \frac{1}{d}\sum_{i=1}^{n}(y - g(x_i, \mathbf{b}))^2 \qquad (4)$$

The quantity $\sum(y_i - g(x_i, \mathbf{b}))^2$ is called the *residual sum of squares*. We divide by d rather than the more intuitive sample size n because this results in an unbiased estimate, $\mathrm{E}(s^2) = \sigma^2$. Many computing formulas for the residuals sum of squares depend only on summary statistics. One that is particularly revealing is

$$\sum_{i=1}^{n}(y - g(x_i, \mathbf{b}))^2 = (n-1)\mathrm{SD}_y^2(1 - R^2) \qquad (5)$$

In both simple and multiple linear regression, the quantity R^2 is the square of the *sample correlation between the observed response, the y_i, and the fitted values $g(x_i, \mathbf{b})$*. In simple regression $R^2 = r_{xy}^2$.

Distribution of Estimates

The estimates (b_0, b_1) are random variables with variances

$$\begin{aligned} \mathrm{Var}(b_0) &= \sigma^2\left(\frac{1}{n} + \frac{m_x^2}{(n-1)\mathrm{SD}_x^2}\right), \\ \mathrm{Var}(b_1) &= \sigma^2\frac{1}{(n-1)\mathrm{SD}_x^2} \end{aligned} \qquad (6)$$

The estimates are correlated, with covariance $\mathrm{Cov}(b_0, b_1) = -\sigma^2 m_x/\{(n-1)\mathrm{SD}_x^2\}$. The estimates are uncorrelated if the predictor is rescaled to have sample mean $m_x = 0$; that is, replace X by a new predictor $X^* = X - m_x$. This will also change the meaning of the intercept parameter from the value of $\mathrm{E}(Y|X = 0)$ to the value of $\mathrm{E}(Y|X = m_x)$. Estimates of the variances and covariances are obtained by substituting s^2 for σ^2. For example, the square root of the estimated variance of b_1 is called its *standard error*, and is given by

$$\mathrm{se}(b_1) = s\frac{1}{\{(n-1)\mathrm{SD}_x^2\}^{1/2}} \qquad (7)$$

Tests and confidence statements concerning the parameters require the *sampling distribution* of the statistic (b_0, b_1). This information can come about in three ways. First, we might assume normality for the conditional distributions, $F(Y|X = x) = \mathrm{N}(g(x, \beta), \sigma^2)$. Since the least squares estimates are linear functions of the y_i, this leads to normal sampling distributions for b_0 and b_1. Alternatively, by the central limit theorem b_0 and b_1 will be approximately normal regardless of the true F, assuming only mild regularity conditions and a large enough sample. A third approach uses the data itself to estimate the sampling distribution of b, and thereby get approximate inference. This last method is generally called the *bootstrap*, and is discussed briefly in Ref. 4 and more completely in Ref. 6.

Regardless of distributional assumptions, the estimate s^2 has a distribution that is independent of $\mathbf{b}$. If we add the normality assumption, then $ds^2 \sim \sigma^2\chi^2(d)$, a chi-squared distribution with d df. The ratio $(b_1 - \beta_1)/\text{se}(b_1)$ has a t-distribution with d df, written $t(d)$. Most tests in linear regression models under normality or in large samples are based either on t-distributions or on the related F-distributions.

Suppose we write $t_\gamma(d)$ to be the quantile of the t-distribution with d df that cuts off probability γ in its upper tail. Based on normal theory, either a normality assumption or large samples, a test of $\beta_1 = \beta_1^*$ versus the alternative $\beta_1 \neq \beta_1^*$ is rejected at level α if $t = (b_1 - \beta_1^*)/\text{se}(b_1)$ exceeds $t_{1-\alpha/2}(d)$, where d is the number of df used to estimate σ^2. Similarly, a $(1-\alpha) \times 100\%$ confidence interval for β_1 is given by the set

$$\{\beta_1 \in (b_1 - t_{1-\alpha/2}(d)\text{se}(b_1), b_1 + t_{1-\alpha/2}(d)\text{se}(b_1))\}$$

Computer Output from Heights Data

Typical computer output from a packaged regression program is shown in Table 1 for the heights data. The usual output includes the estimates (3) and their standard errors (7). The fitted mean function is $g(x, \text{b}) = 29.9174 + 0.5417x$; this function is the straight line drawn on Fig. 1. The column marked "t-value" displays the ratio of each estimate to its standard error, which is an appropriate statistic for testing the hypotheses that each corresponding coefficient is equal to zero against either a one-tailed or two-tailed alternative. The column marked "Pr(> |t|)" is the significance level of this test assuming a two-sided alternative, based on the $t(n-2)$ distribution. In this example the p-values are zero to four decimals, and strong evidence is present that the intercept is nonzero given the slope, and that the slope is nonzero given the intercept. The estimated slope of about 0.54 suggests that each inch increase on mother's height corresponds to an increase in daughter's height of only about 0.54 inches, which indicates that tall mothers have tall daughters but not as tall as themselves. This could have been anticipated from (3): Assuming that heights of daughters and mothers are equally variable, we will have $\text{SD}_x \approx \text{SD}_y$ and so $b_1 \approx r_{xy}$, the correlation. As the scale-free correlation coefficient is always in $[-1, 1]$, the slope must also be in the range. This observation of *regression toward the mean* is the origin of the term *regression* for the study of conditional distributions.

Also included in Table 1 are the estimate s of σ, the degrees of freedom associated with s^2, and $R^2 = r_{xy}^2$. This latter value is usually interpreted as a summary of the comparison of the fit of model (1) with the fit of the "null" mean function

$$\mu_0(Y|X = x) = \beta_0 \tag{8}$$

Mean function (8) asserts that the mean of $Y|X$ is the same for all values of X. Under this mean function the least squares estimate of β_0 is just the sample mean m_y and the residual sum of squares is $(n-1)\text{SD}_y^2$. Under mean function (1), the simple linear regression mean function, the residual sum of squares is given by Equation (5). The proportion of variability unexplained by regression on X is just the ratio of these two residual sums of squares:

$$\begin{aligned}\text{Unexplained variability} &= \frac{(n-1)\text{SD}_y^2(1-R^2)}{(n-1)\text{SD}_y^2} \\ &= 1 - R^2\end{aligned}$$

and so R^2 is the proportion of variability in Y that is explained by the linear regression on X. This same interpretation also applies to multiple linear regression.

An important use of regression is the prediction of future values. Consider predicting the height of a daughter whose mother's height is $X = 61$. Whether data collected on English mother–daughter pairs over 100 years ago is relevant to contemporary mother–daughter pairs is questionable, but if it were, the point prediction would be the estimated mean, $g(61, \text{b}) = 29.9174 + 0.5417 \times 61 \approx 63$ inches. From Fig. 1, even if we knew the mean function exactly, we would not expect the prediction to be prefect because mothers of height 61 inches have daughters of a variety of heights. We therefore expect predictions to have two sources of error: a prediction error of magnitude σ due to the new observation, and an error from estimating the mean function,

$$\text{Var}(\text{Prediction}|X = x^*) = \sigma^2 + \text{Var}(g(x, \text{b}))$$

For simple regression $\text{Var}(g(x, \text{b})) = \text{Var}(b_0 + b_1 x) = \text{Var}(b_0) + x^2\text{Var}(b_1) + x\text{Cov}(b_0, b_1)$. Simplifying and replacing σ^2 by s^2 and taking square roots, we get

$$\text{se}(\text{Prediction}|X = x^*) = s\left(1 + \frac{1}{n} + \frac{(x^* - m_x)^2}{(n-1)\text{SD}_x^2}\right)^{1/2}$$

where the sample size n, sample mean m_x, and sample standard deviation SD_x are all from the data used to estimate β. For the heights data, this standard error at $x^* = 61$ is about 2.3 inches. A 95% prediction interval, based on the $t(n-2)$ distribution, is from 58.5 to 67.4 inches.

Table 1. Typical simple regression computer output, for the heights data

	Estimate	Std. Error	t-value	Pr(> |t|)
b_0	29.9174	1.6225	18.44	0.0000
b_1	0.5417	0.0260	20.87	0.0000

$s = 2.27$, 1373 df, $R^2 = 0.241$.

MULTIPLE LINEAR REGRESSION

The *multiple linear regression model* is an elaboration of the simple linear regression model. We now have a predictor $\mathbf{X}$ with $p \geq 1$ components, $\mathbf{X} = (1, X_1, \ldots, X_p)$. Also, let $\mathbf{x} = (1, x_1, \ldots, x_p)$ be a vector of possible observed values for **X**; the "1" is appended to the left of these quantities to allow for an intercept. Then the mean function in Equation (1) is replaced by

$$\begin{aligned}\mu(Y|\mathbf{X}=\mathbf{x}) &= g(\mathbf{x},\boldsymbol{\beta})\\ &= \beta_0+\beta_1x_1+\cdots+\beta_px_p\\ &= \boldsymbol{\beta}'\mathbf{x}\\ \mathrm{Var}(Y|\mathbf{X}=\mathbf{x}) &= \sigma^2\end{aligned} \tag{9}$$

The parameter vector $\boldsymbol{\beta}=(\beta_0,\ldots,\beta_p)'$ now has $p+1$ components. Equation (9) describes a plane in $p+1$-dimensional space. Each β_j for $j>0$ is called a *partial slope*, and gives the expected change in Y when X_j is increased by one unit, *assuming all other X_k, $k\neq j$, are fixed*. This interpretation can be problematical if changing X_j would require that one or more of the other X_k be changed as well. For example, if X_j was tax rate and X_k was savings rate, changing X_j may necessarily change X_k as well.

Linear models are not really restricted to fitting straight lines and planes because we are free to define **X** as we wish. For example, if the elements of X are different powers or other functions of the same base variables, then when viewed as a function of the base variables the mean function will be curved. Similarly, by including dummy variables, which have values of zero and one only, denoting two possible categories, we can fit separate mean functions to subpopulations in the data (see Ref. 4., Chapter 6).

Estimation

Given data $(y_i,x_{i1},\ldots,x_{ip})$ for $i=1,\ldots,n$, we assume that each case in the data is independent of each other case. This may exclude, for example, time-ordered observations on the same case, or other sampling plans with correlated cases. The least-squares estimates minimize Equation 2, but with $g(\mathbf{x},\mathbf{b}^*)$ from Equation 9 substituting for the simple regression mean function. The estimate s^2 of σ^2 is obtained from Equation 4 but with $d=n-p-1$ df rather than the $n-2$ for simple regression. Numerical methods for least-squares computations are discussed in Ref. 7. High-quality subroutines for least squares are provided by Ref. 8. As with simple regression, the standard least-squares calculations are performed by virtually all statistical computing packages.

For the multiple linear regression model, there is a closed-form solution for **b** available in compact form in matrix notation. Suppose we write $\mathcal{Y}$ to be the $n\times 1$ vector of the response variable and $\mathcal{X}$ to be the $n\times(p+1)$ matrix of the predictors, including a column of ones. The order of rows of $\mathcal{Y}$ and $\mathcal{X}$ must be the same. Then

$$\mathbf{b}=(\mathcal{X}'\mathcal{X})^{-1}\mathcal{X}'\mathcal{Y} \tag{10}$$

provided that the inverse exists. If the inverse does not exist, then there is not a unique least-squares estimator. If the matrix $\mathcal{X}$ is of rank $r\leq p$, then most statistical computing packages resolve the indeterminacy by finding r linearly independent columns of $\mathcal{X}$, resulting in a matrix $\mathcal{X}_1$, and then computing the estimator (10) with $\mathcal{X}_1$ replacing $\mathcal{X}$. This will change interpretation of parameters but not change predictions: All least-squares estimates produce the same predictions.

Equation 10 should never be used in computations, and methods based on decompositions such as the QR decomposition are more numerically stable; see "Linear systems of equation" and Ref. 8.

Distribution

If the $F(Y|\mathbf{X})$ are normal distributions, or if the sample size is large enough, then we will have, assuming $\mathcal{X}$ of full rank,

$$\mathbf{b}\sim \mathrm{N}(\boldsymbol{\beta},\sigma^2(\mathcal{X}'\mathcal{X})^{-1}) \tag{11}$$

The standard error of any of the estimates is given by s times the square root of the corresponding diagonal element of $(\mathcal{X}'\mathcal{X})^{-1}$. Similarly, if $\mathbf{a}'\mathbf{b}$ is any linear combination of the elements of **b**, then

$$\mathbf{a}'\mathbf{b}\sim \mathrm{N}(\mathbf{a}'\boldsymbol{\beta},\sigma^2\mathbf{a}'(\mathcal{X}'\mathcal{X})^{-1}\mathbf{a})$$

In particular, the fitted value at $\mathbf{X}=\mathbf{x}^*$ is given by $\mathbf{x}^{*\prime}\mathbf{b}$, and its variance is $\sigma^2\mathbf{x}^{*\prime}(\mathcal{X}'\mathcal{X})^{-1}\mathbf{x}^*$. A prediction of a future value at $\mathbf{X}=\mathbf{x}^*$ is also given by $\mathbf{x}^{*\prime}\mathbf{b}$, and its variance is given by $\sigma^2+\sigma^2\mathbf{x}^{*\prime}(\mathcal{X}'\mathcal{X})^{-1}\mathbf{x}^*$. Both of these variances are estimated by replacing σ^2 by s^2.

Prescription Drug Cost

As an example, we will use data collected on 29 health plans with pharmacies managed by the same insurance company in the United States in the mid-1990s. The response variable is *Cost*, the average cost to the health plan for one prescription for one day, in dollars. Three aspects of the drug plan under the control of the health plan are *GS*, the usage of generic substitute drugs by the plan, an index between 0, for no substitution and 100, for complete substitution, *RI*, a restrictiveness index, also between 0 and 100, describing the extent to which the plan requires physicians to prescribe drugs from a limited formulary, and *Copay*, the cost to the patient per prescription. Other characteristics of the plan that might influence costs are the average *Age* of patients in the plan, and *RXPM*, the number of prescriptions per year per patient, as a proxy measure of the overall health of the members in the plan. Although primary interest is in the first three predictors, the last two are included to adjust for demographic differences in the plans. The data are from Ref. (4).

Figure 2 is a *scatterplot matrix*. Except for the diagonal, a scatterplot matrix is a two-dimensional array of scatterplots. The variable names on the diagonal label the axes. In Fig. 2, the variable *Age* appears on the horizontal axis of all plots in the fifth column from the left and on the vertical axis of all plots in the fifth row from the top. Each plot in a scatterplot matrix is relevant to a particular one-predictor regression of the variable on the vertical axis given the variable on the horizontal axis. For example, the plot of *Cost* versus *GS* in the first plot in the second column of the scatterplot matrix is relevant for the regression of *Cost* on *GS* ignoring the other variables. From the first row of plots, the mean of *Cost* generally decreases as predictors increase,

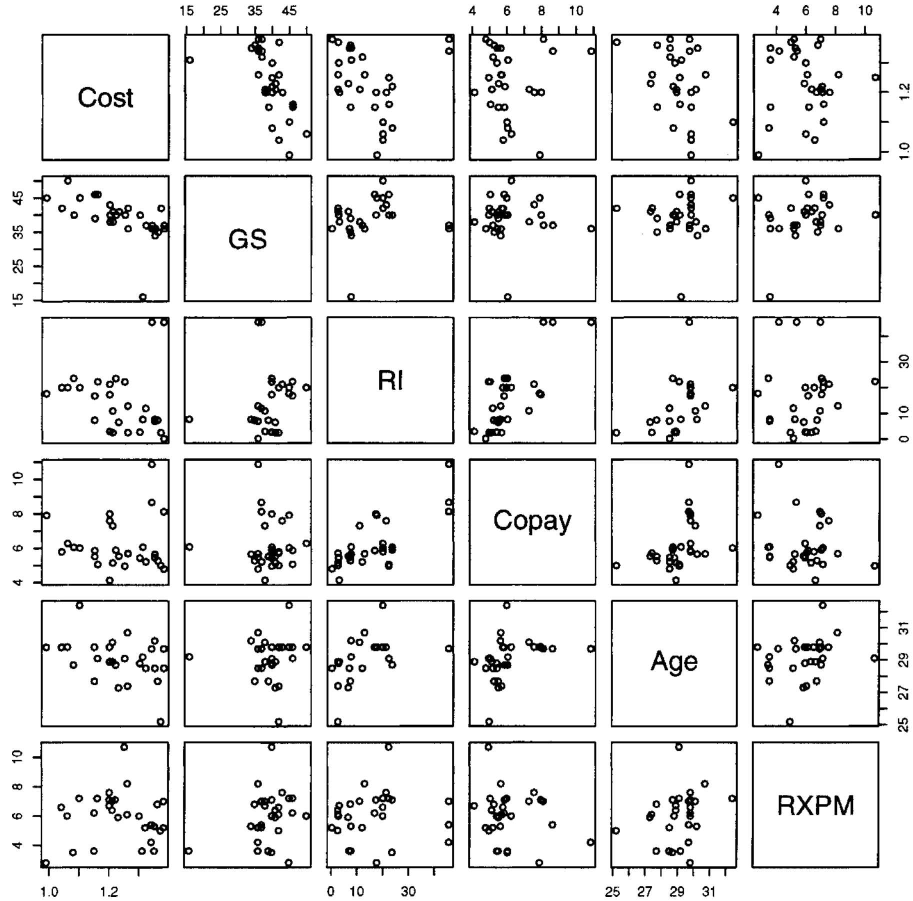

Figure 2. Scatterplot matrix for the drug cost example.

except perhaps *RXPM* where there is not any obvious dependence. This summary is clouded, however, by a few unusual points, in particular one health plan with a very low value for *GS* and three plans with large values of *RI* that have relatively high costs. The scatterplot matrix can be very effective in helping the analyst focus on possibly unusual data early in an analysis.

The pairwise relationships between the *predictors* are displayed in most other frames of this plot. Predictors that have nonlinear joint distributions, or outlying or separated points, may complicate a regression problem; Refs. 4 and 9 present methodology for using the scatterplot matrix to choose transformations of predictors for which a linear regression model is more likely to provide a good approximation.

Table 2 gives standard computer output for the fit of a multiple linear regression model with five predictors. As in simple regression, the value of R^2 gives the proportion of variability in the response explained by the predictors; about half the variability in *Cost* is explained by this regression. The estimated coefficient for *GS* is about -0.012, which suggests that, if all other variables could be held fixed, increasing GI by 10 units is expected to change *Cost* by $10 \times -.012 = \$-0.12$, which is a relatively large change. The t-test for the coefficient for *GS* equal to zero has a very small p-value, which suggests that this coefficient may indeed by nonzero. The coefficient for *Age* also has a small p-value and plans with older members have lower cost per prescription per day. Adjusted for the other predictors, *RI* appears to be unimportant, whereas the coefficient for *Copay* appears to be of the wrong sign.

Table 2. Regression output for the drug cost data.

	Estimate	Std. Error	t-value	Pr(> |t|)
(Intercept)	2.6829	0.4010	6.69	0.0000
GS	−0.0117	0.0028	−4.23	0.0003
RI	0.0004	0.0021	0.19	0.8483
Copay	0.0154	0.0187	0.82	0.4193
Age	−0.0420	0.0141	−2.98	0.0068
RXPM	0.0223	0.0110	2.03	0.0543

$s = 0.0828$, df $= 23$, $R^2 = 0.535$.

Model Comparison. In some regression problems, we may wish to test the null hypothesis NH that a subset of the β_j are simultaneously zero versus the alternative AH that at least one in the subset is nonzero. The usual procedure is to do a *likelihood ratio test*: (*1*) Fit both the NH and the AH models and save the residual sum of squares and the residual df; (*2*) compute the statistic

$$F = \frac{\mathrm{RSS}_{\mathrm{NH}} - \mathrm{RSS}_{\mathrm{AH}}/(\mathrm{df}_{\mathrm{NH}} - \mathrm{df}_{\mathrm{AH}})}{\mathrm{RSS}_{\mathrm{AH}}/\mathrm{df}_{\mathrm{AH}}}$$

Under the normality assumption, the numerator and denominator are independent multiples of χ^2 random variables, and F has an $F(\mathrm{df}_{\mathrm{NH}} - \mathrm{df}_{\mathrm{AH}}\,\mathrm{df}_{\mathrm{AH}})$ distribution, which can be used to get significance levels. For example, consider testing the null hypothesis that the mean function is given by Equation 8, which asserts that the mean function does not vary with the predictors versus the alternative given by Equation 9. For the drug data, $F = 5.29$ with $(5, 23)$ df, $p = 0.002$, which suggests that at least one of the $\beta_j, j \geq 1$ is nonzero.

Model Selection/Variable Selection. Although some regression models are dictated by a theory that specifies which predictors are needed and how they should be used in the problem, many problems are not so well specified. In the drug cost example, *Cost* may depend on the predictors as given, on some subset of them, or on some other functional form other than a linear combination. Many regression problems will therefore include a *model selection* phase in which several competing specifications for the mean function are to be considered. In the drug cost example, we might consider all $2^5 = 32$ possible mean functions obtained using subsets of the five base predictors, although this is clearly only a small fraction of all possible sensible models. Comparing models two at a time is at best inefficient and at worst impossible because the likelihood ratio tests can only be used to compare models if the null model is a special case of the alternative model.

One important method for comparing models is based on estimating a criterion function that depends on both lack of fit and complexity of the model (see also “Information theory.”) The most commonly used method is the *Akaike information criterion*, or *AIC*, given for linear regression by

$$AIC = n\log(\text{Residual sum of squares}) + 2(p+1)$$

where $p + 1$ is the number of estimated coefficients in the mean function. The model that minimizes *AIC* is selected, even if the difference in *AIC* between two models is trivially small; see Ref. 10. For the drug cost data, the mean function with all five predictors has $AIC = -139.21$. The mean function with minimum *AIC* excludes only *RI*, with $AIC = -141.16$. The fitted mean function for this mean function is $m(Y|\mathbf{X} = \mathbf{x}) = 2.6572 - 0.0117\,GS + 0.0181\,Copay - 0.0417Age + 0.0229\,RXPM$. Assuming the multiple linear regression model is appropriate for these data, this suggests that the restrictiveness of the formulary is not related to cost after adjusting for the other variables, plans with more *GS* are associated with lower costs. Both *Copay* and *Age* seem to have the wrong sign.

An alternative approach to model selection is *model aggregation*, in which a probability or weight is estimated for each candidate model, and the “final” model is a weighted combination of the individual models; see Ref. 11 for a Bayesian approach and Ref. 12 for a frequentist approach.

Parameter Interpretation. If the results in Table 2 or the fitted model after selection were a reasonable summary of the conditional mean of *Cost* given the predictors, how can we interpret the parameters? For example, can we infer than increasing *GS* would decrease *Cost*? Or, should we be more cautious and only infer that plans with higher *GS* are *associated* with lower values of *Cost*? The answer to this question depends on the way that the data were generated. If *GS* were assigned to medical plans using a random mechanism, and then we observed *Cost* after the random assignment, then inference of causation could be justified. The lack of randomization in these data could explain the wrong sign for *Copay*, as it is quite plausible that plans raise the copayment in response to higher costs. For observational studies like this one, causal inference based on regression coefficients is problematical, but a substantial literature exists on methods for making causal inference from observational data; see Ref. 13.

Diagnostics. Fitting regression models is predicated upon several assumptions about $F(Y|\mathbf{X})$. Should any of these assumptions fail, then a fitted regression model may not provide a useful summary of the regression problem. For example, if the true mean function were $\mathrm{E}(Y|X = x) = \beta_0 + \beta_1 x + \beta_2 x^2$, then the fit of the simple linear regression model (1) could provide a misleading summary if β_2 were substantially different from zero. Similarly, if the assumed mean function were correct but the variance function was not constant, then estimates would no longer be efficient, and tests and confidence intervals could be badly in error.

Regression diagnostics are a collection of graphical and numerical methods for checking assumptions concerning the mean function and the variance function. In addition, these methods can be used to detect *outliers*, a small fraction of the cases for which the assumed model is incorrect, and *influential cases* (14), which are cases that if deleted would substantially change the estimates and inferences. Diagnostics can also be used to suggest remedial action like transforming predictors or the response, or adding interactions to a mean function, that could improve the match of the model to the data. Much of the theory for diagnostics is laid out in Ref. 15 see also Refs. 4 and 9.

Many diagnostic methods are based on examining the *residuals*, which for linear models are simply the differences $r_i = y_i - g(\mathbf{x}_i, \mathbf{b}), i = 1, \ldots, n$. The key idea is that, if a fitted model is correct, then the residuals should be unrelated to the fitted values, to any function of the predictors, or indeed to any function of data that was not used in the modeling. This suggests examining plots of the residuals versus functions of the predictors, such as the predictors themselves and also versus fitted values. If these graphs show any pattern, such as a curved mean function or nonconstant variance, we have evidence that the model used does not match the data. Lack of patterns in all plots is consistent with an acceptable model, but not definitive.

Figure 3 shows six plots, the residuals versus each of the predictors, and also the residuals versus the fitted values based on the model with all predictors. Diagnostic analysis should generally be done before any model selection based on the largest sensible mean function. In each plot, the dashed line is a reference horizontal line at zero. The dotted line is the fitted least-squares regression line for a quadratic regression with the response given by the residuals and the predictor given by the horizontal axis. The t-test that the coefficient for the quadratic term when added to the original mean function is zero is a numeric diagnostic

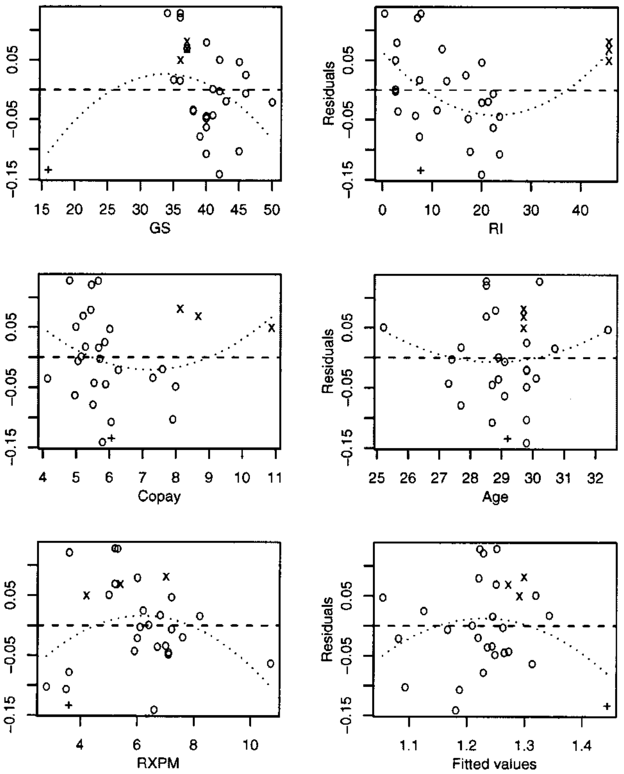

Figure 3. Residual plots for the drug cost data. The "+" symbol indicates the plan with very small *GS*, "x" indicates plans with very high *RI*, and all other plans are indicated with a "o."

that can help interpret the plot. In the case of the plot versus fitted value, this test is called *Tukey's test for non-additivity*, and p-values are obtained by comparing with a normal distribution rather than a t-distribution that is used for all other plots.

In this example, the residual plots display patterns that indicate that the linear model that was fit does not match the data well. The plot for *GS* suggests that the case with a very small value of *GS* might be quite different than the others; the p-value for the lack-of-fit test is about 0.02. Similarly, curvature is evident for *RI* due to the three plans with very high values of *RI* but very high costs. No other plot is particularly troubling, particularly in view of the small sample size. For example, the p-value for Tukey's test corresponding to the plot versus fitted values is about $p = 0.10$. The seemingly contradictory result that the mean function matches acceptably overall but not with regard to *GS* or *RI* is plausible because the overall test will necessarily be less powerful than a test for a more specific type of model failure.

This analysis suggests that the four plans, one with very low *GS* and the other three with very high *RI*, may be cases that should be treated separately from the remaining cases. If we refit without these cases, the resulting residual plots do not exhibit any particular problems. After using *AIC* to select a subset, we end up with the fitted model $g(\mathbf{x}, \mathbf{b}) = 2.394 - 0.014\,GS - 0.004\,RI - 0.024\,Age + 0.020\,RXPM$. In this fitted model, *Copay* is deleted. The coefficient estimate for *GS* is somewhat larger, and the remaining estimates are of the appropriate sign. This seems to provide a useful summary for the data. We would call the four points that were omitted *influential observations*, (14) because their exclusion markedly changes conclusions in the analysis.

In this example, as in many examples, we end up with a fitted model that depends on choices made about the data. The estimated model ignores 4 of 29 data points, so we are admitting that the mean function is not appropriate for all data.

OTHER REGRESSION MODELS

The linear model given by Equation 9 has surprising generality, given that so few assumptions are required. For some problems, these methods will certainly not be useful, for example if the response is not continuous, if the variance depends on the mean, or if additional information about the conditional distributions is available. For these cases, methods are available to take advantage of the additional information.

Logistic Regression

Suppose that the response variable Y can only take on two values, say 1, corresponding perhaps to "success," or 0, corresponding to "failure." For example, in a manufacturing plant where all output is inspected, Y could indicate items that either pass ($Y = 1$) or fail ($Y = 1$) inspection. We may want to study how the probability of passing depends on characteristics such as operator, time of day, quality of input materials, and so on.

We build the logistic regression model in pieces. First, as each Y can only equal 0 or 1, each Y has a Bernoulli distribution, and

$$\begin{aligned}\mu(Y|\mathbf{X} = \mathbf{x}) &= \text{Prob}(Y = 1|\mathbf{X} = \mathbf{x})\\ &= g(\mathbf{x}, \boldsymbol{\beta})\\ \text{Var}(Y|\mathbf{X} = \mathbf{x}) &= g(\mathbf{x}, \boldsymbol{\beta})(1 - g(\mathbf{x}, \boldsymbol{\beta}))\end{aligned} \tag{12}$$

Each observation can have its own probability of success $g(\mathbf{x}, \boldsymbol{\beta})$ and its own variance.

Next, assume that Y depends on $\mathbf{X} = \mathbf{x}$ only through a linear combination $\eta(\mathbf{x}) = \beta_0 + \beta_1 x_1 + \ldots + \beta_p x_p = \boldsymbol{\beta}'\mathbf{x}$. The quantity $\eta(\mathbf{x})$ is called a *linear predictor*. For the multiple linear regression model, we have $g(\mathbf{x}, \boldsymbol{\beta}) = \eta(\mathbf{x})$, but for a binary response, this does not make any sense because a probability is bounded between zero and one. We can make a connection between $g(\mathbf{x}, \boldsymbol{\beta})$ and $\eta(\mathbf{x})$ by assuming that

$$g(\mathbf{x}, \boldsymbol{\beta}) = \frac{1}{1 + \exp(-\eta(\mathbf{x}))} \tag{13}$$

This is called logistic regression because the right side of Equation 13 is the logistic function. Other choices for g are possible, using any function that maps from $(-\infty, \infty)$ to (0, 1), but the logistic is adequate for many applications.

To make the analogy with linear regression clearer, Equation 13 is often inverted to have just the linear predictor on the right side of the equation,

$$\log(\frac{g(\mathbf{x},\boldsymbol{\beta})}{1-g(\mathbf{x},\boldsymbol{\beta})}) = \eta(\mathbf{x}) = \boldsymbol{\beta}'\mathbf{x} \tag{14}$$

In this context, the *logit function*, $\log(g(\mathbf{x},\boldsymbol{\beta})/(1-g(\mathbf{x},\boldsymbol{\beta})))$, is called a *link function* that links the parameter of the Bernoulli distribution, $g(\mathbf{x},\boldsymbol{\beta})$, to the linear predictor $\eta(\mathbf{x})$.

Estimation. If we have data $(y_i, \mathbf{x}_i)$, $i = 1,\ldots,n$ that are mutually independent, then we can write the *log-likelihood function* as

$$\begin{aligned}L(\boldsymbol{\beta}) &= \log\left\{\prod_{i=1}^{n}(g(\mathbf{x}_i,\boldsymbol{\beta}))^{y_i}(1-g(\mathbf{x}_i,\boldsymbol{\beta}))^{1-y_i}\right\}\\ &= \log\left\{\prod_{i=1}^{n}\left(\frac{g(\mathbf{x}_i,\boldsymbol{\beta})}{(1-g(\mathbf{x}_i,\boldsymbol{\beta})}\right)^{y_i}(1-g(\mathbf{x}_i,\boldsymbol{\beta}))\right\}\\ &= \sum_{i=1}^{n}\left\{y_i(\mathbf{x}_i'\boldsymbol{\beta}) + \log\left(1-\frac{1}{(1+\exp(-\mathbf{x}_i'\boldsymbol{\beta}))}\right)\right\}\end{aligned}$$

Maximum likelihood estimates are obtained to be the values of $\boldsymbol{\beta}$ that maximize this last equation. Computations are generally done using Newton–Raphson iteration or using a variant called Fisher scoring; see Ref. 16; for book-length treatments of this topic, see Refs. 17 and 18.

Poisson Regression

When the response is the count of the number of independent events in a fixed time period, Poisson regression models are often used. The development is similar to the Bernoulli case. We first assume that $Y|X = \mathbf{x}$ is distributed as a Poisson random variable with mean $\mu(Y|\mathbf{X} = \mathbf{x}) = g(\mathbf{x},\boldsymbol{\beta})$,

$$\text{Prob}(Y = y|\mathbf{X} = \mathbf{x}) = \frac{g(\mathbf{x},\boldsymbol{\beta})^y}{y!}\exp(-g(\mathbf{x},\boldsymbol{\beta}))$$

For the Poisson, $0 < \mu(Y|\mathbf{X} = \mathbf{x}) = \text{Var}(Y|\mathbf{X} = \mathbf{x}) = g(\mathbf{x},\boldsymbol{\beta})$. The connection between Y and $\mathbf{X}$ is assumed to be through the linear predictor $\eta(\mathbf{x})$, and for a log-linear model, we assume that

$$g(\mathbf{x},\boldsymbol{\beta}) = \exp(\eta(\mathbf{x}))$$

giving the exponential mean function, or inverting we get the log-link,

$$\eta(\mathbf{x}) = \log(g(\mathbf{x},\boldsymbol{\beta}))$$

Assuming independence, the log-likelihood function can be shown to be equal to

$$L(\boldsymbol{\beta}) = \sum_{i=1}^{n}\{y_i(\mathbf{x}_i{'}\boldsymbol{\beta}) - \exp(\mathbf{x}_i'\boldsymbol{\beta})\}$$

Log-linear Poisson models are discussed in Ref. 19.

There are obvious connections between the logistic and the Poisson models briefly described here. Both of these models as well as the multiple linear regression model assuming normal errors, are examples of *generalized linear models*, described in Ref. 16.

Nonlinear Regression

Nonlinear regression refers in general to any regression problem for which the linear regression model does not hold. Thus, for example, the logistic and log-linear Poisson models are nonlinear models; indeed nearly *all* regression problems are nonlinear.

However, it is traditional to use a narrower definition for nonlinear regression that matches the multiple linear regression model except that the mean function $\mu(Y|\mathbf{X} = \mathbf{x}) = g(\mathbf{x},\boldsymbol{\beta})$ is a *nonlinear* function of the parameters $\boldsymbol{\beta}$. For example, the mean relationship between X = age of a fish and Y = length of the fish is commonly described using the *von Bertalanffy* function,

$$\text{E}(Y|X = x) = L_\infty(1-\exp(-K(x-x_0)))$$

The parameters $\boldsymbol{\beta} = (L_\infty, K, x_0)'$ to be estimated are the maximum length L_∞ for very old fish; the growth rate K, and $x_0 < 0$, which allows fish to have positive length at birth.

As with the linear model, a normality assumption for $Y|\mathbf{X}$ is not required to obtain estimates. An estimator $\mathbf{b}$ of $\boldsymbol{\beta}$ can be obtained by minimizing Equation (2), and the estimate of σ^2 assuming constant variance from Equation (4). Computations for a nonlinear mean function are much more difficult; see "Least squares approximation". The nonlinear regression problem generally requires an iterative computational method for solution (7) and requires reasonable starting values for the computations. In addition, the objective function (2) may be multimodal and programs can converge to a local rather than a global minimum. Although software is generally available in statistical packages and in mathematical programming languages, the quality of the routines available is more variable and different packages may give different answers. Additionally, even if normality is assumed, the estimate of $\boldsymbol{\beta}$ is normally distributed only in large samples, so inferences are approximate and particularly in small samples may be in error. See Ref. 20 for book-length treatment.

Nonparametric Regression

For the limited and important goal of learning about the mean function, several newer approaches to regression have been proposed in the last few years. These methods either weaken assumptions or are designed to meet particular goals while sacrificing other goals.

The central idea behind *nonparametric regression* is to estimate the mean function $\mu(Y|\mathbf{X} = \mathbf{x})$ without assuming any particular parametric form for the mean function. In the special case of one predictor, the Naradaya–Watson kernel regression estimator is the fundamental method. It estimates $\mu(Y|X = x)$ at any particular x by a weighed average of the y_i with weights determined by $|x_i - x|$, so points close to x have higher weight than do points far away. In particular, If $H(u)$ is a symmetric unimodal function,

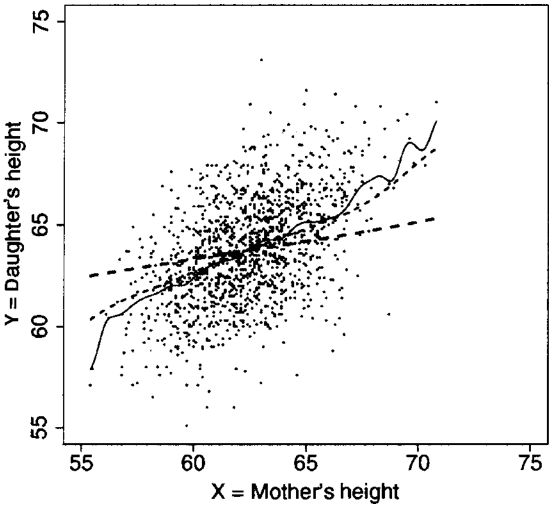

Figure 4. Three Naradaya–Watson kernel smoothing estimates of the mean for the heights data, with $h = 1$ for the solid line and $h = 3$ for the dashed line and $h = 9$ for the dotted line.

then the estimated mean function is

$$m(Y|X = x) = \sum_{i=1}^{n} w_i(h) y_i / \sum_{j=1}^{n} w_j(h)$$
$$w_i(h) = \frac{1}{h} H\left(\frac{x_i - x}{h}\right)$$

One choice for H is the standard normal density function, but other choices can have somewhat better properties. The *bandwidth h* is selected by the analyst; small values of h weigh cases with $|x_i - x|$ small heavily while ignoring other cases, giving a very rough estimate. Choosing h large weighs all cases nearly equally, giving a very smooth, but possibly biased, estimate, as shown in Fig. 4. The bandwidth must be selected to balance bias and smoothness. Other methods for nonparametric regression include smoothing splines, local polynomial regression, and wavelets, among others; see Ref. 21.

Semiparametric Regression

A key feature of nonparametric regression is using nearby observations to estimate the mean at a given point. If the predictor is in many dimensions, then for most points $\mathbf{x}$, there may be either no points or at best just a few points that are nearby. As a result, nonparametric regression does not scale well because of this *curse of dimensionality*, Ref. 22.

This has led to the proposal of *semiparametric* regression models. For example, the *additive regression model*, Refs. 23, 24, suggests modeling the mean function as

$$\mu(Y|\mathbf{X} = \mathbf{x}) = \sum_{j=1}^{p} g_j(x_j)$$

where each g_j is a function of just one predictor x_j that can be estimated nonparametrically. Estimates can be obtained by an iterative procedure that sequentially estimates each of the g_j, continuing until convergence is obtained. This type of model can also be used in the generalized linear model framework, where it is called a *generalized additive model*.

Robust Regression

Robust regression was developed to address the concern that standard estimates such as least-squares or maximum likelihood estimates may be highly unstable in the presence of outliers or other very large errors. For example, the least-squares criterion (2) may be replaced by

$$\mathbf{b} = \arg\min_{\mathbf{b}*} \sum_{i=1}^{n} \rho\{|y_i - g(x, \mathbf{b}^*)|\}$$

where ρ is symmetric about zero and may downweight observations for which $|y_i - g(x, \mathbf{b}^*)|$ is large. The methodology is presented in Ref. 25, although these methods seem to be rarely used in practice, perhaps because they give protection against outliers but not necessarily against model misspecifications, Ref. 26.

Regression Trees

With one predictor, a *regression tree* would seek to replace the predictor by a discrete predictor, such that the predicted value of Y would be the same for all X in the same discrete category. With two predictors, each category created by discretizing the first variable could be subdivided again according to a discrete version of the second predictor, which leads to a tree-like structure for the predictions. Basic methods for regression trees are outlined in Refs. 27 and 28. The exact methodology for implementing regression trees is constantly changing and is an active area of research; see "Machine learning."

Dimension Reduction

Virtually all regression methods described so far require assumptions concerning some aspect of the conditional distributions $F(Y|\mathbf{X})$, either about the mean function on some other characteristic. *Dimension reduction regression* seeks to learn about $F(Y|\mathbf{X})$ but with minimal assumptions. For example, suppose $\mathbf{X}$ is a p-dimensional predictor, now not including a "1" for the intercept. Suppose we could find a $r \times p$ matrix $\mathbf{B}$ of minimal rank r such that $F(Y|\mathbf{X}) = F(Y|\mathbf{BX})$, which means that all dependence of the response on the predictor is through r combinations of the predictors. If $r \ll p$, then the resulting regression problem is of much lower dimensionality and can be much easier to study. Methodology for finding $\mathbf{B}$ and r with no assumptions about $F(Y|\mathbf{X})$ is a very active area of research; see Ref. 29 for the foundations; and references to this work for more recent results.

ROUNDING ERRORS

INTRODUCTION

Human beings are in constant need of making bigger and faster computations. Over the past four centuries, many machines were created for this purpose, and 50 years ago, actual electronic computers were developed specifically to perform scientific computations. The first mechanical calculating machines were *Schikard's machine* (1623, Germany), the *Pascaline* (1642, France), followed by *Leibniz's machine* (1694, Germany). *Babbage's analytical machine* (1833, England) was the first attempt at a mechanical computer, and the first mainframe computer was the *Z4 computer of K. Zuse* (1938, Germany).

Until the beginning of the twentieth century, computations were only done on integer numbers. To perform efficient real numbers computations, it was necessary to wait until the birth of the famous BIT *(BInary digiT)*, which was introduced by C. Shannon (1937, USA) in his PhD thesis. Shannon's work imposed electronics for the building of computers and, then, the base 2 for coding integer or real numbers, although other bases have been tried. It has now been established that the base 2 is the most efficient base on computers for numerical computations, although the base 10 may still be used on pocket calculators.

For coding real numbers, one also has to determine the kind of coding they want to use. The decimal fixed-point notation was introduced at the end of the sixteenth century consecutively by S. Stévin (1582, France), J. Bürgi (1592, Switzerland), and G. Magini (1592, Italy). It remains the notation used worldwide today. Although it is the most natural notation for mental calculations, it is not very efficient for automatic computations. In fact, on this subject, one can say that nothing has changed since J. Napier's logarithm (1614, Scotland) and W. Oughtred's slide rule (1622, England). Logarithms were introduced by J. Napier to make multiplication easier (using logarithm, multiplication becomes addition). Three centuries later, the same idea was kept for the coding of real numbers on computers and led to the floating-point representation (see the next section).

But whatever the representation is on computer, it is a finite representation, like for computations by hand. So, at each operation, because the result needs to be truncated (but is in general), an error may appear that is called the rounding error. Scientists have been well aware of this for four centuries. In the nineteenth century, when numerical computations were presented in an article, they were systematically followed by errors computations to justify the validity of the results. In 1950, in his famous article on eigenvalue computation with his new algorithm, C. Lanczos devoted 30% of his paper to error computation. Unfortunately, this use has completely disappeared since the beginning of the 1960s because of the improvement of computers. When eight billion floating-point operations are performed in one second on a processor, it seems impossible to quantify the rounding error even though neglecting rounding errors may lead to catastrophic consequences.

For instance, for real-time applications, the discretization step may be $h = 10^{-1}$ second. One can compute the absolute time by performing $t_{abs} = t_{abs} + h$ at each step or performing $icount = icount + 1$; $t_{abs} = h * icount$, where *icount* is correctly initialized at the beginning of the process. Because the real-number representation is finite on computers, only a finite number of them can be exactly coded. They are called floating-point numbers. The others are approximated by a floating-point number. Unfortunately, $h = 10^{-1}$ is not a floating-point number. Therefore, each operation $t_{abs} = t_{abs} + h$ generates a small but nonzero error. One hundred hours later, this error has grown to about 0.34 second. It really happened during the first Gulf war (1991) in the control programs of Patriot missiles, which were to intercept Scud missiles (1). At 1600 km/h, 0.34 second corresponds to approximatively 500 meters, the interception failed and 28 people were killed. With the second formulation, whatever the absolute time is, if no overflow occurs for *icount*, then the relative rounding error remains below 10^{-15} using the IEEE double precision arithmetic. A good knowledge of the floating-point arithmetic should be required of all computer scientists (2).

The second section is devoted to the description of the computer arithmetic. The third section presents approaches to study: to bound or to estimate rounding errors. The last section describes methods to improve the accuracy of computed results. A goal of this paper is to answer the question in numerical computing, *"What is the computing error due to floating-point arithmetic on the results produced by a program?"*

COMPUTER ARITHMETIC

Representation of Numbers

In a numeral system, numbers are represented by a sequence of symbols. The number of distinct symbols that can be used is called the radix (or the base). For instance, in the decimal system, where the radix is 10, the 10 symbols used are the digits 0,1, . . . ,9. In the binary system, which is used on most computers, the radix is 2; hence, numbers are represented with sequences of 0s and 1s.

Several formats exist to represent numbers on a computer. The representation of integer numbers differs from the one of real numbers. Using a radix b, if unsigned integers are encoded on n digits, they can range from 0 to $b^n - 1$. Hence, an unsigned integer X is represented by a sequence $a_{n-1}a_{n-2} \ldots a_1a_0$ with

$$X = \sum_{i=0}^{n-1} a_i b^i \quad \text{and} \quad a_i \in \{0, \ldots, b-1\}.$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

With a radix 2 representation, signed integers are usually represented using two's complement. With this rule, signed integers range from $-b^{n-1}$ to $b^{n-1}-1$ and the sequence $a_{n-1}a_{n-2}\ldots a_1a_0$ with $a_i \in \{0,\ldots,b-1\}$ represents the number

$$X = -a_{n-1}b^{n-1} + \sum_{i=0}^{n-2} a_i b^i.$$

The opposite of a number in two's complement format can be obtained by inverting each bit and adding 1.

In numerical computations, most real numbers are not exactly represented because only a finite number of digits can be saved in memory. Two representations exist for real numbers:

- the fixed-point format, available on most embedded systems
- the floating-point format, available on classical computers

In fixed-point arithmetic, a number is represented with a fixed number of digits before and after the radix point. Using a radix b, a number X that is encoded on m digits for its magnitude (e.g., its integer part) and f digits for its fractional part is represented by $a_{m-1}\ldots a_0 \cdot a_{-1}\ldots a_{-f}$, with

$$X = \sum_{i=-f}^{m-1} a_i b^i \quad \text{and} \quad a_i \in \{0,\ldots,b-1\}.$$

If $b = 2$, then unsigned values range from 0 to $2^m - 2^{-f}$ and signed values, which are usually represented with the two's complement format, range from -2^{m-1} to $2^{m-1} - 2^{-f}$.

In a floating-point arithmetic using the radix b, a number X is represented by:

- its sign ε_X which is encoded on one digit that equals 0 if $\varepsilon_X = 1$ and 1 if $\varepsilon_X = -1$,
- its exponent E_X, a k digit integer,
- its mantissa M_X, encoded on p digits.

Therefore, $X = \varepsilon_X M_X b^{E_X}$ with

$$M_X = \sum_{i=0}^{p-1} a_i b^{-i} \quad \text{and} \quad a_i \in \{0,\ldots,b-1\}.$$

The mantissa M_X can be written as $M_X = a_0 \,.\, a_1 \ldots a_{p-1}$. Floating-point numbers are usually normalized. In this case, $a_0 \neq 0$, $M_X \in [1, b)$ and the number zero has a special representation. Normalization presents several advantages, such as the uniqueness of the representation (there is exactly one way to write a number in such a form) and the easiness of comparisons (the signs, exponents, and mantissas of two normalized numbers can be tested separately).

The IEEE 754 Standard

The poor definition of the floating-point arithmetic on most computers created the need for a unified standard in floating-point numbers. Indeed, the bad quality of arithmetic operators could heavily affect some results. Furthermore, simulation programs could provide different results from one computer to another, because of different floating-point representations. Different values could be used for the radix, the length of the exponent, the length of the mantissa, and so on. So, in 1985, the IEEE 754 standard (3) was elaborated to define floating-point formats and rounding modes. It specifies two basic formats, both using the radix 2.

- With the single precision format, numbers are stored on 32 bits: 1 for the sign, 8 for the exponent, and 23 for the mantissa.
- With the double precision format, numbers are stored on 64 bits: 1 for the sign, 11 for the exponent, and 52 for the mantissa.

Extended floating-point formats also exist; the standard does not specify their exact size but gives a minimum number of bits for their storage.

Because of the normalization, the first bit in the mantissa must be 1. As this implicit bit is not stored, the precision of the mantissa is actually 24 bits in single precision and 53 bits in double precision.

The exponent E is a k digit signed integer. Let us denote its bounds by E_{min} and E_{max}. The exponent that is actually stored is a biased exponent E_Δ such that $E_\Delta = E + \Delta$, Δ being the bias. Table 1 specifies how the exponent is encoded.

The number zero is encoded by setting to 0 all the bits of the (biased) exponent and all the bits of the mantissa. Two representations actually exist for zero: $+0$ if the sign bit is 0, and -0 if the sign bit is 1. This distinction is consistent with the existence of two infinities. Indeed $1/(+0) = +\infty$ and $1/(-0) = -\infty$. These two infinities are encoded by setting to 1 all the bits of the (biased) exponent and to 0 all the bits from the mantissa. The corresponding nonbiased exponent is therefore $E_{max} + 1$.

NaN (Not a Number) is a special value that represents the result of an invalid operation such as 0/0, $\sqrt{-1}$, or $0 \times \infty$. NaN is encoded by setting all the bits of the (biased) exponent to 1 and the fractional part of the mantissa to any nonzero value.

Denormalized numbers (also called subnormal numbers) represent values close to zero. Without them, as the integer part of the mantissa is implicitly set to 1, there would be no representable number between 0 and $2^{E_{min}}$ but

Table 1. Exponent Coding in Single and Double Precision

			nonbiased		biased	
precision	length k	bias Δ	E_{min}	E_{max}	$E_{min}+\Delta$	$E_{max}+\Delta$
single	8	127	−126	127	1	254
double	11	1023	−1022	1023	1	2046

2^{p-1} representable numbers between $2^{E_{min}}$ and $2^{E_{min}+1}$. Denormalized numbers have a biased exponent set to 0. The corresponding values are:

$$X = \varepsilon_X M_X 2^{E_{min}} \text{ with } \varepsilon_X = \pm 1,$$

$$M_X = \sum_{i=1}^{p-1} a_i 2^{-i}$$

and

$$a_i \in \{0, 1\}.$$

The mantissa M_X can be written as $M_X = 0.a_1 \ldots a_{p-1}$. Therefore, the lowest positive denormalized number is $\underline{u} = 2^{E_{min}+1-p}$. Moreover, denormalized numbers and gradual underflow imply the nice equivalence $a = b \Leftrightarrow a - b = 0$.

Let us denote by $\mathbb{F}$ the set of all floating-point numbers, (i.e., the set of all machine representable numbers). This set, which depends on the chosen precision, is bounded and discrete. Let us denote its bounds by X_{min} and X_{max}. Let x be a real number that is not machine representable. If $x \in (X_{min}, X_{max})$, then $\{X^-, X^+\} \subset \mathbb{F}^2$ exists such as $X^- < x < X^+$ and $(X^-, X^+) \cap \mathbb{F} = \emptyset$. A rounding mode is a rule that, from x, provides X^- or X^+. This rounding occurs at each assignment and at each arithmetic operation. The IEEE 754 standard imposes a correct rounding for all arithmetic operations (+, −, ×, /) and also for the square root. The result must be the same as the one obtained with infinite precision and then rounded. The IEEE 754 standard defines four rounding modes:

- rounding toward $+\infty$ (or upward rounding), x is represented by X^+,
- rounding toward $-\infty$ (or downward rounding), x is represented by X^-,
- rounding toward 0, if x is negative, then it is represented by X^+, if x is positive, then it is represented by X^-,
- rounding to the nearest, x is represented by its nearest machine number. If x is at the same distance of X^- and X^+, then it is represented by the machine number that has a mantissa ending with a zero. With this rule, rounding is said to be *tie to even*.

Let us denote by X the number obtained by applying one of these rounding modes to x. By definition, an *overflow* occurs if $|X| > \max\{|Y| : Y \in \mathbb{F}\}$ and an *underflow* occurs if $0 < |X| < \min\{|Y| : 0 \neq Y \in \mathbb{F}\}$. Gradual underflow denotes the situation in which a number is not representable as a normalized number, but still as a denormalized one.

Rounding Error Formalization

Notion of Exact Significant Digits. To quantify the accuracy of a computed result correctly, the notion of exact significant digits must be formalized. Let R be a computed result and r the corresponding exact result. The number $C_{R,r}$ of exact significant decimal digits of R is defined as the number of significant digits that are in common with r:

$$C_{R,r} = \log_{10}\left|\frac{R+r}{2(R-r)}\right| \qquad (1)$$

This mathematical definition is in accordance with the intuitive idea of decimal significant digits in common between two numbers. Indeed Equation (1) is equivalent to

$$|R - r| = \left|\frac{R+r}{2}\right| 10^{-C_{R,r}} \qquad (2)$$

If $C_{R,r} = 3$, then the relative error between R and r is of the order of 10^{-3}. R and r have therefore three common decimal digits.

However, the value of $C_{R,r}$ may seem surprising if one considers the decimal notations of R and r. For example, if $R = 2.4599976$ and $r = 2.4600012$, then $C_{R,r} \approx 5.8$. The difference caused by the sequences of "0" or "9" is illusive. The significant decimal digits of R and r are really different from the sixth position.

Rounding Error that Occurs at Each Operation. A formalization of rounding errors generated by assignments and arithmetic operations is proposed below. Let X be the representation of a real number x in a floating-point arithmetic respecting the IEEE 754 standard. This floating-point representation of X may be written as $X = \text{fl}(x)$. Adopting the same notations as in Equation (1)

$$X = \varepsilon_X M_X 2^{E_X} \qquad (3)$$

and

$$X = x - \varepsilon_X 2^{E_X - p} \alpha_X \qquad (4)$$

where α_X represents the normalized rounding error.

- with rounding to the nearest, $\alpha_X \in [-0.5, 0.5)$
- with rounding toward zero, $\alpha_X \in [0, 1)$
- with rounding toward $+\infty$ or $-\infty$, $\alpha_X \in [-1, 1)$

Equivalent models for X are given below. The *machine epsilon* is the distance ε from 1.0 to the next larger floating-point number. Clearly, $\varepsilon 2^{1-p}$, p being the length of the mantissa that includes the implicit bit. The relative error on X is no larger than the *unit round-off u:*

$$X = x(1+\delta) \text{ with } |\delta| \leq u \qquad (5)$$

where $u = \varepsilon/2$ with rounding to the nearest and $u = \varepsilon$ with the other rounding modes. The model associated with Equation (5) ignores the possibility of underflow. To take underflow into account, one must modify it to

$$X = x(1+\delta) + \eta \text{ with } |\delta| \leq u \qquad (6)$$

and $|\eta| \leq \underline{u}/2$ with rounding to the nearest and $|\eta| \leq \underline{u}$ with the other rounding modes, $\underline{u}$ being the lowest positive denormalized number.

Let X_1 (respectively X_2) be the floating-point representation of a real number x_1 (respectively x_2)

$$X_i = x_i - \varepsilon_i 2^{E_i - p}\alpha_i \quad \text{for} \quad i = 1, 2 \tag{7}$$

The errors caused by arithmetic operations that have X_1 and X_2 as operands are given below. For each operation, let us denote by E_3 and ε_3 the exponent and the sign of the computed result. α_3 represents the rounding error performed on the result. Let us denote by $\oplus$, $\ominus$, $\otimes$, $\oslash$ the arithmetic operators on a computer.

$$\begin{aligned} X_1 \oplus X_2 = x_1 + x_2 - \varepsilon_1 2^{E_1 - p}\alpha_1 - \varepsilon_2 2^{E_2 - p}\alpha_2 \\ - \varepsilon_3 2^{E_3 - p}\alpha_3 \end{aligned} \tag{8}$$

Similarly

$$\begin{aligned} X_1 \ominus X_2 = x_1 - x_2 - \varepsilon_1 2^{E_1 - p}\alpha_1 + \varepsilon_2 2^{E_2 - p}\alpha_2 \\ - \varepsilon_3 2^{E_3 - p}\alpha_3 \end{aligned} \tag{9}$$

$$\begin{aligned} X_1 \otimes X_2 = x_1 x_2 - \varepsilon_1 2^{E_1 - p}\alpha_1 x_2 - \varepsilon_2 2^{E_2 - p}\alpha_2 x_1 \\ + \varepsilon_1 \varepsilon_2 2^{E_1 + E_2 - 2p}\alpha_1\alpha_2 - \varepsilon_3 2^{E_3 - p}\alpha_3 \end{aligned} \tag{10}$$

By neglecting the fourth term, which is of the second order in 2^{-p}, one obtains

$$\begin{aligned} X_1 \otimes X_2 = x_1 x_2 - \varepsilon_1 2^{E_1 - p}\alpha_1 x_2 - \varepsilon_2 2^{E_2 - p}\alpha_2 x_1 \\ - \varepsilon_3 2^{E_3 - p}\alpha_3 \end{aligned} \tag{11}$$

By neglecting terms of an order greater than or equal to 2^{-2p}, one obtains

$$\begin{aligned} X_1 \oslash X_2 = \frac{x_1}{x_2} - \varepsilon_1 2^{E_1 - p}\frac{\alpha_1}{x_2} + \varepsilon_2 2^{E_2 - p}\alpha_2 \frac{x_1}{x_2^2} \\ - \varepsilon_3 2^{E_3 - p}\alpha_3 \end{aligned} \tag{12}$$

In the case of an addition with operands of the same sign,

$$E_3 = \max(E_1, E_2) + \delta \text{ with } \delta = 0 \text{ or } \delta = 1$$

The order of magnitude of the two terms that result from the rounding errors on X_1 and X_2 is at most $2^{E_3 - p}$. The relative error on $X_1 \oplus X_2$ remains of the order of 2^{-p}. This operation is therefore relatively stable: It does not induce any brutal loss of accuracy.

The same conclusions are valid in the case of a multiplication, because

$$E_3 = E_1 + E_2 + \delta, \text{ with } \delta = 0 \text{ or } \delta = -1$$

and in the case of a division, because

$$E_3 = E_1 - E_2 + \delta, \text{ with } \delta = 0 \text{ or } \delta = 1$$

In the case of a subtraction with operands of the same sign, $E_3 = \max(E_1, E_2) - k$. If X_1 and X_2 are very close, then k may be large. The order of magnitude of the absolute error remains $2^{\max(E_1,E_2)-p}$, but the order of magnitude of the relative error is $2^{\max(E_1,E_2)-p-E_3} = 2^{-p+k}$. In one operation, k exact significant bits have been lost: It is the so-called *catastrophic cancellation*.

Rounding Error Propagation. A numerical program is a sequence of arithmetic operations. The result R provided by a program after n operations or assignments can be modeled to the first order in 2^{-p} as:

$$R \approx r + \sum_{i=1}^{n} g_i(d) 2^{-p}\alpha_i \tag{13}$$

where r is the exact result, p is the number of bits in the mantissa, α_i are independent uniformly distributed random variables on $[-1, 1]$ and $g_i(d)$ are coefficients depending exclusively on the data and on the code. For instance, in Equation (12), $g_i(d)$ are $\frac{1}{x_2}$ and $\frac{x_1}{x_2^2}$.

The number $C_{R,r}$ of exact significant bits of the computed result R is

$$C_{R,r} = \log_2\left|\frac{R + r}{2(R - r)}\right| \tag{14}$$

$$C_{R,r} \approx -\log_2\left|\frac{R - r}{r}\right| = p - \log_2\left|\sum_{i=1}^{n} g_i(d)\frac{\alpha_i}{x}\right| \tag{15}$$

The last term in Equation (15) represents the loss of accuracy in the computation of R. This term is independent of p. Therefore, assuming that the model at the first order established in Equation (13) is valid, the loss of accuracy in a computation is independent of the precision used.

Impact of Rounding Errors on Numerical Programs

With floating-point arithmetic, rounding errors occur in numerical programs and lead to a loss of accuracy, which is difficult to estimate. Another consequence of floating-point arithmetic is the loss of algebraic properties. The floating-point addition and the floating-point multiplication are commutative, but not associative. Therefore the same formula may generate different results depending on the order in which arithmetic operations are executed. For instance, in IEEE single precision arithmetic with rounding to the nearest,

$$(-10^{20} \oplus 10^{20}) \oplus 1 = 1 \tag{16}$$

but

$$-10^{20} \oplus (10^{20} \oplus 1) = 0 \tag{17}$$

Equation (17) causes a so-called *absorption*. Indeed, an absorption may occur during the addition of numbers with very different orders of magnitude: The smallest number may be lost.

Furthermore, with floating-point arithmetic, the multiplication is not distributive with respect to the addition. Let A, B, and C be floating-point numbers, $A \otimes (B \oplus C)$ may not be equal to $(A \otimes B) \oplus (A \otimes C)$. For instance, in IEEE single precision arithmetic with rounding to the nearest, if A, B and C are respectively assigned to 3.3333333, 12345679 and 1.2345678, for $A \otimes (B \oplus C)$ and $(A \otimes B) \oplus (A \otimes C)$, one obtains 41152264 and 41152268, respectively.

Impact on Direct Methods. The particularity of a direct method is to provide the solution to a problem in a finite number of steps. In infinite precision arithmetic, a direct method would compute the exact result. In finite precision arithmetic, rounding error propagation induces a loss of accuracy and may cause problems in branching statements. The general form of a branching statement in a program is

IF condition THEN sequence 1 ELSE sequence 2.

If the condition is satisfied, then a sequence of instructions is executed, otherwise another sequence is performed. Such a condition can be for instance $A \geq B$. In the case when A and B are intermediate results already affected by rounding errors, the difference between A and B may have no exact significant digit. The choice of the sequence that is executed may depend on rounding error propagation. The sequence chosen may be the wrong one: It may be different from the one that would have been chosen in exact arithmetic.

For instance, depending on the value of the discriminant, a second degree polynomial has one (double) real root, two real roots, or two conjugate complex roots. The discriminant and the roots of the polynomial $0.3x^2 - 2.1x + 3.675$ obtained using IEEE single precision arithmetic with rounding to the nearest are $D = -5.185604\text{E-}07$, $x = 3.4999998 \pm 1.2001855\text{E}03\ i$. Two conjugate complex roots are computed. But the exact values are $D = 0$, $x = 3.5$. The polynomial actually has one double real root. In floating-point arithmetic, rounding errors occur because of both assignments and arithmetic operations. Indeed the coefficients of the polynomial are not floating-point numbers. Therefore, the computed discriminant has no exact significant digit, and the wrong sequence of instructions is executed.

Impact on Iterative Methods. The result of an iterative method is defined as the limit L of a first-order recurrent sequence:

$$L = \operatorname*{Lim}_{n \to \infty} U_n \quad \text{with} \quad U_{n+1} = \mathcal{F}(U_n) \quad \mathbb{R}^m \xrightarrow{\mathcal{F}} \mathbb{R}^m \tag{18}$$

Because of rounding error propagation, the same problems as in a direct method may occur. But another difficulty is caused by the loss of the notion of limit on a computer. Computations are performed until a stopping criterion is satisfied. Such a stopping criterion may involve the absolute error:

$$\|U_n - U_{n-1}\| \leq \varepsilon \tag{19}$$

or the relative error:

$$\|U_n - U_{n-1}\| \leq \varepsilon \, \|U_{n-1}\| \tag{20}$$

It may be difficult to choose a suitable value for ε. If ε is too high, then computations stop too early and the result is very approximative. If ε is too low, useless iterations are performed without improving the accuracy of the result, because of rounding errors. In this case, the stopping criterion may never be satisfied because the chosen accuracy is illusive. The impact of ε on the quality of the result is shown in the numerical experiment described below.

Newton's method is used to compute a root of

$$f(x) = x^4 - 1002x^3 + 252001x^2 - 501000x + 250000 \tag{21}$$

The following sequence is computed:

$$x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)} \quad \text{with} \quad x_0 = 1100 \tag{22}$$

The exact limit is $L = 500$, which is a double root of f. The stopping criterion is $|x_n - x_{n-1}| \leq \varepsilon |x_{n-1}|$, and the maximum number of iterations is set to 1000. Table 2 shows for several values of ε the last value of n and the error $|x_n - L|$ computed using IEEE double precision arithmetic with rounding to the nearest.

It is noticeable that the optimal order of magnitude for ε is 10^{-11}. The stopping criterion can not be satisfied if $\varepsilon \leq 10^{-12}$: The maximum number of iterations is reached. Furthermore, the error is slightly higher than for $\varepsilon = 10^{-11}$.

Impact on Approximation Methods. These methods provide an approximation of a limit $L = \lim_{h \to 0} L(h)$. This approximation is affected by a global error $E_g(h)$, which consists in a truncation error $E_t(h)$, inherent to the method, and a rounding error $E_r(h)$. If the step h decreases, then the truncation error $E_t(h)$ also decreases, but the rounding error $E_r(h)$ usually increases, as shown in Fig. 1. It may therefore seem difficult to choose the optimal step h_{opt}. The rounding error should be evaluated, because the global error is minimal if the truncation error and the rounding error have the same order of magnitude.

The numerical experiment described below (4) shows the impact of the step h on the quality of the approximation. The second derivative at $x = 1$ of the following function

$$f(x) = \frac{4970x - 4923}{4970x^2 - 9799x + 4830} \tag{23}$$

Table 2. Number of Iterations and Error Obtained Using Newton's Method in Double Precision

ε	n	$\lvert x_n - L \rvert$
10^{-7}	26	3.368976E-05
10^{-8}	29	4.211986E-06
10^{-9}	33	2.525668E-07
10^{-10}	35	1.405326E-07
10^{-11}	127	1.273870E-07
10^{-12}	1000	1.573727E-07
10^{-13}	1000	1.573727E-07

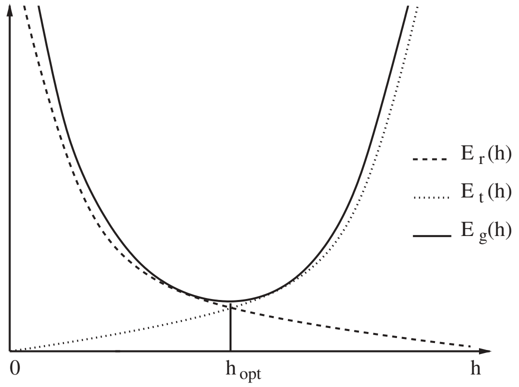

Figure 1. Evolution of the rounding error *$E_r(h)$*, the truncation error *$E_t(h)$* and the global error *$E_g(h)$* with respect to the step h.

is approximated by

$$L(h) = \frac{f(x-h) - 2f(x) + f(x+h)}{h^2} \qquad (24)$$

The exact result is $f''(1) = 94$. Table 3 shows for several steps h the result $L(h)$, and the absolute error $|L(h) - L|$ computed using IEEE double precision arithmetic with rounding to the nearest.

It is noticeable that the optimal order of magnitude for h is 10^{-6}. If h is too low, then the rounding error prevails and invalidates the computed result.

METHODS FOR ROUNDING ERROR ANALYSIS

In this section, different methods of analyzing rounding errors are reviewed.

Forward/Backward Analysis

This subsection is heavily inspired from Refs. 5 and 6. Other good references are Refs. 7–9.

Let X be an approximation to a real number x. The two common measures of the accuracy of X are its *absolute error*

$$E_a(X) = |x - X| \qquad (25)$$

and its *relative error*

$$E_r(X) = \frac{|x - X|}{|x|} \qquad (26)$$

(which is undefined if $x = 0$). When x and X are vectors, the relative error is usually defined with a norm as $\|x - X\|/\|x\|$. This is a *normwise relative error*. A more widely used relative error is the *componentwise relative error* defined by

$$\max_i \frac{|x_i - X_i|}{|x_i|}.$$

It makes it possible to put the individual relative errors on an equal footing.

Table 3. Second Order Approximation of $f''(1) = 94$ Computed in Double Precision

h	$L(h)$	$\|L(h) - L\|$

Well-Posed Problems. Let us consider the following mathematical problem *(P)*

$$(P) : \text{given}\, y,\ \text{find}\, x \text{ such that}\, F(x) = y$$

where F is a continuous mapping between two linear spaces (in general $\mathbb{R}^n$ or $\mathbb{C}^n$). One will say that the problem (P) is *well posed* in the sense of Hadamard if the solution $x = F^{-1}(y)$ exists, is unique and F^{-1} is continuous in the neighborhood of y. If it is not the case, then one says that the problem is *ill posed*. An example of ill-posed problem is the solution of a linear system $Ax = b$, where A is singular. It is difficult to deal numerically with ill-posed problems (this is generally done via regularization techniques). That is why we will focus only on well-posed problems in the sequel.

Conditioning. Given a well-posed problem (P), one wants now to know how to measure the difficulty of solving this problem. This measurement will be done via the notion of *condition number*. Roughly speaking, the condition number measures the sensitivity of the solution to perturbation in the data. Because the problem (P) is well posed, one can write it as $x = G(y)$ with $G = F^{-1}$.

The input space (data) and the output space (result) are denoted by $\mathcal{D}$ and $\mathcal{R}$, respectively the norms on these spaces will be denoted $\|\cdot\|_{\mathcal{D}}$ and $\|\cdot\|_{\mathcal{R}}$. Given $\varepsilon > 0$ and let $\mathcal{P}(\varepsilon) \subset \mathcal{D}$ be a set of perturbation Δy of the data y that satisfies $\|\Delta y\|_{\mathcal{D}} \le \varepsilon$, the perturbed problem associated with problem (P) is defined by

$$\text{Find}\, \Delta x \in \mathcal{R} \text{ such that}\, F(x + \Delta x) = y + \Delta y \text{ for a given}\, \Delta y \in \mathcal{P}(\varepsilon)$$

x and y are assumed to be nonzero. The *condition number* of the problem (P) in the data y is defined by

$$\text{cond}(P, y) := \lim_{\varepsilon \to 0} \sup_{\Delta y \in \mathcal{P}(\varepsilon), \Delta y \neq 0} \left\{ \frac{\|\Delta x\|_{\mathcal{R}}}{\|\Delta y\|_{\mathcal{D}}} \right\} \qquad (27)$$

Example 3.1. (summation). Let us consider the problem of computing the sum

$$x = \sum_{i=1}^{n} y_i$$

assuming that $y_i \neq 0$ for all i. One will take into account the perturbation of the input data that are the coefficients y_i. Let $\Delta y = (\Delta y_1, \ldots, \Delta y_n)$ be the perturbation on $y = (y_1, \ldots, y_n)$. It follows that $\Delta x = \sum_{i=1}^{n} \Delta y_i$. Let us endow $\mathcal{D} = \mathbb{R}^n$ with the relative norm $\|\Delta y\|_{\mathcal{D}} = \max_{i=1,\ldots,n} |\Delta y_i|/|y_i|$ and $\mathcal{R} = \mathbb{R}$ with the relative norm $\|\Delta x\|_{\mathcal{R}} = |\Delta x|/|x|$. Because

$$|\Delta x| = |\sum_{i=1}^{n} \Delta y_i| \leq \|\Delta y\|_{\mathcal{D}} \sum_{i=1}^{n} |y_i|,$$

one has[1]

$$\frac{\|\Delta x\|_{\mathcal{R}}}{\|\Delta y\|_{\mathcal{D}}} \leq \frac{\sum_{i=1}^{n} |y_i|}{|\sum_{i=1}^{n} y_i|} \tag{28}$$

This bound is reached for the perturbation Δy such that $\Delta y_i / y_i = \text{sign}(y_i)\|\Delta y\|_{\mathcal{D}}$ where sign is the sign of a real number. As a consequence,

$$\text{cond}\left(\sum_{i=1}^{n} y_i\right) = \frac{\sum_{i=1}^{n} |y_i|}{|\sum_{i=1}^{n} y_i|} \tag{29}$$

Now one has to interpret this condition number. A problem is considered as ill conditioned if it has a large condition number. Otherwise, it is well conditioned. It is difficult to give a precise frontier between well conditioned and ill-conditioned problems. This statement will be clarified in a later section thanks to the rule of thumb. The larger the condition number is, the more a small perturbation on the data can imply a greater error on the result. Nevertheless, the condition number measures the *worst case* implied by a small perturbation. As a consequence, it is possible for an ill-conditioned problem that a small perturbation on the data also implies a small perturbation on the result. Sometimes, such a behavior is even typical.

Remark 1. It is important to note that the condition number is independent of the algorithm used to solve the problem. It is only a characteristic of the problem.

Stability of an Algorithm. Problems are generally solved using an *algorithm*, which is a set of operations and tests that one can consider as the function G defined above given the solution of our problem. Because of the rounding errors, the algorithm is not the function G but rather a function $\hat{G}$. Therefore, the algorithm does not compute $x = G(y)$ but $\hat{x} = \hat{G}(y)$.

The *forward analysis* tries to study the execution of the algorithm $\hat{G}$ on the data y. Following the propagation of the rounding errors in each intermediate variables, the forward analysis tries to estimate or to bound the difference between x and $\hat{x}$. This difference between the exact solution x and the computed solution $\hat{x}$ is called the *forward error*.

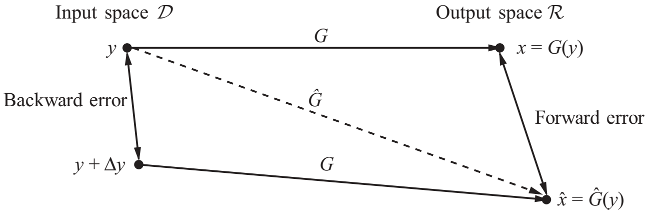

Figure 2. Forward and backward error for the computation of $x = G(y)$.

It is easy to recognize that it is pretty difficult to follow the propagation of all the intermediate rounding errors. The *backward analysis* makes it possible to avoid this problem by working with the function G itself. The idea is to seek for a problem that is actually solved and to check if this problem is "close to" the initial one. Basically, one tries to put the error on the result as an error on the data. More theoretically, one seeks for Δy such that $\hat{x} = G(y + \Delta y)$. Δy is said to be the *backward error* associated with $\hat{x}$. A backward error measures the distance between the problem that is solved and the initial problem. As $\hat{x}$ and G are known, it is often possible to obtain a good upper bound for Δy (generally, it is easier than for the forward error). Figure 2 sums up the principle of the forward and backward analysis.

Sometimes, it is not possible to have $\hat{x} = G(y + \Delta y)$ for some Δy but it is often possible to get Δx and Δy such that $\hat{x} + \Delta x = G(y + \Delta y)$. Such a relation is called a *mixed forward-backward error*.

The *stability* of an algorithm describes the influence of the computation in finite precision on the quality of the result. The backward error associated with $\hat{x} = \hat{G}(y)$ is the scalar $\eta(\hat{x})$ defined by, when it exists,

$$\eta(\hat{x}) = \min_{\Delta y \in \mathcal{D}} \{\|\Delta y\|_{\mathcal{D}} : \hat{x} = G(y + \Delta y)\} \tag{30}$$

If it does not exist, then $\eta(\hat{x})$ is set to $+\infty$. An algorithm is said to be *backward-stable* for the problem (P) if the computed solution $\hat{x}$ has a "small" backward error $\eta(\hat{x})$. In general, in finite precision, "small" means of the order of the rounding unit u.

Example 3.2. (summation). The addition is supposed to satisfy the following property:

$$\hat{z} = z(1 + \delta) = (a + b)(1 + \delta) \text{ with } |\delta| \leq u \tag{31}$$

It should be noticed that this assumption is satisfied by the IEEE arithmetic. The following algorithm to compute the sum $\sum y_i$ will be used.

Algorithm 3.1. Computation of the sum of floating-point numbers

```
function res = Sum($y$)
  $s_1 = y_1$
  for $i = 2 : n$
    $s_{\mathrm{i}} = s_{\mathrm{i}-1} \oplus y_{\mathrm{i}}$
  res = $s_n$
```

Thanks to Equation (31), one can write

$$s_i = (s_{i-1} + y_i)(1 + \delta_i) \text{ with } |\delta_i| \leq u \tag{32}$$

[1] The Cauchy-Schwarz inequality $|\sum_{i=1}^{n} x_i y_i| \leq \max_{i=1,\ldots,n} |x_i| \times \sum_{i=1}^{n} |y_i|$ is used.

For convenience, $1+\theta_j=\prod_{i=1}^{j}(1+\varepsilon_i)$ is written, for $|\varepsilon_i|\leq u$ and $j\in\mathbb{N}$. Iterating the previous equation yields

$$\begin{aligned}\texttt{res} &= y_1(1+\theta_{n-1})+y_2(1+\theta_{n-1})+y_3(1+\theta_{n-2})\\ &\quad+\cdots+y_{n-1}(1+\theta_2)+y_n(1+\theta_1)\end{aligned}\qquad(33)$$

One can interpret the computed sum as the exact sum of the vector z with $z_i=y_i(1+\theta_{n+1-i})$ for $i = 2:n$ and $z_1=y_1(1+\theta_{n-1})$.

As $|\varepsilon_i|\leq u$ for all i and assuming $nu<1$, it can be proved that $|\theta_i|\leq iu/(1-iu)$ for all i. Consequently, one can conclude that the backward error satisfies

$$\eta(\hat{x})=|\theta_{n-1}|\lesssim nu\qquad(34)$$

Because the backward error is of the order of u, one concludes that the classic summation algorithm is backward-stable.

Accuracy of the Solution. How is the accuracy of the computed solution estimated? The accuracy of the computed solution actually depends on the condition number of the problem and on the stability of the algorithm used. The condition number measures the effect of the perturbation of the data on the result. The backward error simulates the errors introduced by the algorithm as errors on the data. As a consequence, at the first order, one has the following *rule of thumb*:

$$\text{forward error}\lesssim\text{condition number}\times\text{backward error}\qquad(35)$$

If the algorithm is backward-stable (that is to say the backward error is of the order of the rounding unit u), then the rule of thumb can be written as follows

$$\text{forward error}\lesssim\text{condition number}\times u\qquad(36)$$

In general, the condition number is hard to compute (as hard as the problem itself). As a consequence, some estimators make it possible to compute an approximation of the condition number with a reasonable complexity.

The rule of thumb makes it possible to be more precise about what were called ill-conditioned and well-conditioned problems. A problem will be said to be ill conditioned if the condition number is greater than $1/u$. It means that the relative forward error is greater than 1 just saying that one has no accuracy at all for the computed solution.

In fact, in some cases, the rule of thumb can be proved. For the summation, if one denotes by $\hat{s}$ the computed sum of the vector y_i, $1\leq i\leq n$ and

$$s=\sum_{i=1}^{n}y_i$$

the real sum, then Equation (33) implies

$$\frac{|\hat{s}-s|}{|s|}\leq\gamma_{n-1}\,\mathrm{cond}\left(\sum_{i=1}^{n}y_i\right)\qquad(37)$$

with γ_n defined by

$$\gamma_n:=\frac{nu}{1-nu}\ \text{for}\ n\in\mathbb{N}\qquad(38)$$

Because $\gamma_{n-1}\approx(n-1)u$, it is almost the rule of thumb with just a small factor $n-1$ before u.

The LAPACK Library. The LAPACK library (10) is a collection of subroutines in Fortran 77 designed to solve major problems in linear algebra: linear systems, least square systems, eigenvalues, and singular values problems.

One of the most important advantages of LAPACK is that it provides error bounds for all the computed quantities. These error bounds are not rigorous but are mostly reliable. To do this, LAPACK uses the principles of backward analysis. In general, LAPACK provides both componentwise and normwise relative error bounds using the rule of thumb established in Equation (35).

In fact, the major part of the algorithms implemented in LAPACK are backward stable, which means that the rule of thumb [Equation (36)] is satisfied. As the condition number is generally very hard to compute, LAPACK uses estimators. It may happen that the estimator is far from the right condition number. In fact, the estimation can arbitrarily be far from the true condition number. The error bounds in LAPACK are only qualitative markers of the accuracy of the computed results.

Linear algebra problems are central in current scientific computing. Getting some good error bounds is therefore very important and is still a challenge.

Interval Arithmetic

Interval arithmetic (11, 12) is not defined on real numbers but on closed bounded intervals. The result of an arithmetic operation between two intervals, $X=[\underline{x},\overline{x}]$ and $Y=[\underline{y},\overline{y}]$, contains all values that can be obtained by performing this operation on elements from each interval. The arithmetic operations are defined below.

$$X+Y = [\underline{x}+\underline{y},\ \overline{x}+\overline{y}]\qquad(39)$$

$$X-Y = [\underline{x}-\overline{y},\ \overline{x}-\underline{y}]\qquad(40)$$

$$\begin{aligned}X\times Y = {}&[\min(\underline{x}\times\underline{y},\ \underline{x}\times\overline{y},\ \overline{x}\times\underline{y},\ \overline{x}\times\overline{y})\\ &\max(\underline{x}\times\underline{y},\ \underline{x}\times\overline{y},\ \overline{x}\times\underline{y},\ \overline{x}\times\overline{y})]\end{aligned}\qquad(41)$$

$$X^2 = \begin{cases}[\min(\underline{x}^2,\ \overline{x}^2),\max(\underline{x}^2,\ \overline{x}^2)]\ \text{if}\ 0\notin[\underline{x},\ \overline{x}]\\ [0,\max(\underline{x}^2,\ \overline{x}^2)]\ \text{otherwise}\end{cases}\qquad(42)$$

$$1/Y = [\min(1/\underline{y},1/\overline{y}),\max(1/\underline{y},1/\overline{y})]\ \text{if}\ 0\notin[\underline{y},\ \overline{y}]\qquad(43)$$

$$X/Y = [\underline{x},\ \overline{x}]\times(1/[\underline{y},\ \overline{y}])\ \text{if}\ 0\notin[\underline{y},\ \overline{y}]\qquad(44)$$

Arithmetic operations can also be applied to interval vectors and interval matrices by performing scalar interval operations componentwise.

Table 4. Determinant of the Hilbert Matrix H of Dimension 8

	det(H)	#exact digits
IEEE double precision	2.73705030017821E-33	7.17
interval Gaussian elimination	[2.717163073713011E-33, 2.756937028322111E-33]	1.84
interval specific algorithm	[2.737038183754026E-33, 2.737061910503125E-33]	5.06

An interval extension of a function f must provide all values that can be obtained by applying the function to any element of the interval argument X:

$$\forall x \in X,\ f(x) \in f(X) \tag{45}$$

For instance, $\exp[\underline{x}, \overline{x}] = [\exp \underline{x}, \exp \overline{x}]$ and $\sin[\pi/6, 2\pi/3] = [1/2, 1]$.

The interval obtained may depend on the formula chosen for mathematically equivalent expressions. For instance, let $f_1(x) = x^2 - x + 1$. $f_1([-2, 1]) = [-2, 7]$. Let $f_2(x) = (x - 1/2)^2 + 3/4$. The function f_2 is mathematically equivalent to f_1, but $f_2([-2, 1]) = [3/4\,, 7] \neq f_1([-2, 1])$. One can notice that $f_2([-2, 1]) \subseteq f_1([-2, 1])$. Indeed a power set evaluation is always contained in the intervals that result from other mathematically equivalent formulas.

Interval arithmetic enables one to control rounding errors automatically. On a computer, a real value that is not machine representable can be approximated to a floating-point number. It can also be enclosed by two floating-point numbers. Real numbers can therefore be replaced by intervals with machine-representable bounds. An interval operation can be performed using directed rounding modes, in such a way that the rounding error is taken into account and the exact result is necessarily contained in the computed interval. For instance, the computed results, with guaranteed bounds, of the addition and the subtraction between two intervals $X = [\underline{x}, \overline{x}]$ and $Y = [\underline{y}, \overline{y}]$ are

$$X + Y \;=\; [\nabla(\underline{x} + \underline{y}), \Delta(\overline{x} + \overline{y})] \supseteq \{x + y | x \in X, y \in Y\} \tag{46}$$

$$X - Y \;=\; [\nabla(\underline{x} - \overline{y}), \Delta(\overline{x} - \underline{y})] \supseteq \{x - y | x \in X, y \in Y\} \tag{47}$$

where ∇ (respectively Δ) denotes the downward (respectively upward) rounding mode.

Interval arithmetic has been implemented in several libraries or softwares. For instance, a C++ class library, C-XSC,[2] and a Matlab toolbox, INTLAB,[3] are freely available.

The main advantage of interval arithmetic is its reliability. But the intervals obtained may be too large. The intervals width regularly increases with respect to the intervals that would have been obtained in exact arithmetic. With interval arithmetic, rounding error compensation is not taken into account.

The overestimation of the error can be caused by the loss of variable dependency. In interval arithmetic, several occurrences of the same variable are considered as different variables. For instance, let $X = [1,2]$,

$$\forall x \in X,\ x - x = 0 \tag{48}$$

but

$$X - X = [-1, 1] \tag{49}$$

Another source of overestimation is the "wrapping effect" because of the enclosure of a noninterval shape range into an interval. For instance, the image of the square $[0, \sqrt{2}] \times [0, \sqrt{2}]$ by the function

$$f(x,y) = \frac{\sqrt{2}}{2}(x + y, y - x) \tag{50}$$

is the rotated square S_1 with corners (0, 0), (1, −1), (2, 0), (1, 1). The square S_2 provided by interval arithmetic operations is: $f([0, \sqrt{2}], [0, \sqrt{2}]) = ([0, 2], [-1, 1])$. The area obtained with interval arithmetic is twice the one of the rotated square S_1.

As the classic numerical algorithms can lead to overpessimistic results in interval arithmetic, specific algorithms, suited for interval arithmetic, have been proposed. Table 4 presents the results obtained for the determinant of Hilbert matrix H of dimension 8 defined by

$$H_{ij} = \frac{1}{i + j - 1} \quad \text{for} \quad i = 1, \ldots, 8 \quad \text{and} \quad j = 1, \ldots 8 \tag{51}$$

computed:

- using the Gaussian elimination in IEEE double precision arithmetic with rounding to the nearest
- using the Gaussian elimination in interval arithmetic
- using a specific interval algorithm for the inclusion of the determinant of a matrix, which is described in Ref. 8, p. 214.

Results obtained in interval arithmetic have been computed using the INTLAB toolbox.

The exact value of the determinant is

$$\mathrm{det(H)} = \prod_{\mathrm{k}=0}^{7} \frac{(\mathrm{k}!)^3}{(8 + \mathrm{k})!} \tag{52}$$

Its 15 first exact significant digits are:

$$\mathrm{det(H)} = 2.73705011379151\mathrm{E} - 33 \tag{53}$$

The number of exact significant decimal digits of each computed result has been reported in Table 4.

One can verify the main feature of interval arithmetic: The exact value of the determinant is enclosed in the computed intervals. Table 4 points out the overestimation of the

[2] http://www.xsc.de.

[3] http://www.ti3.tu-harburg.de/rump/intlab.

error with naive implementations of classic numerical algorithms in interval arithmetic. The algorithm for the inclusion of a determinant that is specific to interval arithmetic leads to a much thinner interval. Such interval algorithms exist in most areas of numerical analysis. Interval analysis can be used not only for reliable numerical simulations but also for computer assisted proofs (cf., for example, Ref. 8).

Probabilistic Approach

Here, a method for estimating rounding errors is presented without taking into account the model errors or the discretization errors.

Let us go back to the question *"What is the computing error due to floating-point arithmetic on the results produced by a program?"* From the physical point of view, in large numerical simulations, the final rounding error is the result of billions and billions of elementary rounding errors. In the general case, it is impossible to describe each elementary error carefully and, then to compute the right value of the final rounding error. It is usual, in physics, when a deterministic approach is not possible, to apply a probabilistic model. Of course, one loses the exact description of the phenomena, but one may hope to get some global information like order of magnitude, frequency, and so on. It is exactly what is hoped for when using a probabilistic model of rounding errors.

For the mathematical model, remember the formula at the first order [Equation (13)]. Concretely, the rounding mode of the computer is replaced by a random rounding mode (i.e., at each elementary operation, the result is rounded toward $-\infty$ or $+\infty$ with the probability 0.5.) The main interest of this new rounding mode is to run a same binary code with different rounding error propagations because one generates for different runs different random draws. If rounding errors affect the result, even slightly, then one obtains for N different runs, N different results on which a statistical test may be applied. This strategy is the basic idea of the CESTAC method (Contrôle et Estimation STochastique des Arrondis de Calcul). Briefly, the part of the N mantissas that is common to the N results is assumed to be not affected by rounding errors, contrary to the part of the N mantissas that is different from one result to another.

The implementation of the CESTAC method in a code providing a result R consists in:

- executing N times this code with the random rounding mode, which is obtained by using randomly the rounding mode toward $-\infty$ or $+\infty$; then, an N-sample (R_i) of R is obtained,
- choosing as the computed result the mean value $\overline{R}$ of R_i, $i = 1, \ldots, N$,
- estimating the number of exact decimal significant digits of $\overline{R}$ with

$$C_{\overline{R}} = \log_{10}\left(\frac{\sqrt{N}|\overline{R}|}{\sigma\tau_\beta}\right) \tag{54}$$

where

$$\overline{R} = \frac{1}{N}\sum_{i=1}^{N} R_i \quad \text{and} \quad \sigma^2 = \frac{1}{N-1}\sum_{i=1}^{N}(R_i - \overline{R})^2 \tag{55}$$

τ_β is the value of Student's distribution for $N-1$ degrees of freedom and a probability level $1-\beta$.

From Equation (13), if the first order approximation is valid, one may deduce that:

1. The mean value of the random variable R is the exact result r,
2. Under some assumptions, the distribution of R is a quasi-Gaussian distribution.

It has been shown that $N = 3$ is the optimal value. The estimation with $N = 3$ is more reliable than with $N = 2$ and increasing the size of the sample does not improve the quality of the estimation. The complete theory can be found in Refs. 13 and 14. The approximation at the first order in Equation (13) is essential for the validation of the CESTAC method. It has been shown that this approximation may be wrong only if multiplications or divisions involve nonsignificant values. A nonsignificant value is a computed result for which all the significant digits are affected by rounding errors. Therefore, one needs a dynamical control of multiplication and division during the execution of the code. This step leads to the synchronous implementation of the method (i.e., to the parallel computation of the N results R_i.) In this approach, a classic floating-point number is replaced by a 3-sample $X = (X_1, X_2, X_3)$, and an elementary operation $\Omega \in \{+, -, \times, /\}$ is defined by $X\Omega Y = (X_1\omega Y_1, X_2\omega Y_2, X_3\omega Y_3)$, where ω represents the corresponding floating-point operation followed by a random rounding. A new important concept has also been introduced: the computational zero.

Definition 3.1. During the run of a code using the CESTAC method, an intermediate or a final result R is a computational zero, denoted by @.0, if one of the two following conditions holds:

- $\forall i$, $R_i = 0$,
- $C_{\overline{R}} \leq 0$.

Any computed result R is a computational zero if either $R = 0$, R being significant, or R is nonsignificant. In other words, a computational zero is a value that cannot be differentiated from the mathematical zero because of its rounding error. From this new concept of zero, one can deduce new order relationships that take into account the accuracy of intermediate results. For instance,

Definition 3.2. X is stochastically strictly greater than Y if and only if:

$$\overline{X} > \overline{Y} \quad \text{and} \quad X - Y \neq @.0$$

or

Definition 3.3. X is stochastically greater than or equal to Y if and only if:

$$\overline{X} \geq \overline{Y} \quad \text{or} \quad X - Y = @.0$$

The joint use of the CESTAC method and these new definitions is called Discrete Stochastic Arithmetic (DSA). DSA enables to estimate the impact of rounding errors on any result of a scientific code and also to check that no anomaly occurred during the run, especially in branching statements. DSA is implemented in the Control of Accuracy and Debugging for Numerical Applications (CADNA) library.[4] The CADNA library allows, during the execution of any code:

- the estimation of the error caused by rounding error propagation,
- the detection of numerical instabilities,
- the checking of the sequencing of the program (tests and branchings),
- the estimation of the accuracy of all intermediate computations.

METHODS FOR ACCURATE COMPUTATIONS

In this section, different methods to increase the accuracy of the computed result of an algorithm are presented. Far from being exhaustive, two classes of methods will be presented. The first class is the class of compensated methods. These methods consist in estimating the rounding error and then adding it to the computed result. The second class are algorithms that use multiprecision arithmetic.

Compensated Methods

Throughout this subsection, one assumes that the floating-point arithmetic adhers to IEEE 754 floating-point standard in rounding to the nearest. One also assume that no overflow nor underflow occurs. The material presented in this section heavily relies on Ref. (15).

Error-Free Transformations (EFT). One can notice that $a \circ b \in \mathbb{R}$ and $a \circledcirc b \in \mathbb{F}$, but in general $a \circ b \in \mathbb{F}$ does not hold. It is known that for the basic operations $+, -, \times, \sqrt{}$ the approximation error of a floating-point operation is still a floating-point number:

$$\begin{array}{lcll} x = a \oplus b & \Rightarrow & a + b = x + y & \text{with} \, y \in \mathbb{F}, \\ x = a \ominus b & \Rightarrow & a - b = x + y & \text{with} \, y \in \mathbb{F}, \\ x = a \otimes b & \Rightarrow & a \times b = x + y & \text{with} \, y \in \mathbb{F}, \\ x = a \oslash b & \Rightarrow & a = x \times b + y & \text{with} \, y \in \mathbb{F}, \\ x = \textcircled{\checkmark}\ (a) & \Rightarrow & a = x^2 + y & \text{with} \, y \in \mathbb{F} \end{array} \tag{56}$$

These example are *error-free* transformations of the pair (a, b) into the pair (x, y). The floating-point number x is the result of the floating-point operation and y is the rounding term. Fortunately, the quantities x and y in Equation (56) can be computed exactly in floating-point arithmetic. For the algorithms, Matlab-like notations are used. For addition, one can use the following algorithm by Knuth.

Algorithm 4.1. (16). Error-free transformation of the sum of two floating-point numbers

```
function [$x$, $y$] = TwoSum($a$, $b$)
  $x = a \oplus b$
  $z = x \ominus a$
  $y = (a \ominus (x \ominus z)) \oplus (b \ominus z)$
```

Another algorithm to compute an error-free transformation is the following algorithm from Dekker (17). The drawback of this algorithm is that $x + y = a + b$ provided that $|a| \geq |b|$. Generally, on modern computers, a comparison followed by a branching and three operations costs more than six operations. As a consequence, TwoSum is generally more efficient than FastTwoSum plus a branching.

Algorithm 4.2. (17). Error-free transformation of the sum of two floating-point numbers.

```
function [$x$, $y$] = FastTwoSum($a$, $b$)
  $x = a \oplus b$
  $y = (a \ominus x) \oplus b$
```

For the error-free transformation of a product, one first needs to split the input argument into two parts. Let p be given by $u = 2^{-p}$, and let us define $s = \lceil p/2 \rceil$. For example, if the working precision is IEEE 754 double precision, then $p = 53$ and $s = 27$. The following algorithm by Dekker (17) splits a floating-point number $a \in \mathbb{F}$ into two parts x and y such that

$$a = x + y \quad \text{with} \, |y| \leq |x| \tag{57}$$

Both parts x and y have at most $s - 1$ non-zero bits.

Algorithm 4.3. (17) Error-free split of a floating-point number into two parts

```
function [$x$, $y$] = Split($a$)
  factor $= 2^s \oplus 1$
  $c =$ factor $\otimes a$
  $x = c \ominus (c \ominus a)$
  $y = a \ominus x$
```

The main point of Split is that both parts can be multiplied in the same precision without error. With this function, an algorithm attributed to Veltkamp by Dekker enables to compute an error-free transformation for the product of two floating-point numbers. This algorithm returns two floating-point numbers x and y such that

$$a \times b = x + y \quad \text{with} \ x = a \otimes b \tag{58}$$

Algorithm 4.4. (17). Error-free transformation of the product of two floating-point numbers

```
function [$x$, $y$] = TwoProduct($a$, $b$)
  $x = a \otimes b$
  $[a_1, a_2] =$ Split($a$)
  $[b_1, b_2] =$ Split($b$)
  $y = a_2 \otimes b_2 \ominus (((x \ominus a_1 \otimes b_1) \ominus a2 \otimes b_1) \ominus a_1 \otimes b_2)$
```

The performance of the algorithms is interpreted in terms of floating-point operations (flops). The following

[4] http://www.lip6.fr/cadna/.

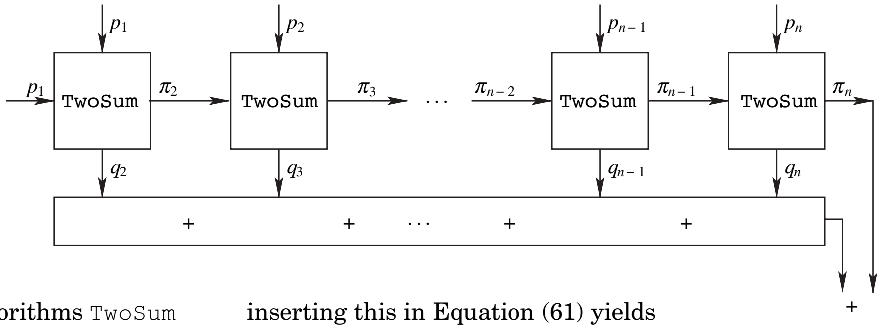

Figure 3. Compensated summation algorithm.

theorem summarizes the properties of algorithms `TwoSum` and `TwoProduct`.

Theorem 4.1. Let $a, b \in \mathbb{F}$ and let $x, y \in \mathbb{F}$ such that $[x, y] =$ `TwoSum`(a, b) (Algorithm 4.1). Then,

$$a + b = x + y, \quad x = a \oplus b, \quad |y| \le u|x|, \quad |y| \le u|a + b|. \tag{59}$$

The algorithm `TwoSum` requires 6 flops.

Let $a, b \in \mathbb{F}$ and let $x, y \in \mathbb{F}$ such that $[x, y] =$ `TwoProduct`(a, b) (Algorithm 4.4). Then,

$$a \times b = x + y, \quad x = a \otimes b, \quad |y| \le u|x|, \quad |y| \le u|a \times b|\,. \tag{60}$$

The algorithm `TwoProduct` requires 17 flops.

A Compensated Summation Algorithm. Hereafter, a compensated scheme to evaluate the sum of floating-point numbers is presented, (i.e., the error of individual summation is somehow corrected).

Indeed, with Algorithm 4.1 (`TwoSum`), one can compute the rounding error. This algorithm can be cascaded and sum up the errors to the ordinary computed summation. For a summary, see Fig. 3 and Algorithm 4.5.

Algorithm 4.5. Compensated summation algorithm

```
function res = CompSum($p$)
  $\pi_1 = p_1$; $\sigma_1 = 0$;
for $i = 2 : n$
  $[\pi_i, q_i]$ = TwoSum($\pi_{i-1}, p_i$)
  $\sigma_i = \sigma_{i-1} \oplus qi$
res = $\pi_n \oplus \sigma_n$
```

The following proposition gives a bound on the accuracy of the result. The notation γ_n defined by Equation (38) will be used. When using $\gamma_n, nu \le 1$ is implicitly assumed.

Proposition 4.2. (15). Suppose Algorithm `CompSum` is applied to floating-point number $p_i \in \mathbb{F}, 1 \le i \le n$. Let $s := \sum p_i, S := \sum |p_i|$ and nu < 1. Then, one has

$$|\mathtt{res} - s| \le u|s| + \gamma_{n-1}^2 S \tag{61}$$

In fact, the assertions of Proposition 4.2 are also valid in the presence of underflow.

One can interpret Equation (61) in terms of the condition number for the summation (29). Because

$$\mathrm{cond}\Big(\sum p_i\Big) = \frac{\sum |p_i|}{|\sum p_i|} = \frac{S}{|s|} \tag{62}$$

inserting this in Equation (61) yields

$$\frac{|\mathtt{res} - s|}{|s|} \le u + \gamma_{n-1}^2 \mathrm{cond}\Big(\sum p_i\Big) \tag{63}$$

Basically, the bound for the relative error of the result is essentially $(nu)^2$ times the condition number plus the rounding u because of the working precision. The second term on the right-hand side reflects the computation in twice the working precision (u^2) thanks to the *rule of thumb*. The first term reflects the rounding back in the working precision.

The compensated summation on ill-conditioned sum was tested; the condition number varied from 10^4 to 10^{40}.

Figure 4 shows the relative accuracy $|\mathtt{res} - s|/|s|$ of the computed value by the two algorithms 3.1 and 4.5. The *a priori* error estimations Equations (37) and (63) are also plotted.

As one can see in Fig. 4, the compensated summation algorithm exhibits the expected behavior, that is to say, the compensated rule of thumb Equation (63). As long as the condition number is less than u^{-1}, the compensated summation algorithm produces results with full precision (forward relative error of the order of u). For condition numbers greater than u^{-1}, the accuracy decreases and there is no accuracy at all for condition numbers greater than u^{-2}.

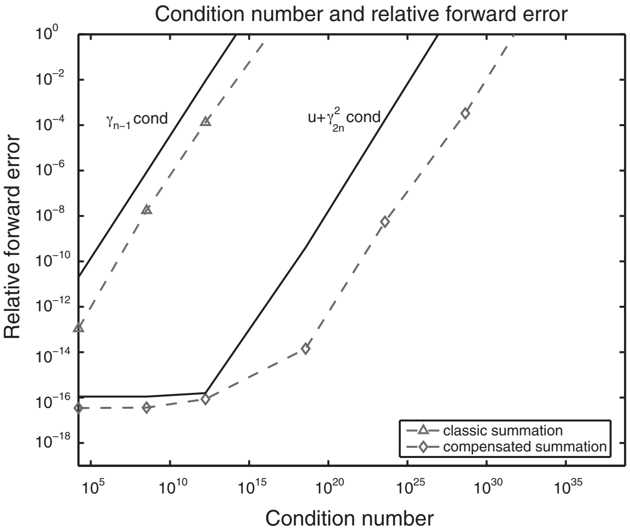

Figure 4. Compensated summation algorithm.

Multiple Precision Arithmetic

Compensated methods are a possible way to improve accuracy. Another possibility is to increase the working precision. For this purpose, some multiprecision libraries have been developed. One can divide the libraries into three categories.

- Arbitrary precision libraries using a *multiple-digit* format in which a number is expressed as a sequence of digits coupled with a single exponent. Examples of this format are Bailey's MPFUN/ARPREC,[5] Brent's MP,[6] or MPFR.[7]
- Arbitrary precision libraries using a *multiple-component* format where a number is expressed as unevaluated sums of ordinary floating-point words. Examples using this format are Priest's[8] and Shewchuk's[9] libraries. Such a format is also introduced in Ref. 18.
- Extended fixed-precision libraries using the *multiple-component* format but with a limited number of components. Examples of this format are Bailey's *double-double*[5] (double-double numbers are represented as an unevaluated sum of a leading double and a trailing double) and *quad-double*.[5]

The double-double library will be now presented. For our purpose, it suffices to know that a double-double number a is the pair (a_h, a_l) of IEEE-754 floating-point numbers with $a = a_h + a_l$ and $|a_l| \leq u\,|a_h|$. In the sequel, algorithms for

- the addition of a double number to a double-double number;
- the product of a double-double number by a double number;
- the addition of a double-double number to a double-double number

will only be presented. Of course, it is also possible to implement the product of a double-double by a double-double as well as the division of a double-double by a double, and so on.

Algorithm 4.6. Addition of the double number b to the double-double number (a_h, a_l)

```
function $[c_h, c_l]$ = add_dd_d($a_h, a_l, b$)
    $[t_h, t_l]$ = TwoSum($a_h, b$)
    $[c_h, c_l]$ = FastTwoSum($t_h, (t_l \oplus a_l)$)
```

Algorithm 4.7. Product of the double-double number (a_h,a_l) by the double number b

```
function $[c_h, c_l]$ = prod_dd_d($a_h, a_l, b$)
    $[s_h, s_l]$ = TwoProduct($a_h, b$)
    $[t_h, t_l]$ = FastTwoSum($s_h, (a_l \otimes b)$)
    $[c_h, c_l]$ = FastTwoSum($t_h, (t_l \oplus s_l)$)
```

Algorithm 4.8. Addition of the double-double number (a_h, a_l) to the double-double number (b_h, b_l)

```
function $[c_h, c_l]$ = add_dd_dd ($a_h, a_l, b_h, b_l$)
    $[s_h, s_l]$ = TwoSum($a_h, b_h$)
    $[t_h, t_l]$ = TwoSum($a_l, b_l$)
    $[t_h, s_l]$ = FastTwoSum($s_h, (s_l \oplus t_h)$)
    $[c_h, c_l]$ = FastTwoSum($t_h, (t_l \oplus s_l)$)
```

Algorithms 4.6 to 4.8 use error-free transformations and are very similar to compensated algorithms. The difference lies in the step of renormalization. This step is the last one in each algorithm and makes it possible to ensure that $|c_l| \leq u|c_h|$.

Several implementations can be used for the double-double library. The difference is that the lower-order terms are treated in a different way. If a, b are double-double numbers and $\circledcirc \in \{+, \times\}$, then one can show (19) that

$$\mathrm{fl}(a \circledcirc b) = (1+\delta)(a \circledcirc b)$$

with $|\delta| \leq 4 \cdot 2^{-106}$.

One might also note that when keeping $[\pi_n, \sigma_n]$ as a pair the first summand u disappears in [Equation (63)] (see Ref. 15), so it is an example for a double-double result.

Let us now briefly describe the MPFR library. This library is written in C language based on the GNU MP library (GMP for short). The internal representation of a floating-point number x by MPFR is

- a mantissa m;
- a sign s;
- a signed exponent e.

If the precision of x is p, then the mantissa m has p significant bits. The mantissa m is represented by an array of GMP unsigned machine-integer type and is interpreted as $1/2 \leq m < 1$. As a consequence, MPFR does not allow denormalized numbers.

MPFR provides the four IEEE rounding modes as well as some elementary functions (e.g., exp, log, cos, sin), all correctly rounded. The semantic in MPFR is as follows: For each instruction $a = b + c$ or $a = f(b, c)$ the variables may have different precisions. In MPFR, the data b and c are considered with their full precision and a correct rounding to the full precision of a is computed.

Unlike compensated methods that need to modify the algorithms, multiprecision libraries are convenient ways to increase the precision without too many efforts.

ACKNOWLEDGMENT

The authors sincerely wish to thank the reviewers for their careful reading and their constructive comments.

ADDRESSING: DIRECT AND INDIRECT

This article focuses on addressing modes—a mechanism machine instructions use to specify operands. Addressing modes are an important aspect of instruction set architecture (ISA). ISA refers to a portion of the computer that is visible to a compiler writer or an assembly language programmer, and it encompasses components such as (*1*) class of ISA, (*2*) memory, (*3*) addressing modes, (*4*) types and sizes of operands, (*5*) data processing and control flow operations supported by machine instructions, and (*6*) instruction encoding. As it is difficult to separate addressing modes from other components of instruction set architecture, we will first give a brief overview of basic ISA components. For a detailed treatment of the remaining ISA components, readers are directed to the article dedicated to instruction set architectures.

Class of ISA. Virtually all recent instruction set architectures have a set of general-purpose registers visible to programmers. These architectures are known as *general-purpose register architectures*. Machine instructions in these architectures specify all operands in memory or general-purpose registers explicitly. In older architectures, machine instructions specified one or more operands implicitly on the stack—so-called *stack architectures*—or in the accumulator—so-called *accumulator architectures*. There are many reasons why general-purpose register architectures dominate in today's computers. Allocating frequently used variables, pointers, and intermediate results of calculations in *registers* reduces memory traffic; improves processor performance since registers are much faster than memory; and reduces code size since naming registers requires fewer bits than naming memory locations directly. A general trend in recent architectures is to increase the number of general-purpose registers.

General-purpose register architectures can be classified into *register-memory* and *load-store architectures,* depending on the location of operands used in typical arithmetic and logical instructions. In register-memory architectures, arithmetic and logical machine instructions can have one or more operands in memory. In load-store architectures, only load and store instructions can access memory, and common arithmetic and logical instructions are performed on operands in registers. Depending on the number of operands that can be specified by an instruction, ISAs can be classified into *2-operand* or *3-operand architectures*. With 2-operand architectures, typical arithmetic and logical instructions specify one operand that is both a source and a destination for the operation result, and another operand is a source. For example, the arithmetic instruction *ADD R1, R2* adds the operands from the registers *R1* and *R2* and writes the result back to the register *R2*. With 3-operand architectures, instructions can specify two source operands and the result operand. For example, the arithmetic instruction *ADD R1, R2, R3* adds the operands from the registers *R1* and *R2* and writes the result to the register *R3*. In this text, we consider general-purpose register architectures that can be either register-memory or load-store.

Memory. Program instructions and data are stored in memory during program execution. Programmers see memory as a linear array of addressable locations as shown in Fig. 1. In nearly all memory systems, the smallest addressable location in memory is a single byte (8 bits). The range of memory that can be addressed by the processor is called an *address space*. For example, any program running on a 32-bit processor can address up to 4 GB (2^{32} bytes) of the address space. Although the smallest addressable object is a byte, bytes are generally grouped into multibyte objects. For example, in a 32-bit architecture, we refer to 2-byte objects as half-words, 4-byte objects as words, and 8-byte objects as double words. Machine instructions can directly reference and operate on words, half-words, or bytes. When referencing a multibyte object in memory, its given address is the address of its first byte. For example, a half-word located in memory at the address 8 will occupy two byte addresses 8 and 9.

Many instruction set architectures require multibyte objects to be *aligned* to their natural boundaries. For example, if we assume a 4-byte wide memory (Fig. 1), half-words must begin at even addresses, whereas words and double words must begin at addresses divisible by 4. This kind of alignment requirement is often referred to as *hard alignment*. It should be noted that hard alignment is not an architectural requirement; rather it makes hardware implementation more practical. Even architectures that do not require hard alignment may benefit from having multibyte objects aligned. Access to unaligned objects may require multiple accesses to memory, resulting in performance penalty. Another important issue related to memory is ordering the bytes within a larger object. There are two different conventions for byte ordering: *little-endian* and *big-endian* (Fig. 2). With little-endian byte ordering, the least significant byte in a word is located at the lowest byte address, and with big-endian, the most significant byte in a word is located at the lowest byte address. For example, let us consider a 32-bit integer variable with a hexadecimal value of 0x1234ABCD stored in memory at word address 8. For both big-endian and little-endian byte ordering, the most significant byte of the variable is 0x12 and the least significant byte is 0xCD. However, with the big-endian scheme, the most significant byte is at address 8, whereas with the little-endian scheme, the most significant byte is at address 11 (Fig. 2).

Types and Sizes of Operands. Machine instructions operate on operands of certain types. Common types supported by ISAs include character (e.g., 8-bit ASCII or 16-bit Unicode), signed and unsigned integers, and single- and double-precision floating-point numbers. ISAs typically support several sizes for integer numbers. For example,

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

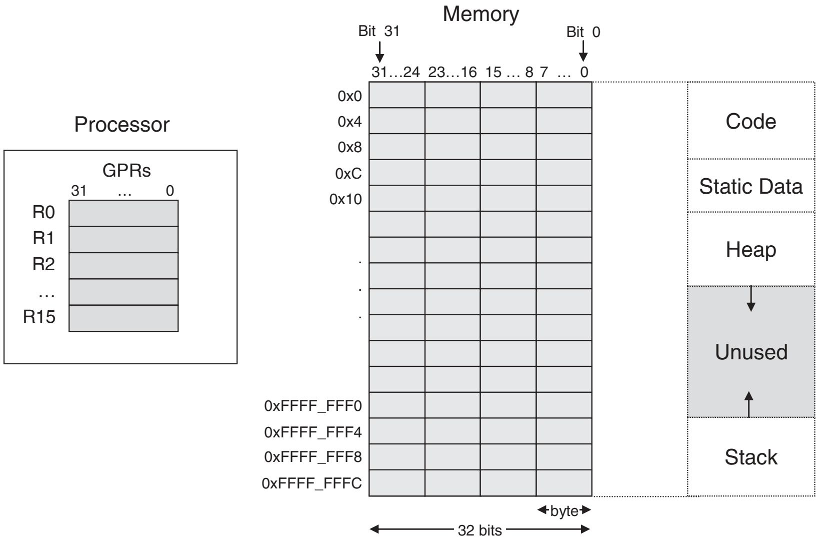

Figure 1. Programming model: general-purpose registers (GPRs) and memory. (This figure is available in full color at http://www.interscience.wiley.com/reference/ecse.)

a 32-bit architecture may include arithmetic instructions that operate on 8-bit integers, 16-bit integers (short integers), and 32-bit integers. Signed integers are represented using two's complement binary representation, whereas floating-point numbers rely on IEEE Standard 754. Some ISAs support less frequently used data types, such as character strings and packed decimal or binary-coded decimal numbers (a decimal digit requires 4 bits, and two decimal digits are packed into a byte).

Instructions. Machine instructions can be broadly classified into data processing and control-flow instructions. Data processing instructions manipulate operands in registers and memory locations. Common data processing instructions support integer arithmetic operations (e.g., add, subtract, compare, multiply, and divide), logic operations (e.g., bitwise and, or, xor, nor, and not); shift operations (e.g., shift to the right or left, and rotate), and data transfer operations *(load* that moves a specified operand from memory to a register, *store* that moves a specified operand from register to a memory location, and *move* that transfers data between registers). If a computer is intended for applications that extensively use floating-point numbers, the ISA may support floating-point arithmetic (e.g., floating-point add, subtract, compare, multiply, and divide). Several older ISAs support instructions that manipulate decimal operands and character string operands. In media and signal processing architectures, we may encounter instructions that operate on more complex data types (e.g., pixels).

Machine instructions are fetched from memory and executed sequentially. Control-flow or branch instructions allow us to make decisions and to change the execution flow to an instruction other than the next one in sequence. These instructions can be classified into conditional (often referred to as branches) and unconditional (often referred to as jumps), procedure calls, and procedure returns. A conditional branch instruction is defined by its outcome that determines whether the branch is taken or not taken; and by its target address that specifies the address of the following instruction in sequence to be executed, if the branch is taken. A jump instruction is defined by its target address only. Branch target addresses can be known at compile time (direct branches) or be determined during program execution (indirect branches).

Binary Encoding of Instructions. Instruction encoding defines the binary representation of machine instructions.

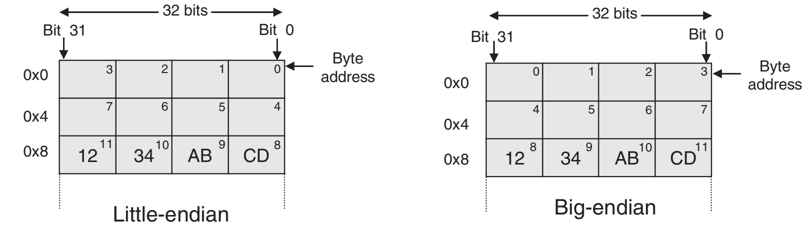

Figure 2. Little-endian and big-endian byte ordering. (This figure is available in full color at http://www. interscience.wiley.com/reference/ecse.)

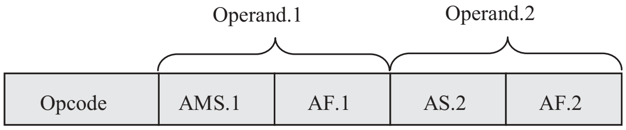

Figure 3. A generalized 2-operand instruction format (AMS—Address Mode Specifier, AF—Address Field). (This figure is available in full color at http://www. interscience.wiley.com/reference/ecse.)

Exact encoding depends on many parameters, such as architecture type, the number of operands, the number and type of instructions, the number of general-purpose registers, operand types, and the size of address space. This representation affects not only the size of the program, but also the processor implementation. The operation and possibly the number of operands are typically specified by one instruction field called the *opcode*. For each operand, the machine instruction includes an *addressing mode specifier*—a field that tells what addressing mode is used to access the operand, and one or more *address fields* that specify the operand address. Figure 3 shows a generalized instruction format for a 2-operand instruction. This approach to instruction encoding is often referred to as *variable length* — each operation can work with virtually all addressing modes that are supported by the ISA. An alternative approach *is fixed-length* instruction encoding where the *opcode* is combined with addressing mode specifiers. Typically a single size is used for all instructions and this approach is used when there are a few addressing modes and operations. A third approach called *hybrid* is somewhere in between. It reduces variability in instruction encoding but allows multiple instruction lengths. In load/store architectures, all instructions except loads and stores find their operands in general-purpose registers; hence, the addressing mode specifiers are not needed. Here we will assume that information about the number of operands and the corresponding addressing mode specifiers are all merged with the opcode field. Fixed-length instruction formats require less complex decoding logic, resulting in faster decoding, but they tend to increase the number of bits needed to encode an instruction, resulting in poor code density. Code density is an important characteristic of an instruction set, and it can be measured by the size of a program needed to complete a particular task.

Addressing Modes. A machine instruction can find its operand in one of three places: (*1*) as a part of the instruction, (*2*) in a general-purpose register, and (*3*) in memory. Operands in registers and memory can be specified directly or indirectly. Consequently, addressing modes can be broadly classified into (*1*) *direct*— the address field specifies the operand address—and (*2*) *indirect*—the address field specifies a location that contains the operand address. A wide variety of addressing modes is used in instruction set architectures, such as *immediate, register direct, register indirect, register indirect with displacement, memory direct,* and *memory indirect,* to name just a few. Table 1 gives a list of the most common addressing modes with examples and usage. Each addressing mode is illustrated by a LOAD instruction that moves the specified operand into a general-purpose register. Figure 4 gives a graphical illustration of these addressing modes.

BASIC ADDRESSING MODES

Three basic addressing modes are (*1*) *immediate or literal* where the operand is a part of the instruction; (*2*) *register direct* where the operand is in a general-purpose register; and (3) *memory direct* where the operand is in memory at a location specified directly by the instruction.

Immediate or *literal* addressing means that the operand is located in the instruction itself (Fig. 4a). Immediately upon instruction decoding, the operand is extracted from the instruction and possibly zero-or sign-extended before it is used in the instruction execution. This addressing mode specifies a data or an address constant, and it is often used in arithmetic operations, in initializing registers and memory locations, and in comparisons. The number of bits used to encode an immediate operand affects the instruction length. Data constants in programs tend to be small and can be encoded by a relatively small number of bits, improving code density. Unlike data constants, address constants tend to be large and require all address bits. An analysis of integer and floating-point programs from the SPEC benchmark suite shows that a 16-bit field captures over 80% of all immediate operands and an 8-bit field captures over 50% of all immediate operands (1). To exploit this characteristic of programs, many architectures support so-called short constants that require just a few bits to encode the most frequently used constants, such as 0, ±1, ±2, and ±4.

Register direct or just *register* addressing means that the operand is located in a general-purpose register and the instruction specifies the register by its name (Fig. 4b). For example, only a 4-bit address field is needed to specify a register in a processor with 16 general-purpose registers (0001 encodes R1 and 0011 encodes R3). This addressing mode is preferred for keeping frequently used operands because it is compact—only a register identifier is stored in the instruction, and access to a register is much faster than access to a memory location. In load/store architectures, this mode is used for all instructions except when an operand is moved from memory into a register or from a register to memory. Many compiler optimizations are employed to determine which variables are the most frequently accessed and to put them in general-purpose registers.

Memory direct addressing (often referred to as *absolute)* means that the operand is located in memory and the address field contains the actual address of the operand (Fig. 4c). This address is specified at the compile-time and cannot be modified by the processor during program execution. Hence, this addressing mode is used to access global variables whose addresses are known at compile time. The number of bits needed to encode a full memory address is directly proportional to the size of address space, and it tends to be large. Several architectures support so-called short absolute addressing—only a portion of the address space is directly accessible by this addressing mode (2). For example, a short direct address has only 16 bits and

Table 1. Data Addressing Modes, Example Instructions, Description, and Typical Use

Addressing Mode	Example Instruction	RTL Description	Typical Use
Immediate	`LOAD #3, R3`	`[R3] ← 0×00000003`	For constants
Register-direct	`LOAD R1, R3`	`[R3] ←[R1]`	When a value is in a register

Memory direct or Absolute	`LOAD $8000, R3`	`EA ← $00008000`
		`[R3] ←[Mem(EA)]`
			Access to static variables in memory

Register indirect	`LOAD (R1), R3`	`EA ←[R1]`
		`[R3] ←[Mem(EA)]`
			Access to variables in memory using a pointer

Register indirect with index	`LOAD (R1+R2), R3`	`EA ←[R1] + [R2]`
		`[R3] ←[Mem(EA)]`
			Access to elements in an array of complex data structures (R1 points to the base, R2 is stride)

Register indirect with scaled index	`LOAD (R1+R2*4),R3`	`EA ←[R1] + [R2] *4`
		`[R3] ←[Mem(EA)]`
			Access to elements in an array of complex data structures (R3 points to the base, R2 is index)

Autoincrement	`LOAD (R1)+, R3`	`EA ←[R1] ; [R1] ←[R1] + 4`
		`[R3] ←[Mem(EA)]`
			Access to elements of an array in a loop; Access to stack (push/pop)

Autodecrement	`LOAD −(R1), R3`	`[R1] ←[R1] − 4; EA ←[R1]`
		`[R3] ←[Mem(EA)]`
			Access to elements of an array in a loop; Access to stack (push/pop)

Register indirect with displacement	`LOAD 0×100(R1), R3`	`EA ←[R1] + 0×0100`
		`[R3] ←[Mem(EA)]`
			Access to local variables

Register indirect with scaled index and displacement	`LOAD 0×100(R1+R2*4), R3`	`EA ← 0×0100 +[R1] +[R2] *4`
		`[R3] ←[Mem(EA)]`
			Access to arrays allocated on the stack

PC relative	`LOAD 0×100(PC), R3`	`EA ← 0×0100 +[PC]`
		`[R3] ←[Mem(EA)]`
			Branches; Jumps; Procedure calls; Static data

PC relative with index	`LOAD (PC+R2),R3`	`EA ←[PC]+[R2]`
		`[R3] ←[Mem(EA)]`
			Branches; Jumps; Procedure calls; Static data

PC relative with scaled index and displacement	`LOAD 0×100(PC+R2*4), R3`	`EA ← 0×0100 +[PC]+[R2] *4`
		`[R3] ←[Mem(EA)]`
			Branches; Jumps; Procedure calls; Static data

Register transfer language (RTL) is used to describe data transfers and operations. Square brackets [ ] indicate content of registers and memory locations, and backward arrows indicate data transfers from the source specified on the right-hand side of the expression to the destination specified on the left-hand side of the expression.

allows access to the first 64-KB of address space, instead of the full 4 GB.

INDIRECT ADDRESSING

An important class of addressing modes is indirect addressing, namely, *register indirect* and *memory indirect*. These modes are called indirect because they do not specify an operand directly. Rather, machine instructions specify the operand indirectly by providing information from which the *effective address* (EA) of the operand can be determined.

Register Indirect and Relative Addressing

Instruction set architectures often support several variations of register indirect addressing, such as *register indirect, register indirect with postincrement* (often referred to as *autoincrement), register indirect with predecrement (autodecrement), register indirect with displacement, register indirect with (scaled) index,* and *register indirect with (scaled) index and displacement*.

With *register indirect* addressing, the instruction specifies a general-purpose register (referred to as an address or a pointer register) that contains the effective address of the memory location where the operand is located (the register R1 in Fig. 4d). If we assume that the content of the register R1 is 0x0000CA00, the operand is fetched from a memory location at address 0x0000CA00. An advantage of this addressing mode is that the instruction can reference an operand in memory without specifying a full memory address. Rather, just several bits are used to specify a general-purpose register. Several ISAs have separate address and data registers. For example, the Motorola 68000's ISA has 8 address registers and 8 data registers (2). This approach may further improve code density because only three bits are needed to specify an address or data register. However, this may require a more complex decoding logic.

Register indirect with index addressing means that the instruction specifies two registers used for computation of the effective address of an operand residing in memory. One register typically acts as a base register pointing to the beginning of an array, and the other register, named an index register, provides an offset from the beginning of the array to the current element (Fig. 4e). For example, let us assume that we want to increment elements of an integer array located in memory at the addresses A, A + 4, A + 8, ... up to the last element in the array. The starting address of the array is placed in the base register, and the index register is initialized to 0. A program loop traverses elements of the integer array, and a separate instruction increments the index register by the size of a single element in each loop iteration (by 4 in this example).

Often the value of the index register is equal to the array index no matter what is the size of one element. The index register is simply incremented or decremented by 1 and can also serve as a loop iteration counter. Hence, in address computations, the content of the index register has to be implicitly multiplied by a scale factor whose value is 1, 2, 4, or 8. The scale factor is inferred from the *opcode* and depends on the size of the operand. This variant is often referred to as *register indirect with scaled index* addressing or *scaled index* or just *scaled.*

Incrementing or decrementing of the index register is such a common operation that it is desirable to be done automatically using so-called *autoindexing (autoincrement* and *autodecrement)* addressing modes. With *autoincrement* addressing, the effective address of an operand is generated in the same way as in register indirect—the effective address is the content of the specified address register. An additional step is carried out—the content of the specified address register is incremented by the size of the operand (by 1 for byte size operands, by 2 for half-word size operands, by 4 for word size operands, and by 8 for double word size operands). With *autodecerement* addressing, the content of the address register is decremented by the size of the operand. Generally, this incrementing/decrementing step can be done before *(preincrement or*

predecrement) or after *(postincrement or postdecrement)* the effective address computation. Instruction set architectures may support some or all of the four combinations pre/post auto-(increment/decrement). The most frequently used are post-autoincrement (Fig. 4f) and pre-autodecrement (Fig. 4g). These addressing modes are a very useful tool in accessing elements in regular arrays. The advantages of using autoindexing addressing modes compared with register indirect with index are as follows: (*1*) The machine instruction needs only one address field (the base register) leading to shorter instructions, (*2*) the program loops are shorter because we do not need an instruction to increment or decrement the index register, and (*3*) we use only one address register instead of two allowing more variables and pointers to be kept in general-purpose registers.

One of the most powerful addressing modes is *register indirect addressing with displacement,* also known as *base plus offset* addressing. It combines the capabilities of memory direct with register indirect addressing. The instruction specifies two address fields for the operand residing in memory, a register field and a displacement field (Fig. 4h). The effective address of the operand is calculated by adding the content of the specified address register (or base) to the content of the displacement field. The displacement field is typically shorter than the full address length; hence, the displacement field is zero- or sign-extended to the number of address bits before adding it to the content of the base register. This addressing mode is commonly used for accessing local variables allocated on the program stack. The base register is pointing to the beginning of the stack frame (also known as frame pointer), and the instruction specifies a displacement (or an offset) from this location to the location where the operand is located. Several architectures support a variant of this mode where the base register is defined implicitly, so instructions specify only the displacement field, thus reducing the number of bits needed to encode an instruction.

A natural extension of the previous addressing modes is *register indirect with index and displacement* addressing (Fig. 4i). An instruction using this mode includes three address fields for the memory operand: the base register, the index register, and the displacement field. The effective address is calculated as a sum of the contents in the base register, the index register, and the zero- or sign-extended displacement field. This addressing mode is a convenient tool in managing access to multidimensional data structures and for accessing local arrays on the stack. If the index register can be scaled, the addressing mode is *register indirect with scaled index and displacement*.

Another important class of addressing modes is so-called *relative addressing*. This class is similar to the register indirect addressing and its derivatives, except that the address of an operand is determined with respect to the content of the program counter (PC), rather than with respect to the content of the explicitly specified address register (Fig. 4j). For *PC relative* addressing, the instruction specifies only the displacement field, and the effective address is calculated as a sum of the contents of the program counter and the zero- or sign-extended displacement field.

Similarly, with *PC relative with index* addressing, the instruction word specifies an index register, and the effective address is calculated as a sum of the program counter and the content of the index register. Finally, for *PC relative with index and displacement* addressing, the instruction specifies the index register and the displacement, and the effective address is equal to the sum of the contents of the program counter, the index register, and the zero- or sign-extended displacement field.

An important question related to all addressing modes with displacement is what should be the size of the displacement field in the instruction. The size of this field directly influences the instruction length; hence, it is desirable to have a short displacement field. However, a shorter displacement field may limit its usefulness. An experimental evaluation of displacement length finds that a 16-bit displacement field is suitable for 32-bit processors (1). Several instruction set architectures with variable instructions lengths support both short and long displacements (d8—8-bit displacement, d16—16-bit displacement, and d32—32-bit displacement) (3).

Memory Indirect Addressing

With *memory indirect* addressing, both the operand and its address are in memory. The instruction specifies the location in memory where the operand address (pointer) is located. First the operand address is read from memory, and then an additional memory read or write is performed to access the operand. There are many variants of memory indirect addressing depending on how we calculate the address of the pointer and how that pointer is used in determining the address of the operand.

The *memory indirect with register* mode means that the instruction specifies a general-purpose register pointing to a location in memory that keeps the pointer to the operand. For example, let us consider the following instruction from Table 2: LOAD ([R1]), R3. The effective address of the operand is in memory at the address determined by the content of the register R1 (Fig. 4k). Once the effective address is fetched from memory, another read from memory is employed to fetch the operand. The *memory indirect absolute* means that the instruction contains the direct address of the pointer location in memory.

The Motorola 68020 instruction set architecture supports a range of memory indirect addressing modes known as *preindexed* and *postindexed memory indirect* and *PC*

Table 2. Memory Indirect Data Addressing Modes, Example Instructions, Description, and Typical Use

Addressing Mode	Example Instruction	RTL Description	Typical Use
Memory indirect with register	`LOAD ([R1] ), R3`	EA ← Mem([R1]) [R3] ←[Mem(EA)]	Jump tables; Linked lists
Memory indirect absolute	`LOAD ([$8000] ), R3`	EA ← Mem($8000) [R3] ←[Mem(EA)]	Access to structures through a pointer

Memory indirect, postindexed	`LOAD ([$100, R1] , R2*4, $200), R3`	Temp ← Mem($100 + R1)
		EA ← Temp + R4*4 + $200
		[R3] ←[Mem(EA)]
			Jump tables; Linked lists; Access to complex data structures through array of pointers

Memory indirect, preindexed	`LOAD ([$100, R1, R2*4] , $200), R3`	Temp ← Mem($100 + R1 + R2*4)
		EA ← Temp + $200
		[R3] ←[Mem(EA)]
			Jump tables; Linked lists; Access to complex data structures through array of pointers

PC memory indirect, postindexed	`LOAD ([$100, PC] , R2*4, $200), R3`	Temp ← Mem($100 + PC)
		EA ← Temp + R2*4 + $200
		[R3] ←[Mem(EA)]
			Jump tables; Linked lists; Access to complex data structures through array of pointers

PC memory indirect, preindexed	`LOAD ([$100, PC, R2*4] , $200), R3`	Temp ← Mem($100 + PC + R2*4)
		EA ← Temp + $200
		[R3] ←[Mem(EA)]
			Jump tables; Linked lists; Access to complex data structures through array of pointers

memory indirect addressing as shown in Table 2. The *memory indirect postindexed* addressing can be specified as follows: ([*bd,* Rx], Ry*sc, *od*). The instruction has 4 address fields for the operand in memory, and they specify a base register *Rx,* an index register *Ry,* a base displacement *bd,* and an outer displacement *od.* The scale factor *sc* depends on the operand size and can be 1, 2, 4, or 8. The processor calculates an intermediate memory address using the base address register and the base displacement *(Rx + bd)* and reads the pointer from this location. The address read from memory is added to the index portion (Ry*sc) and the outer displacement to create the effective address of the operand as follows: $EA = Mem\ [Rx + bd] + Ry^{*}sc + od$. The displacements and the index register contents are sign-extended to 32 bits. In the syntax for this mode, brackets enclose the values used to calculate the intermediate memory address. All four user-specified values are optional and can be suppressed. Both the base and outer displacements may be null, 16-bit, or 32-bit long. When suppressing a displacement or a register, its value is zero in the effective address calculation. A large number of addressing options can be created using suppressing. For example, by suppressing *bd, Ry,* and *od,* the resulting addressing mode is equivalent to the *memory indirect with register* addressing. By suppressing all but the 32-bit outer displacement *od,* the resulting addressing mode is equivalent to the *memory indirect absolute* addressing.

The *memory indirect preindexed* mode is described with the following specification: (*[bd, Rx, Ry*sc], od*). The intermediate indirect address is the sum of the base displacement, the base address register, and the scaled index register. The address fetched from memory at this location is added to the outer displacement to create the effective address of the operand: $EA = Mem[Rx + bd + Ry^{*}sc] + od$. The *PC indirect memory preindexed and postindexed* modes are equivalent to the memory indirect preindexed and postindexed modes, except that the program counter is used instead of the base address register *Rx*.

ADDRESSING MODES FOR CONTROL FLOW INSTRUCTIONS

Addressing modes are important not only for instructions dealing with data, but also for instructions that change the program control flow. The most frequently used addressing mode for branch instructions is *PC relative with displacement* and its derivatives, such as *PC relative with index,* and *PC relative with index and displacement.* The branch instruction specifies an offset or displacement relative to the current program counter. The *PC-relative* addressing is preferred because the target address is often near the current instruction, and hence, an offset field with just a few bits would suffice. The PC-relative addressing also allows *position independence* of the code, meaning that the code can run independently of where it is loaded in memory. This property is useful because it reduces the number of tasks for linkers and makes dynamically linked programs easier to implement.

Other addressing modes are also applicable to indirect branches and jumps. The target address is equal to the effective address specified by the instruction. For example, let us consider an unconditional indirect branch instruction JMP (R3) that specifies the register indirect addressing mode. The branch target address is the content of the register R3 and, hence, determined at runtime. It should be noted that branch instructions operate on addresses rather than data, and hence, we do not fetch the data from memory location pointed to by the register R3. These branches are useful in implementing high-level language constructs such as switch statements, virtual functions and methods, and dynamically shared libraries.

One important design decision made by ISA designers is the size of the offset field for PC-relative addressing. The distributions of branch offsets can be measured on a set of representative benchmarks in order to determine the optimal size of the offset field. One such measurement indicates that shorter offsets that can be encoded using up to 8 bits dominate (1).

A CASE STUDY

Instruction set architectures support only a subset of all addressing modes discussed so far. Which addressing modes are supported depends on many parameters. In selecting addressing modes, computer architects would like to be able to address a large number of locations in memory with maximum flexibility. Flexibility means that each machine instruction can be combined with any addressing mode, allowing compilers to produce more optimized code with maximal code density. These requirements favor a rich set of addressing modes and variable instruction lengths. On the other hand, it is desirable to have fixed and uniform instruction encodings that reduce the complexity of decoding and address calculations as well as latencies for these steps. These often conflicting requirements are carefully evaluated during the design process.

Today almost all programming is done in high-level languages and instructions executed are the output of compilers. Hence, compilers play a critical role and should not be omitted when deciding about the ISA design and addressing modes. Having sophisticated instruction sets including a wide range of powerful addressing modes does not guarantee efficient code if compilers are not able to use them effectively. What memory addressing modes are most frequently used in compiler-generated code? A study based on a few programs indicates that three most frequently used modes account for 88% of all memory accesses: the *register indirect with displacement* accounts on average for 42%, *immediate* accounts for 33%, and *register indirect* accounts for 13% (1). Current technology trends favor *Reduced Instruction Set Computers* (RISC) with load/store architectures, fixed instruction lengths, a rich set of general-purpose registers, and a relatively small set of most frequently used addressing modes. In embedded computers where code density is of utmost importance, hybrid instruction encodings are used with a somewhat richer set of addressing modes.

In this subsection, we give a short overview of addressing modes found in three different instruction set architectures: Intel's IA32 (3), Motorola's 68000 (2), and

Table 3. Summary of Addressing Modes Supported by Intel's IA32, Motorola 68000, and ARM ISA for Data and Control-Flow Instruction

Addressing modes	IA32		M68000		ARM	
	Data	Control	Data	Control	Data	Control
Immediate	X	–	X	–	X	–
Register direct	X	–	X	–	X	–
Absolute (Direct addressing in IA32)	X	X	X	X	–	–

ARM (4). IA32 and Motorola 68000 are representative examples of *Complex Instruction Set Computer* (CISC) instruction sets, with variable instruction encoding, register-memory architectures, a small set of general-purpose registers, 2-operand instructions, and a rich set of addressing modes. The ARM is a RISC processor with load/store architecture, fixed instruction encodings, 16 general-purpose registers, 3-operand instructions, and yet with a very sophisticated addressing. Table 3 gives a summary of addressing modes for data processing and control-flow instructions supported by these three instruction set architectures. Figure 5 shows code produced by the GCC compiler for these ISAs for a simple code snippet that summarizes elements of an integer array. This example demonstrates superior code density achieved by CISC ISAs: Motorola 68000 requires 6 bytes, IA32 13 bytes, and ARM 20 bytes of code.

The text below discusses the instruction encoding for the ARM data transfer instructions and how it achieves many addressing options derived from a single mode, the *register indirect with displacement* addressing (Table 4). Figure 6 shows the binary encoding for single-word (B=0) and unsigned byte (B=1) data transfer instructions, namely for loads (L=1) or stores (L=0). When the program counter is specified as the base register, this addressing mode corresponds to the traditional *PC relative* addressing and its derivatives. The effective address for a memory operand is calculated by adding or subtracting an offset to the content of a base register. The offset is either (*1*) an unsigned immediate directly encoded in

Table 4. ARM Addressing Modes. Note: PC Relative Addressing Modes are Inferred From the Preindexed with the PC Serving as the Base Register

Addressing modes	Example	RTL Description
Immediate offset		

Preindexed	`LD r0,[r1, #±offset12]`	`EA ←[r1] ± offset`
		`[r0] ←[Mem(EA)]`

Preindexed with writeback	`LD r0,[r1, #±offset12] !`	`EA ← r1 ± offset`
		`[r0] ←[Mem(EA)]`
		`[r1] ←[r1] ± offset`

Postindexed	`LD r0,[r1], #±offset12`	`EA ←[r1];`
		`[r0] ←[Mem(EA)]`
		`[r1] ←[r1] ± offset`

(Scaled) register offset		

Preindexed	`LD r0,[r1, ±r2, Sh, #Shift]`	`EA ←[r1] ±([r2] Sh #Shift)`
		`[r0] ←[Mem(EA)]`

Preindexed with writeback	`LD r0,[r1, ±r2, Sh, #Shift] !`	`EA ←[r1] ±([r2] Sh #Shift)`
		`[r0] ←[Mem(EA)]`
		`[r1] ←[r1] ±([r2] Sh #Shift)`

Post-indexed	`LD r0,[r1], ±r2, Sh, #Shift`	`EA ←[r1]`
		`[r0] ←[Mem(EA)]`
		`[r1] ←[r1] ±([r2] Sh #Shift)`

the instruction, (*2*) the content of a register, or (*3*) a scaled value of a register. Bit 25 of the instruction word determines the interpretation of the 12 least significant bits (Fig. 6). When bit 25 is a "0", the effective address of the operand is computed as follows: The 12-bit immediate field is added to (U=1) or subtracted from (U=0) the content of the base register *Rn*. When bit 25 is a "1", the effective address is computed as follows: The content of the scaled index register *Rm* is added to or subtracted from the content of the base register *Rn*. Scaling type is defined by the 2-bit *Sh* field, and the shifting magnitude is defined by a 5-bit *Shift* field. A pre-indexed (P=1) addressing uses the computed address for the load or store operation. If a write-back is requested (W=1), the base register is updated to the computed value. A post-indexed (P=0) addressing uses the unmodified base register for the effective address calculation, and then it updates the base register independently of the W field.

Several addressing modes can be inferred from this encoding. For example, the post-indexed or pre-indexed register indirect with the immediate field equal to zero corresponds to the classic *register indirect* addressing mode. When the immediate value is nonzero, this mode corresponds to *the post- or pre-indexed autoincrement* or *autodecrement* addressing modes. It should be noted that a base register could be incremented or decremented by any value that can be encoded in the 12-bit immediate value, providing an increased flexibility compared with the classic implementations of the autoindexing modes. If the offset address comes from an index register, the addressing mode corresponds to the *register indirect with index mode.* When the value in the index register is scaled, this addressing mode becomes equivalent to the *register indirect with scaled index mode,* but with increased flexibility in selecting a scale factor. Thus, thanks to very clever encodings, a rich set of addressing modes is supported.

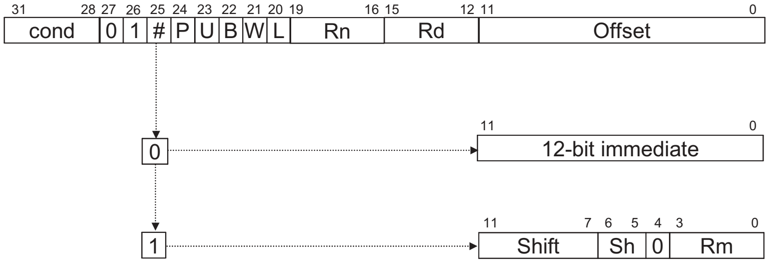

Figure 6. Binary encoding of word-size and unsigned byte-szie data transfer instructions. Legend: Rn - base register, Rd - source/destination register, L-load or store, W - write-back (autoindex), B-unsigned byte or word, U - up/down, P - pre or post index, cond - condition field enabling conditional execution.

ANALOG-TO-DIGITAL CONVERSION IN THE EARLY TWENTY-FIRST CENTURY

Analog-to-digital converters (ADCs) continue to be important components of signal-processing systems, such as those for mobile communications, software radio, radar, satellite communications, and others. This article revisits the state-of-the-art of ADCs and includes recent data on experimental converters and commercially available parts. Converter performances have improved significantly since previous surveys were published (1999–2005). Specifically, aperture uncertainty (jitter) and power dissipation have both decreased substantially during the early 2000s. The lowest jitter value has fallen from approximately 1 picosecond in 1999 to <100 femtoseconds for the very best of current ADCs. In addition, the lowest values for the IEEE Figure of Merit (which is proportional to the product of jitter and power dissipation) have also decreased by an order of magnitude. For converters that operate at multi-GSPS rates, the speed of the fastest ADC IC device technologies (e.g., InP, GaAs) is the main limitation to performance; as measured by device transit-time frequency, f_T, has roughly tripled since 1999. ADC architectures used in high-performance broadband circuits include pipelined (successive approximation, multistage flash) and parallel (time-interleaved, filter-bank) with the former leading to lower power operation and the latter being applied to high-sample rate converters. Bandpass ADCs based on delta-sigma modulation are being applied to narrow band applications with ever increasing center frequencies. CMOS has become a mainstream ADC IC technology because (*1*) it enables designs with low power dissipation and (*2*) it allows for significant amounts of digital-signal processing to be included on-chip. DSP enables correction of conversion errors, improved channel matching in parallel structures, and provides filtering required for delta-sigma converters. Finally, a performance projection based on a trend in aperture jitter predicts 25 fs in approximately 10 years, which would imply performance of 12 ENOB at nearly 1-GHz bandwidth.

INTRODUCTION

During the past three decades, especially the past 7–10 years, the increasingly rapid evolution of digital integrated circuit technologies, as predicted by Moore's Law, has led to ever more sophisticated signal-processing systems. These systems operate on a wide variety of continuous-time signals, which include speech, medical imaging, sonar, radar, electronic warfare, instrumentation, consumer electronics, telecommunications (terrestrial and satellite), and mobile telecommunications (cell phones and associated networks).

Analog-to-digital converters (ADCs) are the circuits that convert these and other continuous-time signals to discrete-time, binary-coded form, that is, from human-recognizable form to computer-recognizable form. Such a conversion can be thought of as a two-step process. First, the input signal is sampled in time, usually at regularly spaced intervals; $f_{samp} = 1/T$, where T = sampling interval (e.g., for $f_{samp} = 1$ gigasample per second, T = 1 ns). The second step is to quantize (or digitize) the samples (usually a voltage) in amplitude. The maximum signal range (full-scale input voltage) is divided into 2^N subranges, where N = the ADC's resolution (number of output leads), (e.g., for $N = 12$ bits, a 1-Volt full-scale range is divided into $2^N = 4096$ levels). The least-significant bit (LSB) is $1\,V / 2^N = 244$ µV. Two potential purposes for these conversions are (*1*) to enable computer analysis of the signal and (*2*) to enable digital transmission of the signal.

The limitations of ADCs in terms of both resolution and sampling rate are determined by the capability of the integrated circuit (IC) process, as well as chip design techniques, used to manufacture them, and, were perceived as a limiting factor (1) to system performances as recently as 1999. However, more recent developments have demonstrated that significant progress has occurred with respect to converter performances, especially for sampling rates in the 100 megasamples/s (MSPS) range as well as in the neighborhood of 1 gigasample/s. The purpose of this article is to provide an update to previous ADC surveys (1–3) and to analyze the new results.

The next section of this article summarizes the characterization and limitations of ADCs, and the section on ADC performance update discusses how ADC performances have changed (improved) during the past 8 years. The next section covers Figures of Merit, and the section on high-performance ADC architectures discusses architectures that are presently in use along with the advantages conferred by increased ADC IC complexity. Then, performance trends and projections are discussed, and finally, the last section gives a summary and provides conclusions. Appendix 1 contains a list of the more than 175 ADCs covered in this work.

PERFORMANCE CHARACTERIZATION AND LIMITATIONS

One of the key parameters describing ADC performances is signal-to-noise plus distortion ratio, (SNDR), which is defined as the ratio of the root mean square signal amplitude to the square root of the integral of the noise power spectrum (including spurious tones) over the frequency band of interest [e.g., for a Nyquist converter, the pertinent band extends from 0 to one-half the sampling rate ($f_{samp}/2$)]. Another way of expressing this ratio is in terms of the effective number of bits (ENOB) which is obtained from SNDR(dB)= $20^{*}\log_{10}$(SNDR) by Ref. 4.

$$\mathrm{ENOB} = \frac{\mathrm{SNDR(dB)} - 1.76}{6.02} \qquad (1)$$

This expression includes the effects of all losses associated with the subject ADC, which include equivalent

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

input-referred thermal noise, $ENOB_{thermal}$, aperture uncertainty (jitter) noise, $ENOB_{aperture}$, and comparator ambiguity, $ENOB_{ambig}$, (1), as well as distortion induced by spurious tones. If we were dealing with a loss-free, distortion-free ADC, then the value of ENOB obtained from Equation (1) would equal the number of output leads *N*, and it would correspond to the (intrinsic) quantization noise case. Expressions for ENOB for thermal noise, jitter, and comparator ambiguity losses (each acting separately) are given below:

$$ENOB_{\text{thermal}} = \log_2\left(\frac{V_{pp}^2}{12kTR_{\text{eff}}f_{\text{sig}}}\right)^{1/2} - 1 \qquad (2)$$

$$ENOB_{\text{aperture}} = \log_2\left(\frac{1}{2\pi f_{\text{sig}}\tau_a}\right) - 1 \qquad (3)$$

$$ENOB_{\text{ambiguity}} = \frac{\pi f_T}{13.9 f_{\text{sig}}} - 1.1 \qquad (4)$$

Here, V_{pp} is the maximum peak-to-peak input voltage presented to the ADC, k is Boltzmann's constant, T is the semiconductor substrate temperature in kelvins, R_{eff} is the effective input resistance, f_{sig} is the analog input frequency, τ_a is the rms aperture jitter, and f_T is the transit-time frequency associated with the transistors used in the given ADC IC process technology.

It is noted that for Nyquist ADCs, f_{sig} in Equations (2)–(4) can be replaced by $f_{samp}/2$, and the resulting expressions would correspond closely, apart from one small numerical difference in Equation (3), to those presented in Ref. 1 with $ENOB_x$ replacing B_x, where *x* is thermal or aperture or ambiguity. However, for non-Nyquist operation, (e.g., under-sampling), Equations (2)–(4) should be used as written above because f_{sig} can be different (greater) than $f_{samp}/2$. Hence, these expressions are more general than those in Ref. 1.

Another important ADC characteristic is spurious-free dynamic range (SFDR), which when expressed in dBc, is the difference of the input signal magnitude and the largest spurious tone in the frequency-band of interest. The quantity SFDR bits is analogous to ENOB and is defined by

$$\text{SFDR bits} = \text{SFDR(dBc)}/6.02 \qquad (5)$$

A complete characterization of an ADC includes measuring the values of SNDR and SFDR as a function of input signal frequency f_{sig} with f_{samp} as a parameter. For a baseband ADC, at low values of f_{sig}, the SNDR is constant with respect to f_{sig} and then decreases as f_{sig} increases. The value of f_{sig} at which the SNDR decreases to 3 dB below the low-frequency value is the effective resolution bandwidth (ERBW). This important characteristic implies the range of frequencies over which the converter may be used. If ERBW $\geq f_{samp}/2$, then the ADC is a Nyquist converter, which is the design goal of many ADCs. Not all published reports on alleged Nyquist ADCs satisfy the conditions for Nyquist conversion. However, some still achieve noteworthy sampling speed, SNDR or SFDR. To include these examples, the values for f_{sig}, f_{samp}, as well as associated SNDR and SFDR are stated clearly herein.

Some converters have ERBW values well beyond $f_{samp}/2$, and, as noted above, imply they can be used in undersampling mode. Because this type of operation involves sampling upper Nyquist zones, an antialiasing filter (AAF) must be placed in the signal path and in front of the converter to prevent contamination by unwanted out-of-zone signals. This Process results in using the ADC as a bandpass converter in which the passband of the AAF defines the band of interest, and, through the natural mixing property of the sampling process, the passband is shifted to baseband. The appropriate value of ENOB for the bandpass case is the midband value. An example would be sampling at 100 MSPS while using an AAF that covers the band 100 MHz $+ \delta$ to 150 MHz - δ (third zone), where δ is determined from the AAF skirts and is large enough to keep out unwanted signals and/or tones.

In addition, delta-sigma ($\Delta\Sigma$) converters (modulator followed by digital decimation filter) are coming more into use for bandpass [intermediate frequency (IF) and radio frequency (RF) sampling] conversion as well as (well-established) lowpass (baseband sampling). These ADCs are each characterized, in this study, as having an effective sampling rate = 2 × $\Delta\Sigma$ passband (determined by the modulator 3-dB bandwidth), and an ERBW = $\Delta\Sigma$ passband. Continuous time $\Delta\Sigma$ ADCs do not usually require AAFs (it is built-into the $\Delta\Sigma$ architecture) whereas discrete-time $\Delta\Sigma$ ADCs do. Again, the midband value of ENOB applies here.

Two-tone intermodulation distortion (IMD) of ADCs is particularly relevant for receiver applications. One excites an ADC with two sinusoids of equal amplitude but with different frequencies, f_1 and f_2, and observes spurious tones in the FFT spectrum of the ADC output. The strongest such tone is usually second- ($\pm f_1 \pm f_2$) or third-order ($\pm f_1 \pm 2f_2$, or $\pm 2f_1 \pm f_2$). Unfortunately, whereas IMD data are reported in the literature, no standard set of conditions are available for IMD evaluation, which makes comparisons between ADCs somewhat difficult. Hence, IMDs must be evaluated by the prospective user for the intended application.

ADC PERFORMANCE UPDATE

Figure 1 shows ENOB as a function of analog input frequency (Fig. 1a) and of sampling rate (Fig. 1b) for state-of-the-art ADCs (as of late 2007). The use of f_{sig} rather than f_{samp} as abscissa in Figs. 1a and 2, and as independent variable in Equations (2)–(4), reflects the fact that many modern converters can sample in upper Nyquist zones. As discussed above, this finding means that the analog input bandwidth for such ADCs extends beyond $f_{samp}/2$ and is indicative of the attainment of lower aperture uncertainty values, and hence higher ENOB via Equation (3). The downward sloping lines, with slopes equal to −3.33 ENOB/decade (−20 dB/decade) and labeled 1999 (jitter = 1 ps) and 2007 (jitter = 100 fs) in the figure, represent the state-of-the-art for those years. It is evident that typical best values for ENOB (Fig. 1a) have increased by more than 3 effective bits, which corresponds to an order of magnitude improvement in resolution. In fact, as will be shown in the next section, most of this advance has

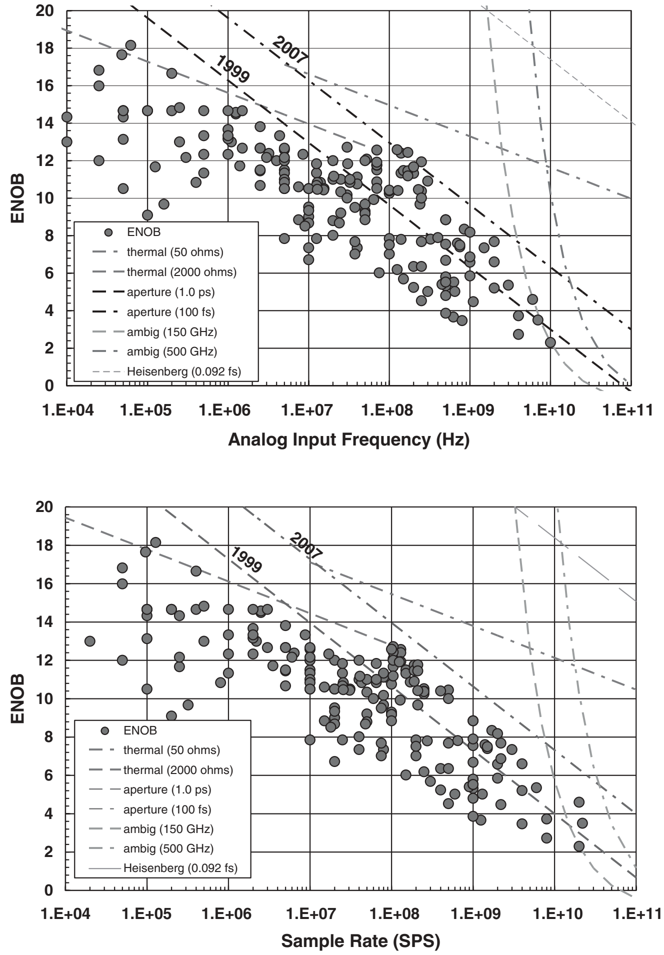

Figure 1. (a) Updated survey of state-of-the-art analog-to-digital converters. The graph shows the effective number of bits (*ENOB*) as a function of analog input frequency for each converter. The downward sloping lines labeled 1999 and 2007 represent the state-of-the-art for those years, and these values correspond to aperture jitter values of 1 ps and 100 fs, respectively. The data indicate an improvement of more than 3 *ENOB* during the past 8 years. The other curves represent the limitations caused by input-referred noise (thermal), comparator ambiguity (ambig), and ultimately the Heisenberg Uncertainty Principle. (b) In this graph, the effective number of bits (*ENOB*) is shown as a function of sample rate for each converter. The downward sloping lines labeled 1999 and 2007 are repeated from Fig. 1a and represent the jitter state-of-the-art for those years. Here, the apparent improvement is approximately 2 ENOB instead of three, which occures because the converters that operate in undersampling mode are not as apparent in this graph.

occurred within the past 4 years. In Fig. 1b, the two jitter lines are repeated using the correspondance $f_{sig} = f_{samp}/2$. Here, the overall improvement seems to be only a little more than 2 ENOB rather than 3 ENOB, because the true performance of converters that operate in undersampling mode is not evident when f_{samp} is used as abscissa. One might interpret this comparison as indicating two thirds of the SNDR increase is caused by improved sampling and one third is caused by an improved capability to undersample.

The thermal noise limitation is indicated by the more gently sloping lines (−10 dB/decade) in Fig. 1a and 1b. At values of $f_{sig} \leq 3$ MHz, the effective input-referred resistance for most ADCs in this range is on the order of a few thousand ohms (lower line is for 2000 ohms) and seems to limit the attained ENOB. For systems that operate at higher input frequencies, the input-referred resistance shifts toward 50 ohms (upper line is for 50 ohms) and is less of a limitation compared with aperture uncertainty. At very high values of f_{sig}, (i.e., a few GHz), ADC performance is limited abruptly by comparator ambiguity (IC technology presently at $f_T \sim 150$ GHz). However, this limitation has been pushed out by about a factor of three since 1999 (1). It is noted that the ultimate limit on ADC performance is suggested by the Heisenberg Uncertainty Principle, [e.g., 16 ENOB at 30 GHz (jitter ∼ 0.1 fs)].

The SFDR for the converters covered in this article is shown in Fig. 2. Here, an improvement of 3 SFDR bits has occurred (essentially the same change as in Fig. 1a). Finally, it is pointed out that the recent improvements in the state-of-the-art have occurred in the frequency range of ∼50 MHz to ∼300 MHz; it is felt that this change was caused by an emphasis on communications applications. Over 175 converters (Appendix 1), which include experimental ADCs and commercially available parts, are represented in Figs. 1 and 2.

It is worthwhile to compare ENOB and SFDR bits with the stated number of bits (number of output pins) because confusion often occurs over the interpretation of these quantities. These comparisons are shown in Fig. 3 in which the differences (stated bits–ENOB) and (stated bits − SFDR bits) are shown as functions of f_{sig}. As can be observed from the graphs in Fig. 3, the differences are not too dissimilar to those reported in 1999 (1), whereas the spreads in the data remain rather broad (stated bits − ENOB = 1.53 ± 1.5 bits; stated bits − SFDR bits = 0.05 ± 3.1 bits). The reasons for such diversity are complex, but most likely include (*1*) the variety of design objectives

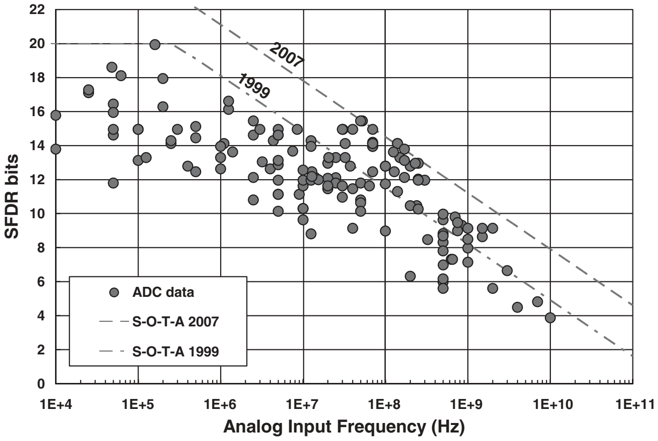

Figure 2. Spur-free dynamic range expressed as SFDR bits plotted against input frequency for each converter. The downward sloping lines labeled 1999 and 2007 represent the state-of-the-art for those years. These data indicate an improvement of approximately 3 SFDR bits during the past 8 years.

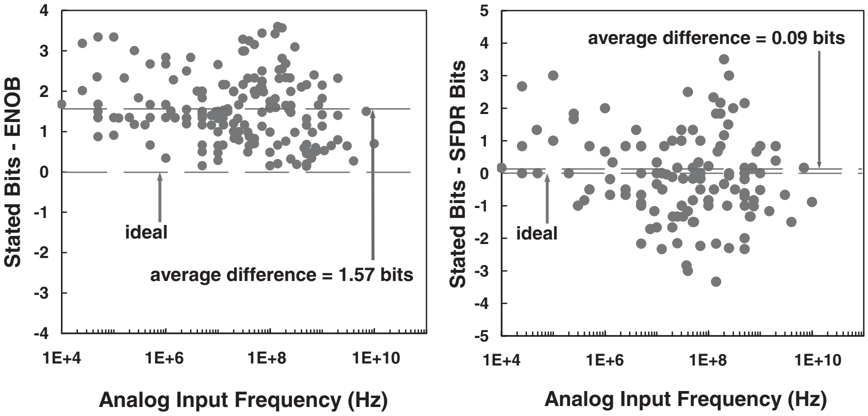

Figure 3. The differences between stated bits (number of outputs) and ENOB and SFDR bits for the ADC population considered in this study are shown here. For ENOB, the average difference is about 1.5 bits, whereas for SFDR bits it is nearly zero. However, a wide range exists in the data: > ± 1.5 bits for ENOB and > ± 3 bits for SFDR.

(high SNDR, or high SFDR, and/or low power dissipation, etc.) and (*2*) the variety of IC technologies (many flavors of CMOS, Si bipolar, SiGe, InP, GaAs, hybrids, etc.) applied to the realization of these circuits.

FIGURES OF MERIT

Figures of Merit are useful for assessing the performance of ADCs. Four examples are presented below, one for performance regardless of power and three that account for it.

The expression for aperture uncertainty,

$$\tau_a = \frac{1}{4 \cdot \pi \cdot \ f_{sig} \cdot 2^{ENOB}} \quad \text{(seconds)} \tag{6}$$

can be used as a performance measure because it contains the product of the quantities f_{sig} and 2^{ENOB} (similar to a gain-bandwidth product), and it is indicative of ADC state-of-the-art (e.g., $\tau_a = 1$ ps and 100 fs in Fig. 1a).

When it is desired to include power dissipation, P_{diss}, an "old" figure of merit (1) could be used,

$$F = \frac{2^{ENOB} \cdot f_{samp}}{p_{diss}} \quad \text{(effective LSBs per Joule)} \tag{7}$$

This expression does not account for the possibility that f_{sig} can be greater than $f_{samp}/2$(i.e., undersampling mode). A "new(er)" figure of merit, which does include this case, is obtained from

$$F_a = \frac{1}{2 \cdot \pi \cdot \tau_a \cdot P_{diss}} = \frac{2 \cdot f_{sig} \cdot 2^{ENOB}}{P_{diss}} \quad \text{(effective LSBs per Joule)} \tag{8}$$

Note that for a Nyquist ADC, F_a reduces to F. Taking this equation a step further, F_a is inverted and then becomes a more general form of the IEEE Figure of Merit,

$$FOM_a = \frac{1}{F_a} = \frac{P_{diss}}{2 \cdot f_{sig} \cdot 2^{ENOB}} \quad \text{(Joules per effective LSB)} \tag{9}$$

Another way of looking at equation (8) is as the product,

$$F_a \cdot \tau_a = \frac{1}{2 \cdot \pi \cdot P_{diss}} \tag{10}$$

which is a function only of power dissipation. Figure 4 shows F_a versus τ_a for the ADC population. A wide variation in P_{diss} is evident nearly six orders of magnitude.

HIGH-PERFORMANCE ADC ARCHITECTURES

The highest-performing ADCs are listed in Table 1(5–13). They are sorted primarily by aperture uncertainty and secondarily by the IEEE Figure of Merit, FOM_a. The list

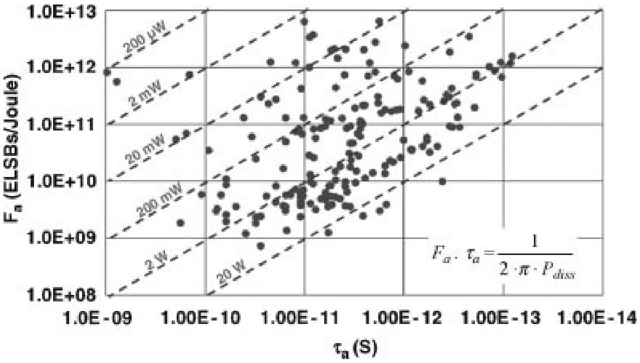

Figure 4. The relationship of F_a and τ_a for the ADCs studied herein. Nearly six orders of magnitude in ADC power dissipation are evident.

Table 1. A list of high-performance ADCs sorted first by aperture uncertainty, t_a, and secondarily by IEEE Figure of Merit, FOMa, Column 1 indexes the converters

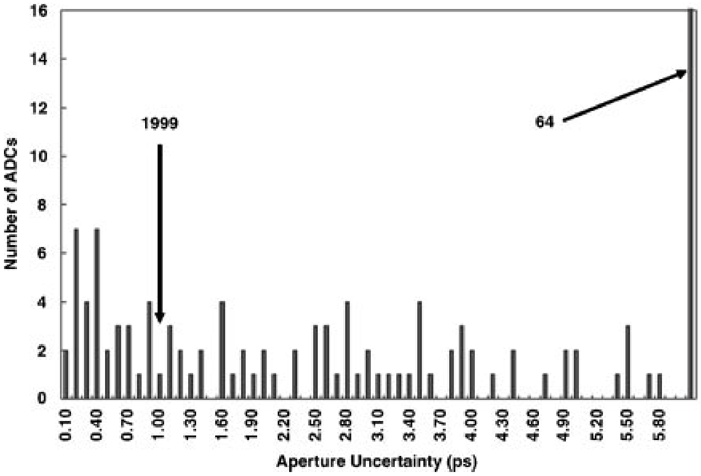

Figure 5. Histogram for aperture jitter. The relatively large number of ADCs situated to the left of the arrow (smallest jitter values) represents the post-1999 activity in the development of high-performance converters.

is dominated by pipelined and multistage flash architectures. Also, time-interleaved, folded flash, and flash ADCs are presented. The two converters at the top of the list, LTC2208 and AD9460, are pipelined and have jitter values of ~80–85 fs, which is an order of magnitude below the best of 1999.

There are eight multiple entries: LTC2208 (#1, #4, #9), AD9460 (#2, #23), AD6645 (#5, #21), ADS5546 (#6, #8, #18), AD9640 (#7, #25), AT84AS008 (#10, #14), LTC2294 (#11, #38), AD9430 (#22, #28). Each of these ADCs has one entry for Nyquist operation and one or more for undersampling mode. Thirty-seven separate converters are represented in the table.

Of the ADC architectures listed in Table 1, flash [# 10, 13, 14, 29, 30, 37, 40 (10), 41, (14), (15)], a parallel technique, is the fastest. It uses 2^N-1 comparators, where N is the stated resolution, but, often includes one or two additional comparators to measure overflow conditions. All comparators sample the analog input voltage simultaneously; hence, it is inherently fast.

The parallelism of the flash architecture has drawbacks for high-resolution applications as the number of comparators grows exponentially with N. In addition, the separation of adjacent reference voltages grows smaller exponentially. Consequently, for large N, this architecture would require very large, power-hungry ICs, and it is difficult to match components in the parallel comparator channels. Finally, increasingly large input capacitance reduces analog input bandwidth. Most flash converters available today have $N \leq 8$. These problems are overcome by using variations on the flash architecture that use relatively few comparators yet retain good speed albeit at the expense of increased latency. They are the pipelined/multistage flash [# 1–9, 11, 12, 15, 16, 20, 21, 22, 28, 33, 34, 43(12), 46], and folded-flash [# 17, 31, 32, 35, 36, 42, 45(13), 47] architectures.

Parallel configurations such as time-interleaved and filter bank offer other ways to attain high-speed conversion. The parallel ADCs listed in Table 1 [# 19(5), 24(6), 26, 27(7)], achieve < 1.5 ps aperture jitter, but some require substantial power, as much as an order of magnitude larger than single-chip converters [e.g., # 24(6)].

Sixteen of the ADCs in Table 1 (#1, 5, 6, 7, 8, 10, 12, 13, 14, 18, 25, 26, 29, 33, 34, 43 and 46) employ some type of on-chip digital signal processing (DSP). All but one of these were introduced after 2003, which implies that increased IC complexity (Moore's Law) is at least partially responsible for the addition of DSP for error correction.

An architecture that trades speed for resolution is delta-sigma ($\Delta\Sigma$) modulation (17); when combined with digital decimation filtering, it forms a complete ADC. For band-pass RF applications, a small geometry Si process [# 39(9)] is beneficial. This example is another instance of the impact of Moore's Law on ADC design and fabrication. On the other hand, III-V technologies (15,18,19) that are intrinsically high bandwidth are still competitors for at least the $\Delta\Sigma$ loop portion of these converters. When IC technologies mature, which include heterogeneous integration (20–22), a single-chip $\Delta\Sigma$ ADC that employs InP and CMOS may eventually be realized.[1] Such techniques may also be applicable to other ADC architectures as well.

PERFORMANCE TRENDS AND PROJECTIONS

Distributions of ADCs as functions of jitter (Fig. 5) and of FOM_a (Fig. 6) show how converter performance and efficiency have progressed over the past 7 years. In Fig. 5, only three ADCs that were announced prior to 2000 (compared to 31 after 2000) had $\tau_a < 1$ ps (6,8), (Table 1 #35). Similarly, in Fig. 6, only two of the ADCs demonstrated prior to 2000 (compared with 32 after 2000) had FOM_a values < 2.5 pJ/

[1] Many heterogeneous integration efforts are aimed at adding photonic capabilities to Si-based circuits, but there is no reason why the addition of very high-speed electronic circuits (e.g., InP) could not be used with high-density Si circuitry as well.

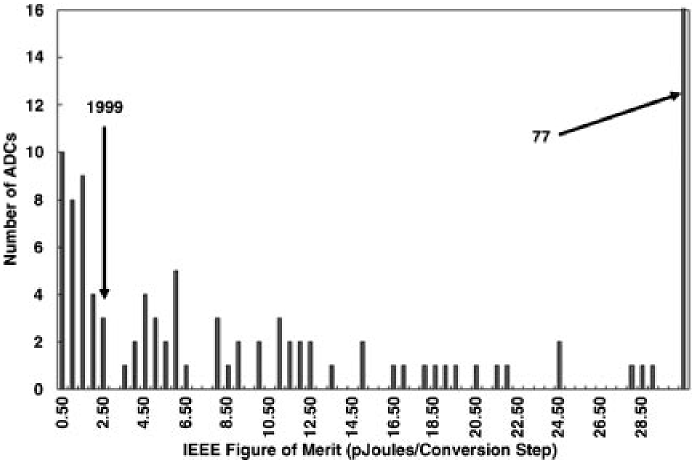

Figure 6. Histogram for IEEE Figure of Merit. The relatively large number of ADCs situated to the left of the arrow (smallest FOMa values) represents the post-1999 activity in the development of high-efficiency converters.

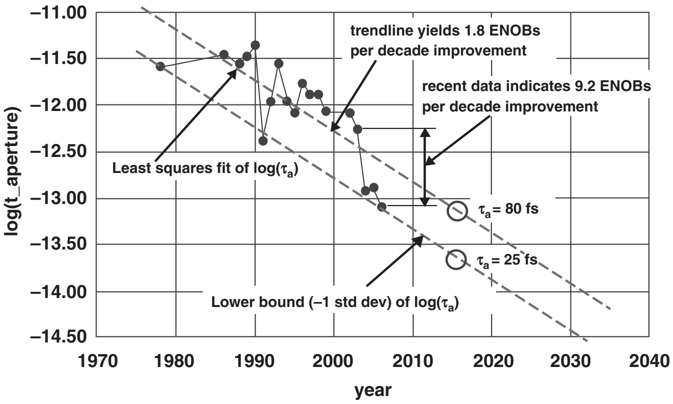

Figure 7. Derived aperture jitter [Equation (3)] for the best ADC performances as a function of the year of introduction. Converter performances are improving, gradually although actual progress is sporadic.

ELSB (23,24). The upsurge in quality of demonstrated converter designs is self-evident.

Another way of probing the data[2] in Figs. 5 and 6 is to examine the performance Figure of Merit (aperture jitter), τ_a, for ADCs over the past three decades (especially the past 4 years). This is done in Fig. 7 where the $\log_{10}$ of the best (lowest) value on an annual basis is graphed. The overall trend over the past 30 years is an improvement of 1.8 ENOB per decade. However, the progress over the past 4 years would correspond to an astounding 9.2 ENOB per decade. Like the similar jump in the early 1990s, this increase is most likely not a sustainable trend. However, at face value it shows an order of magnitude improvement in less than 4 years (not including design and development time). A more-or-less simultaneous occurrence of factors has contributed to this relatively sudden improvement: (*1*) designs that focus on lowering aperture jitter and increasing analog input bandwidth; (*2*) progress in ADC IC technology which includes the addition of on-chip DSP; and (*3*) improved quality of ADC testing.

If the lower trend line in Fig. 7 is used, then a somewhat conservative projection indicates that a jitter value of 25 fs may be reached in the year 2015 or so. This estimation is equivalent to achieving, say, 12 ENOB at an 800 MHz input frequency or 10 ENOB at an input frequency of 3 GHz. The aperture jitter line labeled 2015 in Fig. 8 indicates the possibilities for 25 fs jitter, whereas the comparator ambiguity curve labeled 2015 indicates the limitations imposed by $f_T = 500$ GHz. At lower frequencies (10–100 MHz), thermal noise will limit converter performance, whereas at 10–12 GHz, comparator ambiguity is a limiting factor. Given that f_T, which scales comparator ambiguity, has increased by a factor of three in roughly 7 years for the fastest IC technologies, it is reasonable to assume that

[2] A complete listing of the ADCs discussed in this article is given in the Appendix 1.

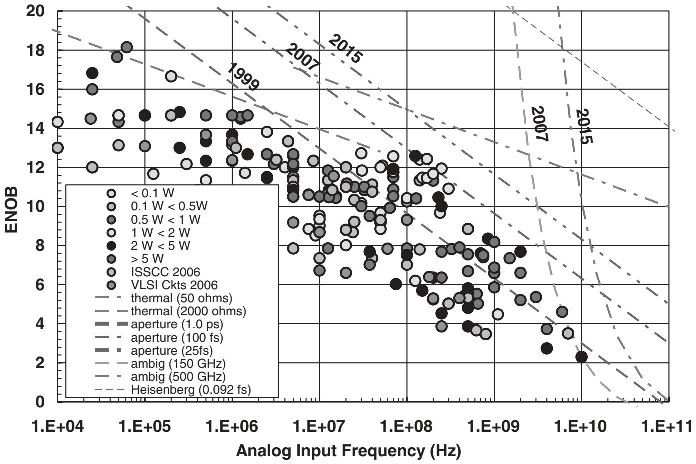

Figure 8. ENOB versus analog input frequency (same data as in Fig. 1a). Here, the ADCs are differentiated according to power dissipation. In addition, converters presented at two conferences (ISSCC, VLSI Circuits Symposium) held in 2006 are indicated. The intersection of the jitter and ambiguity curves, each labeled 2007, indicates 8 ENOB at 3 GHz, close to the current state-of-the-art. The 2015 intersection implies 8 ENOB at 10 GHz.

another factor of about three will come about by the year 2015. Hence in 9–10 years, the state-of-the-art may be defined by the boundaries of the 25 fs jitter line and the 500 GHz ambiguity curve. The intersection of these two curves implies 8 ENOB at 10 GHz.

The data points in Fig. 8 are the same as in Fig. 1a; here, they are sorted by power dissipation. Converters presented at two conferences held in 2006 (ISSCC, VLSI Circuits Symposium) are also delineated.

An examination of how converter performance has progressed with respect to achieving low-power dissipation is shown in Fig. 9. The trend seems to be at the rate of about -1 decade per decade, and the most efficient ADCs have achieved just above 100 fs per conversion step. Using the lower trend line (-1 standard deviation), one might anticipate 10 fs per conversion step by the year 2015. However, the simultaneous achievement of very low τ_a and FOM_a is not necessarily imminent, as implied in Fig. 10. As an example, a design target of 8 ENOB at 3 GHz input frequency (current performance capability) with a dissipation of 0.5 W corresponds to τ_a $\sim$100 fs and $\mathrm{FOM}_a \sim 0.3$ pJ per conversion step. This is beyond the current state-of-the-art.

To improve the present state-of-the-art in ADC performance, significant technical challenges must be met. Specifically, (*1*) a reduction in aperture uncertainty to well below 100 fs, (*2*) an increase in the comparator ambiguity limit to beyond 15 GHz ($f_T > 500$ GHz), and (*3*) accomplishing both (*1*) and (*2*) while maintaining low power consumption (e.g., < 0.5 W). The attainment of these characteristics may involve employment of such technologies as heterogeneous integration (20), photonic clock generation, and distribution (25), and perhaps superconducting circuitry (26) where appropriate. The continued advance of electronic ADC IC techologies is also anticipated.

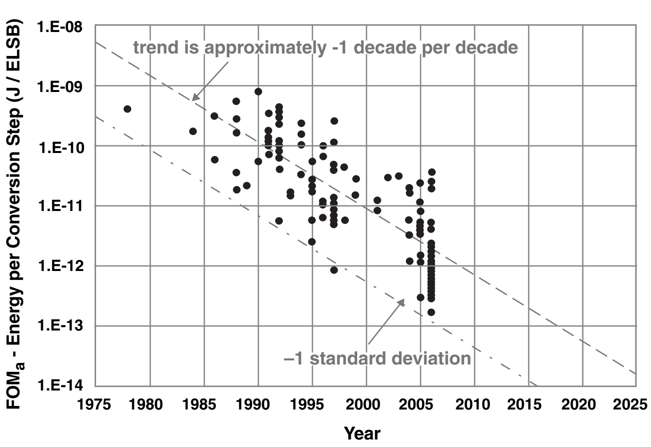

Figure 9. The evolution of the IEEE Figure of Merit for the ADCs studied herein. The rate of decline is approximately -1 decade per decade. If the current trend continues, then converters that operate at 10 fs per conversion step may be realized by the year 2015.

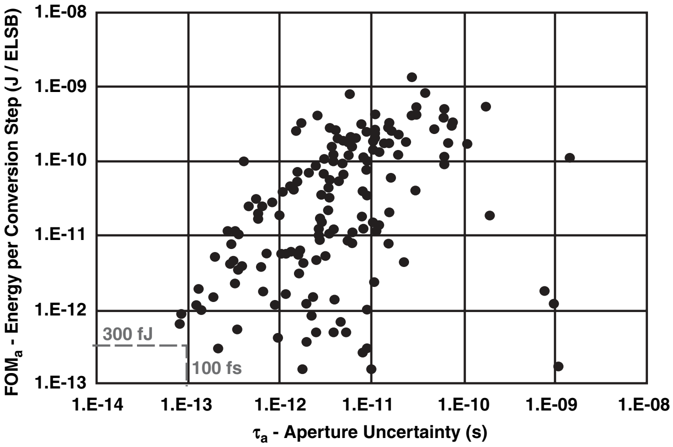

Figure 10. FOM_a versus τ_a for the ADCs studied in this work. The simultaneous achievement of very low τ_a (< 100 fs) and very low FOM_a (< 300 fs per conversion step) seems to be on the horizon, but it has not yet occurred.

SUMMARY

The current state-of-the-art for ADCs has been reviewed and analyzed. Data for SNDR and SFDR as functions of f_{sig} and f_{samp} have been discussed. The SNDR data show that converter performance is limited by input-referred noise, aperture uncertainty, and comparator ambiguity. The best performances have been achieved for pipelined flash (successive approximation, multistage flash) folded flash, and time-interleaved architectures. Many of these converters employ DSP for error correction and channel matching. The best ADCs can operate in undersampling mode.

With respect to aperture uncertainty, about 3 bits of overall improvement has been achieved over the last 4 years in both SNDR and SFDR. The best converters were two pipelined ADCs, which achieved τ_a ~81–85 fs (Table 1 #1, 2). In addition, the best power-efficient converters, as measured by FOM_a, have reached down to nearly 100 fs per conversion step.

It is clear from the data presented above that significant improvements in converter performances have been achieved during the early twenty-first century and that the performance picture is dramatically better than it was in 1999 (1). In addition, ADC power dissipation has also been reduced and is largely caused by the continuing advances in IC technology (Moore's Law).

Although continued progress in ADC IC design and technology will no doubt continue, advancements in converter performance may also be aided by heterogeneous integration, photonic sampling, and/or by superconducting implementations.

ACKNOWLEDGMENT

This work was supported by The Aerospace Corporation's Independent Research and Development Program.

The author gratefully acknowledges G.C. Valley for his encouragement and helpful comments, especially regarding photonic ADCs, and thanks S.C. Moss for his support and helpful suggestions, especially regarding the application of heterogeneous integration to ADCs.

APPENDIX 1 TABLE OF ADCS COVERED IN THIS WORK

The entries in this table are color-coded in the same manner as the points in Figure 8, i.e., according to power dissipation.

AUTOMATIC TEST GENERATION

INTRODUCTION

This article describes the topic of automatic test generation (ATG) for digital circuitsjmd systems. Considered within the scope of ATG are methods and processes that support computer-generated tests and supporting methodologies. Fundamental concepts necessary to understand defect modeling and testing are presented to support later discussions on ATG techniques. In addition, several closely related topics are also presented that affect the ATG process, such as design for test (DFT) methodologies and technologies.

One can test digital systems to achieve one of several goals. First, testing can be used to verify that a system meets its functional specifications. In functional testing, algorithms, capabilities, and functions are verified to ensure correct design and implementation. Once a system has been verified to be correct, it can be manufactured in quantity. Second, one wishes to know whether each manufactured system is defect free. Third, testing can be used to determine whether a system is defect free. Functional tests can provide the basis for defect tests but are ineffective in providing acceptable defect tests. Defect tests can be developed by creating tests in an ad hoc fashion followed by evaluation using a fault simulator. In complex systems, this process can be challenging and time consuming for the test engineer. As a result, many effective techniques have been developed to perform ATG as well as to make ATG more effective.

Technologic trends have continued to offer impressive increases in capability and performance in computing function and capacity, Moore's law noted the annual doubling of circuit complexities in 1966 that continued through 1976 (1).[1] Although the rate of complexity doubling slowed, such increases are both nontrivial and continuous with the increases in complexity comes the added burden of testing these increasingly complex systems.

Supporting the technologic improvements are complementary advances in the many supporting technologies including design tools, design practices, simulation, manufacturing, and testing. Focusing on testing, the technologic advances have impacted testing in several ways. First, the increase in the number of pins for an integrated circuit has not increased at the same rate as the number of devices on the integrated circuit. In the context of testing, the increasing relative scarcity of pins creates a testing bottleneck because more testing stimulus and results must be communicated through relatively fewer pins. Second, design methodologies have changed to reflect the trends in the introduction of increasingly more complex systems. So-called systems on chip (SoC) approaches enable designers to assemble systems using intellectual property (IP) cores purchased from vendors. SoCs present their own challenges in testing. SoC testing is complicated even more by observing that vendors are, understandably, reluctant to provide sufficient detail on the inner workings of their cores to enable the development of a suitable defect test. Indeed, vendors may be unwilling to provide test vectors that can provide hints on the inner workings. As a result, the idea of embedded test has grown out of these challenges. Third, the sheer complexity of the systems can make it prohibitively expensive to develop effective tests manually. As a result, reliance on tools that can generate tests automatically can reduce manufacturing costs. Furthermore, effective testing schemes also rely on the integration of testing structures to improve the coverage, reduce the number of tests required, and complement the ATG process. Fourth, ATG serves as an enabling technology for other testing techniques. For example, synthesis tools remove the burden of implementing systems down to the gate level. At the same time, gate level detail, necessary for assembling a testing regimen, may be hidden from the designer. ATG fills this gap by generating tests for synthesis without requiring the designer to develop test synthesis tools as well.

FUNDAMENTALS OF TESTING

In this section, fundamental concepts from testing are introduced. First, fault modeling is presented todefinelhe target for testing techniques. Second, testing measures are presented to provide a metric for assessing the efficacy of a given testing regimen. Finally, fault simulation is usedto quantify the testing measures. We will use the three universe mode (2) to differentiate the defect from the manifestation of the fault and also the system malfunction. A fault is the modelof the defect that is present physically in the circuit. An error is the manifestation of the fault where a signal will have a value that differs from the desired value. A failure is the malfunction of the system that results from errors.

Fault Modeling

Circuits can fail in many ways. The failures can result from manufacturing defects, infant mortality, random failures, age, or external disturbances (2). The defects qan be localized, which affect function of one circuit element, or distributed, which affect many of all circuit elements. The failures can result in temporary or permanent circuit failure. The fault model provides an analytical target for testing methodologies and strategies. Thus, the fidelity of the fault models, in the context of the implementation technology, can impact the efficacy of the testing (3). For example, the stuck fault model is considered to be an ineffective model for many faults that occur in CMOS

[1] Moore actually stated his trend in terms of "the number of components per integrated circuit for minimum cost" (1)

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

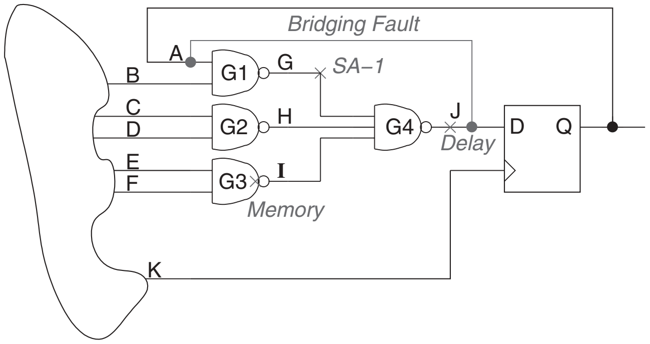

Figure 1. An illustration of fault models.

circuits. In addition, the fault model may influence the overall test strategy.

The fault models selected depend on the technology, used to implement the circuits. Manufacturing defects exist as a consequence of manufacturing the circuit. The introduction and study of manufacturing defects is a heavily studied topic because of its impact on the profitability of the device. Dust or other aerosols in the air can affect the defect statistics of a particular manufacturing run. In addition, mask misalignment and defects in the mask can also increase the defect densities. Other fault models can account for additional failure processes such as transient faults, wear out, and external disturbances. Figure 1 gives some example faults that are discussed in more detail in the following sections.

Stuck-at Fault Models. Stuck-at fault models are the simplest and most widely used fault models. Furthermore, the stuck-at fault model also models a common failure mode in digital circuits. The stuck-at fault model requires the adoption of several fundamental assumptions. First, a stuck-at fault manifests itself as a node being stuck at either of the allowable logic levels, zero or one, regardless of the inputs that are applied to the gate that drive the node. Second, the stuck-at fault model assumes that the faults are permanent. Third, the stuck-at fault model assumes a value for the fault, but otherwise preserves the gate function. The circuit shown in Fig. 1 is used to illustrate the fault model. The output of gate G_1 can be stuck-at 1 (SA-1) as a result of a defect. When the fault is present, the corresponding input to G_4 will always be one. To express the error, a discrepancy with respect to fault-free operation must occur in the circuit as a consequence of the fault. To force the discrepancy, the circuit inputs are manipulated so that $A = B = 1$, and a discrepancy is observed at the output of G1. A second example circuit is shown in Fig. 2, which consists of an OR gate (G_1) that drives one input in each of three AND gates (G_2, G_3, and G_4). Consider the presence of an SA-1 fault on any input to G_1 fault results in the output being 1 as a consequence of the fault. In G_1 input and output SA-1 faults are indistinguishable and for modeling purposes can be “collapsed” into a single fault. A somewhat higher fidelity model can also include gate input stuck faults. For example, in the event gate input I_2 has a stuck-at 1 fault, the situation is somewhat different. In this case, $O_1 = I_3 = I_4$ with G_3 and G_4 not affected directly by the fault.

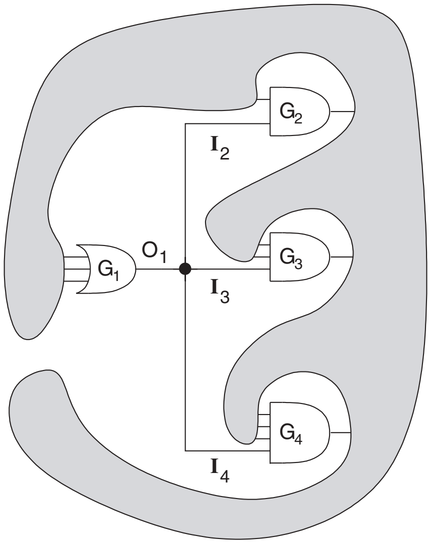

Figure 2. Illustration of input stuck-at faults.

Delay Fault Models. A delay fault is a fault in which a part of the circuit operates slowly compared with a correctly operating circuit. Because normal manufacturing variations result in delay differences, the operation must result in a sufficient delay discrepancy to produce a circuit malfunction. For example, if a delay fault delays a change to a flip-flop excitation input after the expected clock edge, then a fault is manifest. Indeed, when a delay fault is present, the circuit may operate correctly at slower clock rates, but not at speed. Delay faults can be modeled at several levels (4). Gate delay fault models are represented as excessive propagation delay. The transition fault model is slow to transition either a from 0 to 1 or from 1 to 0. A path delay fault is present when the propagation delay through a series of gates is longer than some tolerable worst case delay. Indeed, a current industry practice is to perform statistical timing analysis of parts. The manufacturer can determine that the parts can be run at a higher speed with a certain probability so that higher levels of performance can be delivered to customers. However, this relies on the statistical likelihood that delays will not be worst case (4). By running the device at a higher clock rate indicated by statistical grading, devices and structures that satisfy worst-case timing along the critical path may not meet the timing at the new, higher clock rate. Hence, a delay fault cas seem to be a consequence of the manufacturing decisions. Assuming the indicated delay fault in Fig. 1, Fig. 3 gives a timing diagram that shows the manifestation of the fault. In this circuit, the delay fault causes the flip-flop input, J, to change later, which results in a clock period delay in the flip-flop state change. Because of the nature of delay faults, circuits must be tested at speed to detect the delay fault. As posed here, the delay fault is dynamic, requiring two or more test vectors to detect the fault.

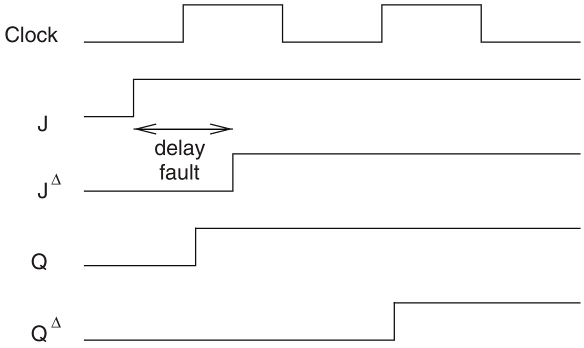

Figure 3. Illustration of a delay faults.

Bridging Faults. Bridging faults exist when an undesirable electrical connection occurs between two nodes resulting in circuit performance degradation or malfunction. Bridging faults between a circuit node and power supply or ground may be manifest as stuck faults. Furthermore, bridging faults may result in behavioral changes such as wired-and, wired-or, and even sequential characteristics when the bridging fault creates a feedback connection (5). Bridging faults require physical proximity between the circuit structures afflicted by the bridging faults. Figure 1 gives an example of a bridging fault that changes the combinational circuit into a sequential circuit.

CMOS Fault Models. CMOS technology has several fault modes that are unique to the technology (5). Furthermore, as a consequence of the properties of the technology, alternative methods for detecting faults in CMOS circuits are necessary. CMOS gates consist of complementary networks of PMOS and NMOS transistors structured such that significant currents are drawn only when signal changes occur. In fault-free operation, when no signal changes occur, the circuit draws very low leakage currents. Understanding the different fault models requires deeper exploration into CMOS circuit structures. CMOS circuits are constructed from complementary pull-up networks of PMOS transistors and pull-down networks of NMOS transistors. In addition, MOS transistors switch based on voltage levels relative to the other transistor terminals. The switching input, or gate, is the input and draws no current other than very low leakage currents. The gate does, however, have significant parasitic capacitance that must be charged and discharged to switch the transistor. Thus, significant currents are drawn when transistors are switched.

Table 1. Input sequence to detect transistor Q_1-stuck-open

A	B	Note
0	0	Set C to 1
0	1	C remains 1 for fault, 0 for no fault

In addition to the stuck faults, CMOS circuits have an interesting failure mode where an ordinary gate can be transformed into a dynamic sequential circuit for certain types of faults. The fault is a consequence of a transistor failure, low quiescent currents, and capacitive gate inputs. In Fig. 4, if transistor Q_1 is stuck open and if $A = 0$, the past value on node C is isolatedelectrically and will act as a storage element through the capacitance on the inverter input. Table 1 summarizes the sequence of inputs necessary to detect the transistor Q_1 stuck open fault. To detect this fault, node C must first be set by assigning $A = B = 0$ followed by setting $B = 1$ to store the value at the input of G_2. Each of the four transistors in the NAND gate will require a similar test.

The CMOS circuit's current draw can be used as a diagnostic for detecting faults. For example, because the CMOS circuit should only draw significant currents when the circuit is switching, any significant deviation from a known current profile suggests faults. Indeed, the CMOS

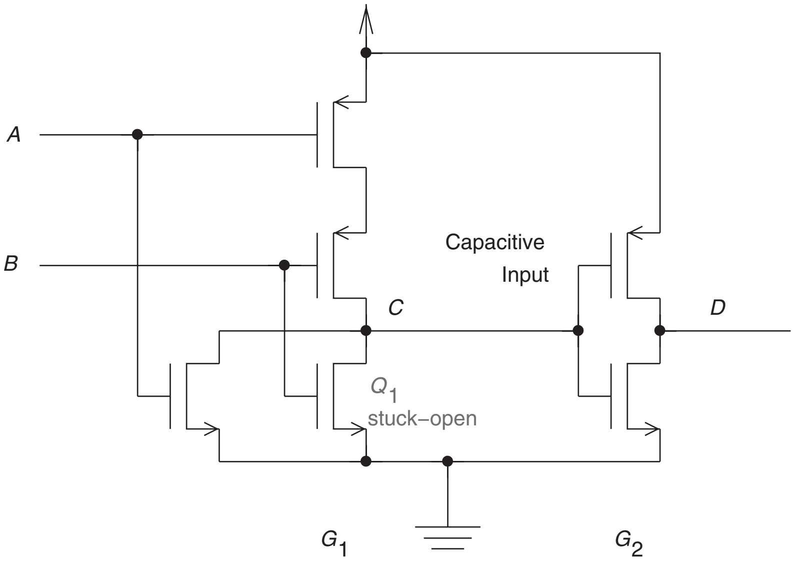

Figure 4. An illustration of a CMOS memory fault.

logic gates may function correctly, but when faults are present, the circuit may draw abnormally large power supply currents. Testing for faults based on this observation is called I_{DDQ} testing. Bridging faults are common in CMOS circuits (6) and are detected effectively with I_{DDQ} testing (7). I_{DDQ} faults can have a significant impact on portable designs where the low current drawn by CMOS circuits is required. Increased I_{DDQ} currents can result from transistors that are degraded because of manufacturing defects such that measurable leakage currents are drawn. In addition, bridging faults can also show increased I_{DDQ} currents.

Memory Faults. Semiconductor memories have structures that are very regular and very dense. As a result, memories can exhibit faults that are not observed ordinarily in other circuits that can complicate the testing process. The faults can affect the memory behavior in unusual ways (8). First, a fault can link two memory cells such that when a value is written into one cell, the value the linked cell toggles. Second, the memory cell can only be written to 0 or 1 but cannot be written the opposite value. Third, the behavior of a memory cell may be sensitive to the contents of neighboring cells. For example, a particular pattern of values stored in surrounding cells may prevent writing into the affected cell. Fourth, the particular pattern of values stored in the cells can result in a change in the value in the affected cell. The nature of these faults make detection challenging because the test must take into account the physical locality of memory cells.

Crosspoint Faults. Crosspoint faults (9) are a type of defect that can occur in programmable logic arrays (PLAs). PLAs consist of AND arrays and OR arrays with functional terms contributing through programming transistors to either include or exclude a term. In field programmable devices, a transistor is programmed to be on or off, respectively, to represent the presence or absence of a connection. A crosspoint fault is the undesired presence or absence of a connection in the PLA. Clearly, because the crosspoint fault can result in a change in the logic function, the stuck fault model cannot model crosspoint defects effectively. A crosspoint fault with a missing connection in the AND array results in a product term of fewer variables, whereas an extra connection results in more variables in the product term. For example, consider function $f(A, B, C, D) = AB + CD$ implemented on a PLA. The existence of a crosspoint fault can change the function to $f^{\mathrm{cpf}}(A, B, C, D) = ABC + CD$. Figure 5 diagrams the structure of the PLA and the functional effect of the crosspoint fault.

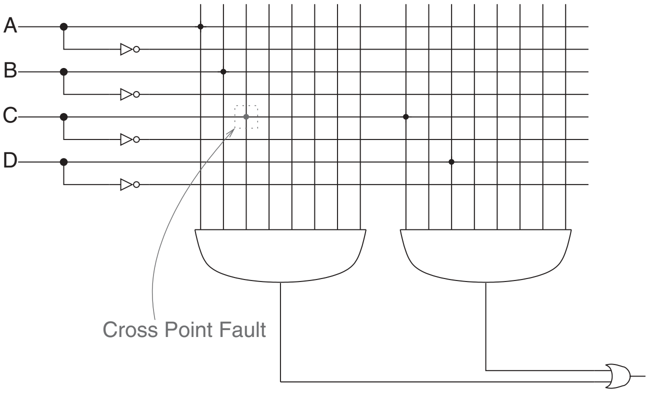

Figure 5. An illustration of a crosspoint fault.

I_{DDQ} Defects. An ideal CMOS circuit draws current only when logic values change. In practice, because transistors are not ideal, a small leakage current is drawn when no circuit changes occur. Many circuit defects result in anomalous significant current that are one type of fault manifestation. Furthermore, many circuits can have a characteristic I_{DDQ} current when switching. Again, this characteristic current can change in response to defects. Detectable I_{DDQ} defects have no relation to the expected correct circuit outputs, which require that testing for I_{DDQ} detectable defects be supplemented with other testing approaches. Furthermore, an integrated circuit is generally integrated with other circuit technologies that draw significant quiescent currents, for example, IC pads, bipolar, and analog circuits. Thus, testing for I_{DDQ} defects requires that the supply for I_{DDQ} testable circuits be isolated from the supply for other parts of the circuit.

Deep Sub-Micron (DSM). Deep sub-micron (DSM) technologies offer the promise of increased circuit densities and speeds. For several reasons, the defect manifestations change with decreasing feature size (3) First, supply voltages are reduced along with an associated reduction in noise margins, which makes circuits more suscepitible to malfunctions caused by noise. Second, higher operating frequencies affect defect manifestations in many ways. Capacitive coupling increases with increasing operating frequency, which increases the likelihood of crosstalk. Furthermore, other errors may be sensitive to operating frequency and may not be detected if testing is conducted at slower frequencies. Third, leakage currents increase with decreasing feature size, which increases the difficulty of using tests to detect current anomalies. Fourth, increasing circuit density has resulted in an increase in the number of interconnect levels, which increases the likelihood of interconnect related defects. Although the classic stuck-at fault model was not conceived with these faults in mind, the stuck-at fault model does focus testing goals on controlling and observing circuits nodes, thereby detecting many interconnect faults that do not conform to the stuck-at fault model.

Measures of Testing. To gauge the success of a test methodology, some metric for assessing the test regimen and any associated overhead is needed. In this section, the measures of test set fault coverage, test set size, hardware overhead, performance impacts, testability, and computational complexity are presented.

Fault Coverage. Fault coverage, sometimes termed test coverage, is the percentage of targeted faults that have been covered by the test regimen. Ideally, 100% fault cover-

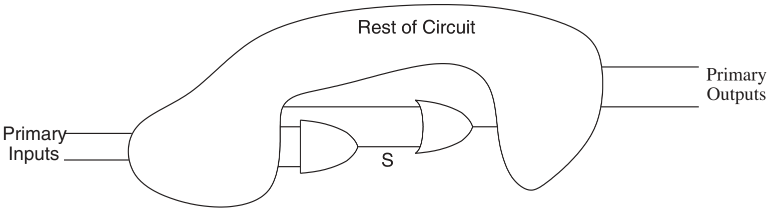

Figure 6. Representative circuit with fault.

age is desired; however, this statistic can be misleading when the fault model does not reflect the types of faults accurately that can be expected to occur (10). As noted earlier, the stuck-at fault model is a simple and popular fault model that works well in many situations. CMOS circuits, however, have several failure modes that are beyond the scope of the simple stuck-at fault model. Fault coverage is determined through fault simulation of the respective circuit. To assess the performance of a test, a fault simulator should model accurately the targeted fault to get a realistic measure of fault coverage.

Size of Test Set. The size of the test set is an indirect measure of the complexity of the test set. Larger test sets increase the testing time, which have a direct a direct impact on the final cost if expensive circuit testers are employed. In addition, the test set size is related to the effort in personnel required computationally to develop the test. The size of the test set depends on many factors including the ease with which the design can be tested as well as integrating DFT methodologies. Use of scan path approaches with flip-flops interconnected as shift registers gives excellent fault coverages, yet the process of scanning into and from the shift register may result in large test sets.

Hardware Overhead. The addition of circuity to improve testability through the integration of built-in test and built-in self test (BIST) capabilities increases the size of a system and can have a significant impact on circuit costs. The ratio of the circuit size with test circuitry to the circuit without test circuitry is a straightforward measure of the hardware overhead. If improved testability is a requirement, then increased hardware overhead can be used as a criterion for evaluating different designs. The additional hardware can simplify the test development process and enable testing for cases that are otherwise impractical, System failure rates are a function of the size and the complexity of the implementation, where ordinarily larger circuits have higher failure rates. As a result, the additional circuitry for test can increase the likelihood of system failure.

Impact on Performance. Likewise, the addition of test circuitry can impact system performance. The impact can be measured in terms of reduced clock rate, higher power requirements, and/or increased cost. For example, scan design methods add circuitry to flip-flops that can switch between normal and test modes and typically with have longer delays compared with circuits not so equipped. For devices with fixed die sizes and PLAs, the addition of test circuitry may displace circuitry that contributes to the functional performance.

Testability. Testability is an analysis and a metric that describes how easily a system may be tested for defects. In circuit defect testing, the goal is to supply inputs to the circuit so that it behaves correctly when no defects are present, but it malfunctions if a single defect is present. In other words, the only way to detect the defect is to force the circuit to malfunction. In general, testability is measured in terms of the specific and the collective observability and controllability of nodes within a design. For example, a circuit that provides the test engineer direct access (setting and reading) to flip-flop contents is estable more easily than one that does not, which gives a corresponding better testability measure. In the test community, testability often is described in the context of controllability and to observability. Controllability of a circuit node is the ability to set the node to a particular value. Observability of a circuit node is the ability to observe the value of the node (either complemented or uncomplemented) at the circuit outputs. Estimating the difficulty to control and to observe circuit nodes forms the basis for testability measures. Figure 6 presents a simple illustration of the problem and the process. The node S is susceptible to many types of faults. The general procedure for testing the correct operation of node S is to control the node to a value complementary to the fault value. Next, the observed value of the signal is propagated to system outputs for observation. Detecting faults in systems that have redundancy of any sort requires special consideration to detect all possible faults. For example, fault-tolerant systems that employ triple modular redundancy will not show any output discrepancies when one masked fault is present (2). To make the modules testable, individual modules must be isolated so that the redundancy does not mask the presence of faults. In addition, redundant gates necessary to remove hazards from combinational circuits result in a circuit where certain faults are untestable. Improved testability can be achieved by making certain internal nodes observable through the addition of test points. The Sandia controllability/observability analysis program is an example application that evaluates the testability of a circuit or system (11).

[2] For example, an exponential time algorithm may double the required resources when the problem size is increased by this result is much like what happens when you double the number of pennies on each successive the square of a chess board.

Computational Complexity. The computational complexity measures both the number of computations and the storage requirements necessary to achieve a particular algorithmic goal. From these measures, bound estimates of the actual amount of time required can be determined. In testing applications, the worst-case computational complexity for many algorithms used to find tests unfortunately is bad. Many algorithms fall in the class of NP-Complete algorithms for which no polynomial time (i.e, good) algorithm exists. Instead, the best known algorithms to solve NP-Complete problems require exponential time.[2] Although devising a perfect test is highly desirable, in practice, 100% coverage generally is not achieved. In most cases, tests are found more quickly than the worst case, and cases taking too long are stopped, which results in a test not being found. Some have noted that most tests are generated in a reasonable amount of time and provide an empirical rationale to support this assertion (12).

Fault Simulation

Fault simulation is a simulation capable of determining whether a set of tests can detect the presence of faults within the circuit. In practice, a fault simulator simulates the fault-free system concurrently with the faulty system. In the event that faults produce circuit responses that differ from the fault-free cases, the fault simulator records the detection of the fault.

To validate a testing approach, fault simulation is employed to determine the efficacy of the test. Fault simulation can be used to validate the success of a test regimen and to give a quantitative measure of fault coverage achieved in the test. In addition, test engineers can use fault simulationfor assessing functional test patterns. By examining the faults covered, the test engineer can identify circuit structures that have not received adequate coverage and can target these structures formore intensive tests.

To assess different fault models, the fault simulator should both model the effect of the faults and also report the faults detected. In the test for bridging faults detectable by I_{DDQ} testing, traditional logic and fault simulators are incapable of detecting such faults because these.faults may not produce a fault value that can differentiate faulty from fault-free instances. In Ref. 13, a fault simulator capable of detecting I_{DDQ} faults is described.

BASIC COMBINATIONAL ATG TECHNIQUES

In ATG, a circuit specification is used to generate a set of tests. In this section, several basic techniques for ATG are presented. The stuck-at fault model described previously provides the test objective for many ATG approaches. The single stuck fault is a fault on a node within the circuit that is either SA-0 or SA-l. Furthermore, only one fault is assumed to be in the circuit at any given time. Presented in detail here are algebraic approaches for ATG, Boolean satisfiability ATG, the D-Algorithm, one of the first ATG algorithms, and PODEM. Subsequent developments in ATG are compared largely with the D-Algorithm and other derived works.

ALGEBRAIC APPROACHES FOR ATG

Algebraic-techniques may be a used to derive tests for faults and can be used in ATG. The Boolean difference (2,14,15) is an algebraic method for finding a test should one exist. Given a Boolean function $F()$ the Boolean difference is defined as

$$\frac{dF(\mathbf{X})}{dx_i} = F(x_1, x_2, , x_{i1}, 0, x_{i+1}, , x_n) \oplus F \times (x_1, x_2, , x_{i1}, 1, x_{i+1}, , x_n) \tag{1}$$

where $\frac{dF(\mathrm{X})}{dx_i}$ is the Boolean difference of the Boolean function $F(\cdot)$, x_i is an input, and $\oplus$ is the exclusive-or. One interpretation of the quantity $\frac{dF(X)}{dx_i}$ is to show the dependence of F(X) on input x_i. If $\frac{dF(\mathrm{X})}{dx_i} = 0$, the function is independent of x_i, which indicates that it is impossible to find a test for a fault on x_i. On the other hand, if $\frac{dF(\mathrm{X})}{dx_i} = 1$, then the output depends on x_i, and a test for a fault on x_i can be found.

The Boolean difference can be used to determine a test because it can be used in an expression that encapsulates both controllability and observability into a Boolean tautology that when satisfied, results in a test for the fault

$$x_i \frac{dF(\mathbf{X})}{dx_i} = 1 \tag{2}$$

for X_i—SA — faults and

$$\bar{x}_i \frac{dF(\mathrm{X})}{dx_i} = 1 \tag{3}$$

for X_i—SA — 1 faults. Note that the Boolean difference represents the observability of input x_i, and the assertion associated with x_i represents its controllability. Equations (2) and (3) can be reduced to SOP or POS forms. A suitable assignment of inputs that satisfies the tautology is the test pattern. Finding a suitable test pattern is intractable computationally if product and sum terms have more than two terms (16).

Boolean Satisfiability ATPG

Boolean satisfiability SAT-ATPG (17) is related to the Boolean difference method for determining test patterns. As in the Boolean difference method, SAT-ATPG constructs the Boolean difference between the fault free and the faulty circuits. Rather than deriving the formula to derive a test, SAT-ATPG creates a satisfiability problem such that the variable assignments to achieve satisfiability are a test for the fault. The satisfiability problem is derived from the combinational circuit by mapping the circuit structure into a directed acyclic graph (DAG). From the DAG, a formula in conjunctive normal form (CNF) is derived that when satisfied, produces a test for a fault in the circuit. Although the SAT problem is NP-Complete (16), the structure of the

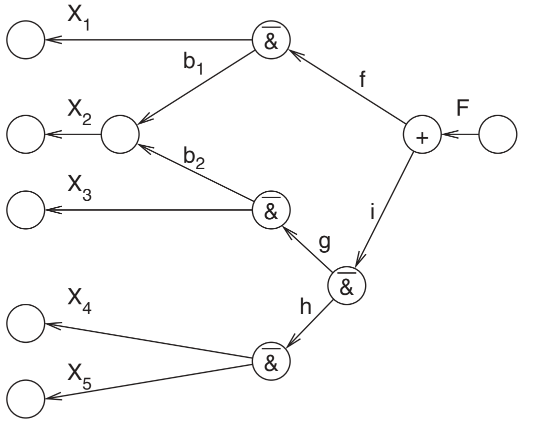

Figure 7. Example combinational circuit.

resulting formula has specific features that tend to reduce the computational effort compared with the general SAT problem. Indeed, the resulting CNF formula is characterized by having a majority of the factors being two terms. Note that satisfiability of a CNF formula with two terms (2SAT) is solvable in linear time. Reference 17 notes that as many as 90% of the factors are two elements. This structure suggests strongly that satisfiability for expressions that results from this construction are solvable in a reasonable amount of time, but the are not guaranteed in polynomial time. The basic SAT-ATPG is described in more detail in the following paragraphs.

As an example, consider the circuit example used to illustrate the D-Algorithm in Fig. 7. The DAG derived is given in Fig. 8. The mapping of the circuit to the DAG is straightforward with each logic gate, input, output, and fanout point mapping to a node in the DAG. Assuming inputs X, Y, and output Z, the conjunctive normal forms for the NAND and OR gates are (17).

$$\begin{array}{l}(Z+X)(Z+Y)(Z+\bar{X}+\bar{Y})\ \text{NAND}\\ (Z+\bar{X})(Z+\bar{Y})(\bar{Z}+X+Y)\ \text{OR}\end{array} \tag{4}$$

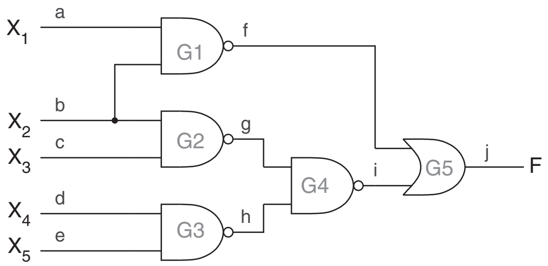

Figure 8. DAG for circuit from Fig. . Logic gate nodes labeled to show original circuit functions.

CNF formulas for other gates and the procedure for handling gates with three or more inputs are also summarized in Ref. 17. The CFN for the fault-free and faulty circuits are derived from the DAG. The exclusive-or of the outputs of fault-free and faulty circuits must be (1) to distinguish between the two expressed as

$$F_{\text{faulty}} \oplus F_{\text{fault - free}} = 1 \tag{5}$$

where satisfication of the tautology results in a test for the desired fault. Starting with the output, the conjunction of all nodes is formed following the edges of the DAG. The fault-free CNF for the circuit is the conjunction of the following conjunctive normal forms for the various circuit structures

$$\begin{array}{ll}(F+\bar{f})(F+\bar{i})(\bar{F}+f+i) & \text{G5}\\ (f+X_1)(f+b_1)(f+\bar{X}_1+\bar{b}_1) & \text{G1}\\ (i+g)(i+h)(i+\bar{g}+\bar{h}) & \text{G4}\\ (g+b_2)(g+X_3)(g+\bar{b}_2+\bar{X}_3) & \text{G2}\\ (\bar{X}_2+b_1)(X_2+\bar{b}_1) & \text{Top fan - out at b}\\ (\bar{X}_2+b_2)(X_2+\bar{b}_2) & \text{Bottom fan - out at b}\\ (h+X_4)(h+X_5)(h+\bar{X}_4+\bar{X}_5) & \text{G3}\end{array} \tag{6}$$

The CNF for the i-SA-0 fault requires a modification to the circuit DAG to represent the presence of the fault. From the DAG structure derived from the circuit and the target fault, a CNF formula is derived. A CNF that represents the fault test is formed by taking the exclusive-or of the fault free circuit with a CNF form that represents the circuit with the fault. The CNF for the faulted circuit is derived by modifying the DAG by breaking the connection at the point of the fault and adding a new variable to represent the fault. The variable $\bar{i}'$ is used to representthe fault i-SA-0. Note that in the faulty circuit, the combinational circuit determining i in the fault-free circuit is redundant, and the CNF formula for the faulted circuit is

$$\begin{array}{ll}(F'+\bar{f})(F'+i')(\bar{F}'+f+\bar{i}') & \text{G5}\\ \bar{i}' & \text{The fault}\\ (f+X_1)(f+b_1)(f+\bar{X}_1+\bar{b}_1) & \text{G1}\\ (\bar{X}_2+b_1)(X_2+\bar{b}_1) & \text{Top fan - out at b}\end{array} \tag{7}$$

Combining Equations (6) and (7), the exclusive-or of the faulty and fault-free formulas, and eliminating redundant terms gives the following formula whose satisfaction is a test for the fault

$$\begin{array}{l}(F+\bar{f})(F+\bar{i})(\bar{F}+f+i)\\ (f+X_1)(f+b_1)(f+\bar{X}_1+\bar{b}_1)\\ (i+g)(i+h)(i+\bar{g}+\bar{h})\\ (g+b_2)(g+X_3)(g+\bar{b}_2+\bar{X}_3)\\ (\bar{X}_2+b_1)(X_2+\bar{b}_1)\\ (\bar{X}_2+b_2)(X_2+\bar{b}_2)\\ (h+X_4)(h+X_5)(h+\bar{X}_4+\bar{X}_5)\\ \bar{i}'\\ (\bar{F}+F'+BD)(F+\bar{F}'+BD)(\bar{X}+\bar{X}'+\bar{B}\bar{D}(X+X'+\bar{B}\bar{D}))\end{array} \tag{8}$$

Note that the last line of Equation (8) represents the exclusive-or for the faulty and the fault-free circuits, and the variable BD is the output that represents the exclusive-

or of the two. Significantly, most terms in Equation (8) have two or fewer terms.

The next step is to determine an assignment that satisfies Equation (8). The problem is broken into two parts where one part represents the satisfaction of the trinary terms and the second the satisfaction of binary terms (solvable in polynomial time) that are consistent with the trinary terms. Efforts that followed (17) concentrated on identifying heuristics that improved the efficiency of finding assignments.

D-Algorithm

The D-Algorithm (18) is an ATG for combinational logic circuits. Furthermore, the D-Algorithm was the first combinational ATG algorithm to guarantee the ability to find a test for a SA-0/1 fault should a test exist. In addition, the D-Algorithm provides a formalism for composing tests for combinational circuits constructed modularly or hierarchically. The D-Algorithm relies on a five-valued Boolean algebra to generate tests, which is summarized in Table 2. Note that the values D and $\bar{D}$ represent a discrepancy between the fault free and faulty signal values where these values can be either the seminal error of the fault or the discrepancy attributable to the fault that has been propagated through several layers of combinational logic. The D-AIgorithm also requires two additional assumptions. First, exactly one stuck-at fault may be present at any given time. Second, other than the faulted node, circuit structures are assumed to operate fault free (i.e., normaly).

To begin the algorithm, the discrepancy that represents the direct manifestation of the fault is assigned to the output of a primitive component. For this component, the input/output combination that forces the manifestation of the fault is called the primitive D cube of failure (PDCF). The PDCF provides a representation of the inputs necessary to result in discrepancies for the faults of interest. The effect of the fault is propagated through logic circuits using the PDC for each circuit. The application of PDCs continues with primitive elements until the discrepancy is propagated to one or more primary outputs. Next, the inputs are justified through a backward propagation step using the singular cover for each component in the backward path. The singular cover is a compressed truth table for the fault-free circuit. Singular covers, PDCFs, and PDCs for several basic gates are shown in Table 3. Note that the PDCFs and PDCs follow straightforwardly from the logic functions and the five valued Boolean logic summarized in Table 2. Theoretic derivation of these terms are presented in Ref. 18.

The D-Algorithm consists principally of two phases. The first phase is the D-drive phase, where the fault is set through the selection of an appropriate PDCF and then propagated to a primary output. Once the D-drive is complete, justification is performed. Justification is the process of determining signal values for internal node and primary inputs consistent with node assignments made during D-drive and intermediate justification steps. In the event a conflict occurs, where at some point a node must be both 0 and 1 to satisfy the algorithm, backtracking occurs to the various points in the algorithm where choices for assignments were possible and an alternate choice is made. An input combination that propagates the fault to the circuit outputs and can be justified at the inputs is a test pattern for the fault. To generate a test for a combinational logic circuit, the D-Algorithm is applied for all faults for which tests are desired.

Table 2. Boolean values

Value	Meaning
1	Logic one
0	Logic zero
D	Discrepancy: expected one, but is zero due to fault
D	Discrepancy: expected zero, but is one due to fault
X	Don’t care, could be either 0 or 1

Table 3. Singular covers, PDCFs, and PDCs for several basic gates

Gate	Singu9lar cover	PDCF	PDC

The D-Algorithm is applied to the circuit given in Fig. 8. For an example demonstration, consider the fault i-SA-0. Figure 9 gives a summary of the algorithmic steps that results in the determination of the test pattern. The resulting test pattern for the example in Fig. 9 is $X_1X_2X_3X_4X_5 = 111XX$, where X is as defined in Table 2. Either fault simulation can be used to identify other faults detected by this test, or the “don’t cares” can be used to combine tests for two or more different faults.

Path-Oriented Decision Making (PODEM)

The D-Algorithm was pioneering in that it provided a complete algorithmic solution to the problem of test pattern generation for combinational circuits. In the years after it was introduced, researchers and practitioners noticed that the D-Algorithm had certain undesirable asymptotic properties and in the general case was found to be NP-Complete (10). This term means the worst case performance is an exponential number of steps in the number of circuit nodes. Despite this finding for many types of problems, the D-Algorithm can find tests in a reasonable amount of time. In Ref. 17, it was noted that the D-Algorithm was particularly inefficient in determining tests for circuit structures typically used in error correcting circuits (ECC). Typically, ECC circuits have a tree of exclusive-OR gates with reconvergent fanout through two separate exclusive-OR trees. The path-oriented decision making (PODEM) test pattern generation algorithm (20) was proposed to speed the search for tests for circuits similar to and used in ECC. In fact, the researchers learned that their approach was in general as effective and more efficient computationally compared with the D-Algorithm.

PODEM is fundamentally different from the D-Algorithm in that test searches are conducted on primary inputs. As a result, the amount of backtracking that might occur is less than the D-Algorithm because fewer places exist where backtracking can occur. Furthermore, the

	Node										
TC	a	b	c	d	e	f	g	h	i	j	Note
1							$\boxed{0}$	$\boxed{X}$	$\boxed{\overline{D}}$		PDCF
2						$\boxed{0}$	0	X	$\overline{D}$	$\boxed{\overline{D}}$	D-Drive
3	$\boxed{1}$	$\boxed{1}$				0	0	X	$\overline{D}$	$\overline{D}$	Justify
4	1	1	$\boxed{1}$			0	0	X	$\overline{D}$	$\overline{D}$	Justify
5	1	1	1	$\boxed{X}$	$\boxed{X}$	0	0	X	$\overline{D}$	$\overline{D}$	Justify

Figure 9. The D-algorithm, step by step. Values in boxes show work for a specific step.

backtracking is simpler computationally. PODEM works by selecting a fault for evaluation and then choosing the inputs one at a time to determine whether the input combination serves as a test pattern. The evaluation process is based on the same five valued logic family used in the D-Algorithm. The algorithm searches for a discrepancy between the good and the faulty circuits. An example decision tree is shown in Fig. 10. The decision tree shows a record of the process for finding a test to detect the i-SA-0 fault. The number of possible nodes in the decision tree are $2^{N+1} - 1$ where each node identifies a possible test. In the worst case, the PODEM algorithm will visit each node in the search tree. A simple search process is employed in this example where each input is assigned trial values in a sequence. The search proceeds for successive inputs from each trial assignment resulting in either the acceptance of this assignment in a test for the desired fault or a rejection because the trial assignment cannot result in a test. The first trial value assigned to an input is 0, and in the event a test is not possible, the trial input is 1. Given this simple structure, the test $X_1X_2X_3X_4X_5 = 11011$ results. Heuristics can be employed to improve the search by taking into account the structure of the circuit (20). For example, if the trial input for $X_3 = 1$, the test $X_1X_2X_3X_4X_5 = 111XX$ results after only three iterations of the search.

SEQUENTIAL ATG TECHNIQUES

Because most interesting digital systems are sequential, sequential ATG is an important aspect of the test generation process. For the purposes of this section, we will assume clocked sequential circuits that conform the structure shown in Fig. 11. The combinational logic in the state machine determines the next state and the output function. A very significant difference between combinational circuits and sequential machines is that the latter have memory elements isolating circuit nodes to be neither directly controllable at the inputs nor observable at the outputs. As a result, the ATG process must be more sophisticated compared with those used in combinational circuits.

A synchronous counter is an example of a simple sequential circuit that also demonstrates some complexities in devejqping defect tests for sequential circuits. Consider a synchronous counter that can be loaded synchronously with an initial count and has one output that is asserted when the counter is at its terminal count. One testing approach is to load the smallest initial count and then clock until the count rolls over after 2^N counts. For long counters, this exhaustive testing of the count function is complete but excessively time consuming. Ad hoc techniques can be employed to devise a test. For example, loading initial counts at selected values that focus on exercising the carry chain within the logic of the counter are very effective because of the regular structure present in most counters. Understanding the intimate structure and the function of the sequential machine produces an effective test. Less-structured sequential circuits are more problematic because tests for specific cases may require more intricate initialization and propagation sequences.

Introduction to Deterministic ATPG for Synchronous Sequential Machines

In this subsection, we will make several observations about ATG in sequential circuits. Clearly, faults will result in incorrect and undesirable behaviors, but the effect of the faulted node may not be observable immediately. In other words, an error is latent for some period of time before it can be detected. Likewise, a faulted node may not be controllable immediately. Consider the simple five state counter, shown in Fig. 12 with an enable input and a terminal count as the output.

After reset, all flip-flop states are set to zero. When enabled, the fault-free counter will cycle through the five

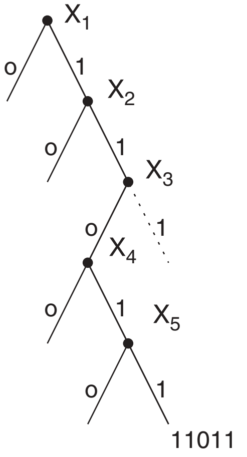

Figure 10. A PODEM decision tree for circuit from Fig. 8.

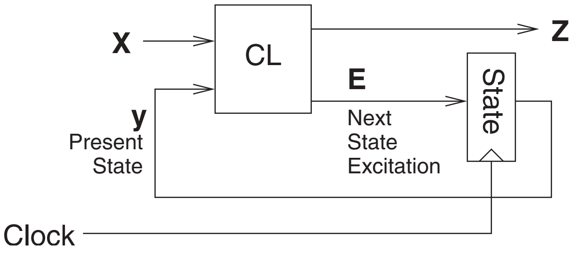

Figure 11. General model of sequential circuit.

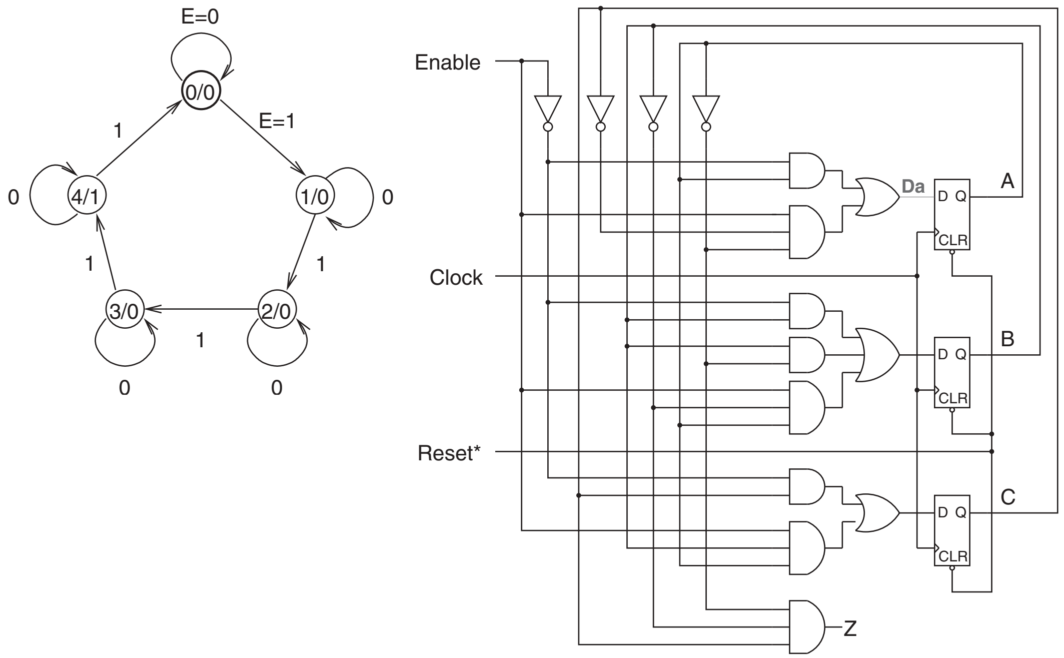
count states. Consider what happens when Da SA-1. With each state update, the fault may cause incorrect operation because discrepancies caused by the fault can be stored in the state. In addition, in subsequent clocks, additional discrepancies can be introduced whereas prior stored discrepancies can be recycled. Indeed, under certain circumstances, faulty behavior may disappear momentarily. As a result of the fault, the state machine operation changes and can be viewed as a change in the state machine operation as shown in Fig. 13.

Using the discrepancy notation from the D Algorithm, the state machine passes through the following states in successive clocks as shown in Fig. 14. Inspecting the state sequencing, $CBA = \{000, 001, 01\bar{D}, \bar{D}D1, D\bar{D}\bar{D}, \bar{D}0\bar{D}, 0\bar{D}1, \bar{D}\bar{D}\bar{D}, 011, 10\bar{D}, 0\bar{D}\,\bar{D}, \bar{D}01, 01\bar{D}\}$ we see that the pattern repeats every eight clocks compared with the expected four clocks. Furthermore, the effect of the fault can be latent because discrepancies are stored in the state and not observable immediately. Because multiple discrepancies can be present simultaneously, the circuit may occasionally show correct operation, for example at T8, despite the occurrence of several discrepancies in prior times. In this example, if the state is observable, the fault can be detected at T2. Suppose that only the inputs and the clock can be controlled and only the output, Z, can be observed. In this case, the detection of the fault is delayed for two clock cycles, until T4.

Synchronous ATG is challenging, but it can be understood and in some cases solved using concepts from combinational ATG methods. Indeed, this leads to one of three approaches. First, tests can be created in an ad hoc fashion. Then, using a technique called fault simulation similar to that presented in Fig. 14, detected faults can be tabulated and reported. Second, the circuit can be transformed in specific ways so that combinational ATG can be applied directly. Such approaches are presented in the following subsections. Third, the circuit operation can be modeled so that the circuit operation gives the illusion of a combinational circuit, and it allows combinational ATG to be used. Indeed, any of these three techniques can be used together as testing needs dictate.

Iterative Array Models for Deterministic ATPG

Clearly, ATG for sequential circuits is more challenging compared with combinational circuits. Many sequential ATG techniques rely on the ability to model a sequential machine in a combina-tional fashion, which makes possible the use of combinational ATG in sequential circuits. Analytical strategies for determining test patterns use iterative array models (19). The iterative array models provide a theoretic framework for making sequential machines seem combinational from the perspective of the ATG process. Iterative arrays follow from unrolling the operation of the



(a) State Diagram

(b) Implementation

Figure 12. Five state counter.

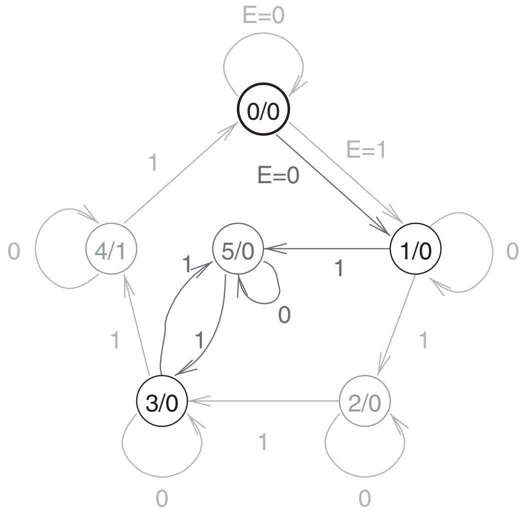


Figure 13. Effect of faults on state diagram.

state machine where each unrolling exposes another time frame or clock edge that can update the state of the state machine. The unrolling process replicates the excitation functions in each time frame, applying the inputs consistent with that particular state. Memory elements are modeled using structures that make them seem combinational. Furthermore, output functions are replicated as well. Each input and output is now represented as a vector of values where each element gives the value within a specific time frame. With this model, combinational ATG methods can be used to determine circuits for specific times.

Iterative array methods complicate the application of sequential ATG methods in our major ways: (*1*) the size of the "combinational circuit" is not known, (*2*) the state contribution is a constrained input, (*3*) multiple iterations express faults multiple times, and (*4*) integration level issues complicate when and how inputs are controlled and outputs are observed. For test pattern generation, the concatenation of the inputs from the different time frames, $\cdots X^{t1}X^{t}X^{t+1}\cdots$, serve as the inputs for the combinational ATG algorithms, where for the actual circuit, the superscript specifies the time frame when that input is set to the required value.. The combinational ATG algorithm outputs are the concatenation of the frame outputs, $\cdots Z^{t1}Z^{t}Z^{t+1}\cdots$, where again, the superscript identifies when an output should be observed to detect a particular fault (Fig. 15).

The size of the circuit is determined by the initial state and the number of array iterations necessary to control and to observe a particular fault. In all iterations, the iterative model replicates combinational circuitry and all inputs and outputs for that time step. The ATG generation process will, by necessity, be required to instantiate, on demand, combinational logic iterations because the required number of iterations necessary to test for a specific fault is not known. For some initial states, it is impossible to determine a test for specific faults because multiple expressions of a fault may mask its presence. Different algorithms will assume either an arbitrary initial state or a fixed state.

From the timing diagram in Fig. 13, the iterative circuit model for the counter example with a Da-SA-1 fault is given in Fig. 16. A discrepancy occurs after the fourth clock cycle, where the test pattern required to detect the fault is $Dc_0Db_0Da_0E_0E_1E_2E_3Z_0Z_1Z_2Z_3 = (00000000001)$, where the input pattern is the concatenation of initial state $Dc_0Db_0Da_0$, the inputs at each time frame $E_0E_1E_2E_3$, and the outputs at each time frame are $Z_0Z_1Z_2Z_3$. Because circuit in Fig. 16 is combinational, algorithms such as the D-Algorithm and PODEM can be employed to determine test patterns. Both algorithms would require modification to handle both variable iterations and multiple faults.

From the iterative array model, two general approaches can be pursued to produce a test for a fault. The first approach identifies a propagation path from the point of the fault and the output. From the selected output, reverse time processing is employed to sensitize a path through the frame iterations to the point of the fault. In the event a path is not found, backtracking and other heuristics are employed. After the propagation path for the fault is established, reverse time processing is used to justify the inputs required to express the fault and to maintain consistency with previous assignments. The second approach employs forward processing from the point of the fault to propagate to the primary outputs and then reverse time processing to justify the conditions to express the fault and consistency (21,22). Additional heuristics are employed to improve the success and the performance of the test pattern generation process, including using hints from fault simulation (22). Several approaches can be applied for determining test patterns.

Genetic Algorithm-Based ATPG

Because of the challenges of devising tests for sequential circuits, many approaches have been studied. Genetic algorithms (GAs) operate by generating and evaluating popu-

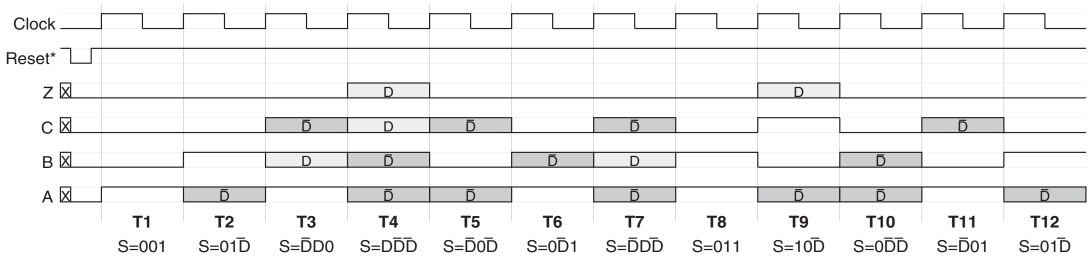

Figure 14. Fault simulation of counter with Da-SA-1.

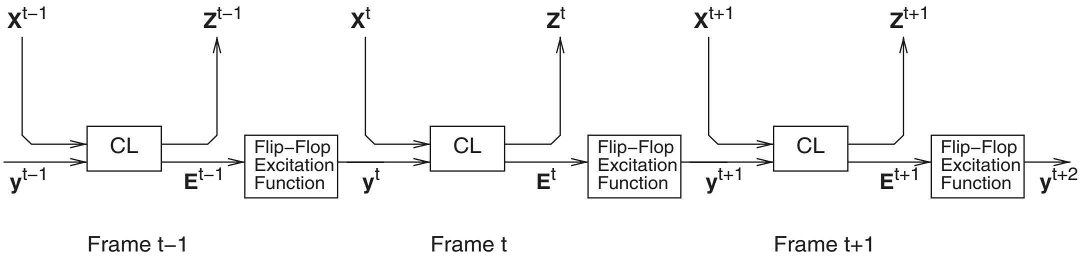

Figure 15. Excerpt from iterative array sequential circuit model.

lations of organisms for fitness to a particular purpose and then using the fitness to identify organisms from which the next generation is created (23). Organism structure and capabilities are defined by a genetic code represented as a string of values that set the configuration of the organism. The organism constructed from the genetic code is then evaluated for fitness. Organisms in the next generation are generated from fit organisms in the current generation using simulated variations of crossover and mutation.

In the context of a DUT, the string of test patterns can serve as the genome for the organism and the fitness can be a function of whether and how well a particular fault is detected from the sequence. The work of Hsiao et al. (24) used GAs to assemble test sequences for faults from promising pieces. In their work, the GA operates in two phases, the first targets controlling the fault and the second targets propagating the faulted node to the primary outputs. Sequences from which a test is assembled are from one of three categories: (*1*) distinguishing sequences, (*2*) set/clear sequences, and (*3*) pseudoregister justification sequences. Distinguishing sequences propagate flip-flop fault effects to the primary outputs. Set/clear sequences justify (i.e., force flip-flop) to specific states. Finally, pseudoregister justification sequences put sets of flip-flops into specific states. These sequences form the basis from which tests are generated for a particular fault. The process is initialized in some random fashion with a set of strings that represent the initial GA generation of test sequences. The likelihood that any given string can detect the fault depends on the complexity and the size of the circuit. Assuming the circuit is sufficiently complex that no organism can detect the fault, the fitness function must include the ability to identify organisms that have good qualities (i.e., have sequencing similar to what one might expect of the actual test sequence). Two fitness functions were formed in Ref. 24 for the justification and the propagation phases. Each was the weighted sum of six components that include the ability to detect the fault, measures of controllability, distinguishing measures, circuit activity measures, and flip-flop justification measures. The GA test generation operates in three stages where the GA is run in each stage until the fault coverage plateaus. In addition, test lengths are allowed to grow in subsequent stages, on the assumption that faults not detectable with shorter sequences may be detected with longer sequences.

DESIGN FOR TESTABILITY

Many ATG techniques provide capabilities that are practical in a variety of situations. DFT is the process and the discipline for designing digital systems to make them easier to test. Furthermore, constructing circuits that facilitate

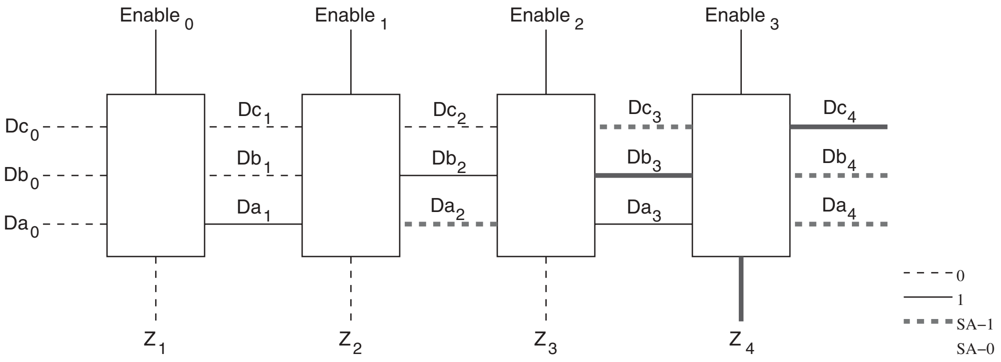

Figure 16. Iterative array model for example circuit for Da-SA-1.

testing also simplifies ATG. In this capacity, DFT can affect the entire testing process, from ATG to testing. DFT techniques apply other concepts and design paradigms including circuit fault models and techniques for detecting faults. Modifying designs themselves to improve and to simplify the testing process can offer many benefits. First, time devoted to test development is reduced with a higher likelihood of guaranteed results. Second, DFT reduces the test set size because individual tests are generally more effective. Third, DFT can reduce the time necessary to test a system. DFT approaches fall into one of two categories. Starting with a traditional design, the first category is exemplified by adding circuit structures to facilitate the testing process. The second category attacks the testing process from basic design principals resulting in systems that are inherently easy to test. In this section, DFT approaches that support ATG are presented.

Circuit Augmentation to Facilitate ATG

Digital systems designed in an ad hoc fashion may be difficult to test. Several basic techniques are available to improve the testability of a given system. These techniques include test point insertion, scan design methods, and boundary scan techniques. These approaches preserve the overall structure of the system.

Test Point Insertion. Test point insertion is a simple and straightforward approach for providing direct controllability and observability of problem circuit nodes. In test point insertion, additional inputs and outputs are provided to serve as inputs and outputs for testing purposes. These additional test point inputs and outputs do not provide any additional functional capabilities. The identification of these points can follow from a testability analysis of the entire system by identifying difficult-to-test internal nodes. Circuit nodes are selected as test points to facilitate testing of difficult-to-test nodes or modules. As test points are identified, the testability analysis can be repeated to determine how well the additional test points improve testability and to determine whether additional test points are necessary. Indeed, the test points enhance clearly the efficacy of ATG (25). Furthermore, test point insertion can provide the basis for structured design for testability approaches. The principal disadvantage of adding test points is the increased expense and reduced performance that results from the addition of test points. One study showed (26) that adding 1% additional test points increases circuit overheads by only 0.5% but can impact system performance by as much as 5%. In the study, test points were internal and inserted by state of the art test point insertion software.

Scan Design Methods. The success of test point insertion relies on the selection of good test points to ease the testing burden. Determining these optimal points for.test point insertion can be difficult. As a result, structured approaches can be integrated to guarantee ATG success. One particularly successful structured design approach is scan design. Scan design methods improve testability by making the internal system state both easily controllable and observable by configuring, in test mode, selected flip-flops as a shift register (27–30), effectively making each flip-flop a test point. Taken to the logical extreme, all flip-flops are part of the shift register and are therefore also test points. The power of this configuration is that the storage elements can be decoupled from the combinational logic enabling the application of combinational ATG to generate fault tests. The shift register organization has the additional benefit that it can be controlled by relatively few inputs and outputs. Because a single shift register might be excessively long, the shift register may be broken into several smaller shift registers.

Historically, scan path approaches follow from techniques incorporated into the IBM System/360 where shift registers were employed to improve testability of the system (27). A typical application of a scan design is given in Fig. 17. Note the switching of the multiplexer at the flip-flop inputs controls whether the circuit is in test or normal operation. Differences between different scan design methods occur in the flip-flop characteristics or in clocking.

Scan Path Design. Relevant aspects of the design include the integration of race free D flip-flops to make the flip-flops fully testabl (29). Level sensitive scan design (28) is formulated similarly. One fundamental difference is the machine state is implemented using special master slave flip-flops clocked with non overlapping clocks to enable testing of all stuck faults in flop-flops.

Boundary Scan Techniques. In many design approaches, the option of applying design for testability to some components is impossible. For example, standard parts that might be used in printed circuit boards that are not typically designed with a full system scandesign in mind. As another example, more and more ASIC designs are integrated from cores, which are subsystems designed by third-party vendors. The core subsystems are typically processors, memories, and other devices that until recently were individual integrated circuits themselves. To enable testing in these situations, boundary scan methods were developed. Boundary scan techniques employ shift registers to achieve controllability and observability for the inputs/outputs to circuit boards, chips, and cores. An important application of boundary scan approaches is to test the interconnect between chips and circuit boards that employ boundary scan techniques. In addition, the boundary scan techniques provide a minimal capability to perform defect testing of the components at the boundary. The interface to the boundary scan is a test access port (TAP) that enables setting and reading of the values at the boundary. In addition, the TAP may also allow internal testing of the components delimited by the boundary scan. Applications of boundary scan approaches include BIST applications (31), test of cores (32), and hierarchical circuits (33). The IEEE (Piscatouoaes NJ) has created and approved the IEEE Std 1149.1 boundary scan standard (34). This standard encourages designers to employ boundary scan techniques by making possible testable designs constructed with subsystems from different companies that conform to the standard.

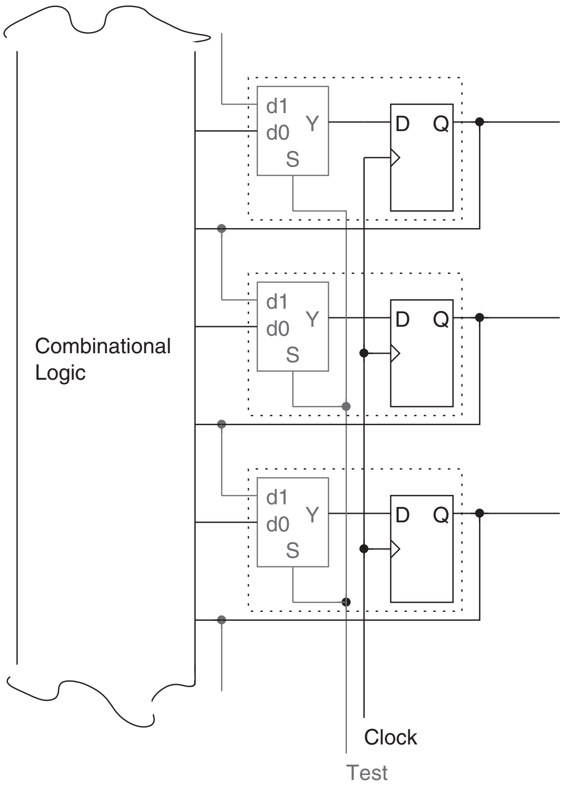

Figure 17. One scan path approach.

ATG and Built-In Test

Background. Requiring built-in tests affects test generation process in two ways. First, the mechanism for generating test patterns must be self-contained within the circuitry itself. Although in theory, circuitry can be designed to produce any desired test pattern sequence, in reality, most are impractical. As a result, simpler circuitry must be employed to generate test patterns. ATG and built-in tests require the circuits to have the ability to generate test sequences and also to determine that the circuits operate correctly after being presented with the test sequence.

Three classes of circuits are typically employed because the patterns have good properties and also have the ability to produce any sequence of test patterns. The first type of circuit is a simple N-bit counter, which can generate all possible assignments to N bits. Counter solutions may be impractical because test sequences are long for circuits with a relatively few inputs and also may be ineffective in producing sequences to test for delay or CMOS faults. Researchers have investigated optimizing count sequences to achieve more reasonable test lengths (35). The second type of circuit generates pseudorandom sequences using linear feedback shift registers (LFSRs). For combinational circuits, as the number of random test patterns applied to the circuit increases, fault coverage increases asymptotically to 100%. Much research has been conducted in the development of efficient pseudorandom sequence generators. An excellent source on many aspects of pseudorandom techniques is Ref. 36. A third type of circuit is constructed to generate specific test patterns efficiently for specific types of circuit structures. In this case, the desired sequence of test patterns is examined and a machine is synthesized to recreate the sequenc. Memory tests have shown some success in using specialized test pattern generator circuits (37).

To determine whether a fault is present, the outputs of the circuit must be monitored and compared with expected fault-free outputs. Test pattern generation equipment solves this by storing the expected circuit outputs for a given sequence of inputs applied by the tester. As noted above, it may be impractical to store or to recreate the exact circuit responses. Alternate approaches employ duplication approaches (several are summarized in Ref. 2) where a duplicate subsystem guarantees the ability to generate correct circuit outputs, assuming a single fault model. A discrepancy between the outputs of the duplicated modules infers the presence of a fault. Although duplication often is used in systems that require tault tolerance or safety, duplication may be an undesirable approach in many situations. An alternative approach, signature analysis, compresses the circuit output responses into a single code word, a signature, which is used to detect the presence of faults. Good circuit responses are taken either from a known good circuit or more frequently from circuit simulations. A fault in a circuit would result in a signature that differs from the expected good signature with high probability.

Signature Analysis. The cost of testing is a function of many influences that include design costs, testing time, and

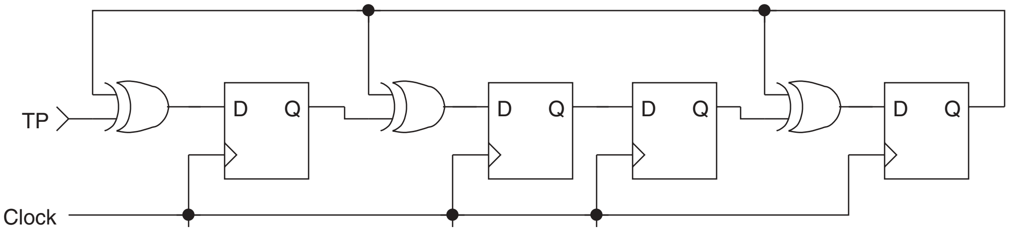

Figure 18. Linear feedback shift register.

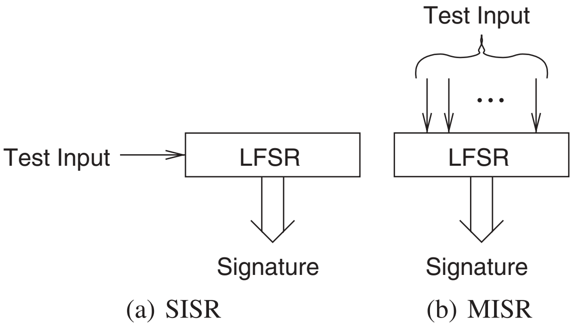
test equipment costs. Thus, reducing the test set size and the ease of determining whether a fault is present has a great influence on the success of the system. In signature analysis, the test set is reduced effectively to one representative value, which is termed a signature. The signature comparison can be performed internally, using the same technology as the system proper. In signature analysis, the signature register is implemented as a LFSR as shown in Fig. 18. The LFSR consists of a shift register of length N, and linear connections fed back to stages nearer the beginning of the shift register. With successive clocks, the LFSR combines its current state with the updated test point values. Figure 19 shows two different LFSR configurations: (*1*) a single input shift register (SISR) compresses the results of a single test point into a signature and (*2*) a multiple input shift register (MISR) compresses several test point results. After the test sequence is complete, the contents of the LFSR is compared with the known good signature to determine whether faults are present. A single fault may result in the LFSR contents differing from the good signature, but generally will not provide sufficient information to identify the specific fault. Furthermore, a single fault may result in a final LFSR state that is identical to the good signature, which is termed allasing. This outcome is acceptable if aliasing occurs with low probability. In Ref. 36, the aliasing probability upper bounds were derived for signatures computed with SISRs. In addition in Ref. 30, methods for developing MISRs with no aliasing for single faults were developed. The circuitry necessary to store the signature, to generate a vector to compre with the signature, and to compare the signature is modular and simple enough to be intergrated with circuit functions of reasonable sizes, which makes signature analysis an important BIST technique. LFSRs can be used in signature analysis in several ways.



(a) SISR (b) MISR

Figure 19. Different signature register configurations.

BILBO. The built-in logic block observer (BILBO) approach has gained a fairly wide usage as a result of its modularity and flexibility (40). The BILBO approach can be used in both scan path and signature analysis test applications by encapsulating several important functions. BILBO registers operate in one of four modes. The first mode is used to hold the state for the circuitry as D flip-flops. In the second mode, the BILBO register can be configured as a shift register that can be used to scan values into the register. In the third mode, the register operates as a multiple input signature register (MISR). In the fourth mode, the register operates as a parallel random pattern generator. These four modes make possible several test capabilities. A four-bit BILBO register is shown in Fig. 20. One example application of BILBO registers is shown in Fig. 21. In test mode, two BILBO registers are configured to isolate one combinational logic block. The BILBO register at the input, R1, is configured as a PRPG, whereas the register at the output, R2, is configured as a MISR. In test mode operation, for each random pattern generated, one output is taken and used to compute the next intermediate signature in the MISR. When all tests have been performed, the signature is read and compared with the known good signature. Any deviation indicates the presence of faults in the combinational circuit. To test the other combinational logic block, the functions of R1 and R2 only need to be swapped. Configuration of the data path to support test using BILBO registers is best achtevedby performing register allocation and data path design with testability in mind (41).

Memory BIST

Semiconductor memories are designed to achieve the high storage densities in specific technologies. High storage densities are achieved by developing manufacturing processes that result in the replication, organization, and optimization of a basic storage element. Although in principle the memories can be tested as other sequential storage elements, in reality the overhead associated with using scan path and similar test approaches would impact severely the storage capacity of the devices. Furthermore, the basic function of a memory typically allows straightforward observability and controllability of stored information. On the other hand, the regularity, of the memory's physical structure and the requisite optimizations result in fault manifestations as a linkage between adjacent memory cells. From a testing perspective, the manifestation of the fault is a function of the state of a memory cell and its

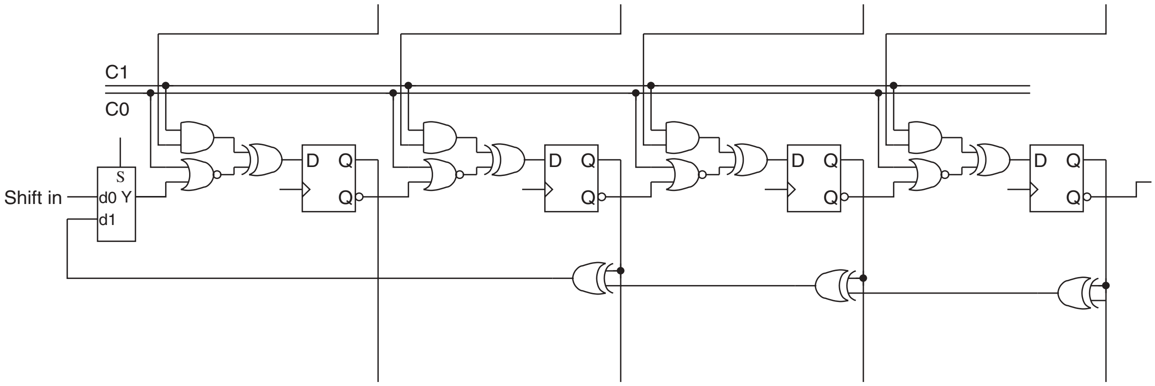


Figure 20. BILBO register.

physically adjacent memory cells. Among the test design considerations of memories is the number of tests as a function of the memory capacity. For example, a test methodology was developed (37) for creating test patterns. These test patterns could be computed using a state machine that is relatively simple and straightforward. The resulting state machine was shown to be implementable in random logic and as a microcode driven sequencer.

Programmable Devices

With seyeral vendors currently (2004) marketing FPGA devices capable of providing in excess of one million usable gates, testing of the programmed FPGA becomes a serious design consideration. Indeed, the capacity and performance of FPGAs makes this class of technology viable in many applications. Furthermore, FPGA devices are an integration of simpler programmable device architectures, each requiring its own testing approach. FPGAs include the ability to integrate memories and programmable logic arrays, which requires ATG approaches most suitable for that component. Summarized previously, PLAs exhibit fault models not observed in other implerneniation technologies. One approach for testing to apply BIST approaches described previously (42). PLA test can be viewed from two perspectives. First, the blank device can be tested and deemed suitable for use in an application. Second, once a device is programmed, the resulting digital system can be tested according to the jpejhods already described. One early and notable ATG methods applied to PLAs is PLATYPUS (43). The method balances random TPG with deterministic TPG to devise tests for both traditional stuck-at faults as well as cross-point faults. Modern FPGAs support standard test interfaces such as JTAG/ IEEE 1149 standards. In this context, ATG techniques can be applied in the context of boundary scan for the programmed device.

Minimizing the Size of the Test Vector Set

In the combinational ATG algorithms presented, specific faults are targeted in the test generation process. To

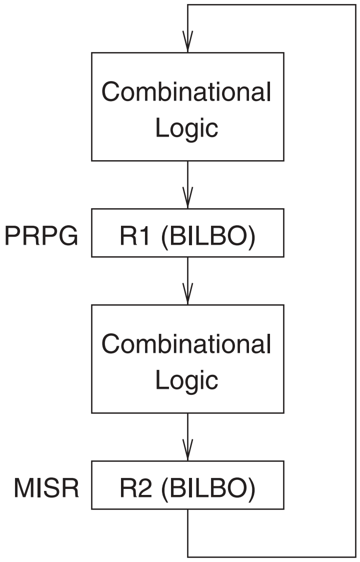

Figure 21. Application of BILBO to testing.

Table 4. Test pattern compaction

Fault	Test
a	00X0
b	001X
c	X00X
d	X011

develop a comprehensive test for a combinational circuit, one may develop a test for each faultlndividually. In most cases, however, the number of tests that results is much larger than necessary to achieve the same fault coverage. Indeed, the techniques of fault collapsing, test compaction, and fault simulation can produce a significant reduction in the test set size.

Fault Collapsing. Distinct faults in a circuit may produce the identical effect when observed at circuit outputs. As a result, the faults cannot be differentiated by any test. For example, if any AND gate input is SA-0, the input fault cannot be differentiated frogi thexiutout SA-0 fault. In this case, the faults can be collapsed into one, output SA-0, which requires a test only for the collapsed fault.

Test Compaction. The D-Algorithm and PODEM can generate test vectors with incompletely specified inputs, providing an opportunity to merge different tests through test compaction. For example, consider a combinational circuit whose tests are given in Table 4. Examining the first two faults in the table, *a*and *b*, shows the test 0010 will test for both faults. Test compaction can be either static or dynamic. In static test compaction, all tests are generated by the desired ATG and then analyzed to determine those tests that can be combined, off-line, thereby creating tests to detect several faults and specifying undetermined input values. In dynamic tests, after each new test is generated, the test is compacted with the cumulative compacted list. For the tests in Table 4, static compaction results in two tests that tests for all faults, 0000, and 0011 for faults {*a*,*c*} and {*b*,*d*} respectively. Dynamic compaction produces a different result, as summarized in Table 5. Note that the number of tests that result from dynamic compaction is more compared with static compaction. From a practical perspective, optimal compaction is computationally expensive and heuristics are often employed (1). Reference 9 also notes that in cases where heuristics are used in static compaction, dynamic compaction generally produces superior results while consuming fewer computational resources. Furthermore, dynamic compaction processes vectors as they come, but more advanced dynamic compaction heuristics may choose to not compact immediately but rather wait until a more opportune time.

Table 5. Simple dynamic test compaction

Sequence	New test	Compacted tests
1	00X0	{00X0}
2	001X	{0010}
3	X00X	{0010,X00X}
4	X011	{0010,X00X,X011}

Compaction Using Fault Simulation. A test that has been found for one fault may also test for several other faults. Those additional tests can be determined experimentally by performing a fault simulation for the test and identifying the additional faults that are also detected. The process is outlined as follows:

1. Initialize fault set
2. Select a fault from the fault set
3. Generate a test pattern for the selected fault
4. Run fault simulation
5. Remove additional detected faults form fault set
6. If fault set empty or fault coverage threshold met then exit, otherwise go to step 2

Test Vector Compression. Test vector compression takes on two forms, lossless and lossy. Lossless compression is necessary in circumstances where the precise input and output values must be known as what might be necessary on an integrated circuit tester. Under certain limited circumstances, lossless compression might make it possible to store test-compressed vectors in the system itself. In lossy compression, the original test vectors cannot be reconstituted. Lossy compression is used in such applications as pseudorandom number generation and signature registers, where input and output vectors are compressed through the inherent structure of the linear feedback shift registers as described previously. Lossy compression is suitable when the probability of not detecting an existing fault is much smaller than the proportion of uncovered faults in the circuit.

ATG CHALLENGES AND RELATED AREAS

As circuit complexity and capabilities evolve, so does the art and science of ATG. Technologic innovations have resulted in the ability to implement increasingly complex and innovative designs. The technologic innovations also drive the evolution of testing. One trend, for example, is that newer CMOS circuits have increased quiescent currents, which impacts the ability to apply I_{DDQ} testing technologies.

ATG in Embedded Systems

The natural evolution of technology advances and design has resulted in systems composed from IP obtained from many sources. Clearly, the use of IP provides developers faster development cycles and quicker entry to market. The use of IP presents several ATG challenges. First, the testing embedded IP components can be difficult. Second, because the internals of the IP components are often not known, the success of ATG techniques that require full knowledge of the circuit structure will be limited. Third, IP developers may be hesitant to provide fault tests for fear that it would give undesired insights into the IP implementation.

Functional ATG

Design tools and rapid prototyping paradigms result in the designer specifying hardware systems in an increasingly abstract fashion. As a result, the modern digital system designer may not get the opportunity develop tests based on gate level implementations. Employing ATG technologies relieves the designer of this task provided the design tools can define and analyze a gate level implementation.

SUMMARY

In this article, many aspects of ATG have been reviewed. ATG is the process of generating tests for a digital system in an automated fashion. The ATG algorithms are grounded in fault models that provide the objective for the test generation process. Building on fault models, ATG for combinational circuits have been shown to be effective. Sequential circuits are more difficult to test as they require the circuits to be unrolled in a symbolic fashion or be the object of specialized test pattern search algorithms. Because of the difficulties encountered in testing sequential circuits, the circuits themselves are occasionally modified to simplify the process of finding test patterns and to improve the overal test fault coverage. The inexorable technology progression provides many challenges in test testing process. As technology advances, new models and techniques must continue to be developed to keep pace.

C

CARRY LOGIC

Addition is the fundamental operation for performing digital arithmetic; subtraction, multiplication, and division rely on it. How computers store numbers and perform arithmetic should be understood by the designers of digital computers. For a given weighted number system, a single digit could represent a maximum value of up to 1 less than the base or radix of the number system. A plurality of number systems exist (1). In the binary system, for instance, the maximum that each digit or bit could represent is 1. Numbers in real applications of computers are multibit and are stored as large collections of 16, 32, 64, or 128 bits. If the addition of multibit numbers in such a number system is considered, the addition of two legal bits could result in the production of a result that cannot fit within one bit. In such cases, a carry is said to have been generated. The generated carry needs to be added to the sum of the next two bits. This process, called carry propagation, continues from the least-significant bit (LSB) or digit, the one that has the least weight and is the rightmost, to the most-significant bit (MSB) or digit, the one with the most weight and is the leftmost. This operation is analogous to the usual manual computation with decimal numbers, where pairs of digits are added with carries being propagated toward the high-order (left) digits. Carry propagation serializes the otherwise parallel process of addition, thus slowing it down.

As a carry can be determined only after the addition of a particular set of bits is complete, it serializes the process of multibit addition. If it takes a finite amount of time, say (Δ_g), to calculate a carry, it will take 64 (Δ_g) to calculate the carries for a 64-bit adder. Several algorithms to reduce the carry propagation overhead have been devised to speed up arithmetic addition. These algorithms are implemented using digital logic gates (2) in computers and are termed *carry logic*. However, the gains in speed afforded by these algorithms come with an additional cost, which is measured in terms of the number of logic gates required to implement them.

In addition to the choice of number systems for representing numbers, they can further be represented as fixed or floating point (3). These representations use different algorithms to calculate a sum, although the carry propagation mechanism remains the same. Hence, throughout this article, carry propagation with respect to fixed-point binary addition will be discussed. As a multitude of 2-input logic gates could be used to implement any algorithm, all measurements are made in terms of the number of 2-input NAND gates throughout this study.

THE MECHANISM OF ADDITION

Currently, most digital computers use the binary number system to represent data. The legal digits, or bits as they are called in the binary number system, are 0 and 1. During addition, a sum S_i and a carryout C_i are produced by adding a set of bits at the ith position. The carryout C_i produced during the process serves as the carry-in C_{i-1} for the succeeding set of bits. Table 1 shows the underlying rules for adding two bits, A_i and B_i, with a carry-in C_i and producing a sum S_i and carry-out, C_i.

FULL ADDER

The logic equations that represent S_i and C_i of Table 1 are shown in Equations (1) and (2). A block of logic that implements these is called full adder, and it is shown in the inset of Fig. 1. The serial path for data through a full adder, hence its delay, is 2 gates, as shown in Fig. 1. A full adder can be implemented using eight gates (2) by sharing terms from Equations (1) and (2):

$$S_i = A_iB_iC_{i-1} + \overline{A}_i\overline{B}_iC_{i-1} + \overline{A}_iB_i\overline{C}_{i-1} + A_i\overline{B}_i\overline{C}_{i-1} \quad (1)$$

$$C_i = A_iB_i + C_{i-1}(A_i + B_i) \quad (2)$$

RIPPLE CARRY ADDER

The obvious implementation of an adder that adds two n-bit numbers A and B, where A is $A_nA_{n-1}A_{n-2}\ldots A_1A_0$ and B is $B_nB_{n-1}B_{n-2}\ldots B_1B_0$, is a ripple carry adder (RCA). By serially connecting n full adders and connecting the carryout C_1 from each full adder as the C_{i-1} of the succeeding full adder, it is possible to propagate the carry from the LSB to the MSB. Figure 1 shows the cascading of n full adder blocks. It is clear that there is no special carry propagation mechanism in the RCA except the serial connection between the adders. Thus, the carry logic has a minimal overhead for the RCA. The number of gates required is $8n$, as each full adder is constructed with eight gates, and there are n such adders. Table 2 shows the typical gate count and speed for RCAs with varying number of bits.

CARRY PROPAGATION MECHANISMS

In a scenario where all carries are available right at the beginning, addition is a parallel process. Each set of inputs A_i, B_i, and C_{i-1} could be added in parallel, and the sum for 2 n-bit numbers could be computed with the delay of a full adder.

The input combinations of Table 1 show that if A_i and B_i are both 0s, then C_i is always 0, irrespective of the value of C_{i-1}. Such a combination is called a carry kill term. For combinations where A_i and B_i are both 1s, C_i is always 1. Such a combination is called a carry generate term. In cases where A_i and B_i are not equal, C_i is equal to C_{i-1}. These are called the propagate terms. Carry propagation originates at a generate term, propagates through

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

CKA	170/17	350/19	695/23

any successive propagate terms, and gets terminated at a carry kill or a new carry generate term. A *carry chain* is a succession of propagate terms that occur for any given input combination of A_i and B_i. For the addition of two n-bit numbers, multiple generates, kills, and propagates could exist. Thus, many carry chains exist. Addition between carry chains can proceed in parallel, as there is no carry propagation necessary over carry generate or kill terms.

Based on the concept of carry generates, propagates, and kills, logic could be designed to predict the carries for each bit of the adder. This mechanism is static in nature. It can be readily seen that different carry chains exist for different sets of inputs. This introduces a dynamic dimension to the process of addition. The dynamic nature of the inputs could also be used and a sum computed after the carry propagation through the longest carry chain is completed. This leads to a classification into static and dynamic carry logic.

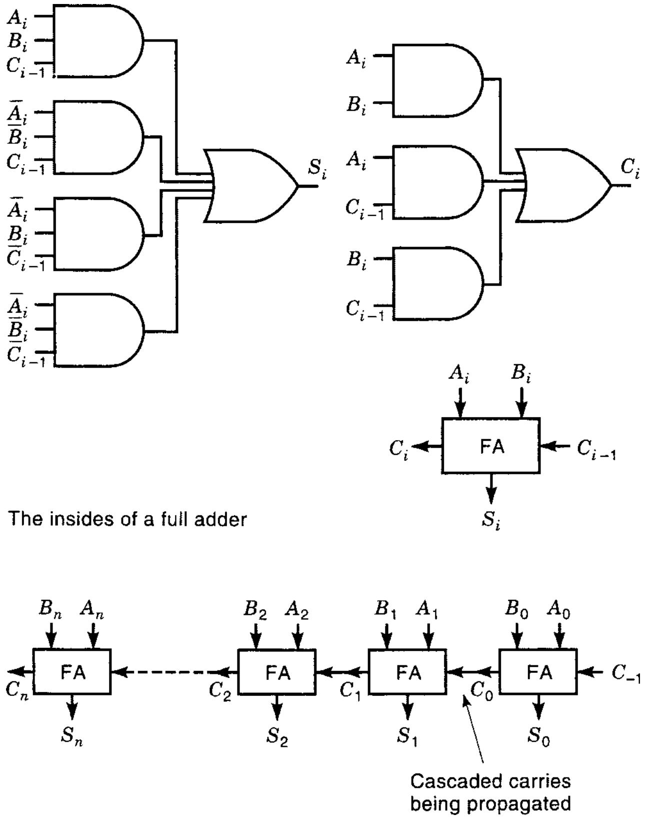

Figure 1. A Ripple Carry Adder ripples the carry from stage to stage using cascaded Full Adders.

An adder that employs static carry propagation always produces a sum after a fixed amount of time, whereas the time taken to compute the sum in a dynamic adder is dependent on the inputs. In general, it is easier to design a digital system with a static adder, as digital systems are predominantly synchronous in nature; i.e., they work in lock step based on a clock that initiates each operation and uses the results after completion of a clock cycle (4).

STATIC CARRY LOGIC

From Equation (1), if A_i and B_i are both true, then C_i is true. If A_i or B_i is true, then C_i depends on C_{i-1}. Thus, the term A_iB_i in Equation (1) is the generate term or g_i, and $A_i + B_i$ is the propagate term or p_i. Equation (1) can be rewritten as in Equation (3):

$$C_i = g_i + p_iC_{i-1} \tag{3}$$

where $g_i = A_iB_i$ and $p_i = A_i + B_i$. Substituting numbers for i in Equation (3) results in Equations (4) and (5):

$$C_1 = g_1 + p_1C_0 \tag{4}$$

$$C_2 = g_2 + p_2C_1 \tag{5}$$

Substituting the value of C_1 from Equation (4) in Equation (5) yields Equation (6):

$$C_2 = g_2 + p_2g_1 + p_2p_1C_0 \tag{6}$$

Generalizing Equation (6) to any carry bit i yields Equation (7):

$$C_i = g_i + p_ig_{i-1} + p_ip_{i-1}g_{i-2} + \cdots + p_ip_{i-1}\cdots p_1g_1 + p_ip_{i-1}p_{i-2}\cdots p_iC_0 \tag{7}$$

By implementing logic for the appropriate value of i in Equation (7), the carry for any set of input bits can be predicted.

Carry Look-Ahead Adder

An adder that uses Equation (7) to generate carries for the various bits, as soon as A and B are available, is called a carry look-ahead adder (CLA). From Equation (7), the carry calculation time for such an adder is two gate delays, and a further two gate delays are required to calculate the sum with bits A_i, B_i, and the generated carry. In general, for a large number of bits n, it is impractical to generate the carries for every bit, as the complexity of Equation (7) increases tremendously. It is commonly practice in such cases to split the addition process into groups of k-bit CLA blocks that are interconnected. A group CLA is shown in Fig. 2. The groups now provide two new output functions G^* and P^*, which are the group generate and propagate terms. Equations (8) and (9) provide examples of how these terms are generated for 4-bit blocks. Equation (10) shows the generation of C_4 using G^*_1 and P^*_1:

$$G^*_1 = g_4 + p_4g_3 + p_4p_3g_2 + p_4p_3p_2g_1 \tag{8}$$

$$P^*_1 = p_4p_3p_2p_1 \tag{9}$$

$$C_4 = G^*_1 + P^*_1C_0 \tag{10}$$

In typical implementations, a CLA computes the sum in $\log_2 n$ time and uses gates to the order of $n\log n$. Table 2 lists the gate count and delay of various CLAs. Thus, with some additional gate investment, considerable speed-up is possible using the CLA carry logic algorithm.

Based on the CLA algorithm, several methods have been devised to speed up carry propagation even further. Three such adders that employ circuit-level optimizations to achieve faster carry propagation are the Manchester Carry Adder (4), Ling Adder (5), and the Modified Ling Adder (6). However, these are specific implementations of the CLA and do not modify carry propagation algorithms.

Carry Select Adder

The discussion in the previous section shows that the hardware investment on CLA logic is severe. Another mechanism to extract parallelism in the addition process is to calculate two sums for each bit, one assuming a carry input of 0 and another assuming a carry input of 1, and choosing one sum based on the real carry generated. The idea is that the selection of one sum is faster than actually propagating carries through all bits of the adder. An adder that employs this mechanism is called a carry select adder (CSA) and is shown in Fig. 3. A CSA works on groups of k-bits, and each group works like an independent RCA. The real carry-in is always known as the LSB, and it is used as C_0. In Fig. 3, C_k is used to select one sum, like $S^1_{3k-2k+1}$ or $S^0_{3k-2k+1}$ from the next group, $gp2$. In general, the selection and the addition time per bit are approximately equal. Thus, for a group that is k bits wide, it approximately takes $2k$ units of time to compute the sums and a further two units of time to select the right sum, based on the actual carry. Thus, the total time for a valid carry to propagate from one group to another is $2(k + 1)$ time units. Thus, for an optimal implementation, the groups in the CSA should be unequal in size, with each succeeding group being 1 bit wider than the preceding group. The gate count and speed of various CSAs is listed in Table 2.

Carry Skip Logic

If an adder is split into groups, gp 0, gp 1, and so on of RCAs of equal width k, and if a carry-in of 0 is forced into each group, then the carry out from each group is its generate term. The propagate term is simple to compute and can be computed by using Equation (9). As the group generate terms and propagate terms are thus available, the real carry-in at each group could be predicted and used to calculate the sum. An adder employing this mechanism for carry propagation is called a carry skip adder (CKA) and is shown in Fig. 3. The logic gates outside of the groups in Fig. 3 implement Equation (11), which is a generalization of Equation (10) for the carry at any position i. Thus, the process of carry propagation takes place at the group level, and it is possible to skip cary propagation over groups of bits:

$$C_i = G^*_{i/k} + P^*_{i/k}C_{ki} \tag{11}$$

It takes $2k$ time units to calculate the carry from any group of size k. Carry propagation across groups takes an additional $n/k - 2$ time units, and it takes another $2k$ time units to calculate the final sum. Thus, the total time is $4k + n/k - 2$ time units. By making the inner blocks larger in size, it is possible to calculate the sum faster, as it is then possible to skip carry propagation over bigger groups. Table 2 lists the gate count and performance of various CKAs.

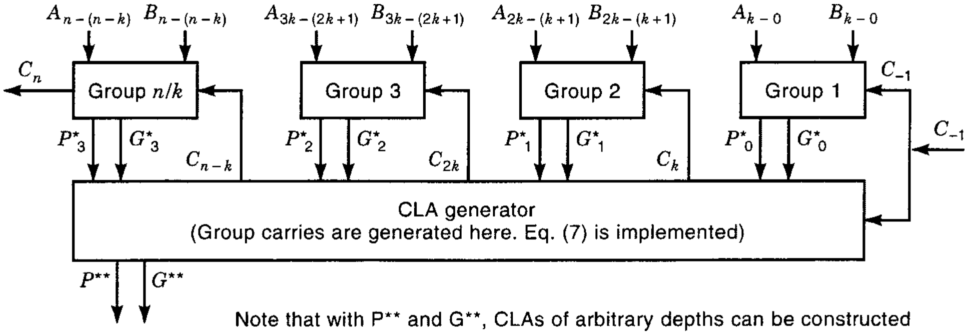

Figure 2. A group Carry Look Ahead Scheme with n/k groups each of size k.

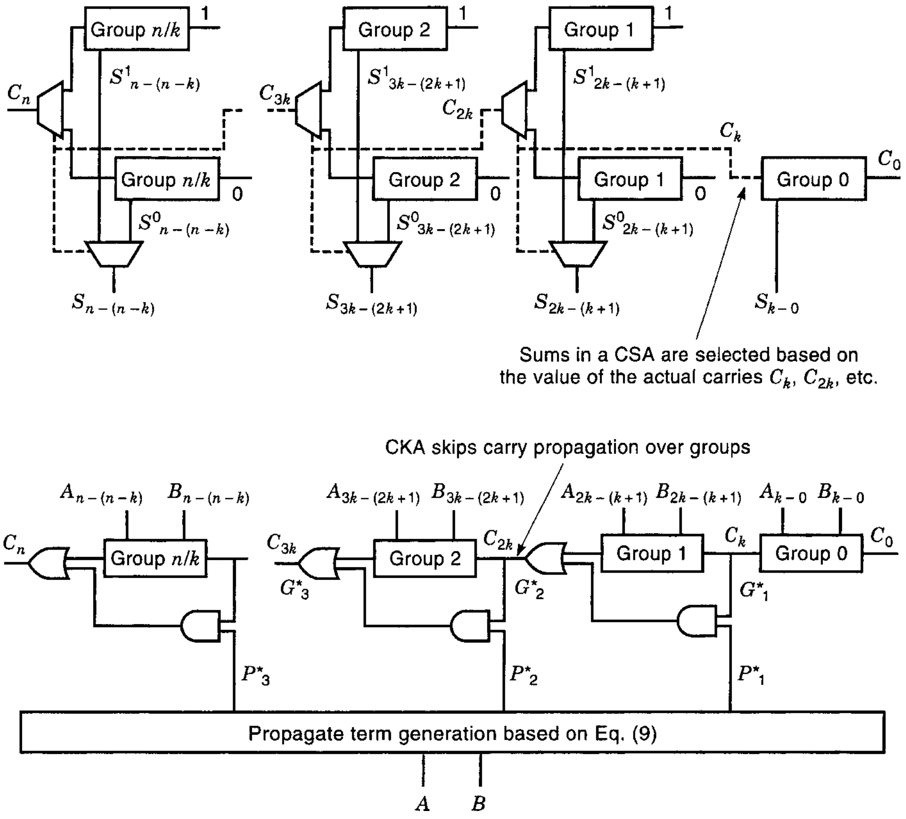

Figure 3. The CSA and CKA propagate carries over groups of k-bits.

Prefix Computation

Binary addition can be viewed as a parallel computation. By introducing an associative operator *, carry propagation and carry generation can be defined recursively. If $C_i = G_i$ in Equation (3), then Equation (12) with * as the concatenation operator holds. P_i is the propagate term, and G_i is the generate term at bit position i at the boundary of a group of size k:

$$(G_i, P_i) = (g_i, p_i) \text{ if } \\ i = 1 \text{ and } (g_i, p_i)^*(G_{i-1}, P_{i-1}) \text{ if } n \geq i > 1 \tag{12}$$

where $(g_t, p_t)^*(g_s, p_s) = (g_t + p_t g_s, p_t p_s)$ by modifying Equation (3). Note that * is NOT commutative. All C_i can be computed in parallel. As * is associative, the recursive Equation (12) can be broken in arbitrary ways. The logic to compute carries can be constructed recursively too. Figure 4 shows an example of carry computation using the prefix computation strategy described in Equation (12), with block size $k = 4$ and how a combination of two 4-bit carry-logic blocks can perform 8-bit carry computation.

The CLA, CKA, CSA, and Prefix computation have been discussed in detail by Swartzlander (7), Henessey (8), and Koren (9).

DYNAMIC CARRY LOGIC

Dynamic carry propagation mechanisms exploit the nature of the input bit patterns to speed up carry propagation and rely on the fact that the carry propagation on an average is of the order of $\log_2 n$. Due to the dynamic nature of this mechanism, valid results from addition are available at different times for different input patterns. Thus, adders that employ this technique have completion signals that flag valid results.

Carry Completion Sensing Adder

The carry-completing sensing adder (CCA) works on the principle of creating two carry vectors, C and D, the primary and secondary carry vectors, respectively. The 1s in C are the generate terms shifted once to the left and are determined by detecting 1s in a pair of A_i and B_i bits, which represent the ith position of the addend and augend, A and B, respectively. The 1s in D are generated by checking the carries triggered by the primary carry vector C, and these are the propagate terms. Figure 5 shows an example for such a carry computation process. The sum can be obtained by adding A, B, C, and D without propagating carries. A n-bit CCA has an approximate gate count of $17n - 1$ and a

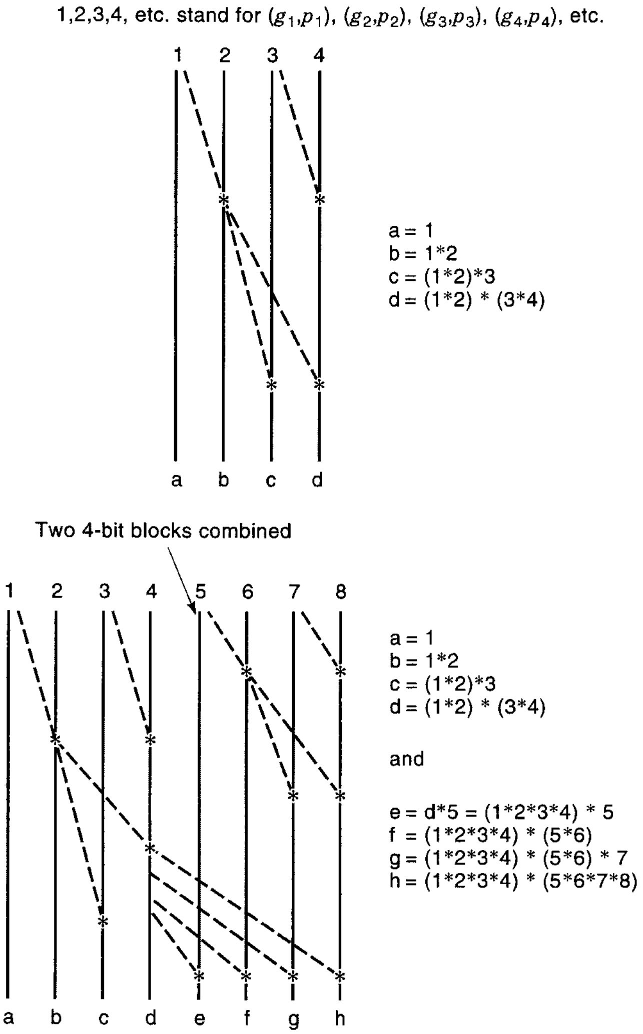

Figure 4. Performing 4-bit prefix computation and extending it to 8-bit numbers.

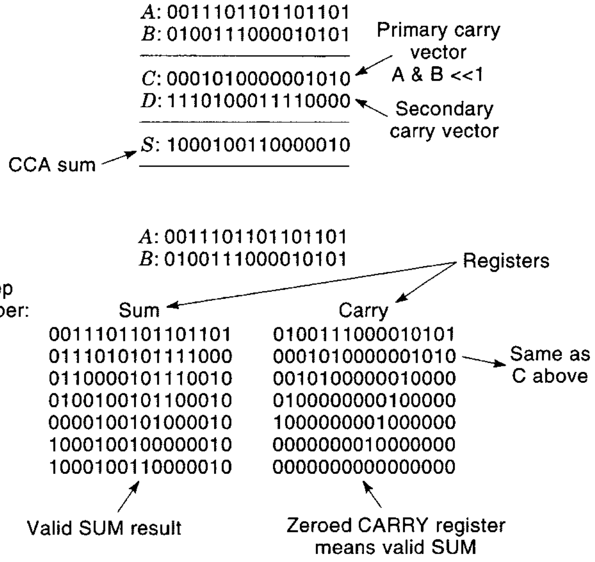
speed of $n + 4$. Hwang (10) discusses the carry-completion sensing adder in detail. Sklansky (11) provides an evaluation of several two-summand binary adders.

Carry Elimination Adder

Ignoring carry propagation, Equation (1) describes a half-adder, which can be implemented by a single XOR gate. In principle, it is possible to determine the sum of 2 n-bit numbers by performing Half Addition on the input operands at all bit positions in parallel and by iteratively adjusting the result to account for carry propagation. This mechanism is similar to the CCA. However, the difference is that the CCA uses primary and secondary carry vectors to account for carry propagation, whereas the carry elimination adder (CEA) iterates. The CEA algorithm for adding two numbers A and B is formalized by the following steps:

1. Load A and B into two n-bit storage elements called SUM and CARRY.



A: 0011101101101101
B: 0100111000010101
C: 0001010000001010
D: 1110100011110000
S: 1000100110000010

A: 0011101101101101
B: 0100111000010101

Step number:	Sum	Carry
1	0011101101101101	0100111000010101
2	0111010101111000	0001010000001010
3	0110000101110010	0010100000010000
4	0100100101100010	0100000000100000
5	0000100101000010	1000000001000000
6	1000100100000010	0000000010000000
7	1000100110000010	0000000000000000

Figure 5. The CCA and CEA use dynamic carry propagation.

2. Bit-wise XOR and AND SUM and CARRY simultaneously.
3. Route the XORed result back to SUM and left shift the ANDed result and route it back to the CARRY.
4. Repeat the operations until the CARRY register becomes zero. At this point, the result is available in SUM.

The implementation of the algorithm and detailed comparisons with other carry-propagation mechanisms have been discussed by Ramachandran (12).

Figure 5 shows an example of adding two numbers using the CEA algorithm. Note that the Primary carry vector C in the CCA is the same as the CARRY register value after the first iteration. The number of iterations that the CEA performs before converging to a sum is equal to the maximum length of the carry chain for the given inputs A and B. On average, the length of a carry chain for n-bit random patterns is $log_2 n$. The gate count of the CEA is about $8n + 22$ gates. It approaches the CLA in terms of speed and the CRA in terms of gate count.

MATHEMATICAL ESTIMATION OF THE CARRY-CHAIN LENGTH

For a given carry chain of length j, the probability of being in the *propagate* state is $k/k^2 = 1/k$. Define $P_n(j)$ as the probability of the addition of two uniformly random n-bit numbers having a maximal length carry chain of length $\geq j$:

$$P_n(j) = 0 \text{ if } n < j, \quad \text{and} \quad P_n(n) = (1/k)^n \qquad (13)$$

$P_n(j)$ can be computed using dynamic programming if all outcomes contributing to probability $P_n(j)$ are split into suitable disjoint classes of events, which include each contributing outcome exactly once. All outcomes contributing to $P_n(j)$ can be split into two disjoint classes of events:

Class 1: A maximal carry chain of length $\geq j$ does not start at the first position. The events of this class consist precisely of outcomes with initial prefixes having 0 up to $(j-1)$ propagate positions followed by one nonpropagate position and then followed with the probability that a maximal carry chain of length $\geq j$ exists in the remainder of the positions. A probability expression for this class of events is shown in Equation (14):

$$\sum_{t=0}^{j-1}\left(\frac{1}{k}\right)^{t}\cdot\frac{(k-1)}{k}\cdot P_{n-t-1}(t) \qquad (14)$$

In Equation (14), each term represents the condition that the first $(t+1)$ positions are not a part of a maximal carry chain. If a position $k < t$ in some term was instead listed as nonpropagating, it would duplicate the outcomes counted by the earlier case $t = k-1$. Thus, all outcomes with a maximal carry chain beginning after the initial carry chains of length less than$j$ are counted, and none is counted twice. None of the events contributing to $P_n(j)$ in class 1 is contained by any case of class 2 below.

Class 2: A maximal carry chain of length $\geq j$ does begin in the first position. What occurs after the end of each possible maximal carry chain beginning in the first position is of no concern. In particular, it is incorrect to rule out other maximal carry chains in the space following the initial maximal carry chain. Thus, initial carry chains of lengths j through n are considered. Carry chains of length less than n are followed immediately by a nonpropagate position. Equation (15) represents this condition:

$$\left(\frac{1}{k}\right)^{m}+\sum_{t=j}^{m-1}\left(\frac{1}{k}\right)^{t}\cdot\frac{(k-1)}{k} \qquad (15)$$

The term $P_m(m) = (1/k)^m$ handles the case of a carry chain of full length m, and the summand handles the individual cases of maximal length carry chains of length j, $j+1$, $j+2, \ldots, m-1$. Any outcome with a maximal carry chain with length $\geq j$ not belonging to class 2 belongs to 1. In summary, any outcome with a maximal carry chain of length $\geq j$, which contributes to $P_n(j)$, is included once and only once in the disjoint collections of classes 1 and 2.

Adding the probabilities for collections 1 and 2 leads to the dynamic programming solution to $P_n(j)$ provided below, where $P_n(j) = p_n(j) + p_n(j+1) + \cdots + p_n(n-1) + p_n(n)$,, where $P_n(i)$ is the probability of the occurrence of a maximal length carry chain of precisely length i. Thus, the expected value of the carry length [being the sum from $i = 1$ to n of $i^{*}P_n(i)$] becomes simply the sum of the $P_n(j)$ from$j = 1$ to n. Results of dynamic programming indicate that the average carry length in the *2*-ary number system for 8 bits is 2.511718750000; for 16 bits it is 3.425308227539; for 32 bits, 4.379535542335; for 64 bits, 5.356384595083; and for 128 bits, 8.335725789691.

APPROXIMATION ADDITION

To generate the correct final result, the calculation must consider all input bits to obtain the final carry out. However, carry chains are usually much shorter, a design that considers only the previous k inputs instead of all previous input bits for the current carry bit can approximate the result (13). Given that the delay cost of calculating the full carry chain length of N bits is proportional to log (N), if k equals to the square root of$N$, the new approximation adder will perform twice as fast as the fully correct adder. With random inputs, the probability of having a correct result considering only k previous inputs is:

$$P(N,k) = \left(1-\frac{1}{2^{k+2}}\right)^{N-k-1}$$

This is derived with the following steps. First consider why the prediction is incorrect. If we only consider k previous bits to generate the carry, the result will be wrong only if the carry propagation chain is greater than $k+1$. Moreover, the previous bit must be in the carry generate condition. This can only happen with a probability of $1/2^{k+2}$ if we consider a k-segment. Thus, the probability of being correct is one minus the probability of being wrong. Second, there are a total of $N-(k+1)$ segments in an N-bit addition. To produce the final correct result, the segment should not have an error condition. We multiply all probabilities to produce the final product. This equation could determine the risk taken by selecting the value of k. For example, assuming random input data, a 64-bit approximation adder with 8-bit look-ahead ($k = 8$) produces a correct result 95% of the time.

Figure 6 shows a sample approximation adder design with $k = 4$. The top and bottom rows are the usual carry, propagate, and generate circuits. The figure also shows the sum circuits used in other parallel adders. However, the design implements the carry chain with 29, 4-bit carry blocks and three boundary cells. These boundary cells are similar but smaller in size. A Manchester carry chain could implement 4-bit carry blocks. Thus, the critical path delay is asymptotically proportional to constant with this design, and the cost complexity approaches N. In comparison with Kogge Stone or Han Carlson adders, this design is faster and smaller.

It is worthwhile to note that an error indication circuit could be and probably should be implemented because we know exactly what causes a result to be incorrect. Whenever a carry propagation chain is longer than k bits, the result given by the approximation adder circuit will be incorrect. That is, for the ith carry bit, if the logic function - (ai-1 XOR bi-1) AND (ai-2 XOR bi-2) AND... AND (ai-k XOR bi-k) AND (ai-k-1 AND bi-k-1) is true, the prediction will be wrong. We could implement this logic function for each carry bit and perform the logical OR of all

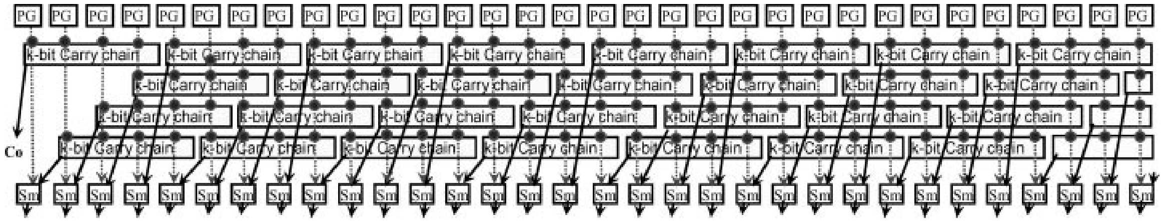


Figure 6. An example 32-bit approximation adder.

these n-4 outputs to signal us if the approximation is incorrect.

HIGH PERFORMANCE IMPLEMENTAION

The most recently reported adder implemented with the state-of-art CMOS technology is (14). The adder style used in that implementation is a variation of the prefix adder previously mentioned. Consideration was given not only to gate delay but also to fan-in, fan-out as well as to wiring delay in the design. Careful tuning was done to make sure the design is balanced, and the critical path is minimized.

CD-ROMs AND COMPUTER SYSTEMS

HISTORY OF DEVELOPMENT: CD-ROM AND DVD

To distribute massive amounts of digital audio data, at reasonable cost and high quality, industry giants, such as Philips (Amsterdam, the Netherlands) and Sony (Tokyo, Japan), developed CD-ROM optical storage technology in the early 1980s, when digital "fever" was taking over the analog stereo music industry.

The obvious attractive features of the audio CD versus the vinyl LP are the relatively low cost of production, duplication, and distribution, as well as the robustness of the media and the significantly clearer and better (a feature that is still disputed by some "artistically bent" ears) sound quality that the digital technology offers over that of the analog.

It might be interesting to note that, as with many new, revolutionary technologies, even in the United States, where society accepts technological change at a faster rate than in most other countries, it took approximately 5 years for the audio CD to take over the vinyl phonograph record industry. (Based on this experience, one wonders how long it will take to replace the current combustion automobile engine for clean electric or other type of power. . . .)

For the computer industry, the compact disc digital audio (CD-DA) became an exciting media for storing any data (i.e., not just audio), including computer-controlled interactive multimedia, one of the most interesting technological innovations of the twentieth century. The approximately $1.00 cost of duplicating 650 Mb of data and then selling it as a recorded product for approximately $200.00 (in those days) created a new revolution that became the multimedia CD-ROM as we know it today.

Although there are not just read-only, but read/write CD-ROMs too (see CD-RW below), typically a CD-ROM is an optical read-only media, capable of storing approximately 650 Mb of uncompressed digital data (as an example a Sony CD-ROM stores 656.10 Mb in 335925 blocks, uncompressed), meaning any mixcture of text, digital video, voice, images, and others.

It is important to note that, with the advancement of real-time compression and decompression methods and technologies, CD recording software packages can put on a CD-ROM over 1.3 Gb of data, instead of the usual 650 Mb.

It is expected that, with increasing computer processor speeds and better integration [see what Apple's (Cupertino, CA) backside cache can do to the overall speed of the machine], real-time compression and decompression will be an excellent solution for many applications that need more than 650 Mb on one CD. Obviously this depends on the cost of the competing DVD technology too! This solution makes the CD-ROM and the emerging even higher capacity DVD technology essential to the digitalization and computerization of photography, the animation and the video industry, and the mass archivation and document storage and retrieval business.

To illustrate the breath and the depth of the opportunities of electronic image capture, manipulation, storage, and retrieval, consider Fig. 1(a) and 1(b), a solid model animation sequence of a short battle created by Richard G. Ranky, illustrating 200 high-resolution frame-by-frame rendered complex images, integrated into an Apple QuickTime digital, interactive movie and stored on CD-ROM, and Fig. 2(a)–(d), by Mick. F. Ranky, an interactively navigatable, panable, Apple QuickTime VR virtual reality movie of Budapest by night, allowing user-controlled zoom-in/out and other hot-spot controlled interactivity. (Note that some of these images and sequences are available in full color at www.cimwareukandusa.com and that more interactive demonstrations are available in the electronic version of this encyclopedia.) Note the difference in terms of the approach and methods used between the two figures. The first set was created entirely by computer modeling and imaging, and it illustrates a totally artificial world, whereas the second was first photographed of real, physical objects and then digitized and "pasted" and integrated into an interactive QTVR (see below) movie (1–11).

CD-ROM TECHNOLOGY, MEDIUM, AND THE STORAGE DENSITY OF DATA

The most important differences between the magnetic (hard disk) versus the optical (compact disc) technology include the storage density of data as well as the way data are coded and stored. This difference is because CD-ROMs (and DVDs) use coherent light waves, or laser beams, versus magnetic fields that are spread much wider than laser beams to encode information.

The other major advantage is that the laser beam does not need to be that close to the surface of the media as is the case with the magnetic hard disk read/write heads. Magnetic read/write heads can be as close as 16 μm, or 0.0016 mm, to the surface, increasing the opportunity of the jet-fighter-shaped, literally flying read/write head to crash into the magnetic surface, in most cases, meaning catastrophic data loss to the user.

The principle of the optical technology is that binary data can be encoded by creating a pattern of black-and-white splotches, just as ON/OFF electrical signals do or as the well-known bar code appears in the supermarket. Reading patterns of light and dark requires a photo detector, which changes its resistance depending on the brightness levels it senses through a reflected laser beam.

In terms of manufacturing, i.e., printing/ duplicating the compact disc, the major breakthrough came when engineers found that, by altering the texture of a surface mechanically, its reflectivity could be changed too, which means that the dark pit does not reflect light as well as a bright mirror. Thus, the CD-ROM should be a reflective mirror that should be dotted with dark pits to encode data,

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

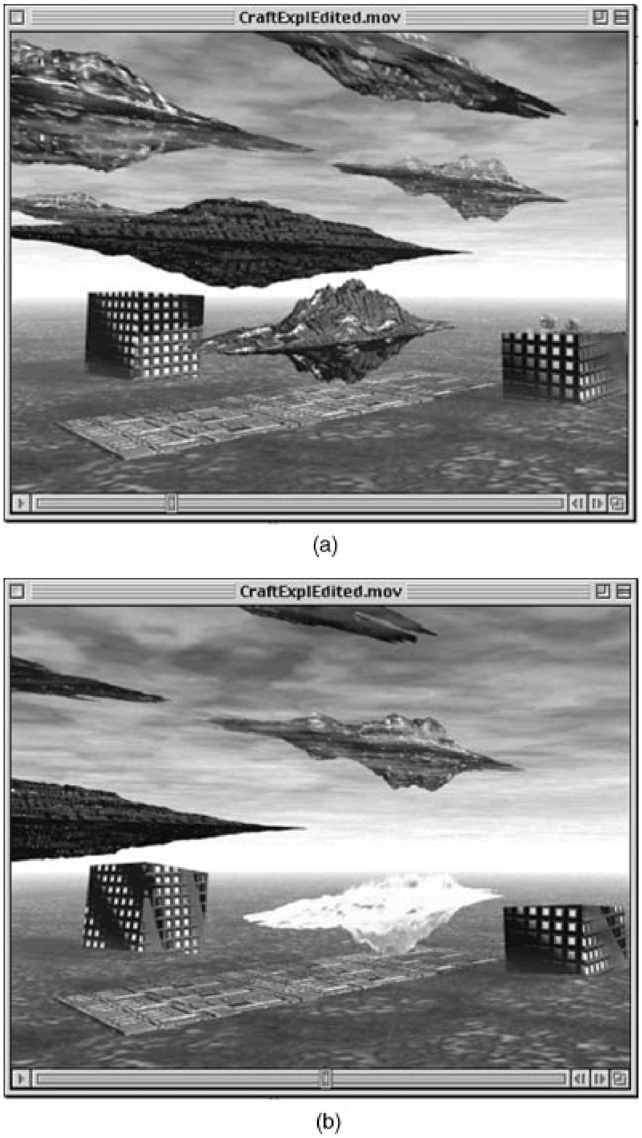

Figure 1. (a) and (b) Example of a 3-D animation scene. Solid model animation sequence of a short battle created by Richard G. Ranky, illustrating 200 high-resolution frame-by-frame rendered complex images, integrated into a QuickTime digital, interactive movie and stored on CD-ROM. (For full-color images, please look up the website: http://www.cimwareukandusa.com.)

by means of a laser beam traveling along a long spiral, just as with the vinyl audio LPs, that blasts pits accurately onto the disc.

The CD is a 80-mm-(i.e., the "minidisc") or a 120-mm-diameter (i.e., the "standard") disc, which is 1.2 mm thick and is spinning, enabling direct data access, just as with the vinyl audio LP, when the needle was dropped to any of the songs in any order. (Note that the more obvious 100 mm diameter would have been too small to provide the approximately 150-Mb-per-square-inch storage density of the optical technology of that of the 1980s, preferred by the classical music industry.) This meant solving the data access problem on a piece of coated plastic disk, in comparison with the magnetic hard disk, mechanically in a much simpler way.

To maximize the data storage capacity of the disc, the linear velocity recording of the compact disc is a constant 1.2 m per second. To achieve this rate both at the inside as well as the outside tracks of the disc, the spin varies between 400 rpm (revolutions per minute) and 200 rpm (at the outside edge). This way the same length of tracks appears to the read/write head in every second.

Furthermore, because of the access time the drive is capable of performing, it is important to note that the track pitch of the CD is 1.6 μm. This is the distance the head moves from the center toward the outside of the disc as it reads/writes data, and that the data bits are at least 0.83 μm long. (In other words, a CD-ROM and its drive are precision electro-mechanical and software instruments.)

It should be noted that, due to such small distances between the tracks, it is extremely important to properly cool CD writers as they cut master CD-ROMs in a professional studio, or inside or outside a PC or Mac on the desktop. Usually fan cooling is adequate; nevertheless, on a warm summer day, air-conditioning even in a desktop environment is advisable! Furthermore, such equipment should not be operated at all in case the inside cooling fan breaks down!

In terms of mass duplication, a master CD (often referred to as the "gold CD") is recorded first, then this master is duplicated by means of a stamping equipment—in principle, it is very similar to the vinyl audio LP production or the photocopying process. A crucial aspect of this process is that the data pits are sealed within layers of the disc and are never reached mechanically, only optically by the laser beam. Therefore, theoretically, quality mass-produced ("silver") CDs never wear out, only when abusing them harshly leaves scratches on the surface of the disc or when exposing them to extreme temperatures (12–17).

CD-ROM BLOCKS AND SECTORS

The recordable part of the compact disc consists of at least three blocks. These are as follows:

- Lead-in-block, holding the directory information, located on the innermost 4 mm of the disc's recording surface.
- Program block, holding the data or audio tracks and fills the next 33 mm of the disc.
- Lead-out-block, which marks the end of the CD at the external 1 mm.

The compact disc is divided into sectors. The actual size that is available is 2352 bytes for each sector. It should be noted that different CD formats use this 2352 bytes in different ways. As an example, an audio CD uses all 2352 bytes for audio data, whereas computer-oriented multimedia data formats need several bytes for error detection and correction.

Figure 2. (a)–(d) An interactively navigatable, 360-degree panable, QuickTime VR virtual reality movie of Budapest by night by Mick F. Ranky, allowing user-controlled zoom-in/out and other hot-spot controlled interactivity. (For full-color images, please look up the website: http://www.cimwareukandusa.com.)

Each sector is then divided further into logical blocks of 512, 1024, or 2048 bytes. These block sizes are part of the definition for each standardized compact disc format.

CD-ROM STANDARDS

As is the case with any successful technology, everyone wants to use CD-ROMs, but in their own way, depending on the applications; therefore, standardization of both the hardware as well as the software has brought at least some order to this "chaos."

Compact disc standards include the following:

- **Red Book:** This is the original compact disc application standardized by the International Standards Organization (ISO 10149) for digital audio data storage that defines digitization and sampling data rates, data transfer rates, and the pulse code modulation used.

  As prescribed by the Red Book, the ISRC-Code holds the serial number for each track in a standardized format.

  Q-Codes contain extra information about sectors such as the ISRC-Code, the Media Catalog Number, and the indices. The Media Catalog Number is a unique identification number (UPC-EAN bar code, Universal Product Code) for the compact disc.

  If required, the ISRC and Q-Codes can be set in specialized CD writing/mastering software, such as in Adaptec's Jam (see the discussion below on CD-ROM software packages).
- **Yellow Book:** Introduced in 1984, it was the first to enable multimedia and it describes the data format standards for CD-ROMs and includes CD-XA, which adds compressed audio data to other CD-ROM data. From a computing, interactive multimedia perspective, this format is the most important.

  The Yellow Book [ISO 10149: 1989(E)] divides the compact disc into two modes, as follows:

  Mode 1, for ordinary computer data.

  Mode 2, for compressed audio and digital video data.

Because Yellow Book CD-ROMs have mixed audio, video, and ordinary computer data, they are often referred to as mixed-mode CDs. (See the discussion on CD-ROM formats below.)

- **The Green Book** is the elaborate extension of the Yellow Book and is a standard for Philips" CD-i, Compact Disc Interactive. It brings together text, video, and sound on a single disc in an interleaved mode as well as extends the amount of digital, stereo audio data that can be put onto a single CD to up to 120 minutes (versus 74 minutes).
- **The Orange Book**, developed jointly by Philips and Sony, defines the hardware as well as the software aspects of the recordable CDs, often referred to as CD-R (Compact Disc Recordable—see below in more detail). Introduced in 1992, the Orange Book enabled multisession technology.

  A session is a collection of one or more tracks. Each recording procedure on a CD-R generates a session that contains all tracks recorded within the same time period, hence the terminology, "session."

  A compact disc recorded in multiple recording sessions is referred to as a multisession CD. In this case, each session has its own lead-in track and table of contents, used by the software. The number of sessions should be minimized, for efficient interactive multimedia playback as well as for saving 13 Mb overhead per session.

  Furthermore, the Orange Book defines the Program Area, which holds the actual data on the disc; a Program Memory Area, which records the track information for the entire disc; including all sessions it contains; the Lead-in Area, which holds the directory information; the Lead-out Area, which marks the end of the CD; and the Power Calibration Area, which is used to calibrate the power of the recording laser beam.
- **The Blue Book** standard was first published in 1995. It introduced stamped multisession compact discs in which the first track is a Red Book audio track. This resolved the "track one compatibility problem." (Formerly this standard was known as CD-Extra. Microsoft calls it CD-Plus.) The Blue Book standard enables compact disc authors to put interactive multimedia data into the unused capacity of music CDs.
- **The White Book** comprises the standards for video CDs. This format is based on CD-i (see the discussion above on the Green Book standard). These CD products are meant to be played on CD-i players.

PROPRIETARY CD-ROM STANDARDS

It should be mentioned that there are other proprietary compact disc standards too, most importantly the following:

- The KODAK Photo CD Sydney, Australia, readable on Macs, PCs, SIGs (computers made by Silicon Graphics Inc.,), and other machines, is a standard for storing high-quality photographic images developed by the Eastman Kodak Company (Rochester, NY).
- MMCD, a multimedia standard for handheld CD players by the Sony Corporation.

CD-ROM TRANSFER RATE

The transfer rate of a compact disc system is a direct function of the revolutions per minute (rpm) at which the disc spins in the player.

Because of the different sizes of blocks and the error correction methods used by different formats, the exact transfer rate at a given spin rate varies from one type of CD to the other.

As an example, in audio mode, the block size of 2362 bytes is transferred using a 1 × drive at 176 Kb per second, and in Mode 1, where the block size is 2048 bytes, the 1 × drive pushes through 153.6 Kb per second.

As with a CD-ROM drive, at 32 × speed, in Mode 1, where the block size is 2048 bytes, the 32 × drive pushes through $32 \times 153.6 = 4915.2$ Kb per second, a value close to a "reasonable" hard disk drive's transfer rate.

CD-ROM ACCESS TIME

In comparison with the magnetic hard disk drives, the CD-ROM's access time is significantly higher, due to the bulkiness of the optical read head, versus the elegant flyweight mechanism of the hard disk. The optical assembly, which moves on a track, carries more mass that translates to longer times for the head to settle into place.

Besides the mass of the optical head, the constant linear velocity recording system of the CD slows further the access of a desired data. With music, for which the CD was originally designed for, this is not a problem, because it is (usually) played back sequentially. As with computer data access, the CD must act as a random access storage device, when the speed (access time, plus read, or write time) becomes crucial.

The typical access time for a modern CD drive is approximately 100 to 200 ms, about ten times longer, than that of a modern magnetic hard disk's access time.

CD-ROM FORMATS

The Yellow Book standard enables multimedia, because it describes the data format standards for CD-ROM discs and includes CD-XA, which adds compressed audio data to other CD-ROM data. However, the Yellow Book does not define how to organize the data into files on the disc. Therefore, the High Sierra Format (HSF) and later the ISO9660 format was developed and standardized.

The only difference between the HFS and the ISO9660 formats is that some CD drives will read HFS CDs only (on old Macs), but the good news is that all recent drives on all platforms (i.e., MacOS, Windows/NT, Unix) should be able to read both.

Note that ISO9660 strictly maintains the 8/3 DOS naming conventions, whereas the HFS format, used on Macs from the very early days, allowed full-length Mac file names. (Long file names are beneficial in particular when a large number of multimedia objects/files has to be named and coded in a meaningful way.)

To fix this problem, for Windows 95, Microsoft (Redmond, WA) has introduced a set of extensions to ISO9660, called the Joliet CD-ROM Recording Specification. These extensions support 128-character-long filenames (not the maximum 255) with a broad character set. Unfortunately, DOS systems before Windows 95 still read according to the 8/3 file naming convention; thus, even some of the latest multimedia CDs are still forced to use the short 8/3 filenames (e.g., for a video clip: 12345678.mov, instead of a more meaningful: JaguarTestDrive_1.mov), to maintain compatibility.

CD-R (CD-RECORDABLE)

The fact that the compact disc is a sequentially recorded, but randomly playable, system (versus the magnetic disk, which is randomly recordable as well as playable) makes writing a CD-R a more complex operation than copying files over to a (magnetic) hard disk.

As CD recorders want to write data (i.e., "burn the CD-R") in a continuous stream, the data files to be recorded onto the CD must be put first into a defragmented magnetic disk folder, often referred to as "writing a virtual image" file. To assure continuous space on a hard drive, the best practice is to reformat the drive or its partition before moving any files into it. This will prevent any interruptions during CD recording (i.e., mastering) that will most likely result in an error in recording. In a normal case, the folder created on the magnetic disk will be copied over/recorded exactly "as is" onto the CD-ROM.

Furthermore, the number of sessions should be minimized too, for efficient interactive multimedia playback (in particular, in the case of several large video files) as well as for saving space (i.e., 13 Mb per session).

For the laser beam to code data onto the CD-R, the CD-R media needs an extra layer of dye. To guide the process even better, in particular in a desktop case, all CD-Rs have a formatting spiral permanently stamped into each disc.

Analyzing the cross section of a CD-R, the outside layer is a Silkscreened Label; then as we move further inside, there is a Protective Layer, and then the Reflective Gold Coating, with the photoreactive Green Layer embedded into a clear polycarbonate base.

As in the case with all CDs, the CD-R has a bottom protective layer, which gives its robustness. On the polycarbonate a thin reflective layer is plated to deflect the CD beam back so that it can be read by the compact disc drive. The dye layer, special to the CD-R, can be found between this reflective layer and the standard protective lacquer layer of the disc. It is photoreactive and therefore changes its reflectivity in response to the laser beam of the CD writer enabling data coding.

CD-RW, CD-ERASABLE, OR CD-E

Ricoh Co. Ltd. (Tokyo, Japan) pioneered the MP6200S CD-ReWritable drive in May 1996. (Note that CD-Erasable or CD-E was the original, confusing terminology.) At that time that was the only solution to a compact disk drive that could read as well as write data onto a CD! Users today enjoy a vastly expanded range of choices, both in terms of manufacturers as of well as of the variety of software bundles and interface options.

CD-RW employ phase-change laser technology to code and decode data. From a user point of view, in operation, CD-RW is similar to that of the magnetic hard disk. The drive can update the disc table of contents any time; thus, files and tracks can be added without additional session overheads. (Note that in the case of the CD-Rs, a session overhead is 13 Mb.)

Where CD-R drives in the past were limited to internal and external small computer system interface (SCSI), today's range of CD-RW/CD-R multifunction drives come with parallel and IDE connections, in addition to SCSI.

Other important aspects of CD-RWs include the following:

- In comparison with the IDE, or parallel-connected drives, SCSI drives can be considerably faster, especially when using a PCI bus-mastering card.
- Most modern PC motherboards support four IDE devices. If two hard drives and two CD-ROM drives are already installed, there is no room for additional IDE devices; thus, something has to be removed to install the CD-RW/CD-R drive.
- At the time of writing, the maximum read-speed of CD-RW drives is 6×; therefore, a faster 12 × to 32 × CD-ROM drive should be installed, in addition to the rewritable drive for fast multimedia playback.

Last, but not least, as with anything as complex as a CD-R, or CD-RW, it is strongly advisable to determine the importance of toll-free technical support, technical support hours of accessibility and availability, and the cost of software, driver, and flash BIOS upgrades.

CD-ROM CARE AND STABILITY

In general, inside the optical disc, there is a data layer on a substrate, which is read by a laser. In the case of CD-ROM, the data layer consists of a reflective layer of aluminum with "pits and plateaus" that selectively reflect and scatter the incident laser beam.

Optical discs are generally constructed from polymers and metallics. The polymers are subject to deformation and degradation. Metallic films are subject to corrosion, delamination, and cracking. Metallic alloys are subject to dealloying.

Optical discs consist of a data layer (pits, bumps, or regions of differing physical or magnetic properties) supported on a much thicker polycarbonate or glass substrate. A reflective layer is also required for CD-ROMs. The data layer/reflective layer is protected with an overcoat.

In optical media, there is a data "pit" that is responsible for reflecting/dispersing of an incident laser beam. Anything that changes the reflectivity or other optical properties for the data "bits" can result in a misread. According to the National Technology Alliance (USA), the optical clarity of the substrate is important in those systems where the laser must pass through this layer. Anything that interferes with the transmission of the beam, such as a scratch, or reduced optical clarity of the substrate, can result in a data error.

CD-ROM technology relies on the difference in reflectivity of "pits" stamped into a polycarbonate substrate and vapor coated with a reflective metallic layer, which is typically aluminum, hence the terminology for the mass-produced CDs, "silver" CDs.

According to the National Technology Alliance (USA), a common cause of CD-ROM failure is a change in the reflectivity of the aluminum coating as a result of oxidation, corrosion, or delamination. Deterioration of the protective overcoat (acrylic or nitrocellulose lacquer) can make the aluminum layer more susceptible to oxidation and corrosion. Some manufacturers use a silver reflecting layer that is subject to tarnishing by sulfur compounds in the environment and CD-ROM packaging.

CD-ROMs can also fail because of deterioration of the polycarbonate substrate. Polycarbonate is subject to crazing, which locally reduces the optical clarity of the substrate. Oils in fingerprints and organic vapors in the environment can contribute to crazing. Scratches in the substrate as a result of mishandling can also cause disk failures.

The relative effectiveness of CD-Recordable media is an issue often bandied about in industry and business circles, where the technology is used and increasingly relied on. Much controversy surrounds finding some useful way of evaluating the blank discs of various brands and types used in CD recorders today.

Several criteria go into evaluating disc usefulness: readability, compatibility with recorders and players, and expected life span. According to the National Technology Alliance (USA), results compiled in a series of tests performed by One-Off CD Shops International between early 1993 and mid-1995 on a variety of disc brands and types shed a great deal of light on the topic, even though the tests were done only to evaluate the readability of recorded discs, and not media longevity or suitability of specific brands or types for use on every system. But the methodological rigor of the narrow focus afforded yielded considerable data that bodes well for the effectiveness of current disc-evaluating mechanisms.

Not every question has been answered by any means, but one finding, according to the National Technology Alliance (USA), is clear: "worry about the quality of CD-R media seems largely unfounded" (18–21). Note that, in reality, the bigger worry is not the disk, but the entire system, in terms of computers, software, as well as CD/DVD readers and writers becoming obsolete within technology periods of approximately 3–5 years, and then after 10–15 years, one might not find a machine (i.e., a system) that can read an "old" CD-ROM or DVD-ROM, even if the data on the media is in good shape. . . .

CD-RECORDABLE VERSUS MASS-REPLICATED ("SILVER") COMPACT DISCS [AN ANALYSIS BY THE NATIONAL TECHNOLOGY ALLIANCE (USA)]

Mass-replicated (i.e., "silver") discs have their data encoded during injection molding, with pits and lands pressed directly into the substrate. The data side of the transparent disc is metalized, usually with aluminum sputtered onto the bumpy surface, which is spincoated with lacquer to protect the metal from corrosion, and then it is usually labeled in some fashion, generally with a silkscreened or offset printed design.

One source of confusion and concern about CD-R discs is their notable physical differences (i.e., “gold/green shine”) from normal (i.e., “silver” shine), pressed compact discs.

Each CD-R blank is designed to meet standards regarding function, but the way each achieves the function of storing digital information in a manner that can be read by standard CD players and drives is distinct. In terms of the top side and bottom side, replicated discs are similar to that of the CD-Rs; it is what comes between the polycarbonate substrate and the top’s lacquer coating that makes the difference.

CD-Rs are polycarbonate underneath, too, but the substrate is molded with a spiral guide groove, not with data pits and lands. This side is then coated with an organic dye, and gold or silver (instead of aluminum as in the case of mass-replicated discs) is layered on the top of the dye as the reflective surface, which in turn is lacquered and sometimes labeled just as replicated discs are.

The dye forms the data layer when the disc is recorded, having a binary information image encoded by a laser controlled from a microcomputer using a pre-mastering and recording program. Where the recording laser hits the dye, the equivalent of a molded “pit” is formed by the laser beam reacting with the photosensitive dye, causing it to become refractive rather than clear or translucent. When read by a CD player or CD-ROM drive, the affected area diffuses the reading laser’s beam, causing it to not reflect back onto the reader’s light-sensor. The alternations between the pickup laser’s reflected light and the refracted light make up the binary signal transmitted to the player’s firmware for unencoding, error detection, and correction, and further transmission to the computer’s processor or the audio player’s digital/analog converter.

According to the National Technology Alliance (USA), the feature that really distinguishes recordable media from replicated discs is the dye layer. The polymer dye formulas used by manufacturers are proprietary or licensed and are one of the distinguishing characteristics between brands.

Two types of dye formulas are in use at the time of writing, cyanine (and metal-stabilized cyanine) and phthalocyanine. One (cyanine) is green, and the other appears gold because the gold metalized reflective layer is seen through the clear dye.

TENETS OF READABILITY TESTING OF CD-ROMS AND CD-RS

At least in theory, however, these differences should have little or no impact on readability, becouse CD-R and CD-ROM media share the “Red Book” standard for CD-DA (Digital Audio). The Red Book specifies several testable measurements that collectively are supposed to determine whether a disc should be readable as an audio CD media. The Yellow Book, or multimedia CD-ROM standard, requires some additional tests.

As CD-Recordable discs, described in the Orange Book, are supposed to be functionally identical to mass-replicated “silver” CD-ROMs, it is logical to assume that the same test equipment and standards should be applied to them as to Yellow Book discs, so no new readability criteria were specified in the Orange Book. According to the National Technology Alliance (USA), several companies have built machines that are used for testing discs during and after the manufacturing process using these criteria, and only recently have new testing devices made specifically for CD-Recordable become available.

ACCELERATED TEST METHODOLOGY BY THE NATIONAL TECHNOLOGY ALLIANCE (USA)

Changes in a physical property involving chemical degradation can usually be modeled by an appropriate Arrhenius model. Error rates can be fit to an appropriate failure time distribution model. Once an appropriate model has been determined and fit to the experimental data, it can be used to estimate media properties or error rates at a future time at a given condition.

In performing accelerated tests, there is a tradeoff between the accuracy and the timeliness of the results. It is impractical to age data storage media at “use” conditions becouse it would take several years to evaluate the product, by which time it would be obsolete. To obtain results in a timely manner, “use” temperatures and humidities are typically exceeded to accelerate the rates of material decomposition.

Severe temperature/humidity aging may allow for a relatively rapid assessment of media stability, but results may not be representative of actual use conditions. Furthermore, samples treated in a laboratory environment may not be in a configuration representative of typical use conditions.

To perform accelerated testing, several media samples are placed in several different temperature/humidity/pollutant environments. The media are removed at periodic intervals, and a key property is measured.

This key property could be a physical characteristic, such as magnetic remanence, or it could be data error rates, if the materials were prerecorded. After a sufficient number of key property versus time data has been collected at each condition, the data can be fit to a predictive model (19,22–31).

ALTERNATIVE, INTERNET/INTRANET-BASED TECHNOLOGIES

With the rapid advancement of the Internet and local, typically much faster and more secure versions of it, often referred to as intranets, mass storage, document archiving, interactive multimedia distribution, and other services, mostly online, will become a reality and to some extent an alternative for data stored and distributed on CD-ROMs and DVDs.

The issue, nevertheless is always the same: online accessible data over a very fast network, under the “network’s control,” or at the desk on a CD-ROM, or DVD disc, under “the user’s/creator’s control.” No doubt there are reasons for both technologies to be viable for a long time, not forgetting the point, that even if it comes online over the fast network, at some point in the system the servers will most likely read

Table 1. Maximum Data Rates of Digital Telecommunications Standards

Standard	Connection type	Downstream rate	Upstream rate
V.34	Analog	33.6 Kbps	33.6 Kbps
SDS 56	Digital	56 Kbps	56 Kbps
ISDN	Digital	128 Kbps	128 Kbps
SDSL	Digital	1.544 Mbps	1.544 Mbps
T1	Digital	1.544 Mbps	1.544 Mbps
E1	Digital	2.048 Mbps	2.048 Mbps
ADSL	Digital	9 Mbps	640 Kbps
VDSL	Digital	52 Mbps	2 Mbps

the data from a CD-ROM or DVD jukebox, or even large-capacity magnetic hard disks.

To understand the importance of the online, networked solution and the areas in which they could, and most likely will, compete with the CD-ROM/ DVD technologies, refer to Table 1. It must be noted that these rates in Table 1 are theoretical maximum data rates, and in practice, unless a direct hired line is used, the actual transfer rates will most likely depend on the actual traffic.

Analyzing Table 1, it is obvious that 128-Kbps ISDN (Integrated Services Digital Network) lines, and upward, such as the T1 lines, representing the bandwidth of 24 voice channel telephone lines combined, provide viable online multimedia solutions. As with anything else, though, simultaneously competing, supporting, and conflicting issues such as speed, ease of use, security, privacy of data, and reliability/robustness will ensure that both the online as well as the, in this sense, offline, CD-ROM, CD-R, and DVD technologies will be used for a very long time.

CD-ROM/DVD-ROM APPLICATIONS

The CD-ROM and DVD-ROM technology is applied in several different areas, but most importantly as audio CDs (note that some rock stars have sold over 100 million CDs), for data and document archiving, for linear and nonlinear (i.e., interactive) video storage and playback, for image compression and storage, for interactive multimedia-based education, marketing, entertainment, and many other fields of interest, where mass storage of data is important.

Since besides the MPEG video standards, Apple's multiplatform as well as Internet-friendly QuickTime and QTVR digital interactive video and virtual reality software tools became the de facto interactive multimedia standards (delivered on CD-ROMs and DVDs as well as usually streamed at lower quality due to the transfer rate and bandwidth over the Internet and intranets), as examples of applications, we introduce these technologies as they are embedded into engineering educational, marketing, or game-oriented CD-ROM and DVD programs. In these examples, one should recognize the importance of accessing a large amount of data (e.g., 5–25-Mb digital, compressed video files), interactively, in a meaningful way, at the time and place the information is needed. (Furthermore, note that many of these interactive examples can be found electronically at the website: http://www.cimwareukandusa.com.)

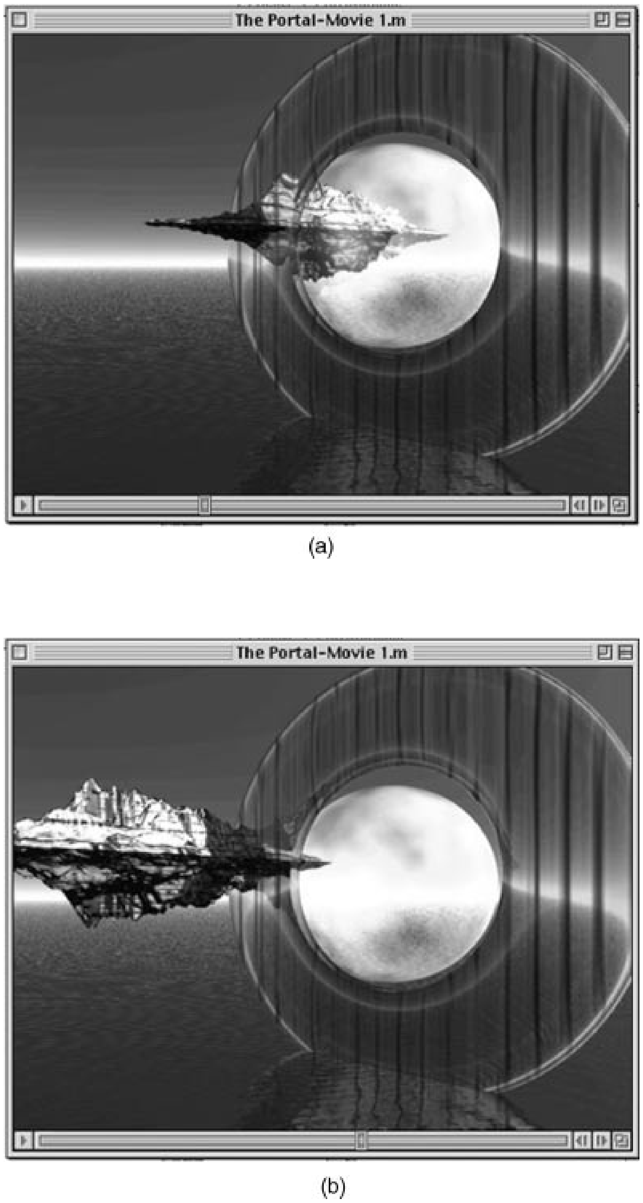

Figure 3. (a) and (b) These screenshots illustrate two frames of an animated space flight (by Gregory N. Ranky) as part of a video-game project on CD-ROM. The individual frames have been computer generated and then rendered and integrated into an interactive QT movie.

As the video-game industry is the prime source for computing and related CD-ROM R&D funding, we felt that we should demonstrate such new developments by showing Fig. 3(a) and (b). These screenshots illustrate two frames of a longer animated space flight (by Gregory N. Ranky) as part of a video-game project on CD-ROM. The individual frames have been computer generated, and then rendered and integrated into an interactive QT movie.

As Apple Computer Inc. defines, QuickTime(QT) is not an application, it is an enabling technology. QuickTime comprises of pieces of software that extend the ability of a Mac's or PC's operating system to handle dynamic media.

Applications then use this technology and turn it into other applications. As an example, many educational titles, games, and reference titles have incorporated QuickTime into their development, including Myst by Broderbund; Microsoft Encarta by Microsoft; DOOM II by Id Software; and Flexible Automation and Manufacturing, Concurrent Engineering, and Total Quality Management by CIMware and others.

QuickTime as a technology became the basis for many of the multimedia/computing industry's most respected digital media tools. QuickTime is much more than just video and sound. It is a true multimedia architecture that allows the integration of text, still graphics, video, animation, 3-D, VR, and sound into a cohesive platform. QuickTime, delivered either on CD-ROMs, DVDs, or in a somewhat less interactive mode over the Internet/intranet makes it easy to bring all of these media types together.

In February 1988, ISO has adopted the QuickTime File Format as a starting point for developing the key component of the MPEG-4 digital video specification, as the next-generation standard. This format is supported by Apple Computer Inc., IBM, Netscape Corp., Oracle Corp., Silicon Graphics Inc., and Sun Microsystems Inc.

"MPEG's decision to utilize the QuickTime file format for the MPEG-4 specification has huge benefits for users and the industry," said Ralph Rogers, Principal Analyst for Multimedia at Dataquest, San Jose, CA. "This strategy will leverage the broad adoption of QuickTime in the professional media space, speed the creation of MPEG-4 tools and content while providing a common target for industry adoption."

At a broader level, interactive multimedia, stored on CD-ROMs, DVDs, and the forthcoming fast Internet and intranets urges the development of anthropocentric systems in which humans and machines work in harmony, each playing the appropriate and affordable (i.e., the best possible) role for the purpose of creating intellectual as well as fiscal wealth. This means creating better educated engineers, managers, and workforce, at all levels, by building on existing skills, ingenuity, and expertise, using new science and technology-based methods and tools, such as interactive multimedia.

Today, and in the forthcoming decade of our information technology revolution, and eventually the Knowledge Age, engineering, science, and technology in combination can create an intellectually exciting environment that molds human creativity, enthusiasm, excitement, and the underlying curiosity and hunger to explore, create, and learn. It is obvious that economic development is not a unidimensional process that can be measured by a narrow view of conventional accounting.

Consequently there is a need to develop new creative and stimulative multimedia-based infrastructures, educational tools, as well as products and means of production that have the embedded intelligence to teach their users about "themselves" and that can meet challenges now faced by many companies and even countries as natural resources become more scarce, the environment becomes more polluted, and major demographic changes and movements of people are taking place.

The fundamental change that has to be recognized is that most existing hi-tech systems were designed with the human operator playing a passive role, and a machine being the "clever" component in the system. This is because accountant-driven management considers the workforce to be a major cost item instead of a major asset!

Anthropocentric technologies, such as flexible, interactive multimedia, make the best use of science and technology, driven by the user at his or her pace and time, enabling the learner to explore and implement concepts further than that of the accountants order-bound fiscal view.

Consequently, interactive multimedia is not war, but a new opportunity to put back humans into harmony with nature and "able" machines, by being better informed, educated, and happier contributors, rather than efficient long-term waste creators and destroyers of nature and the society (32–40).

WHAT IS INTERACTIVE MULTIMEDIA?

Interactive multimedia combines and integrates text, graphics, animation, video, and sound. It enables learners to extend and enhance their skills and knowledge working at a time, pace, and place to suit them as individuals and/or teams and should have a range of choices about the way they might be supported and assessed.

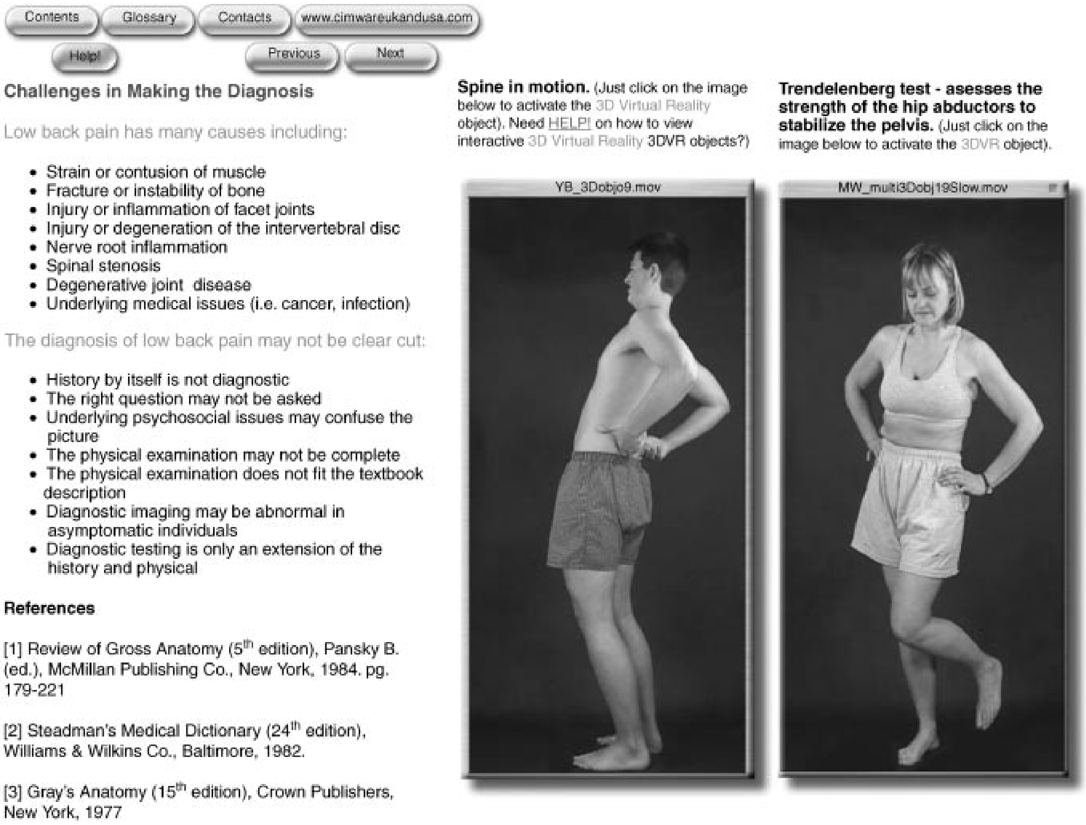
In other words:

- The user has a choice and the freedom to learn.
- He or she is supported by the multimedia-based learning materials and technology.
- The tutors are creating an effective, enjoyable learning environment and infrastructure.
- The learners are simultaneously learners as well as authors.

Figure 4 represents a screen of over 300 interactive screens of an industrial educational program on Servo Pneumatic Positioning, by Flaherty et al. (40) on CD-ROM. The 650 Mb of data includes several hundred color photos and over 45 minutes of interactive digital videos explaining the various aspects of servo pneumatic components, systems, positioning, control, programming, and applications.

Figure 5 is a screen of over 720 interactive screens of an educational multimedia program on Total Quality Control and Management and the ISO 9001 Quality Standard, by Ranky (41) on CD-ROM. The 650 Mb of data includes several hundred color photos and over 45 minutes of interactive digital videos explaining the various aspects of total quality and the international quality standard as applied to design, manufacturing, and assembly in a variety of different industries.

Note the many opportunities we have programmed into these screens to continuously motivate the learners to be responsive and be actively involved in the learning process. To maintain the continuous interactivity not just within the



Challenges in Making the Diagnosis

Low back pain has many causes including:

- Strain or contusion of muscle
- Fracture or instability of bone
- Injury or inflammation of facet joints
- Injury or degeneration of the intervertebral disc
- Nerve root inflammation
- Spinal stenosis
- Degenerative joint disease
- Underlying medical issues (i.e. cancer, infection)

The diagnosis of low back pain may not be clear cut:

- History by itself is not diagnostic
- The right question may not be asked
- Underlying psychosocial issues may confuse the picture
- The physical examination may not be complete
- The physical examination does not fit the textbook description
- Diagnostic imaging may be abnormal in asymptomatic individuals
- Diagnostic testing is only an extension of the history and physical

WHAT IS QUICKTIME VR?

As Apple describes, virtual reality describes a range of experiences that enables a person to interact with and explore a spatial environment through a computer. These environments are typically artistic renderings of simple or complex computer models. Until recently, most VR applications required specialized hardware or accessories, such as high-end graphics workstations, stereo displays, or 3-D goggles or gloves. QuickTime VR now does this in software, with real photographic images, versus rendered artificial models.

Apple's QuickTime VR is now an integral part of QuickTime; it allows Macintosh and Windows users to experience these kinds of spatial interactions using only a personal computer. Furthermore, through an innovative use of 360 panoramic photography, QuickTime VR enables these interactions using real-world representations as well as computer simulations.

To illustrate the power of this technology, when applied to interactive knowledge propagation on CD-ROMs, DVD-ROMs, and to some extent on the Internet, refer to Fig. 6(a)–(c), illustrating a few frames of an interactively controllable (Chevy) automobile image, including opening and closing its doors, under user control; Fig. 7(a)–(d), showing a few frames of an interactively navigatable interior of a Mercedes automobile; and Fig. 8(a)–(b), showing a traditional job-shop, again with all those great opportunities of interactive navigation, zoom/in and out, and hotspot controlled exploration of these hyperlinked images.

As can be recognized, the opportunities for interactivity, for learning by exploring under user (versus teacher control) is wasted, not just in education, but also in marketing and general culture, in terms of showing and illustrating

SMART DART: A SMART DIAGNOSTIC AND REPAIR TOOL IMPLEMENTED IN A VOICE I/O CONTROLLED, INTERACTIVE MULTIMEDIA, MOBILE -WEARABLE COMPUTER-BASED DEVICE FOR THE AUTOMOBILE (AND OTHER) INDUSTRIES

Smart DART is a novel, computer-based prototype mentoring system originally developed at the New Jersey Institute of Technology (NJIT) with industry-partners in 1998 with serious industrial applications in mind, implemented in a voice I/O controlled, interactive multimedia, mobile-wearable device for use by the automobile (and other) industries (see Fig. 9). The Co-Principal Investigators of this R&D project at NJIT were Professor Paul G. Ranky and Professor S. Tricamo and project partners in an R&D Consortium included General Motors, Raytheon, the U.S. National Guard, and Interactive Solutions, Inc.

The system consists of the following components:

- Integrated to the computer diagnostic port of the automobile, or offline, interacting with the technician, *can diagnose* a variety of problems and can communicate the results at the appropriate level, format, and mode, using various multimedia tools and solutions.
- *Can self-tune*, in terms of adjusting to the actual user needs and levels in an "intelligent way."
- Has a *highly interactive* and user-friendly multimedia interface.

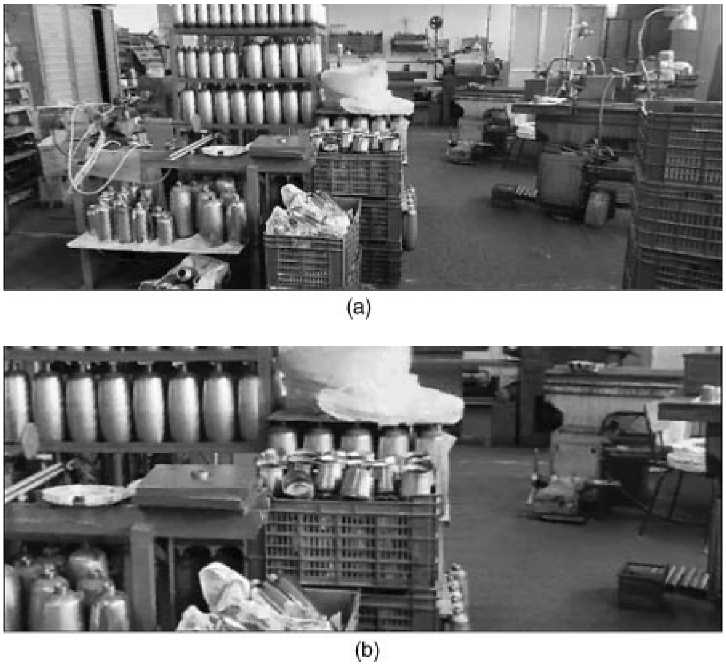

Figure 8. (a) and (b) The figure shows a traditional job-shop, again with all those great opportunities of interactive 3-D navigation, zoom/in and out, and hot-spot controlled exploration of these hyperlinked images in QTVR on CD-ROM. (For full-color images, please look up the website: http://www.cimwareukandusa.com.)

- *Can update itself* (based on either the learned knowledge and/or by means of networked or plugged-in technical fact data).
- Is a *highly parallel, distributed, and networked device*.
- Has command-based *voice recognition*.
- Has a *"hands-free" user interface*.
- Can work in *hazardous environments*.
- *Can automatically generate diagnostic and maintenance reports* and can communicate these reports via its networked communications system to any receiving site or compatible computer.
- To help to improve the next generation of products, the automated mentoring system can feed data as well as learned knowledge in a format and language that is appropriate and understandable to the design, manufacturing, quality control, and so on engineering community and their computer support and design systems (CAD/CAM).
- Smart DART *can diagnose itself* and report its own problems (and possible solutions) as they occur; therefore, it can help to improve the maintenance process as well as the design and the overall quality of the automobile (or other complex product it is trained for).

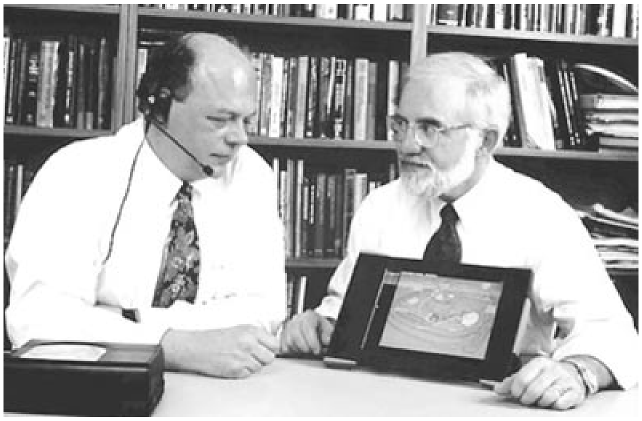

Figure 9. Smart DART is a novel, computer-based prototype mentoring system, originally developed in 1998, with serious industrial applications in mind, implemented in a voice I/O controlled, interactive multimedia, mobile-wearable device for use by the automobile (and other) industries. The R&D Consortium included NJIT, General Motors, Raytheon, the U.S. National Guard, and Interactive Solutions, Inc. (For full color-images, please look up the website: http://www.cimwareukandusa.com.)

About the System Architecture

To achieve the above listed and other functions, Smart DART is implemented as a small, ruggedized, networked mobile-wearable, or desktop networked computer-based device, which runs on a set of core processes, such as:

- The Process Manager.
- The Information Manager.
- The Interface Manager.
- The Team Coordinator.

Smart DART has a set of core modules linked to a fast knowledge-bus, through which various smart cards, or modules, it can execute various processes. These smart cards have embedded various domain expertise and have been integrated following the object-linking methodology.

Smart Dart has an open systems architecture, meaning that as the need arises new smart cards can be developed and plugged-in, in a way enhancing its "field expertise." Due to the well-integrated, object-linked design architecture, these new modules, or smart cards, will automatically integrate with the rest of the system, as well as follow the standard multimedia user-interface design, cutting the learning curve of using a new smart card to minimum.

The Typical Application Scope of Smart DART

To explain the application scope of our system, let us list some broad application areas, with that of the view of the maintenance technician, or engineer, whose job is to diagnose or fix a problem. In general, Smart DART will answer the following questions and resolve the following problems:

- *How does the particular system under test work?* This is explained using highly interactive, multimedia tools and interfaces to a newcomer, or to anybody that wishes to learn about the particular system. Note that a "system" in this sense can be an automobile, a tank, or some other machine, such as a VCR or a medical instrument.
- *What are the subsystems*, *how do they work*, and how do they *interact?*

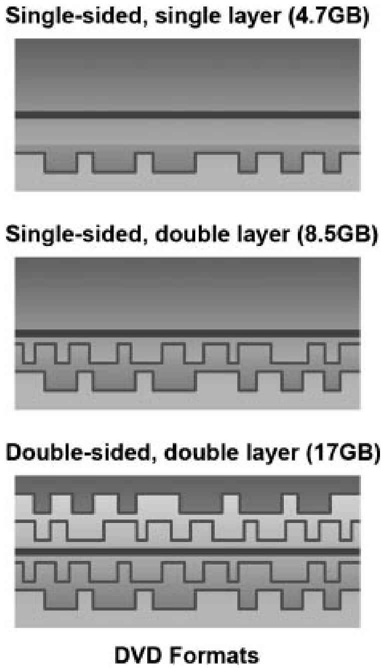
Furthermore, Smart DART can

- *Diagnose the problem*.
- *Offer Go/No-go reporting*.
- *Provide end-to-end versus fault isolation*.
- *Rehearse the repair/fix scenarios and procedures* by means of highly interactive, and if required by the user, individualized interactive multimedia tools and techniques.
- Be used as an *"expert" tutor*, supporting learners at various levels, following different educational scenarios and techniques, best suited to the variety of different users (i.e., maintenance technicians, design, manufacturing and quality engineers, students, managers, and others).

DVD-ROM (DIGITAL VERSATILITY DISC)

The DVD-ROM, or DVD technology, was created by merging two competing proposals, one by the CD-ROM inventors Philips and Sony and the other one by Toshiba (Tokyo, Japan). The purpose of the DVD is to create up-front a universal, digital storage and playback system, not just for audio, but for video, multimedia, archiving, and general digital mass data storage.

DVDs are capable of storing significantly more data than CD-ROMs and come in different sizes and standards.



Single-sided, single layer (4.7GB)
Single-sided, double layer (8.5GB)
Double-sided, double layer (17GB)
DVD Formats

Figure 10. Examples of the structure and storage capacity of different DVD formats; single-sided single and double layer, and double-sided, double layer.

DVD is short for digital video (or versatility) disc and is the successor of the CD or compact disc. Because of its greater storage capacity (approximately seven times that of a CD), a DVD can hold 8 hours of music or 133 minutes of high-resolution video per side. This storage capacity varies depending on whether single-or double-layer discs are used and can range between 4.7 Gb and 8.5 Gb for single-sided discs or 17 Gb for double-sided dual-layer discs (see Fig. 10). The capacity does not directly double when a second layer is added because the pits on each layer are made longer to avoid interference. Otherwise they have the same dimensions as a CD, 12 cm in diameter and 1.2 mm in thickness.

The DVD medium resembles that of the CD-ROM technology. Even the size is the same, 120 mm diameter and 1.2 mm thick.

A DVD or CD is created by injection molding several layers of plastic into a circular shape, which creates a continuous stream of bumps arranged in a spiral pattern around the disc. Next, a layer of reflective material, aluminum for the inner layers, gold for the outermost, is spread to cover the indents. Finally, each layer is covered with lacquer and then compressed and cured under infrared light. Because of its composition, it is far more resistant to water absorption than its predecessor, the laser disc, and do not suffer from "laser rot." Each of these layers could act as fully functional disks on both sides. Individual layers are distinguished (i.e., addressed) by the system by focusing the laser beam. The result is a sandwich that has two layers per side, or in other words four different recording surfaces, hence, the significant data capacity increase.

Because the spiral data track begins in the center of the disc, a single-layer DVD can actually be smaller than 12 cm.

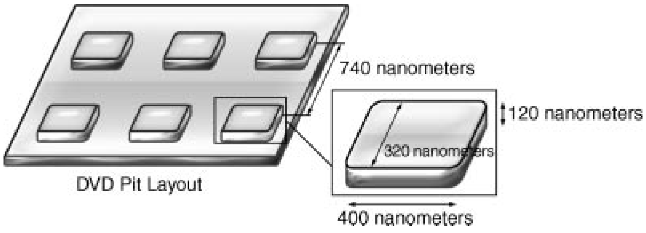


Figure 11. An illustration of the dimensions and spacing of the pits in successive tracks on a DVD.

This is the case for the UMD discs used by the Sony PSP Handheld Console. Each successive spiral is separated by 740 nm (10^{-9}m) of space (see Figs. 11 and 12), with each bump 120 nm in height, 400 nm long, and 320 nm wide; if unrolled, the entire line would be nearly 12 km (12000 m!) long.

These are usually called pits due to their appearance on the aluminum coating, although they are bumps when read by a laser. Because data are stored gradually outward, the speed of the drive is usually 50–70% of the maximum speed. By comparison, the spiral tracks of a CD are separated by 1.6 μm (10^{-6}m), with each bump 100 nm deep, 500 nm wide, and up to 850 nm long. This, combined with a 780 nm wavelength red laser, allows for much less data capacity than a DVD, approximately 700 Mb.

The data are actually stored directly under the label and are read from beneath by the laser. Therefore, if the top surface is scratched, the data can be damaged. If the underside is scratched or smudged, the data will remain, but the laser will have difficulty reading through the distortion.

VIDEO FORMATS

The usual form of data compression for (standard definition or SD) digital video is MPEG-2; the acronym comes from the Moving Picture Experts Group, which establishes video standards. The usual rate is 24 frames per second for video footage, but the display frame depends on the television format. The NTSC format displays footage in 60 fields, whereas PAL displays 50 fields but at a higher resolution. These differences in resolution also entail Pal or NTSC formatting for DVDs. Audio is usually in Dolby Digital formats, although NTSC discs may use PCM as well. Region codes also exist depending on the geographic location, from 1 to 8, with 0 used for universal playability.

Data tracks on a DVD

Figure 12. A simplified illustration of the spiraling layout of the DVD pits.

There are several types of recordable DVD discs; of these, DVD-R for Authoring, DVD-R for General use, DVD + R, and DVD-R are used to record data once like CD-R. The remaining three, DVD + RW, DVD-RW, and DVD-RAM, can all be rewritten multiple times.

As an example, DVD-5 with one side and one layer offers 4.7-Gb storage capacity and 133 minutes of playing time. DVD-9 can store 8.5 Gb on two layers, DVD-10 can store 9.4 Gb, and DVD-18 can store a massive 17.5 Gb and 480 minutes of equivalent playing time. These DVDs will be most likely used in interactive multimedia and digital video applications.

As optical technology has improved significantly since the 1980s when the CD-ROM was created, DVDs (standardized in December 1995) employ more closely spaced tracks and a better focused and high wavelength laser beam (635 to 650 nm, medium red).

The DVD constant linear velocity is 3.49 m per second, and the disc spins between 600 rpm and 1200 rpm, at the inner edge, much faster than the conventional CD-ROM.

DVD raw data transfer rates are high too, 11.08 Mb per second raw and approximately 9.8 Mb per second actual, approximately 7× or 8× in CD-ROM terms, enabling full motion, full-screen video playback.

Besides the computing industry's need to store massive amounts of data, the real commercial driver behind the DVD technology is the mereging, new high-definition (or HD) video industry, because DVDs could replace the old-fashioned, slow, linear, and relatively poor-quality VHS and S-VHS videotape technology.

For videos, DVD uses MPEG-2 encoding that allows a relatively high-quality display with 480 lines of 720 pixels (SD DVD quality), each to fit into a 4-Mb/s datastream. (Note that with MPEG, the actual data rate depends on the complexity of the image, analyzed frame-by-frame at compression stage. Also note that HD DVD video offers 1920 × 1080 or better resolution, meaning approximately 2 megapixels per frame, which is very good quality for most home and even professional users.)

DVD-Audio is excellent too, allowing a 44.1-KHz sampling rate and supporting 24-bit audio as well as several compressed multichannel formats, allowing switchable, multiple-language full-length videos to be stored and played back with additional audio and interactive features.

BLU-RAY

Blu-ray discs are named for the laser wavelength of 405 nm used to encode their data. Their sponsors include Apple Computer Corp., Dell, HP, Panasonic, Walt Disney, and Sun Microsystems.

As DVDs use a longer wavelength red laser, Blu-ray discs have a higher storage capacity. By using a shorter wavelength, as well as using higher quality lenses and a higher numerical aperture, the laser beam can be more tightly focused and therefore used to store more data.

A standard 12-cm Blu-ray disc has a single-layer storage capacity of 23.3, 25, or 27 Gb, equal to approximately 4 hours of high-definition video. They have a dual-layer capacity of 46.6 to 54 GB. Blu-ray discs were initially more vulnerable due to their data being closer to the surface, but with the introduction of a clear polymer coating, they can be cleaned with a tissue or supposedly resist damage by a screwdriver. This makes them more durable than current DVDs, with even fingerprints removable.

Blu-ray DVDs require a much lower rotation speed than HD DVDs to reach a 36 Mbps transfer rate. This results in a 12× BD for a Blu-ray disc but only 9× BD for an HD disc, as the current upper limit for optical drives is 10 rpm.

Unlike the eight DVD region codes, Blu-ray discs have three; region 1 covers the Americas, Japan, and East Asia excluding China; region 2 is for Europe and Africa; and region 3 is for China, Russia, India, and all other countries.

The Blu-ray Disc Association has also added digital watermarking to prevent unofficial distribution, or through HDTVs without an HDCP-enabled interface. Possible codecs used by Blu-ray discs include MPEG-2, H.264, and VC-1 for video and PCM and Dolby Digital for audio.

HD DVD

HD DVD discs, like Blu-ray, use a blue-violet 405-nm laser to encode data. Their promoters include Sanyo, Toshiba, Intel, Microsoft, Paramount Pictures, and Warner Bros.

HD DVDs have storage capacities of 15 Gb and 30 Gb for single-and dual-layer discs, respectively. This allows for approximately 8 hours of high-definition video storage for the 30-Gb model. Unlike Blu-ray, HD DVDs are backward compatible with DVDs, requiring no change in DVD players for the new format. HD DVD discs have a thicker protective coating (0.6 mm compared with 0.1 mm for Blu-ray), which allows greater resistance to damage, but also lower storage capacity, as the laser has more covering to penetrate.

Because HD DVDs use similar manufacturing processes to current DVDs, it is less expensive than having to change facilities to newer systems. A new system by Memory Tech can be adapted to create HD DVDs in 5 minutes. These converted lines will also be able to produce higher quality conventional DVDs, because HD-DVDs require a higher level of manufacturing precision.

CD-ROM/DVD DRIVE MANUFACTURERS AND CURRENT DRIVES

Although companies manufacturing CD-ROM and DVD hardware and software change, this list could be used as a reliable source for searching information and products.

ACKNOWLEDGMENTS

We hereby would like to express our thanks to NSF (USA), NJIT (in particular co-PIs in major research grants, Professors Steven Tricamo, Don Sebastian, and Richard Hatch, and the students), Professor T. Pato at ISBE, Switzerland (co-PI in our European research grants), the students, and faculty who have helped us a lot with their comments in the United Kingdom, the United States, Switzerland, Sweden, Germany, Hungary, Austria, Hong Kong, China, and Japan. We also thank DARPA in the United States, The U.S. Department of Commerce, The National Council for Educational Technology (NCET, United Kingdom), The University of East London, the Enterprise Project team, the Ford Motor Company, General Motors, Hitachi Seiki (United Kingdom) Ltd, FESTO (United Kingdom and United States), Denford Machine Tools, Rolls-Royce Motor Cars, HP (United Kingdom) Ltd., Siemens Plessey, Marconi Instruments, and Apple Computers Inc. for their continuous support in our research, industrial, and educational multimedia (and other) projects. Furthermore, we would like to express our thanks to our families for their unconditional support and encouragement, including our sons, Gregory, Mick Jr. and Richard, for being our first test engineers and for their valuable contributions to our interactive multimedia projects.

COMMUNICATION PROCESSORS FOR WIRELESS SYSTEMS

INTRODUCTION

In this article, we define the term *communication processor* as a device in a wired or wireless communication system that carries out operations on data in terms of either modifying the data, processing the data, or transporting the data to other parts of the system. A communication processor has certain optimizations built inside its hardware and/or software that enables it to perform its task in an efficient manner. Depending on the application, communication processors may also have additional constraints on area, real-time processing, and power, while providing the software flexibility close to general purpose microprocessors or microcontrollers. Although general purpose microprocessors and microcontrollers are designed to support high processing requirements or low power, the need to process data in real-time is an important distinction for communication processors.

The processing in a communication system is performed in multiple layers, according to the open systems interconnection (OSI) model. (For details on the OSI model, please see Ref. 1). When the communication is via a network of intermediate systems, only the lower three layers of the OSI protocols are used in the intermediate systems. In this chapter, we will focus on these lower, three layers of the OSI model, shown in Fig. 1.

The bottom-most layer is called the physical layer (or layer 1 in the OSI model). This layer serializes the data to be transferred into bits and sends it across a communication circuit to the destination. The form of communication can be wired using a cable or can be wireless using a radio device. In a wireless system, the physical layer is composed of two parts: the radio frequency layer (RF) and the baseband frequency layer. Both layers describe the frequency at which the communication circuits are working to process the transmitted wireless data. The RF layer processes signals at the analog level, whereas the baseband operations are mostly performed after the signal has been downconverted from the radio frequency to the baseband frequency and converted to a digital form for processing using a analog-to-digital converter. All signal processing needed to capture the transmitted signal and error correction is performed in this layer.

Above the physical layer is the data link layer, which is known more commonly as the medium access control (MAC) layer. The MAC layer is one of the two sub-layers in the data link layer of the OSI model. The MAC layer manages and maintains communication between multiple communication devices by coordinating access to a shared medium and by using protocols that enhance communication over that medium.

The third layer in the OSI model is the network layer. The network layer knows the address of the neighboring nodes in the network, packages output with the correct network address information, selects routes and quality of service (QOS), and recognizes and forwards to the transport layer incoming messages for local host domain.

Communication processors primarily have optimizations for the lower three layers of the OSI model. Depending on which layer has the most optimizations, communication processors are classified further into physical layer space (or baseband) processors, medium access control processors, or network processors.

The desire to support higher data rates in wireless communication systems implies meeting cost, area, power, and real-time processing requirements in communication processors. These constraints have the greatest impact on the physical layer design of the communication processor. Hence, although we mention the processing requirements of multiple layers, we focus this article on challenges in designing the physical layer of communication processors.

Evolution of Wireless Communication Systems

Over the past several years, communication systems have evolved from low data-rate systems for voice and data (with data rates of several Kbps, such as dial-up modems, cellular systems, and 802.11b local area networks) to high data-rate systems that support multimedia and video applications with data rates of several Mbps and going toward Gbps, such as DSL, cable modems, 802.11n local area networks (LANs), and ultra-wideband personal area networks (PANs) (2). The first generation systems (1G) came in the 1980s mostly for cellular analog voice using AMPS (advanced mobile phone service). This standard evolved into the second generation standard (2G) in the 1990s to support digital voice and low bit rate data services. An example of such a cellular system is IS-54 (2). At the same time, wireless local area networks began service starting at 1 Mbps for 802.11b standards and extending to 11 Mbps close to the year 2000. In the current generation of the standards (3G), cellular services have progressed to higher data rates in terms of hundreds of Kbps to support voice, data, and multimedia, and wireless LANs have evolved to 802.11a and 802.11g to, support data rates around 100 Mbps. In the future, for the fourth generation systems (4G), the data rates are expected to continue to increase and will provide IP-based services along with QoS (3). Table 1 presents the evolution of wireless communication systems as they have evolved from 1G to 4G systems. A range of data rates is shown in the table to account for both cellular and W-LAN data rates in communication systems.

CHALLENGES FOR COMMUNICATION PROCESSORS

This evolution of communication systems has involved radical changes in processor designs for these systems for multiple reasons. First, the increase in data rates has come at the cost of increased complexity in the system design.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

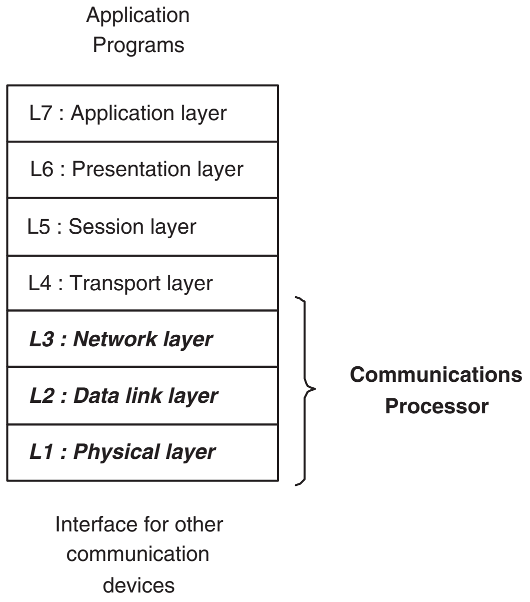

Figure 1. Layers in a OSI model. The communication processors defined in this chapter are processors that have specific optimizations for the lower three layers.

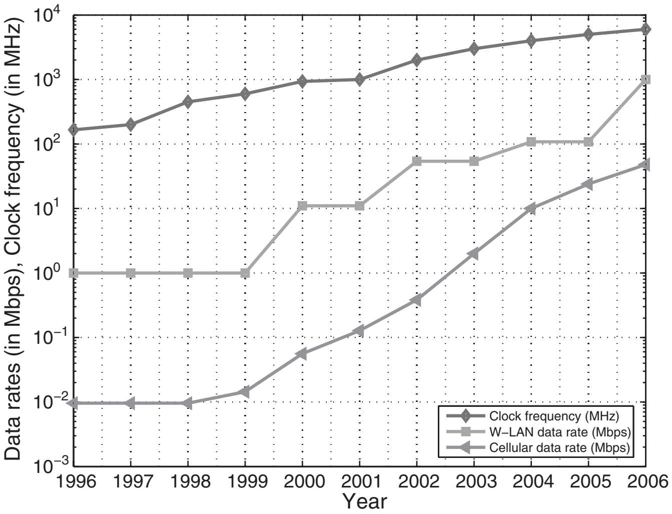

Figure 2. Increase in data rates for communication systems. The data rates in communication systems are increasing at a much greater rate than typical processor clock frequencies, necessitating new processor designs for communication system.

Second, the performance of communication systems have been increasing consistently as communication system designers develop sophisticated signal processing algorithms that enhance the performance of the system at the expense of increased computational complexity. Flexibility is also an important emerging characteristic in communication processors because of the need to support multiple protocols and environments. Also, newer applications have become more complex and they need to be backward-compatible with existing systems. As the number of standards and protocols increase, the demand increases for new standards to be spectrum-efficient, to avoid interference to other systems, and also to mitigate interference from other systems. The flexibility needed in the baseband and radio and regulatory requirements of spectrum and transmit power also add challenges in testing the design of these processors. The interaction and integration between different layers of the communication system also presents interesting challenges. The physical layer is signal processing-based, involving complex, mathematical computations, whereas the MAC layer is data processing-based, involving data movement, scheduling, and control of the physical layer. Finally, the range of consumer applications for communication systems has increased from small low-cost devices, such as RFID tags, to cellular phones, PDAs, laptops, personal computers, and high-end network servers. Processors for different applications have different optimizatio constraints such as the workload characteristics, cost, power, area, and data rate and require significant trade-off analysis. The above changes puts additional constraints on the processor design for communication systems.

Increasing Data Rates

Figure 2 shows the increase in data rates provided by communication systems over time. The figure shows that over the past decade, communication systems have had a 1000× increase in data rate requirements. Systems such as wireless LANs and PANs have evolved from 1 Mbps systems such as 802.11a and Bluetooth to 100 + Mbps 802.11b LANs to now Gbps systems being proposed for ultra-wideband personal area networks. The same has been true even for wired communication systems, going from 10 Mbps ethernet cards to now Gbps ethernet systems. The increase in processor clock frequencies across generations cannot keep up with the increase in raw data rate requirements. During the same period, the processor clock frequencies have only gone up by one order of magnitude. Also, applications (such as multimedia) are demanding more compute resources and more memory than previous processors. This demand implies that silicon process technology advances are insufficient to meet the increase in raw data rate requirements and additional architecture innovations such as exploiting parallelism, pipelining, and algorithm complexity reduction are needed to meet the data rate requirements. We discuss this in more detail in the section on area, time, and power tradeoffs.

Table 1. Evolution of communication systems

Generation	Year	Function	Data rates
1G	1980–1990	Analog voice	Kbps
2G	1990–2000	Voice + low-rate data	10 Kbps–10 Mbps
3G	2000–2010	Voice + data + multimedia	100 Kbps–100 Mbps
4G	2010–2020	Voice + data + multimedia + QoS + IP	10 Mbps–Gbps

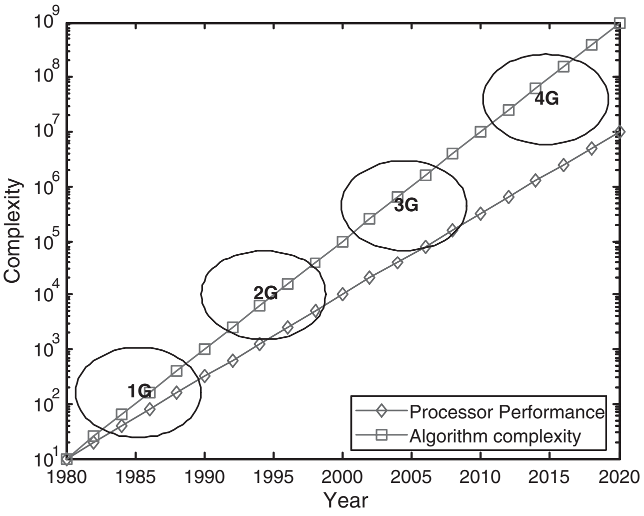

Figure 3. Algorithm complexity increasing faster than silicon process technology advances. (Reprinted with permission from Ref. 4.)

Increasing Algorithm Complexity

Although the data rate requirements of communication processors are increasing, the processor design difficulty is exacerbated by the introduction of more sophisticated algorithms that give significant performance improvements for communication systems. Figure 3 shows the increase in computational complexity as standards have progressed from first generation to second and third generations (4). The figure shows that even if the data rates are assumed constant, the increase in algorithmic complexity cannot be met solely with advances in silicon process technology.

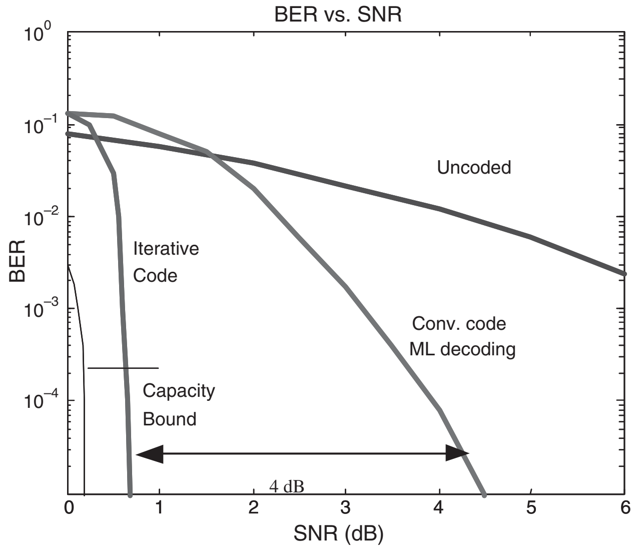

Figure 4. Decoder performance with advanced coding schemes. (Reprinted with permission from Ref. 7.)

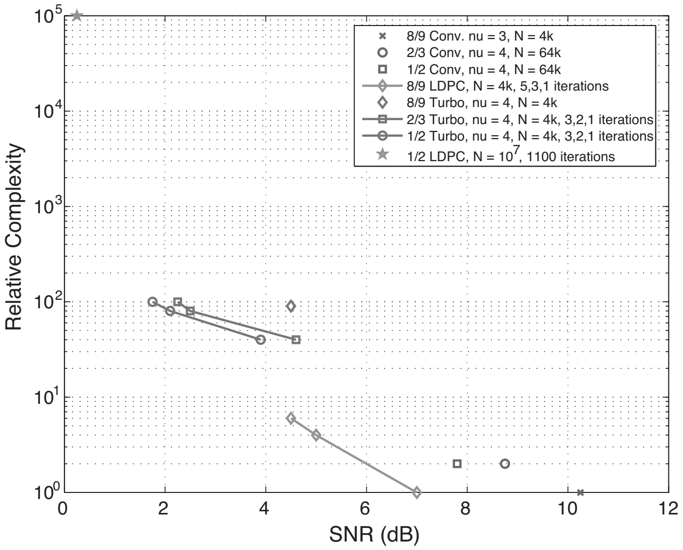

Figure 5. Decoder complexity for various types of coding schemes. (Reprinted with permission from Ref. 7.)

As an example, we consider decoding of error-control codes at the receiver of a communication processor. Figure 4 shows the benefits of coding in a communication system by reducing the bit error rate at a given signal-to-noise ratio. We can see that advanced coding schemes such as low density parity check codes (LDPC) (5) and turbo codes (6) which are iterative decoders that can give 4-dB benefits over conventional convolutional decoders. A 4-dB gain translates into roughly a 60% improvement in communication range of a wireless system. Such advanced coding schemes are proposed and implemented in standards such as HSDPA, VDSL, gigabit ethernet, digital video broadcast, and Wi-Fi. However, this improvement comes at a significant increase in computational complexity. Figure 5 shows the increased complexity of some advanced coding schemes (7). It can be observed that the iterative decoders have 3–5 orders of magnitude increase in computational complexity over convolutional decoders. Thus, to order to implement these algorithms, reduced complexity versions of these algorithms should be investigated for communication processors that allow simpler hardware designs with significant parallelism without significant loss in performance. An example of such a design is presented in Ref. 8.

Flexibility

As communication systems evolve over time, a greater need exists for communication processors to be increasingly flexible. Communication systems are designed to support several parameters such as variable coding rates, variable modulation modes, and variable frequency band. This flexibility allows the communication system to adapt itself better to the environment to maximize data rates over the channel and/or to minimize power. For example, Fig. 6 shows base-station computational requirements

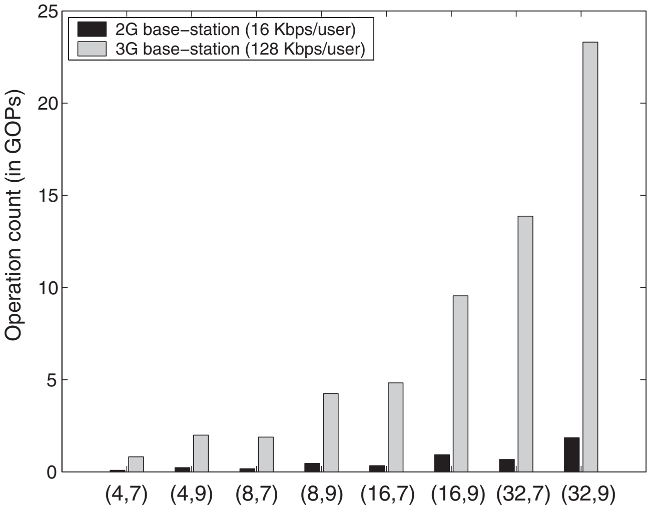

Figure 6. Flexibility needed to support various users, rates (for example), and backward -compatibility to standards. (Reprinted with permission from Ref. 9.)

and the flexibility needed to support several users at variable constraint lengths (9). The figure also shows an example of a 2G station at 16 Kbps/user supporting only voice and a 3G base-station at 128 Kbps/user supporting voice, data, and multimedia. A 3G base-station processor now must be backward-compatible to a 2G base-station processor and hence, must support both the standards as well as adapt its compute resources to save power when the processing requirements are lower. The amount of flexibility provided in communication processors can make the design for test for these systems extremely challenging because of the large number of parameters, algorithms, and radio interfaces that must be tested.

Along with the support for variable standards and protocols, researchers are also investigating the design of a single communication processor that can switch seamlessly between different standards, depending on the availability and cost of that standard. The RENE (Rice Everywhere NEtwork) project (10) demonstrates the design of a multitier network interface card with a communication processor that supports outdoor cellular (CDMA) and indoor wireless (LAN) and changes over the network seamlessly when the user moves from an office environment with wireless LAN into an outdoor environment using cellular services. Figure 7 shows the design of the wireless multitier network interface card concept at Rice University. Thus, flexibility to support various standards is becoming an increasingly desired feature in communication processors.

Spectrum Issues

The wireless spectrum is a scarce resource and is regulated by multiple agencies worldwide. As new standards evolve, they have to coexist with spectrums that are allocated already for existing standards. The regulatory bodies, such as Federal Communications Commission (see www.fcc.gov), demand that new standards meet certain limitations on transmit power and interference avoidance to make sure that the existing services are not degraded by the new standard. Also, because of a plethora of wireless standards in the 1–5 GHz wireless spectrum, new standards are forced to look at much higher RF frequencies, which make the design of radies more challenging as well as increase the need for transmit power because of larger attendation at higher frequencies. Newer standards also need to have interference detection and mitigation techniques to coexist with existing standards. This involves challenges at the radio level, such as to transmit at different frequencies to avoid interference and to develop the need for software-defined radios (11) Spectrum regulations have variations across countries worldwide and devices need to have the flexibility to support different programming to meet regulatory specifications.

Area, Time, and Power Tradeoffs

The design of communication processors is complicated even more by the nature of optimizations needed for the application and for the market segment. A mobile market segment may place greater emphasis on cost (area) and power, whereas a high-data rate market segment may place a greater focus on performance. Thus, even after new algorithms are designed and computationally efficient versions of the algorithms have been developed, tradeoffs between area-time and power consumptions occur for the implementation of the algorithm on the communication processor. Also, other parameters exist that need to be traded off such as the silicon process technology (0.18- vs. 0.13-vs. 0.09-μm CMOS process) and voltage and clock frequencies. For example, the area-time tradeoffs for Viterbi decoding are shown in Fig. 8(12). The curve shows that the area needed for the Viterbi decoder can be traded off at the cost of increasing the execution time for the Viterbi decoder.

In programmable processors, the number of functional units and the clock frequency can be adjusted to meet

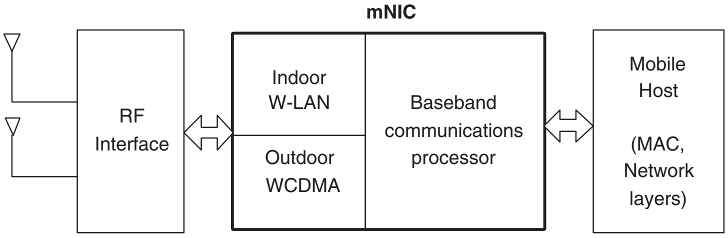

Figure 7. Multi-tier network interface card concept. (Reprinted with permission from Ref. 10.)

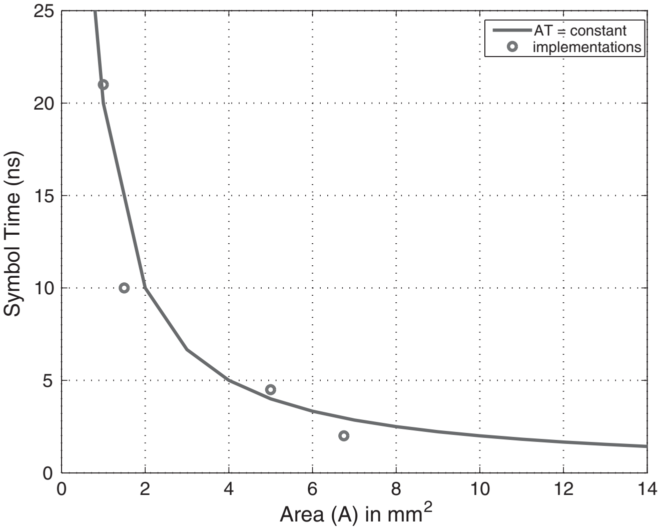

Figure 8. Normalized area-time efficiency for viterbi decoding. (Reprinted with permission from Ref. 12.)

real-time requirements for an application. An example of this application is shown in Fig. 9 (13). The figure shows that as the number of adders and multipliers in a programmable processor are increased, the clock frequency needed to meet real-time for an application decreases until a certain point, at which no more operations can be scheduled on the additional adders and multipliers in the processor. The numbers on the graph indicate the functional unit use of the adders and multipliers in the processor.

Interaction Between Multiple Layers

The interaction between the different layers in a communications system also presents challenges to the processor design. As will be shown in the following sections, the characteristics of the physical layer in a communication system are completely different than the characteristics of the MAC or network layer. The physical layer of a communication system consists of signal processing algorithms that work on estimation of the channel, detection of the received bits, and decoding of the data, and it requires computational resources. The MAC and network layers are more data flow-oriented and have more control and data-grouping operations. The combination of these two divers requirements make the task of design of a single integrated communication processor (which does both the PHY as well as the MAC) difficult. Hence, these layers are implemented typically as separate processors, although they may be present on the same chip.

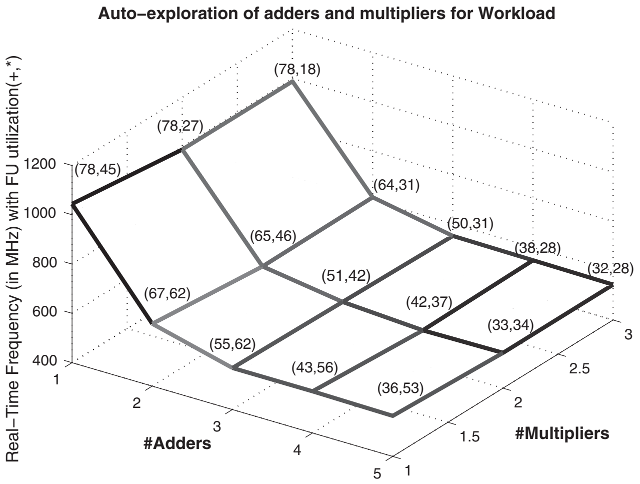

Figure 9. Number of adders and multipliers to meet real-time requirements in a programmable processor. (Reprinted with permission from Ref. 13.)

For example, it is very common in communication processor design to have a coprocessor-based approach for the physical layer that performs sophisticated mathematical operations in real-time, while having a microcontroller that handles the control and data management.

PHYSICAL LAYER OR BASEBAND PROCESSORS

The physical layer of wireless communication systems presents more challenges to the communication processor design than wired communication systems. The nature of the wireless channel implies the need for sophisticated algorithms on the receiver to receive and decode the data. Challenges exist in both the analog/RF radio and the digital baseband of the physical layer in emerging communication processors. The analog and RF radio design challenge is dominated by the need to support multiple communication protocols with varying requirements on the components in the transmitter and receiver chain of the radio. This need has emerged into a stream of research called software defined radios (11). We focus on the challenges in meeting the computational, real-time processing requirements and the flexibility requirements of the physical layer in the communication processor.

Characteristics of Baseband Communication Algorithms

Algorithms for communication systems in the physical layer process signals for transmission and reception of analog signals over the wireless (or the even wired) link. Hence, most algorithms implemented on communication processors are signal-processing algorithms and show certain characteristics that can be exploited in the design of communication processors.

1. Communication processors have stringent real-time requirements that imply the need to process data at a certain throughput rate while also meeting certain latency requirements.
2. Signal processing algorithms are typically compute-bound, which implies that the bottle neck in the processing are the computations (as opposed to memory) and the architectures require a significant number of adders and multipliers.

Figure 10. Typical operations at a transmitter of a baseband processor. (Reprinted with permission from Texas Instruments.)

3. Communication processors require very low fixed-point precision in computations. At the transmitter, the inputs are sent typically as bits. At the receiver, the ADCs reduce the dynamic range of the input signal by quantizing the signal. Quantization in communication processors is acceptable because the quantization errors are typically small compared with the noise added through the wireless channel. This finding is very useful to design low power and high speed arithmetic and to keep the size of memory requirements small in communication processors.
4. Communication algorithms exhibit significant amounts of data parallelism and show regular patterns in computation that can be exploited for hardware design.
5. Communication algorithms have a streaming dataflow in a producer-consumer fashion between blocks with very little data reuse. This dataflow can be exploited to avoid storage of intermediate values and to eliminate hardware in processors such as caches that try to exploit temporal reuse.

Figure 10 shows a typical transmitter in a communication processor. The transmitter, in the physical layer of a communication system is typically much simpler compared with the receiver. The transmitter operations typically consist of taking the data from the MAC layer and then scrambling it to make it look sufficiently random, encoding it for error protection, modulating it on certain frequencies, and then precompensating it for any RF impairments or distortions.

Figure 11 shows a typical receiver in a communications processor. The receiver estimates the channel to compensate for it, and then it demodulates the transmitted data and decodes the data to correct for any errors during transmission. Although not shown in the figure, many other impairments in the channel and the radio, such as fading, interference, I/Q imbalance, frequency offsets, and

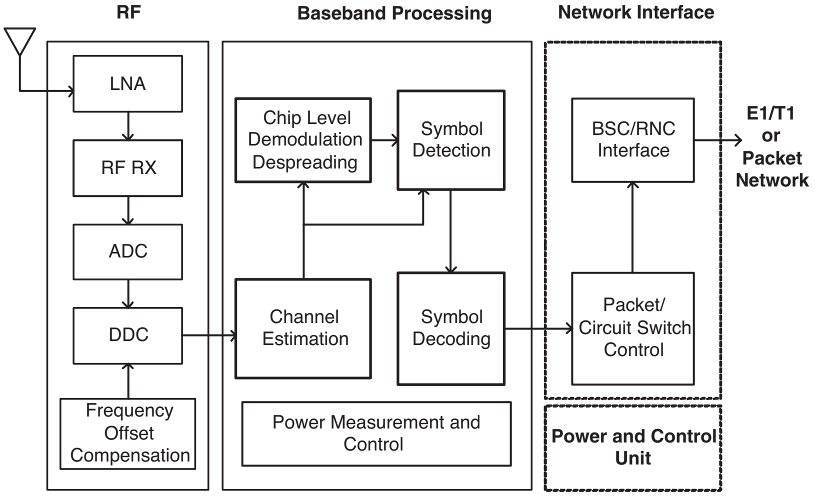

Figure 11. Typical operations at the receiver of a baseband processor (Reprinted with permission from Texas Instruments.)

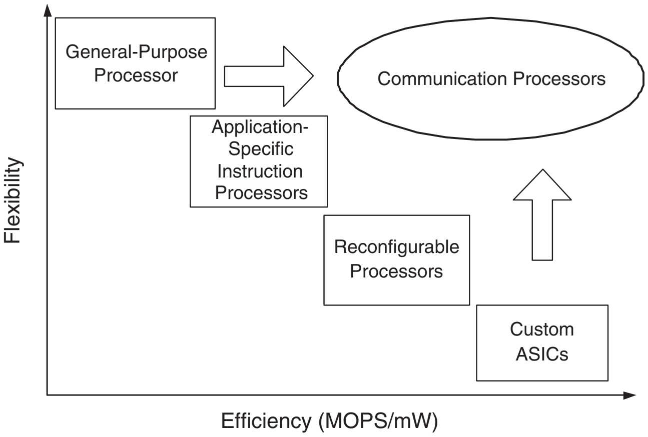

Figure 12. Desired characteristics of communication processors.

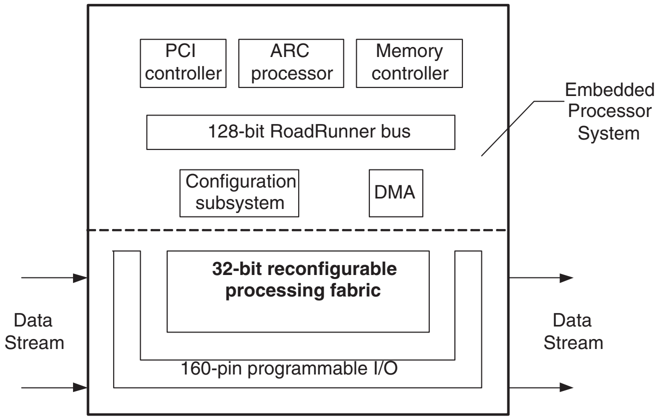

Figure 13. Reconfigurable communication processors. (Reprinted with permission from Ref. 15.)

phase offsets are also corrected at the receiver. The algorithms used at the receiver involve sophisticated signal processing and in general, have increased in complexity over time while providing more reliable and stable communication systems.

Architecture Designs

A wide range of architectures can be used to design a communication processor. Figure 12 shows the desired characteristics in communication processors and shows how different architectures meet the characteristics in terms of performance and flexibility. The efficiency metric on the x-axis is characterized as MOPs/mW (millions of operations performed per mW of power). The architectures shown in the figure trade flexibility with performance/power and are suited for different applications. A custom ASIC has the best efficiency in terms of data rate at unit power consumption at the same time it has the least amount of flexibility (14). On the other hand, a fully programmable processor is extremely flexible but is not area/power/throughput efficient. We discuss the tradeoffs among the different types of architectures to use them as communication processors.

Custom ASICs. Custom ASICs are the solution for communication processors that provide the highest efficiency and the lowest cost in terms of chip area and price. This, however, comes at the expense of a fairly large design and test time and lack of flexibility and scalability with changes in standards and protocols. Another issue with custom ASICs is that fabrication of these ASICs are extremely expensive (millions of dollars), which implies that extreme care needs to be taken in the functional design to ensure first pass success. Also, the volume of shipment for these custom chips must be high to amortize the development cost. A partial amount of flexibility can be provided as register settings for setting transmission or reception parameters or for tuning the chip that can then controlled by the MAC or higher layers in firmware (software). For example, the data rate to be used for transmission can be programmed into a register in the custom ASIC from the MAC and that can be used to set the appropriate controls in the processor.

Reconfigurable Processors. Reconfigurable processors are a relatively new addition to the area of communication processors. Typically, reconfigurable processors consist of a CISC type instruction set processor with a reconfigurable fabric attached to the processor core. This reconfigurable fabric is used to run complex signal processing algorithms that have sufficient parallelism and need a large number of adders and multipliers. The benefits of the reconfigurable fabric compared with FPGAs is that the reconfiguration can be done dynamically during run-time. Figure 13 shows an example of the Chameleon reconfigurable communication processor (15).

The reconfigurable fabric and the instruction set computing seek to provide the flexibility needed for communication processor while providing the dedicated logic in the reconfiguration fabric for efficient computing that can be reprogrammed dynamically. One of the major disadvantages of reconfigurable processors is that the software tools and compilers have not progressed to a state where performance/power benefits are easily visible along with the ease of programming the processor. The Chameleon reconfigurable processor is no longer an active product. However, several researchers in academia, such as GARP at Berkeley (16), RAW at MIT (17). Stallion at Virginia Tech (18), and in industry such as PACT (19) are still pursuing this promising architecture for communication processors.

Application-Specific Instruction Processors. Application-specific instruction processors (ASIPs) are processors with an instruction set for programmability and with customized hardware tailored for a given application (20). The programmability of these processors followed by the customization for a particular application to meet data rate and power requirements make ASIPs a viable candidate for communication processors.

A DSP is an example of such an application-specific instruction processor with specific optimizations to support signal processing operations. Because standards are typi-

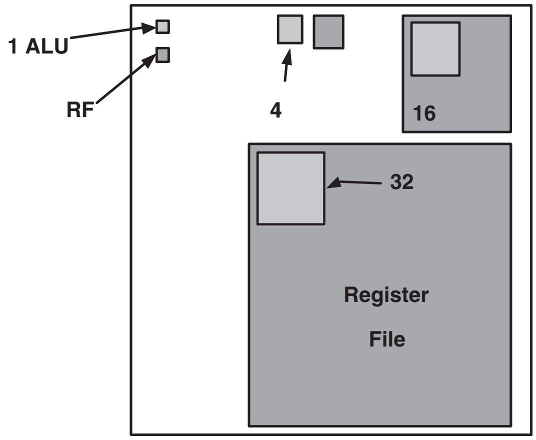

Figure 14. Register file expansion with increasing number of functional units in a processor. (Reprinted with permision from Ref. 23.)

cally driven by what is possible from an ASIC implementation feasibility for cost, performance, and power, it is difficult for a programmable architecture to compete with a fully custom, based ASIC design for wireless communications. DSPs fail to meet real-time requirements for implementing sophisticated algorithms because of the lack of sufficient functional units. However, it is not simple to increase the number of adders and multipliers in a DSP. Traditional single processor DSP architectures such as the C64x DSP by Texas Instruments (Dallas, TX) (21) employ VLIW architectures and exploit instruction level parallelism (ILP) and subword parallelism. Such single-processor DSPs can only have limited arithmetic units (less than 10) and cannot extend directly their architectures to 100s of arithmetic units. This limitation is because as the number of arithmetic units increases in an architecture, the size of the register files increases and the port interconnections start dominating the chip area (21,22). This growth is shown as a cartoon in Fig. 14 (28). Although the use of distributed register files may alleviate the register file explosion at the cost of increased pepalty in register allocation (21), an associated cost exists in exploiting ILP because of the limited size of register files, dependencies in the computations, and the register and functional unit allocation and use efficiency of the compiler. It has been shown that even with extremely good techniques, it is very difficult to exploit ILP beyond 5 (24). The large number of arithmetic and logic units (ALUs) also make the task of compiling and scheduling algorithms on the ALUs and keeping all the ALUs busy difficult.

Another popular approach to designing communication processors is to use a DSP with coprocessors (25–27). The coprocessors are still needed to perform more sophisticated operations that cannot be done real-time on the DSP because of the lack of sufficient adders and multipliers. Coprocessor support in a DSP can be both tightly coupled and loosely coupled (27). In a tightly coupled coprocessor (TCC) approach, the coprocessor interfaces directly to the DSP core and has access for specific registers in the DSP core. The TCC approach is used for algorithms that work with small datasets and require only a few instruction cycles to complete. The DSP processor freezes when the coprocessor is used because the DSP will have to interrupt the coprocessor immediately in the next few cycles. In time, the TCC is integrated into the DSP core with a specific instruction or is replaced with code in a faster or lower-power DSP. An example of such a TCC approach would be the implementation of a Galois field bit manipulation that may not be part of the DSP instruction set (27). The loosely coupled coprocessor approach (LCC) is used for algorithms that work with large datasets and require a significant amount of cycles to complete without interruption from the DSP. The LCC approach allows the DSP and coprocessor to execute in parallel. The coprocessors are loaded with the parameters and data and are initiated through application-specific instructions. The coprocessors sit on an external bus and do not interface directly to the DSP core, which allows the DSP core to execute in parallel. Figure 15 shows an example of the TMS320C6416 processor from Texas Instruments which has Viterbi and Turbo coprocessors for decoding (28) using the LCC approach. The DSP provides the flexibility needed for applications and the coprocessors provide the compute resources for more sophisticated computations that are unable to be met on the DSP.

Programmable Processors. To be precise with definitions, in this subsection, we consider programmable processors as processors that do not have an application-specific optimization or instruction set. For example, DSPs without coprocessors are considered in this subsection as programmable processors.

Stream processors are programmable processors that have optimizations for media and signal processing. They are able provide hundreds of ALUs in a processor by

arranging the ALUs into groups of clusters and by exploiting data parallelism across clusters. Stream processors are able to support giga-operations per second of computation in the processor. Figure 16 shows the distinction between DSPs and stream processors. Although typical DSPs exploit ILP and sub-word parallelism (SubP), stream processors also exploit data-parallelism across clusters to provide the needed computational horsepower.

Streams are stored in a stream register file, which can transfer data efficiently to and from a set of local register files between major computations. Local register files, colocated with the arithmetic units inside the clusters, feed those units directly with their operands. Truly global data, data that is persistent throughout the application, is stored off-chip only when necessary. These three explicit levels of storage form an efficient communication structure to keep hundreds of arithmetic units efficiently fed with data. The Imagine stream processor developed at Stanford is the first implementation of such a stream processor (29). Figure 17 shows the architecture of a stream processor with $C + 1$ arithmetic clusters. Operations in a stream processor all consume and/or produce streams that are stored in the centrally located stream register file (SRF). The two major stream instructions are memory transfers and kernel operations. A stream memory transfer either loads an entire stream into the SRF from external memory or stores an entire stream from the SRF to external memory. Multiple stream memory transfers can occur simultaneously, as hardware resources allow. A kernel operation performs a computation on a set of input streams to produce a set of output streams. Kernel operations are performed within a data parallel array of arithmetic clusters. Each cluster performs the same sequence of operations on independent stream elements. The stream buffers (SBs) allow the single port into the SRF array (limited for area/power/delay reasons) to be time-multiplexed among all the interfaces to the SRF, making it seen that many logical ports exist the array. The SBs also act as prefetch buffers and prefetch the data for kernel operations. Both the SRF and the stream buffers are banked to match the number of clusters. Hence, kernels that need to access data in other SRF banks must use the intercluster communication network for communicating data between the clusters.

The similarity between stream computations and communication processing in the physical layer makes stream-based processors an attractive architecture candidate for communication processors (9).

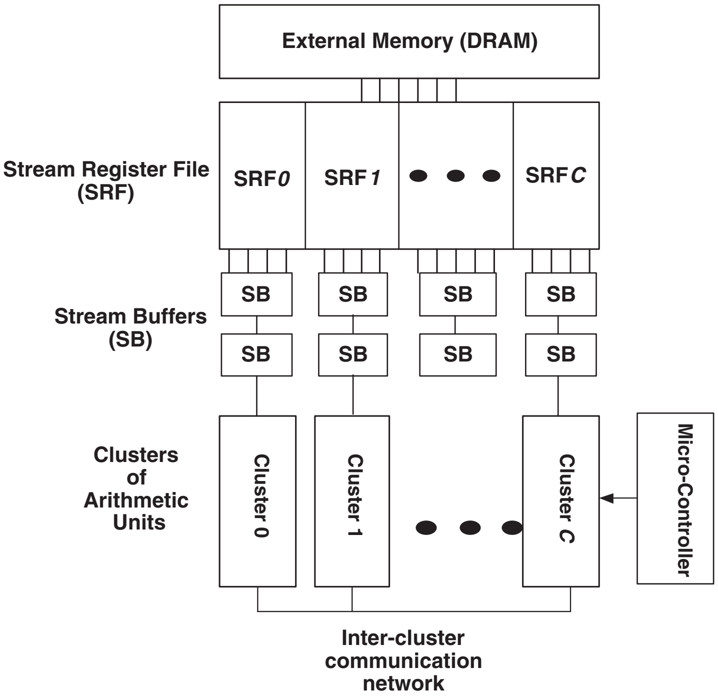

Figure 17. Stream processor architecture. (Reprinted with permission from Ref. 25.)

MAC AND NETWORK PROCESSORS

Although the focus of this article is on the physical layer of the communication processor, the MAC and network layers have a strong interaction with the physical layer especially in wireless networks. In this section, we briefly discuss the challenges and the functionality needed in processors for MAC and network layers (30).

MACs for wireless networks involve greater challenges than MACs for wired networks. The wireless channel necessitates the need for retransmissions when the received data is not decoded correctly in the physical layer. Wireless MACs also need to send out beacons to notify the access point that an active device is present on the network.

Typical functions of a wireless MAC include:

1. Transmissions of beacons in regular intervals to indicate the presence of the device on the network.
2. Buffering frames of data that are received from the physical layer and sending requests for re-transmissions for lost frames.
3. Monitoring radio channels for signals, noise and interference.
4. Monitoring presence of other devices on the network.
5. Encryption of data using AES/DES to provide security over the wireless channel.
6. Rate control of the physical layer to decide what data rates should be used for transmission of the data.

From the above, it can be seen that the MAC layer typically involves significant data management and processing. Typically, MACs are implemented as a combination of a RISC core that provides the control to different parts or the processor and dedicated logic for parts such as encryption for security and host interfaces.

Some functions of the network layer can be implemented on the MAC layer and vice-versa, depending on the actual protocol and application used. Typical functions at the network layer include:

1. Pattern matching and lookup. This involves matching the IP address and TCP port.
2. Computation of checksum to see if the frame is valid and any additional encryption and decryption.
3. Data manipulation that involves extracting and insertion of fields in the IP header and also, fragmentation and reassembly of packets.
4. Queue management for low priority and high priority traffic for QoS.
5. Control processing for updating routing tables and timers to check for retransmissions and backoff and so on.

CONCLUSIONS

Communication processor designs are evolving rapidly as silicon process technology advances have proven unable to keep up with increasing data rates and algorithm complexity. The need for greater flexibility to support multiple protocols and be backward compatible exacerbates the design problem because of the need to design programmable solutions that can provide high throughput and meet real-time requirements while being area and power efficient. The stringent regulatory requirements on spectrum, transmit power, and interference mitigation makes the design of the radio difficult while the complexity, diverse processing characteristics, and interaction between the physical layers and the higher layers complicates the design of the digital part of the communication processor Various tradeoffs can be made in communication processors to optimize throughputs versus area versus power versus cost, and the decisions depend the actual application under consideration. We present a detailed look at the challenges involved in designing these processors and present sample communication processor architectures that are considered for communication processors in the future.

C

COMPUTER ARCHITECTURE

The term *computer architecture* was coined in the 1960s by the designers of the IBM System/360 to mean the structure of a computer that a machine language programmer must understand to write a correct program for a machine (1).

The task of a computer architect is to understand the state-of-the-art technologies at each design level and the changing design tradeoffs for their specific applications. The tradeoff of cost, performance, and power consumption is fundamental to a computer system design. Different designs result from the selection of different points on the cost-performance-power continuum, and each application will require a different optimum design point. For high-performance server applications, chip and system costs are less important than performance. Computer speedup can be accomplished by constructing more capable processor units or by integrating many processors units on a die. For cost-sensitive embedded applications, the goal is to minimize processor die size and system power consumption.

Technology Considerations

Modern computer implementations are based on silicon technology. The two driving parameters of this technology are die size and feature size. Die size largely determines cost. Feature size is dependent on the lithography used in wafer processing and is defined as the length of the smallest realizable device. Feature size determines circuit density, circuit delay, and power consumption. Current feature sizes range from 90 nm to 250 nm. Feature sizes below 100 nm are called deep submicron. Deep submicron technology allows microprocessors to be increasingly more complicated. According to the Semiconductor Industry Association (2), the number of transistors (Fig. 1) for high-performance microprocessors will continue to grow exponentially in the next 10 years. However, there are physical and program behavioral constraints that limit the usefulness of this complexity. Physical constraints include interconnect and device limits as well as practical limits on power and cost. Program behavior constraints result from program control and data dependencies and unpredictable events during execution (3).

Much of the improvement in microprocessor performance has been a result of technology scaling that allows increased circuit densities at higher clock frequencies. As feature sizes shrink, device area shrinks roughly as the square of the scaling factor, whereas device speed (under constant field assumptions) improves linearly with feature size.

On the other hand, there are a number of major technical challenges in the deep submicron era, the most important of which is that interconnect delay (especially global interconnect delay) does not scale with the feature size. If all three dimensions of an interconnect wire are scaled down by the same scaling factor, the interconnect delay remains roughly unchanged, because the fringing field component of wire capacitance does not vary with feature size. Consequently, interconnect delay becomes a limiting factor in the deep submicron era.

Another very important technical challenge is the difficulty faced trying to dissipate heat from processor chip packages as chip complexity and clock frequency increases.

Indeed, special cooling techniques are needed for processors that consume more than 100W of power. These cooling techniques are expensive and economically infeasible for most applications (e.g., PC). There are also a number of other technical challenges for high-performance processors. Custom circuit designs are necessary to enable GHz signals to travel in and out of chips. These challenges require that designers provide whole-system solutions rather than treating logic design, circuit design, and packaging as independent phases of the design process.

Performance Considerations

Microprocessor performance has improved by approximately 50% per year for the last 20 years, which can be attributed to higher clock frequencies, deeper pipelines, and improved exploitation of instruction-level parallelism. However, the cycle time at a given technology cannot be too small, or we will sacrifice overall performance by incurring too much clock overhead and suffering long pipeline breaks. Similarly, the instruction-level parallelism is usually limited by the application, which is further diminished by code generation inefficiencies, processor resource limitations, and execution disturbances. The overall system performance may deteriorate if the hardware to exploit the parallelism becomes too complicated.

High-performance server applications, in which chip and system costs are less important than total performance, encompass a wide range of requirements, from computation-intensive to memory-intensive to I/O-intensive. The need to customize implementation to specific applications may even alter manufacturing. Although expensive, high-performance servers may require fabrication microproduction runs to maximize performance.

Power Considerations

Power consumption has received increasingly more attention because both high-performance processors and processors for portable applications are limited by power consumption. For CMOS design, the total power dissipation has three major components as follows:

1. switching loss,
2. leakage current loss, and
3. short circuit current loss.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

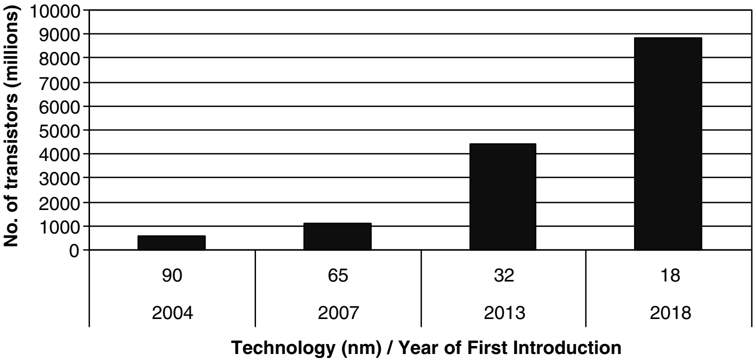

Figure 1. Number of transistors per chip. (Source: National Technology Roadmap for Semiconductors)

Among these three factors, switching loss is usually the most dominant factor. Switching loss is proportional to operating frequency and is also proportional to the square of supply voltage. Thus, lowering supply voltage can effectively reduce switching loss. In general, operating frequency is roughly proportional to supply voltage. If supply voltage is reduced by 50%, operating frequency is also reduced by 50%, and total power consumption becomes one-eighth of the original power. On the other hand, leakage power loss is a function of CMOS threshold voltage. As supply voltage decreases, threshold voltage has to be reduced, which results in an exponential increase in leakage power loss. When feature size goes below 90 nm, leakage power loss can be as high as switching power loss.

For many DSP applications, the acceptable performance can be achieved at a low operating frequency by exploiting the available program parallelism using suitable parallel forms of processor configurations. Improving the battery technology, obviously, can allow processors to run for an extended period of time. Conventional nickel-cadmium battery technology has been replaced by high-energy density batteries such as the NiMH battery. Nevertheless, the energy density of a battery is unlikely to improve drastically for safety reasons. When the energy density is too high, a battery becomes virtually an explosive.

Cost Considerations

Another design tradeoff is to determine the optimum die size. In the high-performance server market, the processor cost may be relatively small compared with the overall system cost. Increasing the processor cost by 10 times may not significantly affect the overall system cost. On the other hand, system-on-chip implementations tend to be very cost sensitive. For these applications, the optimum use of die size is extremely important.

The area available to a designer is largely a function of the manufacturing processing technology, which includes the purity of the silicon crystals, the absence of dust and other impurities, and the overall control of the diffusion and process technology. Improved manufacturing technology allows larger die with higher yields, and thus lower manufacturing costs.

At a given technology, die cost is affected by chip size in two ways. First, as die area increases, fewer die can be realized from a wafer. Second, as the chip size increases, the yield decreases, generally following a Poisson distribution of defects. For certain die sizes, doubling the area can increase the die cost by 10 times.

Other Considerations

As VLSI technology continues to improve, there are new design considerations for computer architects. The simple traditional measures of processor performance—cycle time and cache size—are becoming less relevant in evaluating application performance. Some of the new considerations include:

1. Creating high-performance processors with enabling compiler technology.
2. Designing power-sensitive system-on-chip processors in a very short turnaround time.
3. Improving features that ensure the integrity and reliability of the computer.
4. Increasing the adaptability of processor structures, such as cache and signal processors.

Performance-Cost-Power Tradeoffs

In the era of deep-submicron technology, two classes of microprocessors are evolving: (1) high-performance server processors and (2) embedded client processors. The majority of implementations are commodity system-on-chip processors devoted to end-user applications. These highly cost-sensitive client processors are used extensively in consumer electronics. Individual application may have specific requirements; for example, portable and wireless applications require very low power consumption. The other class consists of high-end server processors, which are performance-driven. Here, other parts of the system dominate cost and power issues.

At a fixed feature size, area can be traded off for performance (expressed in term of execution time, T). VLSI complexity theorists have shown that an $A \cdot T^n$ bound exists for microprocessor designs (1), where n usually falls between 1 and 2. By varying the supply voltage, it is also possible to tradeoff time T for power P with a $P \cdot T^3$ bound.

Figure 2. Design tradeoffs for high-end and low-end processors.

Figure 2 shows the possible tradeoff involving area, time, and power in a processor design (3). Embedded and high-end processors operate in different design regions of this three-dimensional space. The power and area axes are typically optimized for embedded processors, whereas the time axis is typically optimized for high-end processors.

Alternatives in Computer Architecture

In computer architecture, the designer must understand the technology and the user requirements as well as the available alternatives in configuring a processor. The designer must apply what is known of user program behavior and other requirements to the task of realizing an area-time-power optimized processor. User programs offer differing types and forms of parallelism that can be matched by one or more processor configurations. A primary design goal is to identify the most suitable processor configuration and then scale the concurrency available within that configuration to match cost constraints.

The next section describes the principle functional elements of a processor. Then the various types of parallel and concurrent processor configuration are discussed. Finally, some recent architectures are compared and some concluding remarks are presented.

PROCESSOR ARCHITECTURE

The processor architecture consists of the instruction set, the memory that it operates on, and the control and functional units that implement and interpret the instructions. Although the instruction set implies many implementation details, the resulting implementation is a great deal more than the instruction set. It is the synthesis of the physical device limitations with area-time-power tradeoffs to optimize cost-performance for specified user requirements. As shown in Fig. 3, the processor architecture may be divided into a high-level programming model and a low-level microarchitecture.

Instruction Set

Computers deal with many different kinds of data and data representations. The operations available to perform the requisite data manipulations are determined by the data types and the uses of such data. Processor design issues are closely bound to the instruction set. Instruction set behavior data affects many of these design issues

The *instruction set* for most modern machines is based on a register set to hold operands and addresses. The register set size varies from 8 to 64 words, each word consisting of 32 to 64 bits. An additional set of floating-point registers (16 to 64 bits) is usually also available. A

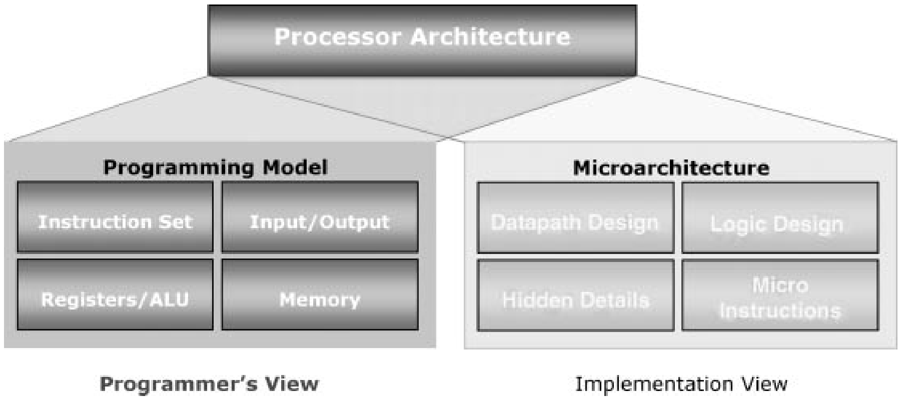

Figure 3. Processor architecture block diagram.

typical instruction set specifies a program status word, which consists of various types of control status information, including condition codes set by the instruction. Common instruction sets can be classified by format differences into three types as follows:

1. the L/S, or Load-Store architecture;
2. the R/M, or Register-Memory architecture; and
3. the R+M, or Register-plus-Memory architecture.

The *L / S* or *Load-Store* instruction set describes many of the RISC (reduced instruction set computer) microprocessors (5). All values must be loaded into registers before an execution can take place. An ALU ADD instruction must have both operands with the result specified as registers (three addresses). The purpose of the RISC architecture is to establish regularity of execution and ease of decoding in an effort to improve overall performance. RISC architects have tried to reduce the amount of complexity in the instruction set itself and regularize the instruction format so as to simplify decoding of the instruction. A simpler instruction set with straightforward timing is more readily implemented. For these reasons, it was assumed that implementations based on the L/S instruction set would always be faster (higher clock rates and performance) than other classes, other parameters being generally the same.

The *R / M* or *Register-Memory* architectures include instruction that can operate both on registers and with one of the operands residing in memory. Thus, for the R/M architecture, an ADD instruction might be defined as the sum of a register value and a value contained in memory, with the result going to a register. The R/M instruction sets generally trace their evolution to the IBM System/360 introduced in 1963. The mainframe computers follow the R/M style (IBM, Amdahl, Hitachi, Fujitsu, etc., which all use the IBM instruction set), as well as the basic Intel x86 series.

The *R+M* or *Register-plus-Memory* architectures allow formats to include operands that are either in memory or in registers. Thus, for example, an ADD may have all of its operands in registers or all of its operands in memory, or any combination thereof. The R+M architecture generalizes the formats of R/M. The classic example of the R+M architecture was Digital Equipment's VAX series of machines. VAX also generalized the use of the register set through the use of register modes. The use of an extended set of formats and register modes allows a powerful and varied specification of operands and operation type within a single instruction. Unfortunately, format and mode variability complicates the decoding process so that the process of interpretation of instructions can be slow (but R+M architectures make excellent use of memory/bus bandwidth).

From the architect's point of view, the tradeoff in instruction sets is an area-time compromise. The register-memory (R/M and R+M) architectures offer a more concise program representation using fewer instructions of variable size compared with L/S. Programs occupy less space in memory and smaller instruction caches can be used effectively. The variable instruction size makes decoding more difficult. The decoding of multiple instructions requires predicting the starting point of each. The register-memory processors require more circuitry (and area) to be devoted to instruction fetch and decode. Generally, the success of Intel-type x86 implementations in achieving high clock rates and performance has shown that the limitations of a register-memory instruction set can be overcome.

Memory

The *memory system* comprises the physical storage elements in the memory hierarchy. These elements include those specified by the instruction set (registers, main memory, and disk sectors) as well as those elements that are largely transparent to the user's program (buffer registers, cache, and page-mapped virtual memory). Registers have the fastest access and, although limited in capacity (32 to 128 bits), in program execution, is the most often referenced type of memory. A processor cycle time is usually defined by the time it takes to access one or more registers, operate their contents, and return the result to a register.

Main memory is the type of storage usually associated with the simple term memory. Most implementations are based on DRAM (e.g., DDR and DDR-2 SDRAM), although SRAM and Flash technologies have also been used. DRAM memory is accessible in order of 10s of cycles (typically 20 to 30) and usually processors have between 128 MB and 4 GB of such storage. The disk contains all the programs and data available to the processor. Its addressable unit (sector) is accessible in 1 to 10 ms, with a typical single-unit disk capacity of 10 to 300 GB. Large server systems may have 100s or more such disk units. As the levels of the memory system have such widely differing access times, additional levels of storage (buffer registers, cache, and paged memory) are added that serve as a buffer between levels attempting to hide the access time differences.

Memory Hierarchy. There are basically three parameters that define the effectiveness of the memory system: latency, bandwidth, and the capacity of each level of the system. Latency is the time for a particular access request to be completed. Bandwidth refers to the number of requests supplied per unit time. To provide large memory spaces with desirable access time latency and bandwidths, modern memory systems use a multiple-level memory hierarchy.

Smaller, faster levels have greater cost per bit than larger, slower levels. The multiple levels in the storage hierarchy can be ordered by their size and access time from the smallest, fastest level to the largest, slowest level. The goal of a good memory system design is to provide the processor with an effective memory capacity of the largest level with an access time close to the fastest. How well this goal is achieved depends on a number of factors—the characteristics of the device used in each level as well as the behavioral properties of the programs being executed.

Suppose we have a memory system hierarchy consisting of a cache, a main memory, and a disk or backing storage. The disk contains the contents of the entire virtual memory space. Typical size (S) and access time ratios (t) are as follows:

Size: memory/cache	≈	1000
Access time: memory/cache	≈	30
Size: disk/memory	≈	100–1000+
Access time: disk/memory	≈	100,000

Associated with both the cache and a paged main memory are corresponding tables that define the localities that are currently available at that level. The page table contains the working set of the disk—those disk localities that have been recently referenced by the program, and are contained in main memory. The cache table is completely managed by the hardware and contains those localities (called lines) of memory that have been recently referenced by the program.

The memory system operates by responding to a virtual effective address generated by a user program, which is translated into a real address in main memory. This real address accesses the cache table to find the entry in the cache for the desired value.

Paging and caching are the mechanisms to support the efficient management of the memory space. Paging is the mechanism by which the operating system brings fixed-size blocks (or pages)—a typical size is 4 to 64 KB—into main memory. Pages are fetched from backing store (usually disk) on demand (or as required) by the processor. When a referenced page is not present, the operating system is called and makes a request for the page, then transfers control to another process, allowing the processor resources to be used while waiting for the return of the requested information. The real address is used to access the cache and main memory. The low-order (least significant) bits address a particular location in a page. The upper bits of a virtual address access a page table (in memory) that:

1. determines whether this particular partial page lies in memory, and
2. translates the upper address bits if the page is present, producing the real address.

Usually, the tables performing address translation are in memory, and a mechanism for the translation called the translation lookaside buffer (TLB) must be used to speed up this translation. The TLB is a simple register system usually consisting of between 64 and 256 entries that save recent address translations for reuse.

Control and Execution

Instruction Execution Sequence. The semantics of the instruction determines that a sequence of actions must be performed to produce the specified result (Fig. 4). These actions can be overlapped (as discussed in the pipelined processor section) but the result must appear in the specified serial order. These actions include the following:

1. fetching the instruction into the instruction register (IF),
2. decoding the op code of the instruction (ID),

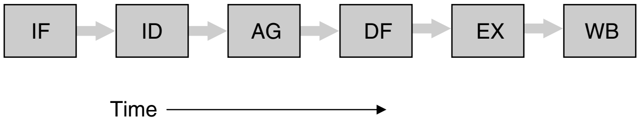

Figure 4. Instruction execution sequence.

3. generating the address in memory of any data item residing there (AG),
4. fetching data operand(s) into executable registers (DF),
5. executing the specified operation (EX), and
6. returning the result to the specified register (WB).

Decode: Hardwired and Microcode. The decoder produces the control signals that enable the functional units to execute the actions that produce the result specified by the instruction. Each cycle, the decoder produces a new set of control values that connect various registers and functional units. The decoder takes as an initial input the op code of the instruction. Using this op code, it generates the sequence of actions, one per cycle, which completes the execution process. The last step of the current instruction's execution is the fetching of the next instruction into the instruction register so that it may be decoded. The implementation of the decoder may be based on Boolean equations that directly implement the specified actions for each instruction. When these equations are implemented with logic gates, the resultant decoder is called a *hardwired decoder*.

For extended instruction sets or complex instructions, another implementation is sometimes used, which is based on the use of a fast storage (or microprogram store). A particular word in the storage (called a *microcode*) contains the control information for a single action or cycle. A sequence of microinstructions implements the instruction execution.

Data Paths: Busses and Functional Units. The data paths of the processor include all the functional units needed to implement the vocabulary (or op codes) of the instruction set. Typical functional units are the ALU (arithmetic logic unit) and the floating-point unit. Busses and other structured interconnections between the registers and the functional units complete the data paths.

PROGRAM PARALLELISM AND PARALLEL ARCHITECTURE

Exploiting program parallelism is one of the most important elements in computer architecture design. Programs written in imperative languages encompass the following four levels of parallelism:

1. parallelism at the instruction level (fine-grained),
2. parallelism at the loop level (middle-grained),

3. parallelism at the procedure level (middle-grained), and
4. parallelism at the program level (coarse-grained).

Instruction-level parallelism (ILP) means that multiple operations can be executed in parallel within a program. ILP may be achieved with hardware, compiler, or operating system techniques. At the loop level, consecutive loop iterations are ideal candidates for parallel execution provided that there is no data dependency between subsequent loop iterations. Next, there is parallelism available at the procedure level, which depends largely on the algorithms used in the program. Finally, multiple independent programs can obviously execute in parallel.

Different computer architectures have been built to exploit this inherent parallelism. In general, a computer architecture consists of one or more interconnected processor elements that operate concurrently, solving a single overall problem. The various architectures can be conveniently described using the stream concept. A stream is simply a sequence of objects or actions. There are both instruction streams and data streams, and there are four simple combinations that describe the most familiar parallel architectures (6):

1. SISD – single instruction, single data stream; The traditional uniprocessor (Fig. 5).
2. SIMD – single instruction, multiple data stream, which includes array processors and vector processors (Fig. 6).
3. MISD – multiple instruction, single data stream, which are typically systolic arrays (Fig. 7).
4. MIMD – multiple instruction, multiple data stream, which includes traditional multiprocessors as well as the newer work of networks of workstations (Fig. 8).

The stream description of computer architectures serves as a programmer's view of the machine. If the processor architecture allows for parallel processing of one sort or another, then this information is also visible to the programmer. As a result, there are limitations to the stream categorization. Although it serves as useful shorthand, it ignores many subtleties of an architecture or an implementation. Even an SISD processor can be highly parallel in its execution of operations. This parallelism is typically not visible to the programmer even at the assembly language level, but becomes visible at execution time with improved performance.

There are many factors that determine the overall effectiveness of a parallel processor organization. Interconnection network, for instance, can affect the overall speedup. The characterizations of both processors and networks are complementary to the stream model and, when coupled with the stream model, enhance the qualitative understanding of a given processor configuration.

SISD – Single Instruction, Single Data Stream

The SISD class of processor architecture includes most commonly available computers. These processors are known as uniprocessors and can be found in millions of embedded processors in video games and home appliances as well as stand-alone processors in home computers, engineering workstations, and mainframe computers. Although

a programmer may not realize the inherent parallelism within these processors, a good deal of concurrency can be present. Pipelining is a powerful technique that is used in almost all current processor implementations. Other techniques aggressively exploit parallelism in executing code whether it is declared statically or determined dynamically from an analysis of the code stream.

During execution, a SISD processor executes one or more operations per clock cycle from the instruction stream. An instruction is a container that represents the smallest execution packet managed explicitly by the processor. One or more operations are contained within an instruction. The distinction between instructions and operations is crucial to distinguish between processor behaviors. Scalar and superscalar processors consume one or more instructions per cycle where each instruction contains a single operation. VLIW processors, on the other hand, consume a single instruction per cycle where this instruction contains multiple operations.

A SISD processor has four primary characteristics. The first characteristic is whether the processor is capable of executing multiple operations concurrently. The second characteristic is the mechanisms by which operations are scheduled for execution—statically at compile time, dynamically at execution, or possibly both. The third characteristic is the order that operations are issued and retired relative to the original program order—these operations can be in order or out of order. The fourth characteristic is the manner in which exceptions are handled by the processor—precise, imprecise, or a combination. This last condition is not of immediate concern to the applications programmer, although it is certainly important to the compiler writer or operating system programmer who must be able to properly handle exception conditions. Most processors implement precise exceptions, although a few high-performance architectures allow imprecise floating-point exceptions.

Tables 1, 2, and 3 describe some representative scalar, processors, superscalar processors, and VLIW processors.

Scalar Processor. Scalar processors process a maximum of one instruction per cycle and execute a maximum of one operation per cycle. The simplest scalar processors, sequential processors, process instructions atomically one after another. This sequential execution behavior describes the sequential execution model that requires each instruction executed to completion in sequence. In the sequential execution model, execution is *instruction-precise* if the following conditions are met:

1. All instructions (or operations) preceding the current instruction (or operation) have been executed and all results have been committed.
2. All instructions (or operations) after the current instruction (or operation) are unexecuted and no results have been committed.
3. The current instruction (or operation) is in an arbitrary state of execution and may or may not have completed or had its results committed.

For scalar and superscalar processors with only a single operation per instruction, instruction-precise and operation-precise executions are equivalent. The traditional definition of sequential execution requires instruction-precise execution behavior at all times, mimicking the execution of a nonpipelined sequential processor.

Sequential Processor. Sequential processors directly implement the sequential execution model. These processors process instructions sequentially from the instruction stream. The next instruction is not processed until all execution for the current instruction is complete and its results have been committed.

Although conceptually simple, executing each instruction sequentially has significant performance drawbacks—a considerable amount of time is spent in overhead and not in actual execution. Thus, the simplicity of directly implementing the sequential execution model has significant performance costs.

Pipelined Processor. Pipelining is a straightforward approach to exploiting parallelism that is based on concurrently performing different phases (instruction fetch, decode, execution, etc.) of processing an instruction. Pipelining assumes that these phases are independent between different operations and can be overlapped; when this condition does not hold, the processor stalls the downstream phases to enforce the dependency. Thus, multiple operations can be processed simultaneously with each operation at a different phase of its processing. Figure 9 illustrates the instruction timing in a pipelined processors, assuming that the instructions are independent. The

[1] For some Intel ×86 family processors, each instruction is broken into a number of microoperation codes in the decoding stage. In this article, two different issue widths are given for these processors: The first one is the maximum number of instructions issued per cycle, and the second one is the maximum number of microoperation codes issued per cycle.

meaning of each pipeline stage is described in the Instruction Execution Sequence system.

For a simple pipelined machine, only one operation occurs in each phase at any given time. Thus, one operation is being fetched, one operation is being decoded, one operation is accessing operands, one operation is in execution, and one operation is storing results. The most rigid form of a pipeline, sometimes called the static pipeline, requires the processor to go through all stages or phases of the pipeline whether required by a particular instruction or not. Dynamic pipeline allows the bypassing of one or more of the stages of the pipeline depending on the requirements of the instruction. There are at least three levels of sophistication within the category of dynamic pipeline processors as follows:

- *Type 1:* Dynamic pipelines that require instructions to be decoded in sequence and results to be executed and written back in sequence. For these types of simpler dynamic pipeline processors, the advantage over a static pipeline is relatively modest. In-order execution requires the actual change of state to occur in order specified in the instruction sequence.
- *Type 1-Extended:* A popular extension of the Type 1 pipeline is to require the decode to be in order, but the execution stage of ALU operations need not be in order. In these organizations, the address generation stage of the load and store instructions must be completed before any subsequent ALU instruction does a writeback. The reason is that the address generation may cause a page execution and affect the

Table 3. Typical VLIW Processors (SISD)

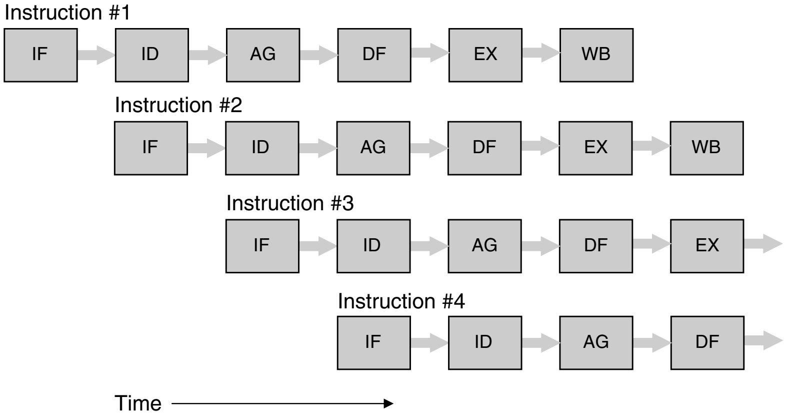

Figure 9. Instruction timing in a pipelined processor.

processor state. As a result of these restrictions and the overall frequency of load and store instructions, the Type 1-Extended pipeline behaves much as the basic Type-1 pipeline.

- *Type 2:* Dynamic pipelined machines that can be configured to allow out-of order execution yet retain in-order instruction decode. For this type of pipelined processor, the execution and writeback of all instructions is a function only of dependencies on prior instruction. If a particular instruction is independent of all preceding instructions, its execution can be completed independently of the successful completion of prior instructions.
- *Type 3:* The third type of dynamic pipeline allows instructions to be issued as well as completed out of order. A group of instruction is analyzed together, and the first instruction that is found to be independent of prior instructions is decoded.

Instruction-level Parallelism. Although pipelining does not necessarily lead to executing multiple instructions at exactly the same time, there are other techniques that do. These techniques may use some combination of static scheduling and dynamic analysis to perform concurrently the actual evaluation phase of several different operations, potentially yielding an execution rate of greater than one operation every cycle. This kind of parallelism exploits concurrency at the computation level. As historically most instructions consist of only a single operation, this kind of parallelism has been named instruction-level parallelism (ILP).

Two architectures that exploit ILP are superscalar and VLIW, which use radically different techniques to achieve greater than one operation per cycle. A superscalar processor dynamically examines the instruction stream to determine which operations are independent and can be executed. A VLIW processor depends on the compiler to analyze the available operations (OP) and to schedule independent operations into wide instruction words, which then executes these operations in parallel with no further analysis.

Figure 10 shows the instruction timing of a pipelined superscalar or VLIW processor executing two instructions per cycle. In this case, all the instructions are independent so that they can be executed in parallel.

Superscalar Processor. Dynamic out-of-order pipelined processors reach the limits of performance for a scalar processor by allowing out-of-order operation execution. Unfortunately, these processors remain limited to executing a single operation per cycle by virtue of their scalar nature. This limitation can be avoided with the addition of multiple functional units and a dynamic scheduler to process more than one instruction per cycle. These resulting superscalar processors can achieve execution rates of more than one instruction per cycle. The most significant advantage of a superscalar processor is that processing multiple instructions per cycle is done transparently to the user, and that it can provide binary compatibility while achieving better performance.

Compared with an out-of-order pipelined processor, a superscalar processor adds a scheduling instruction window that dynamically analyzes multiple instructions from the instruction stream. Although processed in parallel, these instructions are treated in the same manner as in an out-of-order pipelined processor. Before an instruction is issued for execution, dependencies between the instruction and its prior instructions must be checked by hardware.

As a result of the complexity of the dynamic scheduling logic, high-performance superscalar processors are limited to processing four to six instructions per cycle (refer to the Examples of Recent Architecture section). Although superscalar processors can take advantage of dynamic execution behavior and exploit instruction-level parallelism from the dynamic instruction stream, exploiting high degrees of instruction requires a different approach. An alternative approach is to rely on the compiler to perform the dependency analyses and to eliminate the need for complex analyses performed in hardware.

VLIW Processor. In contrast to dynamic analyses in hardware to determine which operations can be executed in parallel, VLIW processors rely on static analyses in the compiler. VLIW processors are, thus, less complex than superscalar processor and have the potential for higher performance. A VLIW processor executes operations from statically scheduled instructions that contain multiple

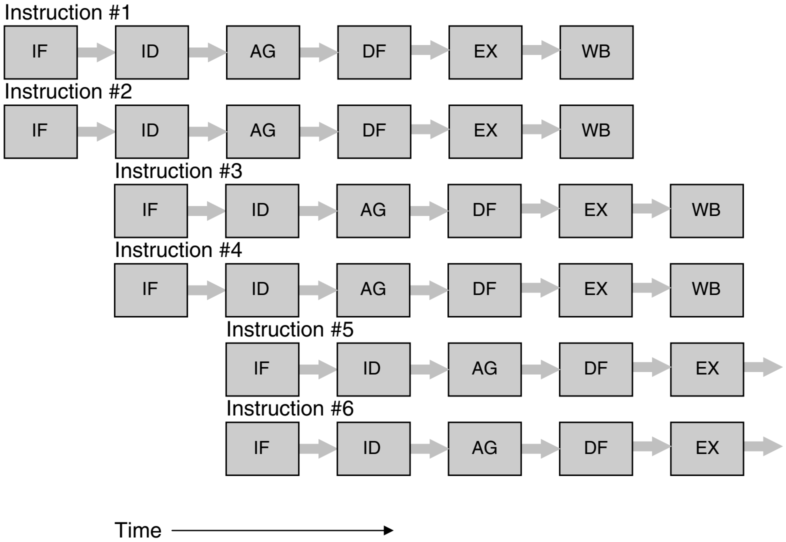

Figure 10. Instruction timing of a pipelined ILP processor.

independent operations. Although it is not required that static processors exploit instruction-level parallelism, most statically scheduled processors use wide instruction words. As the complexity of a VLIW processor is not significantly greater than that of a scalar processor, the improved performance comes without the complexity penalties.

On the other hand, VLIW processors rely on the static analyses performed by the compiler and are unable to take advantage of any dynamic execution characteristics. As issue widths become wider and wider, the avoidance of complex hardware logic will rapidly erode the benefits of out-of-order execution. This benefit becomes more significant as memory latencies increase and the benefits from out-of-order execution become a less significant portion of the total execution time. For applications that can be statically scheduled to use the processor resources effectively, a simple VLIW implementation results in high performance.

Unfortunately, not all applications can be effectively scheduled for VLIW processors. In real systems, execution rarely proceeds exactly along the path defined by the code scheduler in the compiler. These are two classes of execution variations that can develop and affect the scheduled execution behavior:

1. Delayed results from operations whose latency differs from the assumed latency scheduled by the compiler.
2. Interruptions from exceptions or interrupts, which change the execution path to a completely different and unanticipated code schedule.

Although stalling the processor can control delayed results, this solution can result in significant performance penalties from having to distribute the stall signal across the processor. Delays occur from many causes including mismatches between the architecture and an implementation as well as from special-case conditions that require additional cycles to complete an operation. The most common execution delay is a data cache miss; another example is a floating-point operation that requires an additional normalization cycle. For processors without hardware resource management, delayed results can cause resource conflicts and incorrect execution behavior. VLIW processors typically avoid all situations that can result in a delay by not using data caches and by assuming worst-case latencies for operations. However, when there is insufficient parallelism to hide the exposed worst-case operation latency, the instruction schedule will have many incompletely filled or empty instructions that can result in poor performance.

Interruptions are usually more difficult to control than delayed results. Managing interruptions is a significant problem because of their disruptive behavior and because the origins of interruptions are often completely beyond a program's control. Interruptions develop from execution-related internal sources (exceptions) as well as arbitrary external sources (interrupts). The most common interruption is an operation exception resulting from either an error condition during execution or a special-case condition that requires additional corrective action to complete operation execution. Whatever the source, all interruptions require the execution of an appropriate service routine to resolve the problem and to restore normal execution at the point of the interruption.

SIMD – Single Instruction, Multiple Data Stream

The SIMD class of processor architecture includes both array and vector processors. The SIMD processor is a natural response to the use of certain regular data structures, such as vectors and matrices. From the reference point of an assembly-level programmer, programming SIMD architecture appears to be very similar to programming a simple SISD processor except that some operations perform computations on aggregate data. As these

Table 4. Typical Vector Computers (SIMD)

Processor	Year of introduction	Memory- or register-based	Number of processor units	Maximum vector length
Cray 1	1976	Register	1	64
CDC Cyber 205	1981	Memory	1	65535

Cray T90	1995	Register	1–32	128
NEC SX-5	1998	Register	1–512	256

regular structures are widely used in scientific programming, the SIMD processor has been very successful in these environments.

The two popular types of SIMD processor are the array processor and the vector processor. They differ both in their implementations and in their data organizations. An array processor consists of many interconnected processor elements that each have their own local memory space. A vector processor consists of a single processor that references a single global memory space and has special function units that operate specifically on vectors. Tables 4 and 5 describe some representative vector processors and array processors.

Array Processors. The array processor is a set of parallel processor elements connected via one or more networks, possibly including local and global interelement communications and control communications. Processor elements operate in lockstep in response to a single broadcast instruction from a control processor. Each processor element has its own private memory and data is distributed across the elements in a regular fashion that is dependent on both the actual structure of the data and also on the computations to be performed on the data. Direct access to global memory or another processor element's local memory is expensive, so intermediate values are propagated through the array through local interprocessor connections, which requires that the data be distributed carefully so that the routing required to propagate these values is simple and regular. It is sometimes easier to duplicate data values and computations than it is to affect a complex or irregular routing of data between processor elements.

As instructions are broadcast, there is no means local to a processor element of altering the flow of the instruction stream; however, individual processor elements can conditionally disable instructions based on local status information—these processor elements are idle when this condition occurs. The actual instruction stream consists of more than a fixed stream of operations; an array processor is typically coupled to a general-purpose control processor that provides both scalar operations as well as array operations that are broadcast to all processor elements in the array. The control processor performs the scalar sections of the application, interfaces with the outside world, and controls the flow of execution; the array processor performs the array sections of the application as directed by the control processor.

A suitable application for use on an array processor has several key characteristics: a significant amount of data that has a regular structure; computations on the data that are uniformly applied to many or all elements of the dataset; and simple and regular patterns relating the computations and the data. An example of an application that has these characteristics is the solution of the Naviér– Stokes equations, although any application that has significant matrix computations is likely to benefit from the concurrent capabilities of an array processor.

The programmer's reference point for an array processor is typically the high-level language level; the programmer is concerned with describing the relationships between the data and the computations but is not directly concerned with the details of scalar and array instruction scheduling or the details of the interprocessor distribution of data within the processor. In fact, in many cases, the programmer is not even concerned with size of the array processor. In general, the programmer specifies the size and any

Table 5. Typical Array Processors (SIMD)

Processor	Year of introduction	Memory model	Processor element	Number of processors
Burroughs BSP	1979	Shared	General purpose	16
Thinking Machine CM-1	1985	Distributed	Bit-serial	Up to 65,536
Thinking Machine CM-2	1987	Distributed	Bit-serial	4,096–65,536
MasPar MP-1	1990	Distributed	Bit-serial	1,024–16,384

specific distribution information for the data and the compiler maps the implied virtual processor array onto the physical processor elements that are available and generates code to perform the required computations. Thus, although the size of the processor is an important factor in determining the performance that the array processor can achieve, it is not a fundamental characteristic of an array processor.

The primary characteristic of a SIMD processor is whether the memory model is shared or distributed. In this section, only processors using a distributed memory model are described as this configuration is used by SIMD processors today and the cost of scaling a shared-memory SIMD processor to a large number of processor elements would be prohibitive. Processor elements and network characteristics are also important in characterizing a SIMD processor.

Vector Processors. A vector processor is a single processor that resembles a traditional SISD processor except that some of the function units (and registers) operate on vectors—sequences of data values that are seemingly operated on as a single entity. These function units are deeply pipelined and have a high clock rate; although the vector pipelines have as long or longer latency than a normal scalar function unit, their high clock rate and the rapid delivery of the input vector data elements results in a significant throughput that cannot be matched by scalar function units.

Early vector processors processed vectors directly from memory. The primary advantage of this approach was that the vectors could be of arbitrary lengths and were not limited by processor resources; however, the high start-up cost, limited memory system bandwidth, and memory system contention proved to be significant limitations. Modern vector processors require that vectors be explicitly loaded into special vector registers and stored back into memory, the same course that modern scalar processors have taken for similar reasons. However, as vector registers can rapidly produce values for or collect results from the vector function units and have low startup costs, modern register-based vector processors achieve significantly higher performance than the earlier memory-based vector processors for the same implementation technology.

Modern processors have several features that enable them to achieve high performance. One feature is the ability to concurrently load and store values between the vector register file and main memory while performing computations on values in the vector register file. This feature is important because the limited length of vector registers requires that vectors that are longer be processed in segments—a technique called strip-mining. Not being able to overlap memory accesses and computations would pose a significant performance bottleneck.

Just like SISD processors, vector processors support a form of result bypassing—in this case called chaining—that allows a follow-on computation to commence as soon as the first value is available from the preceding computation. Thus, instead of waiting for the entire vector to be processed, the follow-on computation can be significantly overlapped with the preceding computation that it is dependent on. Sequential computations can be efficiently compounded and behave as if they were a single operation with a total latency equal to the latency of the first operation with the pipeline and chaining latencies of the remaining operations but none of the startup overhead that would be incurred without chaining. For example, division could be synthesized by chaining a reciprocal with a multiply operation. Chaining typically works for the results of load operations as well as normal computations. Most vector processors implement some form of chaining.

A typical vector processor configuration consists of a vector register file, one vector addition unit, one vector multiplication unit, and one vector reciprocal unit (used in conjunction with the vector multiplication unit to perform division); the vector register file contains multiple vector registers. In addition to the vector registers, there are also a number of auxiliary and control registers, the most important of which is the vector length register. The vector length register contains the length of the vector (or the loaded subvector if the full vector length is longer than the vector register itself) and is used to control the number of elements processed by vector operations. There is no reason to perform computations on non-data that is useless or could cause an exception.

As with the array processor, the programmer's reference point for a vector machine is the high-level language. In most cases, the programmer sees a traditional SISD machine; however, as vector machines excel on vectorizable loops, the programmer can often improve the performance of the application by carefully coding the application, in some cases explicitly writing the code to perform strip-mining, and by providing hints to the compiler that help to locate the vectorizable sections of the code. This situation is purely an artifact of the fact that the programming languages are scalar oriented and do not support the treatment of vectors as an aggregate data type but only as a collection of individual values. As languages are defined (such as Fortran 90 or High-Performance Fortran) that make vectors a fundamental data-type, then the programmer is exposed less to the details of the machine and to its SIMD nature.

The vector processor has one primary characteristic. This characteristic is the location of the vectors; vectors can be memory-or register-based. There are many features that vector processors have that are not included here because of their number and many variations. These features include variations on chaining, masked vector operations based on a boolean mask vector, indirectly addressed vector operations (scatter/gather), compressed/expanded vector operations, reconfigurable register files, multiprocessor support, and soon. Vector processors have developed dramatically from simple memory-based vector processors to modern multiple-processor vector processors that exploit both SIMD vector and MIMD style processing.

MISD – Multiple Instruction, Single Data Stream

Although it is easy to both envision and design MISD processors, there has been little interest in this type of parallel architecture. The reason, so far anyway, is that there are no ready programming constructs that easily map programs into the MISD organization.

Conceptually, MISD architecture can be represented as multiple independently executing function units operating on a single stream of data, forwarding results from one function unit to the next, which, on the microarchitecture level, is exactly what the vector processor does. However, in the vector pipeline, the operations are simply fragments of an assembly-level operation, as distinct from being a complete operation. Surprisingly, some of the earliest attempts at computers in the 1940s could be seen as the MISD concept. They used plug boards for programs, where data in the form of a punched card was introduced into the first stage of a multistage processor. A sequential series of actions was taken where the intermediate results were forwarded from stage to stage until, at the final stage, a result would be punched into a new card.

There are, however, more interesting uses of the MISD organization. Nakamura has pointed out the value of an MISD machine called the SHIFT machine. In the SHIFT machine, all data memory is decomposed into shift registers. Various function units are associated with each shift column. Data is initially introduced into the first column and is shifted across the shift register memory. In the SHIFT machine concept, data is regularly shifted from memory region to memory region (column to column) for processing by various function units. The purpose behind the SHIFT machine is to reduce memory latency. In a traditional organization, any function unit can access any region of memory and the worst-case delay path for accessing memory must be taken into account. In the SHIFT machine, we must only allow for access time to the worst element in a data column. The memory latency in modern machines is becoming a major problem – the SHIFT machine has a natural appeal for its ability to tolerate this latency.

MIMD – Multiple Instruction, Multiple Data Stream

The MIMD class of parallel architecture brings together multiple processors with some form of interconnection. In this configuration, each processor executes completely independently, although most applications require some form of synchronization during execution to pass information and data between processors. Although no requirement exists that all processor elements be identical, most MIMD configurations are homogeneous with all processor elements identical. There have been heterogeneous MIMD configurations that use different kinds of processor elements to perform different kinds of tasks, but these configurations have not yielded to general-purpose applications. We limit ourselves to homogeneous MIMD organizations in the remainder of this section.

MIMD Programming and Implementation Considerations. Up to this point, the MIMD processor with its multiple processor elements interconnected by a network appears to be very similar to a SIMD array processor. This similarity is deceptive because there is a significant difference between these two configurations of processor elements—in the array processor, the instruction stream delivered to each processor element is the same, whereas in the MIMD processor, the instruction stream delivered to each processor element is independent and specific to each processor element. Recall that in the array processor, the control processor generates the instruction stream for each processor element and that the processor elements operate in lock step. In the MIMD processor, the instruction stream for each processor element is generated independently by that processor element as it executes its program. Although it is often the case that each processor element is running pieces the same program, there is no reason that different processor elements should not run different programs.

The interconnection network in both the array processor and the MIMD processor passes data between processor elements; however, in the MIMD processor, it is also used to synchronize the independent execution streams between processor elements. When the memory of the processor is distributed across all processors and only the local processor element has access to it, all data sharing is performed explicitly using messages and all synchronization is handled within the message system. When the memory of the processor is shared across all processor elements, synchronization is more of a problem—certainly messages can be used through the memory system to pass data and information between processor elements, but it is not necessarily the most effective use of the system.

When communications between processor elements is performed through a shared-memory address space, either global or distributed between processor elements (called distributed shared memory to distinguish it from distributed memory), there are two significant problems that develop. The first is maintaining memory consistency; the programmer-visible ordering effects of memory references both within a processor element and between different processor elements. The second is cache coherency; the programmer-invisible mechanism ensures that all processor elements see the same value for a given memory location. Neither of these problems is significant in SISD or SIMD array processors. In a SISD processor, there is only one instruction stream and the amount of reordering is limited so the hardware can easily guarantee the effects of perfect memory reference ordering and thus there is no consistency problem; because a SISD processor has only one processor element, cache coherency is not applicable. In a SIMD array processor (assuming distributed memory), there is still only one instruction stream and typically no instruction reordering; because all interprocessor element communications is via message, there is neither a consistency problem nor a coherency problem.

The memory consistency problem is usually solved through a combination of hardware and software techniques. At the processor element level, the appearance of perfect memory consistency is usually guaranteed for local memory references only, which is usually a feature of the processor element itself. At the MIMD processor level, memory consistency is often only guaranteed through explicit synchronization between processors. In this case, all nonlocal references are only ordered relative to these synchronization points. Although the programmer must be aware of the limitations imposed by the ordering scheme, the added performance achieved using nonsequential ordering can be significant.

The cache coherency problem is usually solved exclusively through hardware techniques. This problem is significant because of the possibility that multiple processor elements will have copies of data in their local caches, each copy of which can have different values. There are two primary techniques to maintain cache coherency. The first is to ensure that all processor elements are informed of any change to the shared-memory state—these changes are broadcast throughout the MIMD processor and each processor element monitors these changes (commonly referred to as snooping). The second is to keep track of all users of a memory address or block in a directory structure and to specifically inform each user when there is a change made to the shared-memory state. In either case, the result of a change can be one of two things, either the new value is provided and the local value is updated or all other copies of the value are invalidated.

As the number of processor elements in a system increases, a directory-based system becomes significantly better as the amount of communications required to maintain coherency is limited to only those processors holding copies of the data. Snooping is frequently used within a small cluster of processor elements to track local changes – here the local interconnection can support the extra traffic used to maintain coherency because each cluster has only a few processor elements in it.

The primary characteristic of a MIMD processor is the nature of the memory address space; it is either separate or shared for all processor elements. The interconnection network is also important in characterizing a MIMD processor and is described in the next section. With a separate address space (distributed memory), the only means of communications between processor elements is through messages and thus these processors force the programmer to use a message-passing paradigm. With a shared address space (shared memory), communications between processor elements is through the memory system—depending on the application needs or programmer preference, either a shared memory or message passing paradigm can be used.

The implementation of a distributed-memory machine is far easier than the implementation of a shared-memory machine when memory consistency and cache coherency is taken into account. However, programming a distributed memory processor can be much more difficult because the applications must be written to exploit and not be limited by the use of message passing as the only form of communications between processor elements. On the other hand, despite the problems associated with maintaining consistency and coherency, programming a shared-memory processor can take advantage of whatever communications paradigm is appropriate for a given communications requirement and can be much easier to program. Both distributed-and shared-memory processors can be extremely scalable and neither approach is significantly more difficult to scale than the other.

MIMD Rationale. MIMD processors usually are designed for at least one of two reasons: fault tolerance or program speedup. Ideally, if we have n identical processors, the failure of one processor should not affect the ability of the multiprocessor to continue program execution. However, this case is not always true. If the operating system is designated to run on a particular processor and that processor fails, the system fails. On the other hand, some multiprocessor ensembles have been built with the sole purpose of high-integrity, fault-tolerant computation. Generally, these systems may not provide any program speedup over a single processor. Systems that duplicate computations or that triplicate and vote on results are examples of designing for fault tolerance.

MIMD Speedup: Partitioning and Scheduling. As multiprocessors simply consist of multiple computing elements, each computing element is subject to the same basic design issues. These elements are slowed down by branch delays, cache misses, and so on. The multiprocessor configuration, however, introduces speedup potential as well as additional sources of delay and performance degradation. The sources of performance bottlenecks in multiprocessors generally relate to the way the program was decomposed to allow concurrent execution on multiple processors. The speedup (*Sp*) of an MIMD processor ensemble is defined as:

$$Sp = T(1)/T(n)$$

or the execution time of a single processor (*T*(*1*)) divided by the execution time for *n* processors executing the same application *(T(n))*. The achievable MIMD speedup depends on the amount of parallelism available in the program (partitioning) and how well the partitioned tasks are scheduled.

Partitioning is the process of dividing a program into tasks, each of which can be assigned to an individual processor for execution at run time. These tasks can be represented as nodes in a control graph. The arcs in the graph specify the order in which execution of the subtasks must occur. The partitioning process occurs at compile time, well before program execution. The goal of the partitioning process is to uncover the maximum amount of parallelism possible without going beyond certain obvious machine limitations.

The program partitioning is usually performed with some a priori notion of program overhead. Program overhead (*o*) is the added time a task takes to be loaded into a processor before beginning execution. The larger the size of the minimum task defined by the partitioning program, the smaller the effect of program overhead. Table 6 gives an instruction count for some various program grain sizes.

The essential difference between multiprocessor concurrency and instruction-level parallelism is the amount of overhead expected to be associated with each task. Overhead affects speedup. If uniprocessor program P_1 does operation W_1, then the parallel version of P_1 does operations W_p, where $W_p \geq W_1$.

For each task T_i, there is an associated number of overhead operations o_{i}, so that if T_i takes W_i operations without

Table 6. Grain Size

Grain Description	Program Construct	Typical number of instructions
Fine grain	Basic block “Instruction-level parallelism”	5 to 10
Medium grain	Loop/Procedure “Loop-level parallelism” “Procedure-level parallelism”	100 to 100,000
Coarse grain	Large task “Program-level parallelism”	100,000 or more

overhead, then

$$W_P = \Sigma(W_i + o_i) \geq W_1$$

where W_p is the total work done by P_p, including overhead. To achieve speedup over a uniprocessor, a multiprocessor system must achieve the maximum degree of parallelism among executing subtasks or control nodes. On the other hand, if we increase the amount of parallelism by using finer- and finer-grain task sizes, we necessarily increase the amount of overhead. Moreover, the overhead depends on the following factors.

- Overhead time is configuration-dependent. Different shared-memory multiprocessors may have significantly different task overheads associated with them, depending on cache size, organization, and the way caches are shared.
- Overhead may be significantly different depending on how tasks are actually assigned (scheduled) at run time. A task returning to a processor whose cache already contains significant pieces of the task code or dataset will have a significantly lower overhead than the same task assigned to an unrelated processor.

Increased parallelism usually corresponds to finer task granularity and larger overhead. Clustering is the grouping together of subtasks into a single assignable task. Clustering is usually performed both at partitioning time and during scheduling run time. The reasons for clustering during partition time might include when

- The available parallelism exceeds the known number of processors that the program is being compiled for.
- The placement of several shorter tasks that share the same instruction or data working set into a single task provides lower overhead.

Scheduling can be performed statically at compile time or dynamically at run time. Static scheduling information can be derived on the basis of the probable critical paths, which alone is insufficient to ensure optimum speedup or even fault tolerance. Suppose, for example, one of the processors scheduled statically was unavailable at run time, having suffered a failure. If only static scheduling had been done, the program would be unable to execute if assignment to all n processors had been made. It is also oftentimes the case that program initiation does not begin with n designated idle processors. Rather, it begins with a smaller number as previously executing tasks complete their work. Thus, the processor availability is difficult to predict and may vary from run to run. Although run-time scheduling has obvious advantages, handling changing systems environments, as well as highly variable program structures, it also has some disadvantages, primarily its run-time overhead.

Run-time scheduling can be performed in a number of different ways. The scheduler itself may run on a particular processor or it may run on any processor. It can be centralized or distributed. It is desirable that the scheduling not be designated to a particular processor, but rather any processor, and then the scheduling process itself can be distributed across all available processors.

Types of MIMD processors. Although all MIMD architectures share the same general programming model, there are many differences in programming detail, hardware configuration, and speedup potential. Most differences develop from the variety of shared hardware, especially the way the processors share memory. For example, processors may share at one of several levels:

- Shared internal logic (floating point, decoders, etc.), shared data cache, and shared memory.
- Shared data cache—shared memory.
- Separate data cache but shared bus—shared memory.
- Separate data cache with separate busses leading to a shared memory.
- Separate processors and separate memory modules interconnected with a multistage interconnection network.
- Separate processor-memory systems cooperatively executing applications via a network.

The basic tradeoff in selecting a type of multiprocessor architecture is between resource limitations and synchronization delay. Simple architectures are generally resource-limited and have rather low synchronization communications delay overhead. More robust processor-memory configurations may offer adequate resources for extensive communications among various processors in memory, but these configurations are limited by

- delay through the communications network and
- multiple accesses of a single synchronization variable.

The simpler and more limited the multiprocessor configuration, the easier it is to provide synchronization communications and memory coherency. Each of these functions requires an access to memory. As long as memory bandwidth is adequate, these functions can be readily handled. As processor speed and the number of processors increase, eventually shared data caches and busses run out of bandwidth and become the bottleneck in the multiprocessor system. Replicating caches or busses to provide additional bandwidth requires management of not only the original traffic, but the coherency traffic also. From the system's point of view, one would expect to find an optimum level of sharing for each of the shared resources—data cache, bus, memory, and so on—fostering a hierarchical view of shared-memory multiprocessing systems.

Multithreaded or shared resource multiprocessing. The simplest and most primitive type of multiprocessor system is what is sometimes called multithreaded or what we call here *shared-resource multiprocessing* (SRMP). In SRMP, each of the processors consists of basically only a register set, which includes a program counter, general registers, instruction counter, and so on. The driving principle behind SRMP is to make the best use of processor silicon area. The functional units and busses are time-shared. The objective is to eliminate context-switching overhead and to reduce the realized effect of branch and cache miss penalties. Each "processor" executes without significant instruction-level concurrency, so it executes more slowly than a more typical SISD, which reduces per instruction effect of processing delays; but the MIMD ensemble can achieve excellent speedup because of the reduced overhead. Note that this speedup is relative to a much slower single processor.

Shared-memory multiprocessing. In the simplest of these configurations, several processors share a common memory via a common bus. They may even share a common data cache or level-2 cache. As bus bandwidth is limited, the number of processors that can be usefully configured in this way is quite limited. Several processors sharing a bus are sometimes referred to as a "*cluster*."

Interconnected multiprocessors. Realizing multiprocessor configurations beyond the cluster requires an interconnection network capable of connecting any one of n processor memory clusters to any other cluster. The interconnection network provides n switched paths, thereby increasing the intercluster bandwidth at the expense of the switch latency in the network and the overall (considerable) cost of the network. Programming such systems may be done either as a shared-memory or message-passing paradigm. The shared-memory approach requires significant additional hardware support to ensure the consistency of data in the memory. Message passing has simpler hardware but is a more complex programming model.

Cooperative computing: networked multiprocessors. Simple processor-memory systems with LAN of even Internet connection can, for particular problems, be quite effective multiprocessors. Such configurations are sometimes called *network of workstations (NOW)*.

Table 7 illustrates some of the tradeoffs possible in configuring multiprocessor systems. Note that the application determines the effectiveness of the system. As architects consider various ways of facilitating interprocessor communication in a shared-memory multiprocessor, they must be constantly aware of the cost required to improve interprocessor communications. In a typical shared-memory multiprocessor, the cost does not scale linearly; each additional processor requires additional network services and facilities. Depending on the type of interconnection, the cost for an additional processor may increase at a greater than linear rate.

For those applications that require rapid communications and have a great deal of interprocessor communications traffic, this added cost is quite acceptable. It is readily justified on a cost-performance basis. However, many other applications, including many naturally parallel applications, may have limited interprocessor communications. In many simulation applications, the various cases to be simulated can be broken down and treated as independent tasks to be run on separate processors with minimum interprocessor communication. For these applications, simple networked systems of workstations provide perfectly adequate communications services. For applications whose program execution time greatly exceeds its interprocessor communication time, it is a quite acceptable message passing time.

The problem for the multiprocessor systems architect is to create a system that can generally satisfy a broad spectrum of applications, which requires a system whose costs scale linearly with the number of processors and whose overall cost effectively competes with the NOW—the simple network of workstations—on the one hand, and satisfies the more aggressive communications requirement for those applications that demand it on the other. As with any systems design, it is impossible to satisfy the requirements of all applications. The designer simply must choose

Table 7. Various Multiprocessor Configurations

Type	Physical sharing	Programmer's model	Remote data access latency	Comments
Multi-threaded	ALU, data cache, memory	Shared memory	No delay	Eliminates context switch overhead but limited possible Sp.
Clustered	Bus and memory	Shared memory	Small delay due to bus congestion	Limited Sp due to bus bandwidth limits.
Interconnection network (1)	Interconnection network and memory	Shared memory	Order of 100 cycles.	Typically 16–64 processors; requires memory consistency support.
Interconnection network (2)	Interconnection network	Message passing	Order of 100 cycles plus message decode overhead	Scalable by application; needs programmer's support.
Cooperative multiprocessors	Only LAN or similar network	Message passing	More than 0.1 ms.	Limited to applications that require minimum communications.

Table 8. Typical MIMD Systems

	Year of	Processor	Number of	Memory	Programming	introduction
System	Interconnection	element	processors	distribution	paradigm	type‡

a broad enough set of applications and design a system robust enough to satisfy those applications. Table 8 shows some representative MIMD computer systems from 1990 to 2000.

COMPARISONS AND CONCLUSIONS

Examples of Recent Architectures

This section describes some recent microprocessors and computer systems, and it illustrates how computer architecture has evolved over time. In the last section, scalar processors are described as the simplest kind of SISD processor, capable of executing only one instruction at a time. Table 1 depicts some commercial scalar processors (7,8).

Intel 8086, which was released in 1978, consists of only 29,000 transistors. In contrast, Pentium III (from the same x86 family) contains more than 28,000,000 transistors. The huge increase in the transistor count is made possible by the phenomenal advancement in VLSI technology. These transistors allow simple scalar processors to emerge to a more complicated architecture and achieve better performance. Many processor families, such as Intel x86, HP PA-RISC, Sun SPARC and MIPS, have evolved from scalar processors to superscalar processors, exploiting a higher level of instruction-level parallelism. In most cases, the migration is transparent to the programmers, as the binary codes running on the scalar processors can continue to run on the superscalar processors. At the same time, simple scalar processors (such as MIPS R4000 and ARM processors) still remain very popular in embedded systems because performance is less important than cost, power consumption, and reliability for most embedded applications.

Table 2 shows some representative superscalar processors from 1992 to 2004 (7,8). In this period of time, the number of transistors in a superscalar processor has escalated from 1,000,000 to more than 100,000,000. Interestingly, most transistors are not used to improve the instruction-level parallelism in the superscalar architectures. Actually, the instruction issue width remains roughly the same (between 2 to 6) because the overhead (such as cycle time penalty) to build a wider machine, in turn, can adversely affect the overall processor performance. In most cases, many of these transistors are used in the on-chip cache to reduce the memory access time. For instance, most of the 140, 000,000 transistors in HP PA-8500 are used in the 1.5MB on-chip cache (512 KB instruction cache and 1MB data cache).

Table 3 presents some representative VLIW processors (7,9). There have been very few commercial VLIW processors in the past, mainly due to poor compiler technology. Recently, there has been major advancement in VLIW compiler technology. In 1997, TI TMS320/C62x became the first DSP chip using VLIW architecture. The simple architecture allows TMS320/C62x to run at a clock frequency (200MHz) much higher than traditional DSPs. After the demise of Multiflow and Cydrome, HP acquired their VLIW technology and co-developed the IA-64 architecture (the first commercial general-purpose VLIW processor) with Intel.

Although SISD processors and computer systems are commonly used for most consumer and business applications, SIMD and MIMD computers are used extensively for scientific and high-end business applications. As described in the previous section, vector processors and array processors are the two different types of SIMD architecture. In the last 25 years, vector processors have developed from a single processor unit (Cray 1) to 512 processor units (NEC SX-5), taking advantage of both SIMD and MIMD processing. Table 4 shows some representative vector processors. On the other hand, there have not been a significant number of array processors due to a limited application base and market requirement. Table 5 shows several representative array processors.

For MIMD computer systems, the primary considerations are the characterization of the memory address space and the interconnection network among the processing elements. The comparison of shared-memory and message-passing programming paradigms was discussed in the last section. At this time, shared-memory programming paradigm is more popular, mainly because of its flexibility and ease of use. As shown in Table 8, the latest Cray supercomputer (Cray T3E-1350), which consists of up to 2176 DEC Alpha 21164 processors with distributed memory modules, adopts the shared-memory programming paradigm.

Concluding Remarks

Computer architecture has evolved greatly over the past decades. It is now much more than the programmer's view of the processor. The process of computer design starts with the implementation technology. As the semiconductor technology changes, so to does the way it is used in a system. At some point in time, cost may be largely determined by transistor count; later as feature sizes shrink, wire density and interconnection may dominate cost. Similarly, the performance of a processor is dependent on delay, but the delay that determines performance changes as the technology changes. Memory access time is only slightly reduced by improvements in feature size because memory implementations stress size and the access delay is largely determined by the wire length across the memory array. As feature sizes shrink, the array simply gets larger.

The computer architect must understand technology, not only today's technology, but the projection of that technology into the future. A design begun today may not be broadly marketable for several years. It is the technology that is actually used in manufacturing, not today's technology that determines the effectiveness of a design.

The foresight of the designer in anticipating changes in user applications is another determinant in design effectiveness. The designer should not be blinded by simple test programs or benchmarks that fail to project the dynamic nature of the future marketplace.

The computer architect must bring together the technology and the application behavior into a system configuration that optimizes the available process concurrency, which must be done in a context of constraints on cost, power, reliability, and usability. Although formidable in objective, a successful design is a design that provides a lasting value to the user community.

DATAFLOW COMPUTERS: THEIR HISTORY AND FUTURE

INTRODUCTION AND MOTIVATION

As we approach the technological limitations, concurrency will become the major path to increase the computational speed of computers. Conventional parallel/concurrent systems are based mainly on the control-flow paradigm, where a primitive set of operations are performed sequentially on data stored in some storage device. Concurrency in conventional systems is based on instruction level parallelism (ILP), data level parallelism (DLP), and/or thread level parallelism (TLP). These parallelisms are achieved using techniques such as deep pipelining, out-of-order execution, speculative execution, and multithreaded execution of instructions with considerable hardware and software resources.

The dataflow model of computation offers an attractive alternative to control flow in extracting parallelism from programs. The execution of a dataflow instruction is based on the availability of its operand(s); hence, the synchronization of parallel activities is implicit in the dataflow model. Instructions in the dataflow model do not impose any constraints on sequencing except for the data dependencies in the program. The potential for elegant representation of concurrency led to considerable interest in dataflow model over the past three decades. These efforts have led to successively more elaborate architectural implementations of the model. However, studies from past projects have revealed a number of inefficiencies in dataflow computing: the dataflow model incurs more overhead during an instruction cycle compared with its control-flow counterpart, the detection of enabled instructions and the construction of result tokens generally will result in poor performance for applications with low degrees of parallelism, and the execution of an instruction involves consuming tokens on the input arcs and *generating* result token(s) at the output arc(s), which involves communication of tokens among instructions. Recent advances that may address these deficiencies have generated a renewed interest in dataflow. In this article we will survey the various issues and the developments in dataflow computing.

This chapter is organized as follows: the Dataflow Principles section reviews the basic principles of the dataflow model. The discussion includes languages supporting dataflow model. The Dataflow Architectures section provides a general description of the dataflow architecture. The discussion includes a comparison of the architectural characteristics and the evolutionary improvements in dataflow computing, including pioneering pure dataflow architectures, hybrid architectures attempting to overcome the shortcoming of pure dataflow systems, and recent attempts to improve the hybrid systems. The next section outlines research issues in handling data structures, program allocation, and application of cache memories. Several proposed methodologies will be presented and analyzed. Finally, the last section concludes the article.

DATAFLOW PRINCIPLES

The dataflow model of computation deviates from the conventional control-flow method in two fundamental ways: asynchrony and functionality. Dataflow instructions are enabled for execution when all the required operands are available, in contrast to control-flow instructions, which are executed sequentially under the control of a program counter. In dataflow, any two enabled instructions do not interfere with each other and thus can be executed in any order, or even concurrently. In a dataflow environment, conventional concepts such as “variables” and “memory updating” are nonexistent. Instead, objects (data structures or scalar values) are consumed by an actor (instruction) that yields a result object that is passed to the next actor(s). It should be noted that some dataflow languages and architectures, however, use variables and memory locations for the purposes of convenience and of efficiency.

Dataflow Graphs

Dataflow graphs can be viewed as the machine language for dataflow computers. A dataflow graph is a directed graph, $G(N, A)$, where nodes (or actors) in N represent instructions and arcs in A represent data dependencies among the nodes. The operands are conveyed from one node to another in data packets called tokens. The basic primitives of the dataflow graph are shown in Fig. 1. A data value is produced by an operator as a result of some operation f. A true or false control value is generated by a decider (a predicate), depending on its input tokens. Data values are directed by means of either a switch or a merge actor. A switch actor directs an input data token to one of its outputs, depending on the control input. A Merge actor passes one of its input tokens to the output based on the value of the control token. Finally, a copy is an identity operator which duplicates input tokens. Figure 2 depicts the dataflow graph of the following expression:

$$sum = \sum_{i=1}^{\mathrm{N}} f(i)$$

Note the elegance and flexibility of the dataflow graph to describe parallel computation. In this example, the implicit parallelism within an iteration is exposed. Furthermore,

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

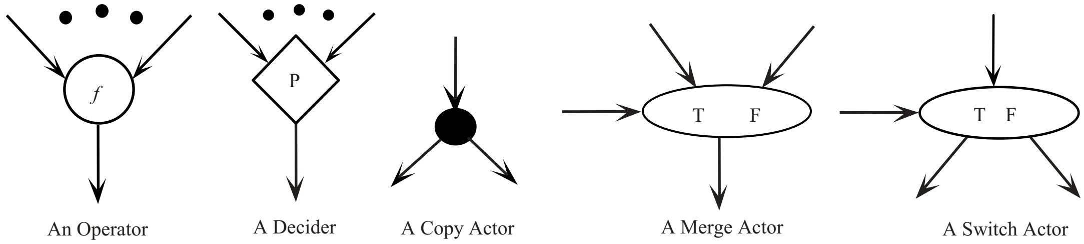

Figure 1. Basic primitives of the dataflow graph.

because of the functional properties of operations, the function *f* can be invoked simultaneously for all values of *i*. Thus, given sufficient amount of resources, *N* iterations of function *f* can be executed concurrently.

Dataflow Languages

Any dataflow language should permit the specification of programs that observe dataflow principles. In terms of programming language semantics, these principles translate into freedom from side-effects (prohibit modification of variables either directly or indirectly), single assignment (values associated with variables cannot be modified), and locality of effect (instructions do not have unnecessary far-reaching data dependencies). In this section we introduce three dataflow languages that received considerable attention in the literature.

VAL: A Value-oriented Algorithmic Language. VAL is a high level programming language developed at MIT (1), and can be viewed as a textual representation of dataflow graphs. VAL relies on pure functional language semantics to exploit implicit concurrency. Since dataflow languages use single assignment semantics, the implementation and the use of arrays present unique challenges (see Research Issues). In VAL, array bounds are not part of the type declarations. Operations are provided to find the range of indices for the declared array. Array construction in VAL is also unusual to improve concurrency in handling arrays. It should be noted that because we must maintain single assignment feature of functional languages, traditional language syntax to accumulate values (for example, the sum in Fig. 2) need some changes. To express such concurrencies, VAL provides parallel expressions in the form of *forall*. Consider the following examples:

```
1. forall i in [array_liml(a), array_limh(a)]

                a[i] := f(i);

2. forall i in [array_liml(a), array_limh(a)]

                eval plus a[i];
```

If one applies imperative semantics, both examples proceed sequentially. In the first case, the elements of the array *a* are constructed sequentially by calling the function *f* with different values of the index *i*. In the second example, we compute a single value that represents the sum of the elements of the array *a*, which represents sequential accumulation of the result. In VAL, the construction of the array elements in example 1 can proceed in parallel because all functions in VAL are side-effect free. Likewise, the accumulation in example 2 also exploits some concurrency because VAL translates such accumulations into a binary tree evaluation.

In addition to loops, VAL provides sequencing operations, *if-then-else* and *tagcase* expressions. When dealing with one of data type, tagcase provides a means of interrogating values with the discriminating unions.

VAL did not provide good support for input/output operation nor for recursion. These limitations allowed for a straightforward translation of programs to dataflow architectures, particularly static dataflow machines (see the earlier Dataflow Architectures section). The dynamic features of VAL can be translated easily if the machine supported dynamic graphs, such as the dynamic dataflow architectures.

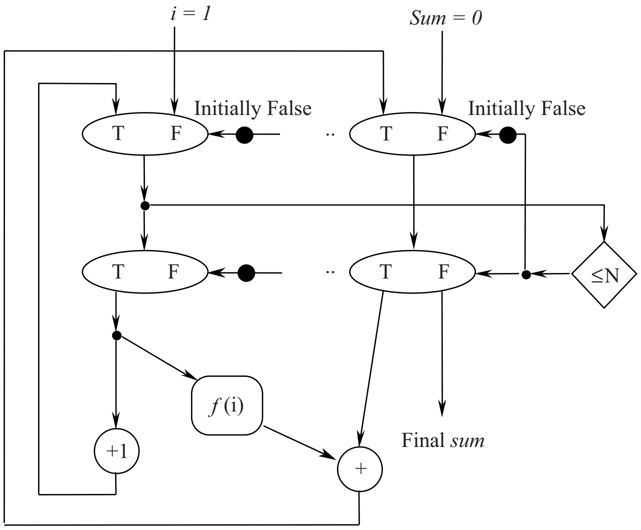

Figure 2. A dataflow graph representation of $sum = \sum_{i=1}^{N} f(i)$.

Id: Irvine Dataflow language. Id is a dataflow language that originated at the University of California-Irvine (2), and was designed to permit high-level programming language for the dynamic dataflow architecture proposed by Arvind (see the Earlier Dataflow Architectures section). Id is a block-structured, expression-oriented, single assignment language. An interpreter was designed to execute Id programs on dynamic dataflow architectures. Data types in Id are associated with values, and variables are typed implicitly by the values they carry. Structures include both arrays and (record) structures; and elements can be accessed using either integer indices or string values that define the name of the element (for example, t[“height”]). Structures are defined with two operators: select and append. Select is used to get the value of an element, whereas append is used to define a new structure by copying the elements of the original structure and adding new values defined by the append operation.

Id programs consist of side-effect free expressions and expressions (or subexpressions) can be executed in any order or concurrently based on the availability of input data. Loops in Id can be understood easily from the following example, which computes $\sum_{i=1}^{N} f(i)$

```
(initial i ← 1; sum ← 0;
while i ≤ N do new i ← i+1;
          new sum ← sum + f(i);
          return sum)
```

Id uses the concept of “new” to define a new value associated with an expression. It should be noted that a variable is not assigned a new value (like in conventional languages), but a new value is generated – variables are used only for the convenience of writing programs. It is also convenient to remember that the expressions in a loop can form recurrence expressions.

Procedures and functions in Id are pure functions and represent value(s) returned by the application of the function on the input values. Recursive procedures can be defined by associating names with procedure declarations. For example:

$$\mathrm{y} \leftarrow \text{procedure } \mathrm{f(n)}(\text{if } \mathrm{n} = 0 \text{ then } 1\text{else } \mathrm{n}^{*}\mathrm{f(n\text{-}1)})$$

defines factorial recursively, and we can invoke the procedure, for example as y(3).

Because no translators to convert Id programs to conventional (control-flow) architectures were developed, Id was used mostly by those with access to dynamic dataflow processors and to Id interpreters.

SISAL: Streams and Iterations in a Single Assignment Language. Sisal is the best-known dataflow language, mostly because of the support provided by the designers. Sisal received a fairly wide acceptance during the 1990s, because Sisal compilers generated optimized C as their intermediate representations and thus could be run on any platform with a C compiler. Although it is not as widely known now, Sisal translator and run-time support software are still available for Unix based systems and can be obtained from the web at http://sisal.sourceforge.net/. Sisal 2.0 provided multitasking (or multithreading) to support dataflow-style parallelism on conventional shared memory multiprocessors (4).

Sisal programs consist of one or more separately compilable units, which include a simple program, modules, and interfaces. A module is similar to a program but is not a starting point of execution. It pairs with an interface to export some of its types and function names. Like Id, Sisal supports scalar data types and structures (records, union, arrays, and streams). A stream is a sequence of values produced in order by one expression (thus it consists of homogeneous typed values), and is consumed in the same order by one or more other expressions. Sisal permits the creation of new values (and associates them with the same name).

```
for i := 1;
while ( i <5) do
          new i := i+2;
          j := i + new i;
returns product (i+j)
end for
```

This program constructs implicitly a stream of values inside the loop and returns the product of the elements of the stream. The values of the stream are the values of (i + j): 7, 13. Thus 91 is returned by the loop.

Sisal expressions can loop over the elements of an array (called array scattering) or over the elements of a stream (stream scattering) (5). As with VAL, Sisal can perform reduction operations concurrently using binary tree evaluations. Sisal has predefined reduction operations to evaluate sum, product, min, and max of a set of values. Catenate is a reduction that returns the concatenation of a sequence of one-dimensional array or a stream. Consider:

```
for i in[ 1..N] do
          return sum f(i);
```

which uses sum as a reduction operation to produce $\sum_{i=1}^{N} f(i)$.

Additional reduction functions can be defined by the programmer. Consider the following example to build histograms.

```
reduction histo(v, N: integer returns array of integer)
initial
          hacc := array[0..N+1:0] ;
 in

          idx := if(v <1) then 0
                    elseif (v > N) then n+1
                    else v
                    end if;
          new hacc := hacc[idx: hacc[ idx] +1]
returns hacc
end reduction
```

Sisal’s popularity also is caused by the concept of modules and interfaces: The interface shows the function templates that are visible publicly and the module defines the implementations of the functions. Sisal implementations also permit foreign code (written in a different language), by associating an interface with the foreign

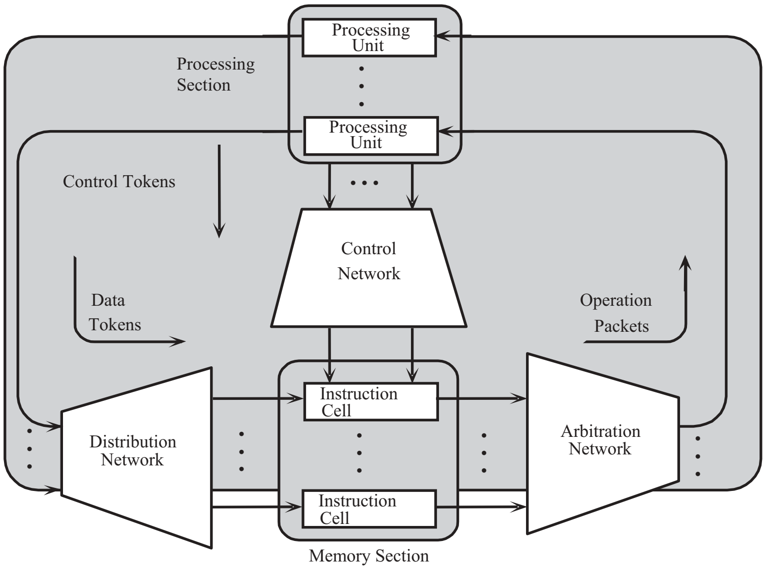

Figure 3. The basic organization of the static dataflow model.

code. Consider for example to import MathLib functions to Sisal programs:

```
interface MathLib in FORTRAN
          function sin (x: real returns real);
          function tan (x: real returns real);
end interface
```

DATAFLOW ARCHITECTURES

Architectural implementations of dataflow traditionally have been classified as either static or dynamic. The static approach allows at most one instance of a node to be enabled for firing, i.e., a dataflow actor can be executed only when all of its input tokens are available and no tokens exist on any of its output arcs. On the other hand, the dynamic approach permits simultaneous activation of several instances of a node during the run-time by viewing arcs as buffers containing multiple data items. To distinguish between different instances of a node (and routing data for different instantiations of the node), a tag is associated with each token that identifies the context in which a particular token was generated. An actor is considered executable when all of its input tokens with identical tags are available.

The static dataflow model has a simplified inherent mechanism to detect enabled nodes, but the model limits the performance because iterations are executed one at a time. The dynamic dataflow allows greater exploitation of parallelism; however, this advantage comes at the expense of the overhead in terms of the generation of tags, larger data tokens, and complexity of the matching tokens. A more subtle problem with the token matching is the complexity involved in allocation of resources (i.e., memory cells). A failure to find a match implicitly allocates memory within the matching hardware. If the matching unit becomes overcommitted, the program may deadlock.

Dataflow architectures have also been classified as pure dataflow architectures, macro dataflow architectures, and hybrid dataflow architectures. Detailed discussion about this classification is beyond the scope of this article and interested reader is referred to Ref. 6.

Earlier Dataflow Architectures

This section discusses three classic dataflow machines: the static dataflow machine, the (dynamic) manchester machine, and the explicit token store. These projects represent the pioneering work in the area of dataflow. The foundation they provide has inspired many other dataflow projects.

Static Model. The general organization of the original (static) dataflow machine is depicted in Fig. 3 (Table 1) (7). The memory section is a collection of memory cells, each cell composed of three memory words that represent an instruction template. The first word of each instruction cell contains op-code and destination address(es), and the next two words represent the operands. The design has envisioned six types of templates that represent binary and unary operators, binary and unary deciders (predicates), and binary and unary Boolean operators. The processing section is composed of five pipelined functional units, which perform the operations, form the result packet(s), and send the result token(s) to the memory section. The arbitration network is intended to establish a smooth flow of enabled instructions (i.e., instruction packet) from the memory section to the processing section. An instruction packet contains the corresponding op-code, operand value(s), and destination address(es). The distribution network is intended to transfer the result packets from the processing section to the memory section. Finally, the control network in designed to reduce the load on the distribution network by transferring the Boolean tokens and the acknowledgement signals from the processing section to the memory section.

Figure 4 shows the dataflow graph and the contents of the memory section for the $Y(t) = A^*X(t) + B^*Y(t\text{-}1)$

$+C^*Y(t\text{-}2)$. For the sake of simplicity, representation details in the memory are omitted. Note that each memory cell is numbered to correspond to the node number in the dataflow graph.

Manchester Dynamic Model. Figure 5 shows the block diagram of the *dynamic dataflow* system prototyped at the Manchester University (Table 1). It is designed as a back-end, composed of five units organized as a pipeline ring: The switch unit establishes communication between the front-end and back-end processor, and routes the result tokens back to the pipeline ring. The token queue is a First-in-first-out buffer that stores temporarily tokens traversing on the data-flow graph arcs. The basic operation of the matching unit is to bring together tokens with identical tags by pairing associatively tokens with the same destination node address and context. The dataflow program that represents the code for an operation is stored in the node store. The processing unit, a micro-programmed, 2-stage pipeline unit, executes the dataflow operations. The first stage handles the generation of result tokens and the association of tags with tokens. The second pipeline stage consists of 15 functional units to perform the necessary operations.

Explicit Token Store. Despite the potential parallelism promised by the dynamic dataflow model, early experiences have identified the following shortcomings in implementing the model:

- Overhead involved in matching tokens (and the need for associative matching),
- Complex resource allocation,
- The inefficiency of the dataflow instruction cycle (token driven models require multiple cycles through the pipeline to complete execution), and
- Nontrivial mechanisms to handle data structures (see the Research Issues section).

Performance of the dynamic dataflow architecture is related directly to the rate at which the matching unit operates. To facilitate this process while considering the cost, Arvind proposed a pseudo-associative matching mechanism that requires typically several memory accesses (9). A failure in finding a match implicitly allocates

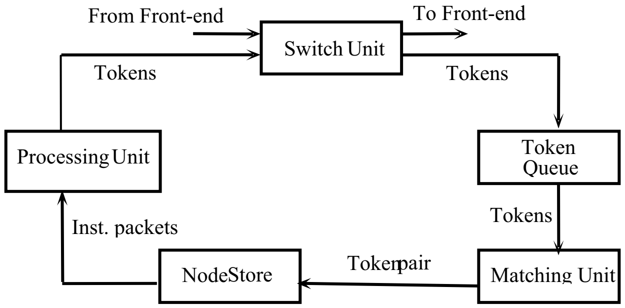

Figure 5. The Manchester Dynamic dataflow Machine.

memory within the matching unit — mapping a code-block to a processor places an unspecified commitment on the processor's matching unit. This can result in a deadlock if this resource becomes overcommitted. Another problem with dataflow processing is caused by the duration of the instruction cycle relative to its control-flow counterpart.

To overcome the inefficient matching of dynamic dataflow model, explicit token store (ETS) proposed a direct matching (9). Storage (called *activation frames*) is allocated dynamically for all the tokens that can be generated by a code block (a code block represents a function or a loop iteration). The usage of memory locations within the activation frame is determined at compile time; however the allocation of storage is determined at run time. A computation is described completely by an instruction pointer (IP) and an activation frame pointer (FP) and the pair <FP. IP> called a *continuation*. A typical instruction specifies an opcode, an offset in the activation frame where a match for its inputs will take place, and one or more displacements that define the destination instructions that will receive the result token(s). Each displacement is also accompanied by an input port (left/right) indicator that specifies the appropriate input arc for a destination actor. Figure 6 shows an example of the ETS code block invocation and its corresponding instruction and frame memory. When a token arrives at an actor (for example, Add), the IP part of the continuation points to the instruction that contains an offset *r* as well as displacements for the destination instructions. The system achieves the actual matching process by checking the disposition of the slot in the frame memory pointed to by $FP + r$. If the slot is empty, the system writes the token's value in the slot and sets its presence bit to indicate that the slot is full. If the slot is already full, the system extracts the value, leaving the slot empty, executes the corresponding instruction, and communicates the result tokens to the destination instructions by updating the IP according to the destinations encoded in the instruction.

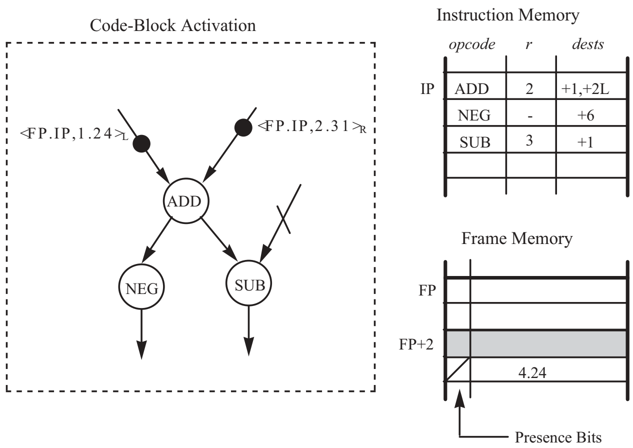

Figure 6. Explicit-token-store representation of a dataflow program.

Table 1 lists early dataflow architectures that have been advanced in the literature. Because of the space constraints, additional discussion about these architectures are beyond the scope of this article and the interested reader is referred to the cited references.

Dataflow Architectures of the 1980s and the 1990s

Relying on the lessons learned from early designs, several dataflow prototypes were designed during the 1980s and the 1990s. These include Monsoon, Epsilon-2, EM-4, P-RISC, and TAM. Table 2 summarizes the architectural characteristics of these designs (18–23).

These prototypes use the dynamic dataflow paradigm, primarily because of the success of direct matching of tokens proposed in ETS. The concept of a code-block in ETS permitted localization and efficient management of tokens. Activation frames can be allocated for different iterations of a loop, thus permitting the "unfolding" of loops.

Another major architectural change was the integration of the control-flow sequencing with the dataflow model. Dataflow architectures that are based on the pure dataflow model, such as the Manchester dataflow machine, provide well-integrated synchronization at the instruction level. However, this process is very inefficient when compared with the synchronization used in control-flow systems. It has been shown that it is more efficient to assign some of these responsibilities to the compiler and to use a simpler control-flow sequencing at run-time. The overhead of constructing and communicating result tokens can be reduced by using processor registers to hold intermediate results (similar to control-flow processors). The hybrid of dataflow flow with control-flow sequencing and usage of registers can be found in EM-4, and the Epsilon-2.

In contrast to these hybrid systems, the threaded abstract machine (TAM) provided a conceptually different perspective on the implementation of the dataflow model of computation. In TAM, the execution model for fine-grain parallelism is supported by an appropriate compilation strategy and program representation rather than by elaborate hardware. By assigning the synchronization, the scheduling, and the storage management tasks to the compiler, the use of processor resources can be optimized for the expected case, rather than for the worst case. In addition, because the scheduling of threads is visible to the compiler, TAM allowed for a more flexible use of registers across thread boundaries.

Recent Dataflow Projects

Since the mid 1980s, computer architecture has expended a considerable effort in exploitation of ILP as a means to improve performance. These efforts manifested in the

Table 2. Dataflow architectures of 80’s and 90’s.

Architecture	Key features
Monsoon (18)	• Joint venture between MIT and Motorola was an outgrowth of the MIT Tagged-Token Dataflow Architecture. • A collection of processing elements communicating with each other and a set of interleaved I-structure memory modules through a multistage packet switching network. • Direct matching of tokens based on the Explicit Token Store concept.
EM-4 (19)	• A highly parallel dataflow multiprocessor based on the SIGMA-1 project. It was an attempt to simplify the architecture by a RISC-based single-chip design, a direct matching scheme, and use of strongly connected arc model. • Use of registers to reduce the instruction cycle time and the communication overhead of transferring tokens. • Integration of a token-based circular pipeline and a register-based advanced control pipeline. • The prototyped processing element consists of a memory module and a single chip processor called EMC-R.
Epsilon-2 (20)	• Epsilon-2 is a multiprocessor dynamic dataflow model evolved from the Epsilon-1 project. It is composed of a set of processing modules contented via a global interconnection network. • Direct matching of tokens. • Repeat fan-out mechanism to reduce the overhead in copying tokens. • Control-flow type of sequencing and use of registers. Register contents are not necessarily preserved across grain boundaries. • Load balancing (adaptive routing).
P-RISC (21)	• P-RISC is a multiprocessor architecture strongly influenced by Iannucci’s dataflow/von Neumann hybrid architecture. It utilizes a RISC-like Instruction set and its generalization for parallel-RISC. Can use both conventional and dataflow compiling technologies. • Application of multithread using a token queue and circulating thread descriptors. • Introduction of Fork and Join instructions to spawn and synchronize multiple threads. • Synchronization of memory accesses by using I-structure semantics.
TAM (22)	• Placing all synchronization, scheduling, and storage management responsibility for execution of fine-grain parallelism explicit and under compiler control to relieve hardware complexity. This allows execution of dataflow languages on conventional control-flow processors. • Providing a basis for scheduling a number of threads within an activation as a quantum while carrying values in registers across threads. • Once an activation is made resident, all enabled threads within the activation execute to completion. • Having the compiler produce specialized message handlers as inlets to each code-block. • A prototype TAM instruction set, TL0 (Threaded Language Version 0), has been developed at the University of California at Berkeley.
*T (23)	• Tokens do not carry data, only continuations. • Provides limited token matching. • Overhead is reduced by off-loading the burden of message handling and synchronization to separate coprocessors.

design and the implementation of the so called superscalar, Very Long Instruction Word, super-speculative, and superpipelined organizations. In these organizations, ILP is exploited through deep pipelining and out-of-order execution of instructions. Aggressive exploitation of ILP is made possible by wide dispatch and issue of instruction, by a large issue buffers, by a large number of physical registers for register renaming, by a large number of functional units, and by a speculative execution of branches. Whether the instruction placement and issue are done statically as in VLIW architecture, or dynamically as in superscalar paradigm, the hardware complexity of these architectures, combined with the diminishing performance gains, renewed an interest in dataflow processing. This interest has resulted in several dataflow based architectures, such as the scheduled dataflow (SDF) (24), the EDGE (Explicit Data Graph Execution) (25), the WaveScalar (26), and the D^{2}NOW (Data-Driven Network of Workstations) (27).

Scheduled Dataflow (SDF). Unlike instruction level dataflow systems, SDF (24) uses dataflow-like synchronization at the thread-level, and control-flow semantics within a thread. A thread is allocated as an activation frame for receiving its inputs, similar to Cilk (28). A thread is enabled for execution when it has received all its inputs, and completes execution without interruption (viz., non-blocking threads). This approach minimizes instruction level communication, and because SDF threads are very fine-grained (typically a basic block), the amount of parallelism lost because of the sequential execution of instructions within a thread is minimal. Additionally, SDF decouples completely all memory accesses from execution pipelines, resulting in overlapped execution of threads. When a thread is enabled, SDF allocates a register set for the thread. Data is *pre-loaded* into the register set context prior to its scheduling on the execution pipeline. After a thread completes execution, the results are *post-stored* from its registers into memory. All memory accesses are performed by synchronization processors (SPs). The execution engines (EPs) rely on in-order execution of instructions within a thread. This architecture exploits two levels of parallelism: Multiple threads can be active simultaneously, permitting thread level parallelism, and the three phases of a thread execution (pre-load, execute, and post-store) can be overlapped with those of other threads. It is also possible to select appropriate number of SPs and EPs to meet application needs. Thread level speculation to improve performance of imperative programs is simplified in SDF system. Similar to the WaveScalar design, epoch numbers are associated with threads along with extended cache coherency protocols to commit (post-store) the results of a speculative thread in program order.

Explicit Data Graph Execution (EDGE). EDGE (25) is a static placement dynamic issue instruction model. It is designed to allow direct instruction communication: hardware delivers a producer's output directly as an input to a consumer instruction, (i.e., fine grained instruction scheduling). The TRIP architecture is an instantiation of an EDGE design. The TRIP prototype is a collection of 16 execution units that communicate with each other via a thin operand routing network. Each processing element includes an integer unit, a floating point unit, an operand router, and an instruction buffer of depth 128 (to hold multiple instructions and their operands). The scheduler determines which instructions to be assigned in each processor buffer (viz., Static placement). However, the availability of operands determines the order of the execution (viz., Dynamic issue).

WaveScalar. Similar to EDGE, WaveScalar (26) is a tiled architecture. It is a tagged-token dynamic dataflow machine composed of processing elements. Instructions are bound dynamically to processing elements during the execution phase. It should be noted that once an instruction is bound to a processing element, it can remain there for many dynamic executions. A processing element is composed of an interface to receive data tokens: a storage medium to store data tokens awaiting their matching partner. Upon the execution of an instruction, the output tokens are routed to the consumer processing element(s). To reduce the communication costs, the processing elements are connected through a hierarchical interconnection infrastructure—pairs of processing elements are coupled into *pods* sharing ALU results via a common bypass network. Four pods are grouped into *domains* that communicate over a set of pipelined busses. Four domains form a cluster supported by conventional memory hierarchy. To build larger machines, multiple clusters can be connected with each other by a grid-based, on-chip network.

Data-Driven Network of Workstations. D^{2}NOW (27) is a collection of off-the-shelf Pantium microprocessors interconnected through a fine-grained interconnection network that supports the thread level synchronization. The design is based on an earlier Decoupled Data Driven model of execution and in principal similar to the SDF model (24). To tolerate the communication latency, D^{2}NOW employs three mechanisms: fine-grained communication, medium-grained communication, and coarse-grained communication. The fine-grained communication is used for consumer identification and for data-token transfer. The medium-grained communication is for the medium size messages that identify a code block. The coarse-grained communication is through the Ethernet to support large data block transfers.

SOME RESEARCH ISSUES

Handling Data Structures

In pure dataflow model, no concept of a variable exists and data is exchanged in the form of tokens flowing between instructions (or if memory is used to store data, then variables can only be assigned a value once – the single assignment principle). To apply this property to arrays and structures, the entire structure must be carried as tokens (or new arrays and structures must be allocated, by copying unchanged items and by assigning new values to the elements that have been modified). In practical dataflow systems, a more efficient treatment of structures and of arrays is needed. The proposed solutions can be classified as either direct access or indirect access methods.

Direct Access Method. The direct access scheme treats each array elements as individual (scalar) data tokens — which eliminates the concept of an array (or structure). The token relabeling scheme proposed by Gaudiot is an example of direct access method (29). In this approach, tokens are identified by tags, associating the values with specific array elements. Although this method is simple, it requires entire data structures be passed from one node to the next or to be duplicated among different nodes. Moreover, in many applications, the notion of array as a single entity cannot be done away with completely, and thus the direct access method is inappropriate for such applications.

Indirect Access Method. In an indirect access scheme, arrays are stored in special (separate) memory units and their elements are accessed through explicit "read" and "write" operations. For example, in MIT, static dataflow machine arrays are represented as a heap forming a tree (30). VAL (see section on Dataflow Languages) provides constructs to generate and to access arrays. Arrays can be appended with new values, and arrays (and elements of arrays) are accessed using pointers. Modified elements can be made inaccessible by using reference counts with pointers (when the count becomes zero the element becomes inaccessible). The disadvantages of this method are: O(log n) time to access successive elements of an array and sequential nature of the append operations (only one element of an array can be modified at a time), which limits the performance of the system. It also becomes necessary to perform garbage collection of inaccessible elements.

I-structure. I-structures are asynchronous array-like structures that include a "presence" bit with each element of the structure, thus preventing access to undefined array elements and enforcing single assignment property (31).

University of Manchester Approach. This approach combines the concept of streams (i.e., a sequence of values communicated between two portions of a code) with conventional arrays (32). However, in contrast to streams, the size of the array structure must be known at the time it is created. Thus, a finite component is defined as a collection of elements, a "unit," on which the basic storage operations are performed. This scheme implies that the modification of any element(s) in an array requires copying the entire array. Sisal language (see the Dataflow Languages section) provides constructs to create and access arrays, as well as streams. An enhanced version permitted "in-place" updates to alleviate the need to copy unaffected elements.

Hybrid Scheme. The basic idea behind the hybrid scheme is to associate a template, called the structure template, with each conceptual array (33). For selective updates, this minimizes copying by allowing only the modified elements to be appended to the new array. Each array is represented by a hybrid structure that consists of a structure template and a vector of array elements. A structure template is subdivided into three fields:

- The reference count field; an integer indicating the number of references to the array,
- The location field; a string of 1's and 0's where the length of the string equals the total number of elements in the array. Each location bit determines whether the desired array element resides in the vector indicated by either the left ("0") or the right ("1") pointer, and
- The status bit (S); when an array is initially created, the status bit (S) is initialized to "0," which indicates that the vector contains the original array. Whenever a modification is made to an array with more than one reference, a new hybrid structure is created (the status bit set to "1") where all the modified elements can be accessed from the vector pointed by the right pointer. The sharing of array elements between the original and the modified array is achieved by linking the left pointer of the modified hybrid structure back to the original hybrid structure.

Program Allocation

To achieve maximum parallelism, programs must be partitioned and assigned to available resources. The goal is to maximize the parallelism (partition program into independent executable units) while minimizing communication among the executable units (by assigning dependent units to the same processing element). It has been shown that obtaining an optimal allocation of a graph with precedence requirements is an NP-complete problem. Two main (heuristic) approaches exist to allocate subtasks of a dataflow graph: static and dynamic. In static allocation, the tasks are allocated at compile-time using global information about the program and system resources. A dynamic allocation uses run-time information on processing loads and on program behavior to distribute tasks.

A number of heuristic algorithms have been developed for the allocation problem based on critical path list schedules. The basic idea behind these approaches is to assign a weight to each node of a directed graph that equals the maximum execution time from that node to an exit node (i.e., critical path). An ordered list of nodes is constructed according to their weights, which is then used to assign dynamically nodes with highest weights to processors as they become available. One major problem with critical path list schedules is the communication among the nodes. Enforcing only critical path scheduling, without considering the communication overhead, will not necessarily minimize the overall execution time.

In response, Ravi et. al. (34) proposed a variation of the critical path list scheduling which takes into account inter processor communication. In this method, rather than simply choosing the topmost node on the list, several top candidates whose critical paths fall within a certain range are considered for allocation. From this set of candidates, a node is selected which maximizes savings in communication time. To determine the compromise between computation and communication costs, the vertically layered (VL) allocation scheme was proposed in Ref. (35). The VL allocation scheme consists of two phases: separation and optimization. The basic idea behind the separation phase is to partition a dataflow graph into vertical layers such that each vertical layer represents a set of data dependent nodes that are executed in sequence (i.e., a thread). A density factor is used to distribute the directed paths among the processors. The optimization phase attempts to minimize the inter-processor communication costs by considering whether the inter-processor communication overhead offsets the advantage gained by overlapping the execution of two subsets of nodes on separate processors (collapsing the vertical layers assigned to different processors). The VL allocation scheme succeeds in balancing the load among the processors, however, by its very nature, it may not always reduce the total execution time.

A more general approach to program allocation was proposed by Sarkar and Hennessy (36). In contrast to the VL allocation scheme, this approach uses a greedy approximation algorithm. The algorithm begins with the trivial partition that places each node in a separate block. A table that represents the decrease in the critical path length obtained from merging a pair of blocks is maintained. It then merges iteratively blocks that result in the largest decrease in the critical path length. The algorithm is terminated when no remaining merger could possibly reduce the critical path length.

Despite the effectiveness of the aforementioned allocation schemes, one major problem still remains unresolved— the issue of handling dynamic parallelism. For example, a dynamic architecture unfolds a loop at run-time by generating multiple instances of the loop body and attempts to execute the instances concurrently. However, a single processor does not allow two simultaneous executions of a node, consequently, mapping the source dataflow graphs to processors, without special provisions to detect dynamic loop unfolding, results in the inability to exploit parallelism fully.

One solution is to provide a code-copying facility, where an instruction within a code block is duplicated among the available resources. Arvind has proposed a mapping scheme in which the instructions within a code block (called the logical domain) are mapped onto available procesors (called the physical domain) based on a hashing scheme (37). For example, if a physical domain consists of n processors, then the destination processor number can be $\text{processor}_{\text{base}} + i \bmod n$, where i is the iteration number. This will distribute the code uniformly over the physical domain. Because each of the n processors has a copy of the code, n iterations may be executed simultaneously. However, because not all program constructs can be unfolded in this manner, the question still remains as to how dynamic parallelism can be detected at compile-time effectively.

Cache in Dataflow

Multithreading can address memory latencies by context-switching to other thread while awaiting a memory access. In pure dataflow, each instruction can be viewed as a thread, causing excessive overheads. ETS based models and hybrid systems (see the Dataflow Architectures of the 1980s and the 1990s section) have created coarser grained threads using code blocks. Within the context of dataflow, threads are nonblocking: A thread is enabled for execution when it receives all inputs, and executes to completion without interruption or context switch. The nonblocking makes it difficult to overcome memory latencies because a thread cannot be context switched during its execution. Cache memories provide a solution, but in pure dataflow, because instruction execution is based on the availability of data, localities of instructions and data cannot be determined easily, making the inclusion of cache memories wasteful. Several innovative proposals for synthesizing localities in the context of dataflow exist. In Ref. (38), the concept of simultaneity of execution is used to define localities with code. A weight that represents the distance from the root is assigned to each dataflow node. The nodes with the same weight are then clustered on the same (cache) page. This strategy partitions the dataflow graph into K horizontal layers, such that the nodes in layer K_i are data independent from each other (hence they can likely be executed in parallel) and are data dependent on nodes in layer K_{i-1} ($1 < \mathrm{i} \leq \mathrm{K}$).

Other approaches to improve localities and cache in dataflow can be found in Ref. (39). Partitioning dataflow programs into threads will have a direct impact on localities. Allocation of threads to processing resources should use “cache affinities” to minimize cache misses and conflicts. An important issue in multithreading is the partitioning of programs into multiple sequential threads (see the Program Allocation section). The costs associated with creating threads and synchronization among threads will impact the granularity of threads and placement of threads. Schauser et al. (40) proposed a partitioning scheme using dual graphs. A dual graph is a directed graph with data, control, and dependence arcs: A data arc represents the data dependence between producer and consumer nodes. A control arc represents the scheduling order between two nodes, and a dependence arc specifies long latency operation caused by the message handlers (i.e., inlets and outlets) sending/receiving messages across code-block boundaries. The actual partitioning is performed using only the control and the dependence edges by first grouping the nodes based on dependence sets. The dependence sets are used to create safe partitions with no cyclic dependencies. A safe partition has the following characteristics: (1) no output of the partition needs to be produced before all inputs to the partition are available, (2) when the inputs to the partition are available, all the nodes in the partition can be executed, and (3) no arc connects a node in the partition to an input node of the same partition. A number of optimization techniques are performed on initial partitions to reduce synchronization costs. The output of the partitioner is a set of threads where the nodes in each thread are executed sequentially and the synchronization requirement determined statically only occurs at the beginning of a thread. SDF and TAM (see the Dataflow Architectures section) use similar ideas for thread generation.

In the static dataflow architecture, localities can be exploited by concentrating on the static order of the dataflow program. The dynamic approach permits the activation of several instances of a node during run-time. To exploit the temporal and the spatial localities in dataflow programs that run on dynamic dataflow models, it is necessary to separate instruction memory from the operand memory. However, asynchrony of the dataflow instructions means frequent context switching, and in general, lack of temporal and spatial localities in accessing instruction and operand memories (41). To cope with these problems, one needs to adopt proper mechanisms to partition the dataflow graphs into subgraphs, to allocate subgraphs among processors, and to control the number of instances of a subgraph in a processor. It should be noted that because of the functional and asynchronous nature of the dataflow instructions, the addresses of the nodes in a dataflow graph can be set as desired without affecting the result of the execution. This property should be the basis of establishing localities in dataflow programs. Moreover, in support of the cache organization, one should study the effectiveness of the traditional statistical replacement algorithms (e.g., LRU) for instruction and operand memories. Therefore, in a processor with the load control mechanism, a sophisticated deterministic algorithm to replace dataflow blocks needs to be developed. Finally, the operand memory plays a dominant role to achieve satisfactory performance in a dataflow machine, and hence the operand cache must be managed effectively. In a dataflow machine, it is not only necessary to maintain spatial locality for the input arguments of a code-block (frame), but also is necessary to maintain spatial locality for the result tokens of the code-block. In the other words, the cache management must keep track of several active frames to avoid cache misses in accessing arguments while storing the results. These design principles motivated the organizations of operand and instruction caches in the literature (41).

CONCLUSION

As modern architects find it difficult to design highly parallel architectures that can exploit high degrees of instruction level parallelism, it may be time to look back to dataflow model of computation. The dataflow model was investigated in 1970s and 1980s but no commercially viable systems were implemented. Nevertheless, several features of the dataflow principle and dataflow computation have found their place in modern processor architectures and compiler technology. Most modern processors use complex hardware techniques to detect data hazards, control hazards, and dynamic parallelism — to bring the execution engine closer to an idealized dataflow engine. Some researchers have proposed hybrid designs in which the dataflow scheduling is applied only at thread level (i.e., macro-dataflow), whereas each thread is comprosed of conventional control-flow instructions.

The advances from the development of dataflow projects indicate potential high performance computation based on the dataflow principles. However, before a successful implementation of dataflow machines is possible, the various issues discussed in this article must be resolved.

It is our contention that a more careful mix of dataflow principles with recent technological advances will pave the way to future tera and peta instructions per second performance. Current multicore and multithreaded systems do not scale well. Instruction level dataflow implementations potentially can scale with processing resources, but they require excessive hardware support for synchronization, distribution, and communication among the instructions. A combination of static (compile time) and dynamic techniques for the creation and distribution of threads (or a unit of concurrent activity) may provide a balance between performance and hardware complexity.

The implementation of imperative memory systems within the context of a dataflow model is yet another issue that is not addressed satisfactorily. In addition to the management of structures, techniques for the management of pointers, dealing with aliasing, and dynamic memory management are needed. Ordering of memory updates (a critical concept in shared memory concurrency) is an alien concept to pure dataflow. However, to be commercially viable, it is essential to provide shared memory based synchronization among concurrent activities. Some ideas such as those presented in Wavescalar and SDF hold some promise in this connection.

We believe that several factors are motivating a renewed interest in the design and implementation of scalable dataflow processors. These include the recent technological advances in increased chip density; the complex interconnections among multiple processing elements on a single chip (Network-on-a-chip); the hardware complexity of the superscalar, super pipeline, and VLIW architectures and the diminishing performance gains of these systems with additional hardware; the large and multi-level caches; the compliers that perform extensive global and interprocedural analyses to extract as much parallelism as possible, and finally, the success of the recent dataflow projects (Recent Dataflow Projects section). At the same time, if dataflow architecture is to address the challenges of future processing architectures containing hundreds, if not thousands, of processing elements, it is necessary to evaluate carefully different forms of dataflow organizations for their suitability for implementation.

DATA STORAGE ON MAGNETIC DISKS

INTRODUCTION

Data storage can be performed with several devices, such as hard disk drives (HDDs), tape drives, semiconductor memories, optical disks, and magneto-optical disks. However, the primary choice of data recording in computer systems has been based on HDDs. The reasons for this choice include the faster access times at relatively cheaper costs compared with other candidates. Although the semiconductor memories may be faster, they are relatively more expensive than the HDDs. On the other hand, storage on optical disks used to be cheaper than the hard disk storage, but they are slower. In the recent past, HDD technology has grown at such a rapid pace that it is faster than the optical disks but costs almost the same in terms of cost per bit.

HDDs have grown at an average rate of 60% during the last decade. This growth has led to enhanced capacity. The increase in the capacity of hard disks, while maintaining the same manufacturing costs, leads to a lower cost per GB (gigabytes $= 1 \times 10^9$ bytes). At the time of writing (August 2007), HDDs with a capacity of about 1 TB (terabytes $= 1 \times 10^{12}$ bytes) have been released. At the same time, the size of the bits in HDDs has reduced significantly, which has led to an increase of areal density (bits per unit area, usually expressed as Gb/in^2, gigabits per square inch). The increase of areal density has enabled HDDs to be used in portable devices as well as in digital cameras, digital video cameras, and MP3 players.

To fuel this tremendous improvement in technology, significant inventions need to be made in the components as well as in the processes and technologies associated with HDDs. This article will provide a brief background of the magnetic disks that store the information in HDDs. Several articles on the Web are targeted at the novice (1–3). Also, several articles in the research journals, are targeted at the advanced reader (4–7). This article will try to strike a balance between basic and advanced information about the HDDs.

DATA STORAGE PRINCIPLES

Any data storage device needs to satisfy certain criteria. It needs to have a storage medium (or media) to store the data, ways to write the data, ways to read the data, and ways to interpret the data. Let us take the example of a book. In a printed book, paper is the storage medium. Writing information (printing) is done using ink, and reading is carried out with the user's eyes. Interpretation of the data is carried out using the user's brain. Components with similar functions exist in an HDD too.

Figure 1(a) shows the components of a typical HDD, used in desktop PCs. Some key components that make up an HDD are marked. A disk, a head, a spindle motor, an actuator, and several other components are included. The disk is the recording medium that stores the information, which is similar to the paper of a book. The head performs two functions (similar to pen and eye in our example), which are writing and reading information. The spindle motor helps to spin the disk so that the actuator (that moves along the radial direction) can carry the head to any part of the disk and read/write information. The printed circuit board [Fig. 1(b)] is the brain of the HDD, which helps to control the HDD and pass meaningful information to the computer or whatever device that uses the HDD. Before we learn about these components in detail, let us understand the principles of magnetic recording, which is the basis for storage of information in HDDs.

Magnetic recording was demonstrated successfully as a voice signal recorder by Vladimir Poulsen about 100 years ago. Later, it was exploited for storing all kinds of information. In simple terms, magnetic recording relies on two basic principles: (*1*) Magnets have north and south poles. The field from these poles can be sensed by a magnetic field sensor, which is a way of reading information. (*2*) The polarity of the magnets can be changed by applying external magnetic fields, which is a way of writing information. Although earlier systems of magnetic recording such as audio tapes and video tapes are analog devices, HDDs are digital devices, which make use of a string of 1 s and 0 s to store information. In the next few sections, the key technologies that aid in advancing the storage density of HDDs will be discussed briefly. The main focus of the article is, however, on the magnetic disks that store the information.

HEADS

The head is a tiny device [as shown in Fig. 1(a)] that performs the read–write operation in an HDD. The heads have undergone tremendous changes over the years. In the past, both reading and writing operations were carried out using an inductive head. Inductive heads are a kind of transducer that makes use of current-carrying coils wound on a ferromagnetic material to produce magnetic fields (see Fig. 2). The direction of the magnetic field produced by the poles of the ferromagnetic material can be changed by changing the direction of the electric current. This field can be used to change the magnetic polarities of the recording media (writing information).

Inductive heads can also be used for reading information, based on Faraday's law, which states that a voltage will be generated in a coil, if a time-varying flux (magnetic field lines) is in its vicinity. When the magnetic disk (in which information is written) rotates, the field that emanates from the recording media bits will produce a time-varying flux, which will lead to a voltage in the inductive head. This voltage can be used to represent "1"s or "0"s. The inductive head technology was prevalent until the early 1990s. However, to increase the bit density, the bit size had to be decreased, which led to a decrease in the magnetic flux

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

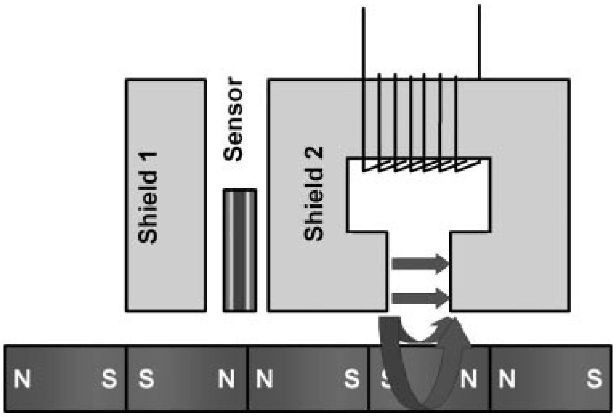

Figure 2. Schematic diagram of a head in an HDD showing the writer (inductive head), reader, and media below.

from the bits. The inductive heads were not sensitive enough to the magnetic field from the smaller bits as the technology progressed. Therefore, more advanced read sensors found their way into the head design. Modern HDDs have two elements in a head: One is a sensor for reading information (analogy: eye), and the other is an inductive writer for writing information (analogy: pen). Such components where the sensor and writer are integrated are called integrated heads or simply heads.

Figure 2 shows the schematic diagram of an integrated head, which consists of a writer and a reader. The inductive head on the right side of the image is the writer that produces the magnetic field to change the magnetic state of the region of the magnetic disk to be in one way or the other. Figure 2 also shows a read-sensor (or reader), sandwiched between two shields. The shield 2, as shown in the figure, is usually substituted with one side of the core of the inductive head. The shields are ferromagnetic materials that would shunt away any field from bits that are away from the region of interest, in a similar way as the blinders prevent a horse from seeing on either side. Because of the shields, only the magnetic field from the bit (that is being read) is sensed by the reader.

The HDDs used magneto-resistive (MR) heads for some time (early to late 1990s) before switching to prevalent giant magneto-resistive (GMR) sensors. Unlike inductive heads, MR and GMR heads work on the basis of change in the resistance in the presence of a magnetic field. The GMR sensor, which is shown in multicolor, is in fact made of several magnetic and nonmagnetic layers. GMR devices make use of the spin-dependent scattering of electrons. Electrons have "up" and "down" spins. When an electric current is passed through a magnetic material, the magnetic orientation of the magnetic material will favor the movement of electrons with a particular spin— "up" or "down". In GMR devices, the magnetic layers can be designed in such a way that the device is "more resistive" or "less resistive" to the flow of electrons depending on the direction of the field sensed by the sensors. Such a change in the resistance can be used to define "1" and "0" needed for digital recording.

RECORDING MEDIA

As mentioned, this article will discuss the recording media—the magnetic disks that store the information—in more detail. Historically, the first recording media for HDD was made by spraying a magnetic paint on 24” aluminium disks. These types of recording media, where fine magnetic particles are embedded in a polymer-based solvent, are called particulate media. However, they became obsolete in the late 1980s. Thin film technology took the place of the old technology to coat the recording media.

Fabrication of Magnetic Disks

In thin film technology, the recording media consists of several layers of thin films deposited by a process called sputtering. Figure 3 shows a typical schematic cross section of the layers that may constitute a perpendicular recording medium, which is an emerging technology at the time of writing. Sputtering, simply said, is a process of playing billiards with atoms to create thin film layers. The sputtering process is carried out in vacuum chambers and is described here briefly. The sputtering chamber, where the thin film deposition would take place, is pumped down to a low pressure at first. The objective of achieving this low pressure, called the base pressure, is to minimize the water vapor or other contaminating elements in the deposition chamber. After the base pressure is achieved, whose value depends on the application, argon (Ar) or some other inert gas is passed into the chamber. When a high negative voltage is applied between the target (the material that needs to be ejected) and the sputtering chamber (ground), the Ar ions that were created by the discharge in the sputtering chamber and accelerated because of the high-voltage knock on the target and release atoms. These atoms are scattered in different directions, and if the sputtering system was optimized well, most of them would arrive at the substrate (the disk that has to be coated).

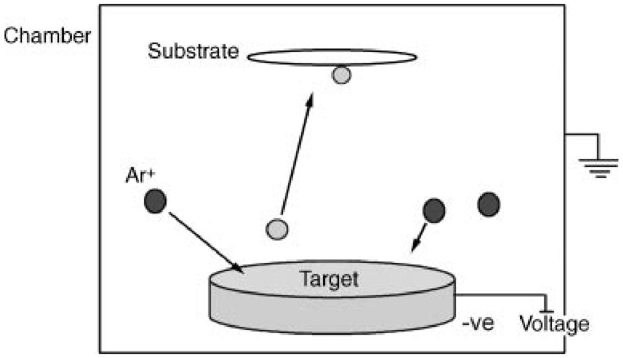

Figure 4. Illustration of the sputtering process inside a sputtering chamber.

Several modifications can be made to the process described above to improve the quality of the films that are obtained. In modern sputtering machines used in the hard disk industry, magnetron sputtering, where magnets are arranged below the targets and can even be rotated, is used to deposit thin film at faster deposition rates with good uniformity over the entire substrate. Moreover, since the recording media have several layers, the modern machines also have several sputtering chambers in a single sputtering machine, so that all layers can be deposited subsequently without exposing the layers to the ambient conditions. Figure 4 illustrates the sputtering process. Figure 5 shows the configuration of chambers in a sputtering system from Oerlikon (8). In the media fabrication process, the disk goes through all the chambers to coat the various layers depicted in Fig. 3.

Magnetic Recording Schemes

Figure 6 shows the way the data are organized on magnetic disks (also called platters). Several platters may be stacked in an HDD to multiply capacity. In almost all HDDs, the information is stored on both sides of the disks. Read/write heads exist on both surfaces, which perform reading and writing of information. For the sake of simplicity, only one side of the disk surface is shown here. As can be shown, the information is stored in circular tracks. Within the tracks, addressed sectors exist, in which the information can be written or read. The randomness in access/storage of information from/in an address provided by the CPU comes from the ability to move the head to the desired sector. In the state-of-the-art hard-disk media, about 150,000 tracks exist running from the inner diameter (ID) of the disk to the outer diameter (OD). The tracks are packed at such a high density that it is equivalent to squeezing about 600 tracks in the width of a typical human hair (considering the average diameter of the human hair to be around 100 μm). In each track, the bits are packed at a density of 1 million bits in an inch (about 4000 bits in the width of a human hair). If a nano-robot has to run on all the tracks to have a look at the bits of a contemporary hard disk, it would have almost completed a marathon race. That is how dense are the bits and tracks in an HDD. This trend of squeezing the tracks and bits in a smaller area will continue. Figure 7

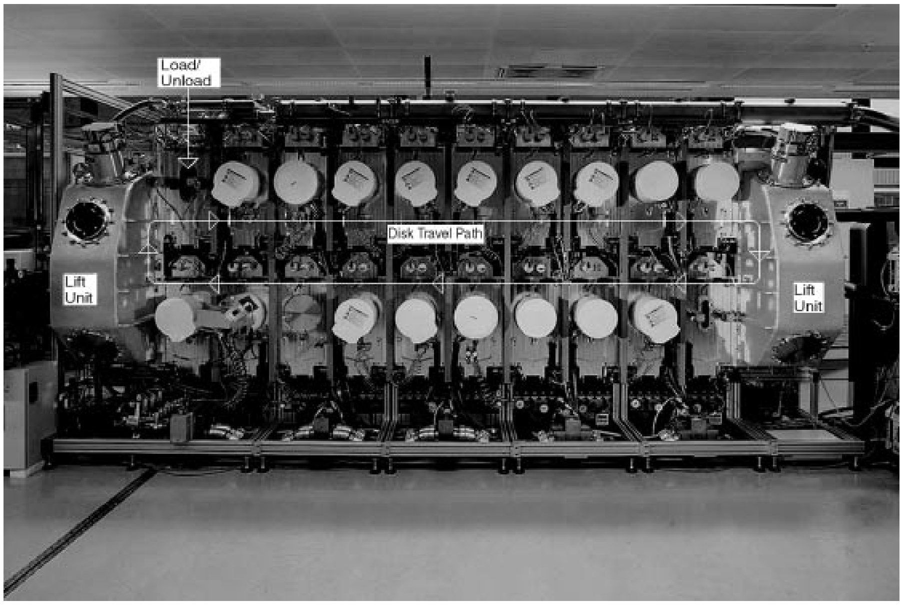

Figure 5. Picture of a sputtering system with different chambers for manufacturing hard disk media. The direction of movement of the disk is marked by arrows.

shows the trend of increase in the areal density (number of bits in a square-inch) as a function of time. It can be noticed that the areal density has increased by about 100 million times in the past five decades.

Figure 8 illustrates the recording process in the longitudinal recording technology. In this technology, the polarities of the magnets are parallel to the surface of the hard disk. When two identical poles (S–S or N–N) are next to each other, a strong magnetic field will emerge from the recording medium, whereas no field will emerge when opposite poles (S–N) are next to each other. Therefore, when a magnetic field sensor (GMR sensor, for example) moves across this surface, a voltage will be produced only when the GMR sensor goes over the transitions (regions where like poles meet). This voltage pulse can be synchronized with a clock pulse. If during the clock window, the GMR sensor produces a voltage, it represents 1. If no voltage is produced during the clock window, it represents 0. This simple illustration shows how "1"s and "0"s are stored in hard disk media.

In our previous discussion, groups of bar magnets were used to illustrate the way bits are organized. However, in real hard disk media, the bits are stored in a collection of nano-magnets called grains for several reasons. Grains (tiny crystallites) are regions of a material within which atoms are in arrangement of a crystal. The grains of current hard disk media have an average size of about 7 nm. Figure 9 shows a close-up view of the bits in a recording medium (bit-boundary is shown by the dark lines). It can be noticed that the bits are not perfectly rectangular. The bit boundaries are not perfectly straight lines, but they are mostly determined by the grain boundaries in modern-day magnetic disks. Also, several grains are between the bit boundaries. In current technology, about 60 grains are included in a bit.

The reasons for using several grains to store information derive mainly from the fabrication process. The traditional deposition methods of making the magnetic disks (such as sputtering) lead to a polycrystalline thin film. If the grains of the polycrystalline material are magnetic, their easy

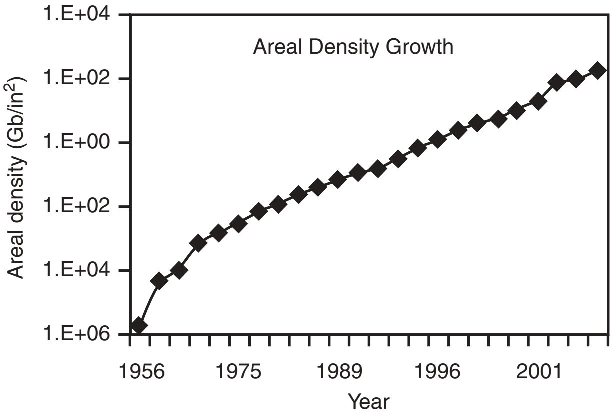

Figure 7. Trend in the increase of areal density of HDDs.

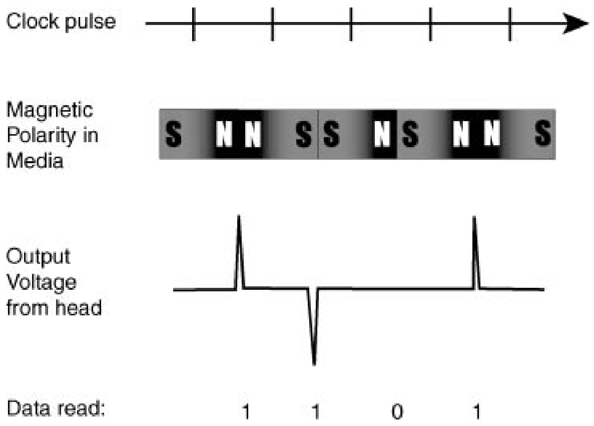

Figure 8. Recording principle of longitudinal recording.

axes (the direction in which north and south poles will naturally align themselves) will be in random directions. Moreover, the grains are also arranged in random positions within the magnetic media so that relying on one grain to store one bit is not possible. In addition, relying on several grains to store information provides us with the convenience of storing information in any part of the recording media.

It can be noticed from Fig. 10 that the easy axes are pointing in different directions. The magnetic field, which produces the signal in the read-sensor, depends on the component of magnetization parallel to the track. If more grains have their magnetization orientated parallel to the track, then the recording media will exhibit a high signal and a low noise. When designing a recording medium, it is important to achieve a high signal-to-noise ratio (SNR) at high densities, as a high SNR will enable the bits to be read reliably. Hard disk media makes use of a mechanical-texturing technology to maximize the number of grains whose easy axes are parallel to the track. However, even by improving this technology, not all grains can be arranged when their easy axis direction is parallel to the track. Because of these reasons, several grains of a magnetic disk are used to store one bit.

Design of a Magnetic Recording Medium

In the previous section, it was highlighted that several grains (tiny crystals) are used for storing information. The SNR, which determines how reliably the bits can be read, depends on the number of grains in a bit. When the areal density needs to be increased in an HDD, the bit size needs to be shrunk. Therefore, to maintain an acceptable SNR, the grain size also needs to be shrunk, so that the number of grains per bit remains more or less the same. Therefore, reduction of grain size is one of the areas, where the attention of researchers is always focused (9,10). Figure 11 shows the reduction of grain size in recording media over several generations. As the technology progressed, the grain size decreased. However, significant improvements in other parts of HDDs can also relax the requirement on grain size. Although the hard disk media of a decade ago had about 600 grains per bit, current media have only about 60 grains per bit. This decrease shows that, along with improvements in recording media technologies, the other components (such as head) or technologies (such as signal processing) have also progressed significantly enough to read a bit reliably from just 60 grains.

It is also essential to achieve sharper bit boundaries to pack bits closer together. The sharpness of the bit boundaries deteriorates in the case of longitudinal recording because identical magnetic poles facing at a bit boundary do not favor a sharp magnetic change at the boundary. On the other hand, in the case of perpendicular recording, which will be described in detail later, where the magnetization is formed in the perpendicular direction to the disk plane, opposite magnetic poles facing at a bit boundary help to from a sharp magnetic change. Therefore, the sharpness

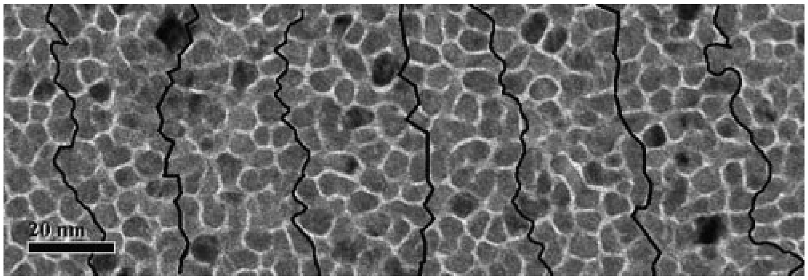

Figure 9. Close-up view of bits in a recording medium.

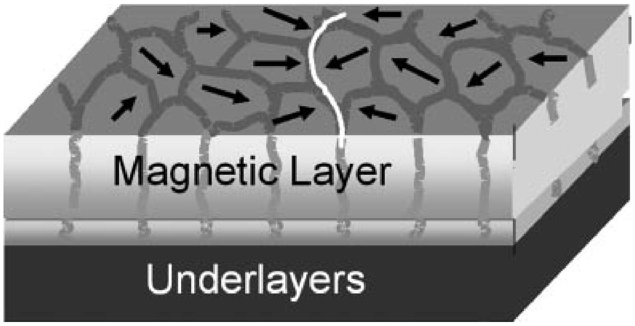

Figure 10. Magnetic orientations of grains in a recorded bit.

of the bit boundaries is determined by the nature of grains in the recording medium.

If the grains are isolated from each other, each grain will act as magnet by itself. In this case, the bit boundaries will be sharper. On the other hand, if the grains are not well isolated, a few grains could switch together. In this case, the bit boundaries will be broader. It is essential to achieve a good inter-grain separation, when the recording medium is designed. In the emerging perpendicular recording, the hard disk media are an alloy of CoCrPt:SiO_2. Significant presence of Co makes this alloy magnetic, and Pt helps to improve the magneto-crystalline anisotropy energy. If this energy is greater, the reversal of magnetic direction becomes difficult, leading to a long-term storage without self-erasure or erasure from small external fields. The addition of Cr and SiO_2 are responsible for improving inter-grain separation. When the magnetic layer is formed from CoCrPt:SiO_2, oxides of Cr and Si are formed in the grain boundary. Because these oxides are nonmagnetic, the magnetic grains are isolated from each other, and this helps to obtain a narrower bit-boundary.

It is also important to achieve a desired crystallographic orientation when a recording medium is designed. The cobalt crystal, which is the most commonly used hard disk media layer, has a hexagonal close-packed structure. In a cobalt crystal, the north and south poles prefer to lie along the C-axis (center of the hexagon). Therefore, when a recording medium is made, it is necessary to orient the C-axis in a desired way. For example, it is necessary to orient the C-axis perpendicular to the disk in the emerging perpendicular recording technology (and parallel to the disk in longitudinal recording technology). If the recording medium is deposited directly on the substrate, it may not be possible to achieve the desired orientation. Therefore, usually several layers are deposited below the recording layer (see Fig. 3) to improve the desired orientation. In recording media design, the choice of materials and the process conditions for the layers play a critical role.

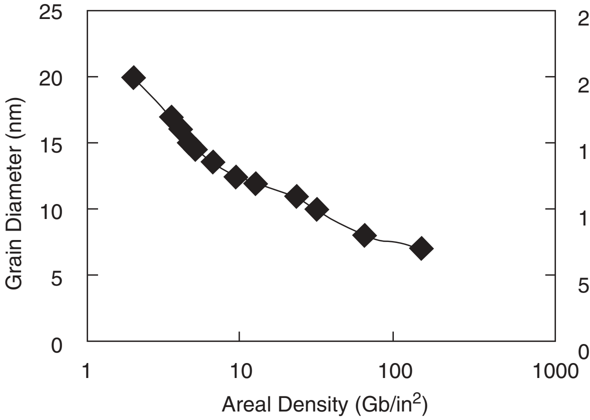

Figure 11. Average size of grains in recording media of different generations.

In addition, several requirements such as corrosion-resistance and a smooth surface must be met when designing recording media. The designed media must not corrode at least for a period of 10 years. The protection layers that have to prevent corrosion cannot be thicker than 4 nm (as of the year 2007). In the future, the protection layers need to be thinned down closer to 1 nm (1/100000th thickness of a human hair). The surface of the media should be very smooth with a roughness of only about 0.2 nm to enable smooth flying of the head over the media surface without crashing. All requirements must be met while maintaining the cost of the hard disk media below about US$5.

OTHER COMPONENTS

The HDD involves several other advanced technologies in its components and mechanisms. For example, the slider that carries the read/write head has to fly at a height of about 7 nm (or lower in future). This flying condition is achieved when the disk below rotates at a linear velocity of 36 kmph. If a comparison is made between the slider and a B747 jet, flying the slider at a height of 7 nm is like flying the jumbo jet at a height of 7 mm above the ground. In some modern HDDs, the flying height of the slider can be lowered by about 2 nm when information needs to be read or written. This decrease will allow the head to fly at safer heights during the idle state and fly closer when needed.

Several challenges are associated with almost all components of an HDD. Because the head needs to fly at a very low height over the media surface, the hard disk needs to be in a very clean environment. Therefore, HDDs are sealed with a rubber gasket and protected from the outside environment. The components inside the HDD (including the screws) should not emit any contaminant particle or gas, as that will contaminate the environment leading to a crash between the head and the media. The motor of the HDDs should provide sufficient torque for the heavy platters to rotate. Yet the motor should be quiet, stable in speed, and free from vibrations. In addition, it should be thin enough to fit into smaller HDDs and consume less power.

OTHER TECHNOLOGIES

HDDs also use several advanced technologies to achieve an ever increasing demand of higher capacity and lower cost per gigabyte. For an Olympic sprinter who is sprinting at a speed of 10 m/s, staying in his track with a width of about 1.25 m is not a serious problem. However, in HDDs, the head that moves at similar speeds has to stay in its track, which is only about 160 nm wide (about 8 million times narrower than the Olympic track). Following the track gets more complicated in the presence of airflow. The airflow inside the HDD causes vibrations in the actuator and the suspension that move and carry the head. Therefore, it is necessary to study the air-flow mechanism and take the necessary steps to minimize the vibrations and stay in the track. These issues will be more challenging in the future, as the tracks will be packed at even higher densities than before. It was also mentioned that the HDDs use fewer grains per bit now than in the recent past, which leads to a reduction in the SNR and makes signal processing more complicated. Therefore, it is very clear that the HDD involves creation of new technologies that should go hand-in-hand. HDD technology is one of the few technologies that needs multidisciplinary research.

RECENT DEVELOPMENTS

In magnetic recording, as mentioned, small grains help to store the information. The energy that helps to make the information stable depends on the volume of the grain. When the grains become smaller (as technology progresses), this energy becomes smaller, which leads to a problem called superparamagnetism. In superparamagnetism, the north and south poles of a magnet fluctuate from thermal agitation, without the application of any external field. Even if 5% of the grains of a bit are superparamagnetic, data will be lost. It was once reported that the areal density of 35 Gb/in^2 would be the limit of magnetic recording (11). However, HDD technology has surpassed this limit, and the current areal density of the products is at least four times larger. Several techniques are employed to overcome the limit of 35 Gb/in^2, but describing those techniques is beyond the scope of this article. One technology, which can carry forward the recording densities to higher values, at least as high as 500 Gb/in^2 (which is roughly three times the areal density in the products of 2006), is called perpendicular recording technology.

Although perpendicular recording technology was proposed in the mid-1970s, successful implementation of perpendicular recording technology has been offered only since 2006. In this technology, the north and south poles of the magnetic grains that store the information lie perpendicular to the plane of the disk (12). In addition, this technology has two main differences in the head and media design. First, the media design includes the presence of a soft magnetic underlayer (a material whose magnetic polarity can be changed with a small field)— marked in Fig. 3 as SUL1 and SUL2. Second, the head has a different architecture in that it produces a strong perpendicular magnetic field that goes through the recording layer and returns back through another pole with a weaker field via the SUL (see Fig. 12). The field becomes weaker at the return pole because of the difference in the geometry of the two poles. This configuration achieves a higher writing field than what is possible with the prevalent longitudinal recording technology. When higher writing fields are possible, it is possible to make use of smaller grains (whose magnetic polarities are more stable) to store information. When smaller grains are used, the bit sizes can be smaller leading to higher areal densities. This increase in the writability is one reason that gives the edge to perpendicular recording technology.

Perpendicular recording technology offers larger M_r.t (which is the product of remanent moment M_r and thickness t or the magnetic moment per unit area) values for the media without degrading the recording resolution. The resolution and the noise are governed by the size of the magnetic clusters (or the grain size in the extreme case). It also offers increased thermal stability at high linear densities. All these characters come from the difference in the demagnetizing effect at the magnetic transitions.

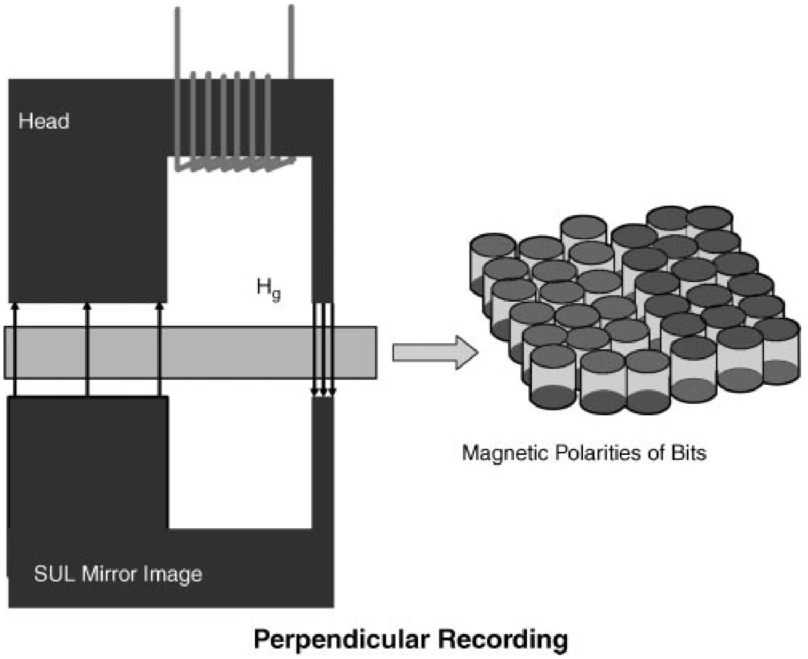

Figure 12. Illustration of perpendicular recording technology.

FUTURE STORAGE: WHAT IS IN STORE?

The recently introduced perpendicular recording technology is expected to continue for the next four to five years without significant hurdles. However, some new technologies would be needed after five years or so, to keep increasing the areal density of the HDDs. One such technology that is investigated intensively is heat-assisted magnetic recording (HAMR). In this technology, a fine spot (about 30 nm) of the recording medium is heated to enable the writing operation. Without heating, writing/erasure cannot be achieved. Once the writing is carried out, the media are cooled to room temperature, at which the data are thermally stable.

Several challenges are associated with this technology, which are being investigated. Another technology that is considered as a competitor to HAMR is bit-patterned media recording. In bit-patterned media recording technology, the media are (lithographically or otherwise) defined to have regions of magnetic and nonmagnetic material. Although the magnetic material will store the information, the nonmagnetic material will define the boundary and help to reduce the inter-bit magnetic interactions and, hence, noise. Since the magnetic material in this technology is larger than that of a single grain in perpendicular recording technology, the information is more stable with bit-patterned media technology. However, to be competitive, feature sizes of about 10 nm need to be achieved lithographically without significantly increasing costs. Although a 10-nm feature size over larger areas at a cheaper costs is a challenge that cannot be tackled so soon, challenges also come from other components to meet the requirement of bit-patterned media recording technology. At this point, it is not clear which technology will take the lead. But, it is foreseen widely that far-future HDDs may combine both technologies. Therefore, research has been going on for both of these technologies.

When the new technologies described above enter into HDDs, in about six to seven years from now, the areal density will be about 1000 Gb/in^2. With this kind of areal densities, a desktop HDD could store about 5 TB or higher. You could carry your laptop with an HDD that stores 1 TB. It is almost certain that all of these high-capacity devices would be available at the same price of a 400-GB desktop drive available now.

SUMMARY

The working principle of an HDD is introduced, with detailed attention given to the magnetic disks that store the information. In an HDD, the head that has a sensor and a writer are used for reading and writing information. The information is stored in magnetic disks. To achieve high densities, it is necessary to reduce the size of the grains (tiny-magnets) that store the information. Recently, perpendicular recording technology has been introduced in the market to continue the growth of HDD technology. Although perpendicular recording technology may last for five to eight more years, alternative technologies are being sought. Heat-assisted magnetic recording and bit-patterned media recording are a few candidates for future.

ELECTRONIC CALCULATORS

People have used calculating devices of one type or another throughout history. The abacus, which uses beads to keep track of numbers, was invented over 2000 years ago and is still used today. Blaise Pascal invented a "numerical wheel calculator," a brass box with dials for performing addition, in the seventeenth century. (1) Gottfried Wilhelm von Leibniz soon created a version that could also multiply, but mechanical calculators were not widely used until the early nineteenth century, when Charles Xavier Thomas de Colmar invented a machine that could perform the four basic functions of addition, subtraction, multiplication, and division. Charles Babbage proposed a steam-powered calculating machine around 1822, which included many of the basic concepts of modern computers, but it was never built. A mechanical device that used punched cards to store data was invented in 1889 by Herman Hollerith and then used to mechanically compile the results of the U.S. Census in only 6 weeks instead of 10 years. A bulky mechanical calculator, with gears and shafts, was developed by Vannevar Bush in 1931 for solving differential equations (2).

The first electronic computers used technology based on vacuum tubes, resistors, and soldered joints, and thus they were much too large for use in portable devices. The invention of the transistor (replacing vacuum tubes) followed by the invention of the integrated circuit by Jack Kilby in 1958 led to the shrinking of electronic machinery to the point where it became possible to put simple electronic computer functionality into a package small enough to fit into a hand or a pocket.

Logarithms, developed by John Napier around 1600, can be used to solve multiplication and division problems with the simpler operations of addition and subtraction. Slide rules are mechanical, analog devices that are based on the idea of logarithms and use calibrated sticks or disks to perform multiplication and division to three or four significant figures. Slide rules were an indispensable tool for engineers until they were replaced by handheld scientific calculators starting in the early 1970s (3).

CALCULATOR TYPES AND USES

Electronic calculators come in a variety of types: four-function (addition, subtraction, multiplication, and division), desktop, printing, and scientific. Figure 1 shows various calculators with prices ranging from \$5 to \$150. Scientific calculators can calculate square roots, logarithms and exponents, and trigonometric functions. The scientific category includes business calculators, which have time-value-of-money, amortization, and other money management functions. Graphing calculators are a type of scientific calculator with a display that can show function plots. Advanced scientific and graphing calculators also have user programming capability that allows the user to enter and store programs. These programs can record and automate calculation steps, be used to customize the calculator, or perform complicated or tedious algorithms. Some handheld calculators are solar powered, but most advanced scientific calculators are powered by batteries that last for many months without needing replacement.

Scientific Calculators

Scientific calculators can perform trigonometric functions and inverse trigonometric functions (sin x, cos x, tan x, arcsin x, arccos x, arctan x) as well as hyperbolic and inverse hyperbolic functions (sinh x, cosh x, tanh x, arcsinh x, arccosh x, arctanh x). They can also find natural and common logarithms (ln x, log x), exponential functions ($e^x, y^x, y^{1/x}$), factorials ($n!$), and reciprocals ($1/x$). Scientific calculators contain a representation for the constant π, and they can convert angles between degrees and radians. Most scientific calculators accept numbers with 10 to 12 digits and exponents ranging from -99 to 99, although some allow exponents from -499 to 499.

Graphing Calculators

Graphing calculators were first developed in the late 1980s as larger liquid-crystal displays (LCDs) became available at lower cost. The pixels in an LCD display can be darkened individually and so can be used to plot function graphs. The user keys in a real-valued function of the form $y = f(x)$ and makes some choices about the scale to use for the plot and the set of values for x. Then the calculator evaluates $f(x)$ for each x value specified and displays the resulting $(x,f(x))$ pairs as a function graph. Graphing calculators can also plot polar and parametric functions, three-dimensional (3-D) wireframe plots, differential equations, and statistics graphs such as scatter plots, histograms, and box-and-whisker plots. (See Fig. 2.) Once a graph has been displayed, the user can move a small cursor or crosshairs around the display by pressing the arrow or cursor keys and then obtain information about the graph, such as the coordinates of points, the x-intercepts, or the slope of the graph at a certain point. The user can also select an area of interest to zoom in on, and the calculator will replot the graph using a different scale (4).

Programmable Calculators

If a series of steps is to be repeated using various different inputs, it is convenient to be able to record those steps and replay them automatically. Simple programmable calculators allow the user to store a sequence of keystrokes as a program. More complicated programmable calculators provide programming languages with many of the components of high-level computer languages, such as branching and subroutines.

Given all these types and uses of calculators, what is it that defines a calculator? The basic paradigm of a calculator is key per function. For example, one key is dedicated to the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Figure 1.

square root function on most scientific calculators. All the user has to do is input a number and then press one key, and the calculator performs a complicated series of steps to obtain an answer that a person could not easily calculate on their own. Another way to say this is that there is an asymmetry of information flow: Given a small amount of input, the calculator does something nontrivial and gives you back results that you could not have easily found in your head or with pencil and paper.

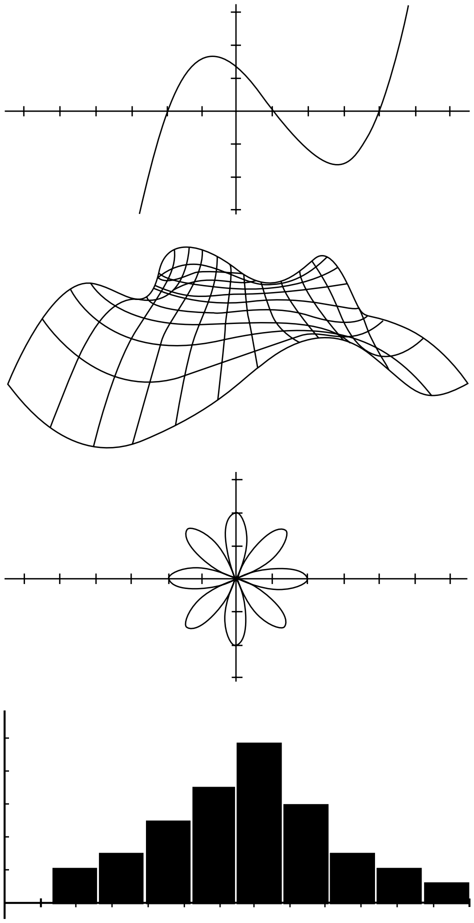

Figure 2.

CALCULATOR HARDWARE COMPONENTS

Today's advanced scientific and graphing calculators have many similarities to computers. The block diagram in Fig. 3 shows the system architecture of an advanced scientific graphing calculator (5). The two main components of a calculator are hardware and software. The hardware includes plastic and metal packaging, display, keypad, optional additional input/output devices (such as infrared, serial ports, card slots, and beeper parts to produce sound), power supply circuit, and an electronic subsystem. The electronic subsystem consists of a printed circuit board with attached electronic components and integrated circuits, including a central processing unit (CPU), display controllers, random access memory (RAM), and the read-only memory (ROM) where software programs are stored permanently.

The mechanical design of a calculator consists of subassemblies such as a top case with display and keypad, a bottom case, and a printed circuit or logic assembly. Figure 4 shows the subassemblies of a graphing calculator. A metal chassis in the top case supports the keypad, protects and frames the glass display, and provides a negative battery contact. The metal chassis is also part of the shielding, which protects the electronic circuitry from electrostatic discharge (ESD). The bottom case may contain additional metal shielding, a piezoelectric beeper part, and circuitry for battery power. The subassemblies are connected electrically with flexible circuits (6).

Display

Early calculators used light-emitting diode (LED) displays, but liquid crystal displays (LCDs) are used in most modern

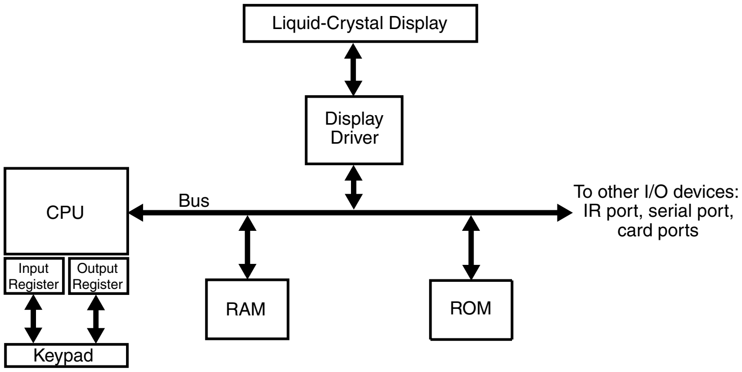

Figure 3.

calculators because they have low voltage requirements, good visibility in high ambient light conditions, and they can produce a variety of character shapes and sizes (7). An LCD consists of two pieces of glass with a layer of liquid crystal in between which will darken in specific areas when a voltage signal is applied. These areas can either be relatively large segments that are combined a few at a time to represent a number or character, or they can be a grid of very small rectangles (also called picture elements or pixels) that can be darkened selectively to produce characters, numbers, and more detailed graphics. Basic calculators have one line displays that show one row of numbers at a time, whereas today's more advanced calculators can display up to eight or more rows of characters with 22 or more characters per row, using a display with as many as 100 rows and 160 columns of pixels.

Keypad

Calculator keypads are made up of the keys that the user presses, an underlying mechanism that allows the keys to be depressed and then to return to their initial state, and circuit traces that allow the system to detect a key press. When a key is pressed, an input register line and an output register line make contact, which causes an interrupt to be generated. This interrupt is a signal to the software to scan the keyboard to see which key is pressed. Keypads have different tactile feel, depending on how they are designed and of what materials they are made. Hinged plastic keys and dome-shaped underlying pads are used to provide feedback to the user with a snap when keys are pressed. An elastomer membrane separating the keys from the underlying contacts helps to protect the electronic system from dust (8).

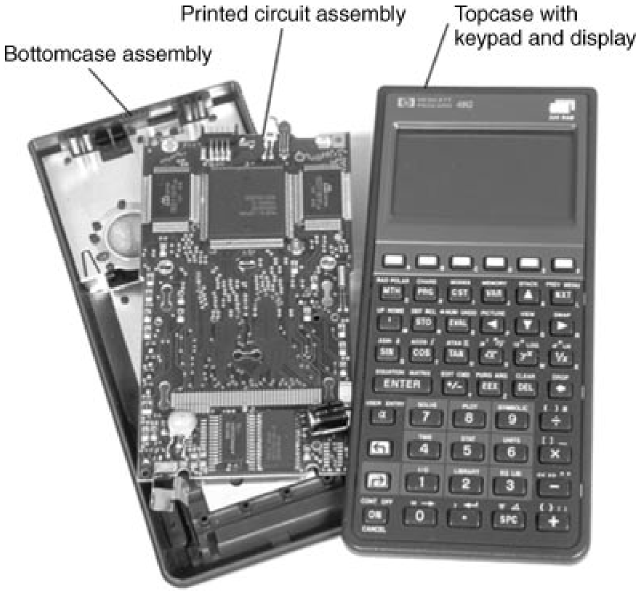

Figure 4.

The keypad is an input device, because it is a way for the user to provide information to the calculator. The display is an output device, because it allows the calculator to convey information to the user. Early calculators, and today's simple calculators, make do with only these input and output devices. But as more and more memory has been added to calculators, allowing for more data storage and for more extensive programs to be stored in calculator memory, the keypad and display have become bottlenecks. Different ways to store and input data and programs have been developed to alleviate these input bottlenecks. Infrared and serial cable ports allow some calculators to communicate with computers and other calculators to quickly and easily transfer data and programs.

Circuits

The electronic components of a calculator form a circuit that includes small connecting wires, which allow electric current to flow to all parts of the system. The system is made up of diodes; transistors; passive components such as resistors, capacitors, and inductors; as well as conventional circuits and integrated circuits that are designed to perform certain tasks. One of these specialized circuits is an oscillator that serves as a clock and is used to control the movement of bits of information through the system. Another type of specialized circuit is a logic circuit, or processor, which stores data in registers and performs manipulations on data such as addition.

Printed Circuit Assembly

A printed circuit board (PCB) forms the backbone of a calculator's electronic circuit system, allowing various

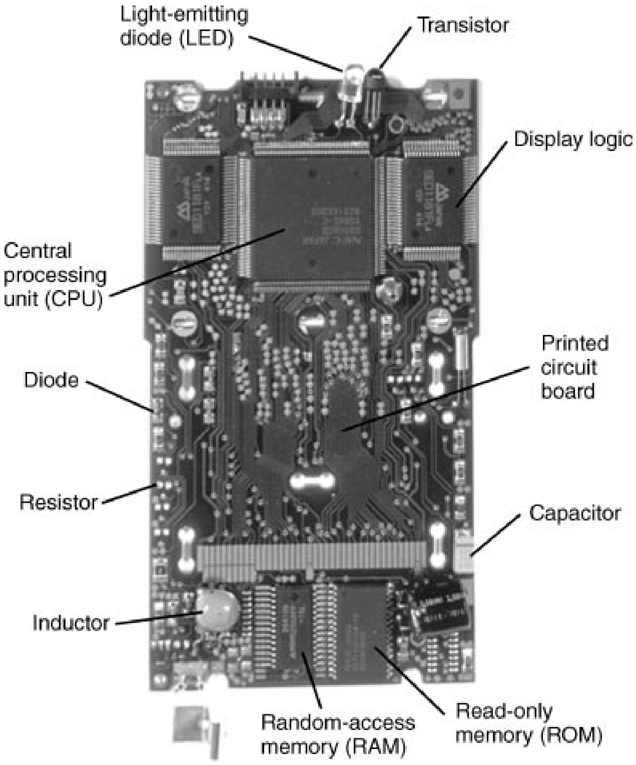

Figure 5.

components to be attached and connected to each other (9). Figure 5 shows a calculator printed circuit assembly with many electronic components labeled. Wires that transmit data and instructions among the logic circuits, the memory circuits, and the other components are called buses. Various integrated circuits may be used in a calculator, including a central processing unit (CPU), RAM, ROM, and Flash ROM memory circuits, memory controllers that allow the CPU to access the memory circuits, a controller for the display, quartz-crystal-controlled clocks, and controllers for optional additional input/output devices such as serial cable connectors and infrared transmitters and receivers. Depending on the design of the calculator and the choice of components, some of these pieces may be incorporated in a single integrated circuit called an application-specific integrated circuit (ASIC).

Central Processing Unit

The central processing unit (CPU) of a calculator or computer is a complicated integrated circuit consisting of three parts: the arithmetic-logic unit, the control unit, and the main storage unit. The arithmetic-logic unit (ALU) carries out the arithmetic operations of addition, subtraction, multiplication, and division and makes logical comparisons of numbers. The control unit receives program instructions, then sends control signals to different parts of the system, and can jump to a different part of a program under special circumstances such as an arithmetic overflow. The main storage unit stores data and instructions that are being used by the ALU or control unit.

Many calculators use custom microprocessors because commercially available microprocessors that have been designed for larger computers do not take into account the requirements of a small, handheld device. Calculator microprocessors must operate well under low power conditions, should not require too many support chips, and generally must work with a smaller system bus. This is because wider buses use more power and require additional integrated circuit pins, which increases part costs. Complementary metal-oxide semiconductor or CMOS technology is used for many calculator integrated circuits because it is well suited to very low power systems (10). CMOS has very low power dissipation and can retain data even with drastically reduced operating voltage. CMOS is also highly reliable and has good latch up and ESD protection.

Memory

RAM integrated circuits are made up of capacitors, which represent bits of information. Each bit may be in one of two possible states, depending on whether the capacitor is holding an electric charge. Any bit of information in RAM can easily be changed, but the information is only retained as long as power is supplied to the integrated circuit. In continuous memory calculators, the information in RAM is retained even when the calculator is turned OFF, because a small amount of power is still being supplied by the system. The RAM circuits used in calculators have very low standby current requirements and can retain their information for short periods of time without power, such as when batteries are being replaced.

ROM circuits contain information that cannot be changed once it is encoded. Calculator software is stored in ROM because it costs less and has lower power requirements than RAM. As software is encoded on ROM by the manufacturer and cannot be changed, the built-in software in calculators is often called firmware. When calculator firmware is operating, it must make use of some amount of RAM whenever values need to be recorded in memory. The RAM serves as a scratch pad for keeping track of inputs from the user, results of intermediate calculations, and final results. The firmware in most advanced scientific calculators consists of an operating system (which is a control center for coordinating the low-level input and output, memory access, and other system functions), user interface code, and the mathematical functions and other applications in which the user is directly interested.

Some calculators use Flash ROM instead of ROM to store the programs provided by the calculator manufacturer. This type of memory is more expensive than ROM, but it can be erased and reprogrammed, allowing the calculator software to be updated after the calculator has been shipped to the customer. Flash ROM does not serve as a replacement for RAM, because Flash ROM can only be reprogrammed a limited number of times (approximately tens of thousands of times), whereas RAM can accommodate an effectively unlimited number of changes in the value of a variable that may occur while a program is running.

OPERATING SYSTEM

The operation of a calculator can be broken down into three basic steps of input, processing, and output. For example, to find the square root of a number, the user first uses the keypad to enter a number and choose the function to be computed. This input generates electronic signals that are processed by the calculator's electronic circuits to produce a result. The result is then communicated back to the user via the display. The processing step involves storing data using memory circuits and making changes to that data using logic circuits, as well as the general operation of the system, which is accomplished using control circuits.

A calculator performs many tasks at the system level, of which the user is not normally aware. These tasks include those that go along with turning the calculator ON or OFF, keeping track of how memory is being used, managing the power system, and all the overhead associated with getting input from the keypad, performing calculations, and displaying results. A calculator's operations are controlled by an operating system, which is a software program that provides access to the hardware computing resources and allows various application software programs to be run on the computer (or calculator).

The operating system deals with memory organization, data structures, and resource allocation. The resources that it is controlling include CPU time, memory space, and input/output devices such as the keypad and the display. When an application program is executed, the operating system is responsible for running the program by scheduling slices of CPU time that can be used for executing the program steps, and for overseeing handling of any interrupts that may occur while the program is executing. Interrupts are triggered by events that need to be dealt with in a timely fashion, such as key presses, requests from a program for a system-level service such as refreshing the display, or program errors. Some types of errors that may occur when a program is running are low power conditions, low memory conditions, arithmetic overflow, and illegal memory references. These conditions should be handled gracefully, with appropriate information given to the user. Operating systems provide convenience and efficiency: they make it convenient to execute application programs, and they manage system resources to get efficient performance from the computer or calculator (11).

USER INTERFACE

The user interface for one-line-display calculators is very simple, consisting of a single number shown in the display. The user may have some choice about the format of that number, such as how many digits to display to the right of the decimal point, or whether the number should be shown using scientific notation. Error messages can be shown by spelling out short words in the display. For more complicated calculators than the simple four-function calculators, the number of keys on the keypad may not be enough to use one per operation that the calculator can perform. Then it becomes necessary to provide a more extensive user interface than just a simple keypad. One way to increase the number of operations that the keypad can control is to add shifted keys. For example, one key may have the square-root symbol on the key and the symbol x^2 printed just above the key, usually in a second color. If the user presses the square-root key, the square-root function is performed. But if the user first presses the shift key and then presses the square-root key, the x-squared function will be performed instead.

ENTER MINIMUM HORIZONTAL VALUE

Figure 6.

Advanced scientific and graphing calculators provide systems of menus that let the user select operations. These menus may appear as lists of items in the display that the user can scroll through using arrow or cursor keys and then select by pressing the Enter key. Changeable labels in the bottom portion of the display, which correspond to the top row of keys, can also be used to display menu choices. These are called soft keys, and they are much like the function keys on a computer. Methods for the user to enter information into the calculator depend on the type of calculator. On simple, one-line-display calculators, the user presses number keys and can see the corresponding number in the display. Graphing calculators, with their larger displays, can prompt the user for input and then display the input using dialog boxes like the ones used on computers (12). Figure 6 shows a graphing calculator dialog box used to specify the plot scale.

NUMBERS AND ARITHMETIC

The most basic level of functionality that is apparent to the calculator user is the arithmetic functions: addition, subtraction, multiplication, and division. All calculators perform these functions, and some calculators are limited to these four functions. Calculators perform arithmetic using the same types of circuits that computers use. Special circuits based on Boolean logic are used to combine numbers, deal with carries and overdrafts, and find sums and differences. Various methods have been developed to perform efficient multiplication and division with electronic circuits (13).

Binary Numbers

Circuits can be used to represent zeros or ones because they can take on two different states (such as ON or OFF). Calculator (and computer memory) at any given time can be thought of as simply a large collection of zeros and ones. Zeros and ones also make up the binary or base-2 number system. For example, the (base-10) numbers 1, 2, 3, 4 are written in base-2 as 1, 10, 11, 100, respectively. Each memory circuit that can be used to represent a zero or one is called a binary digit or bit. A collection of eight bits is called a byte (or a word). Some calculator systems deal with four bits at a time, called nibbles. If simple binary numbers were used to represent all numbers that could possibly be entered into a calculator, many bits of memory would be needed to represent large numbers. For example, the decimal number 2^n is represented by the binary number consisting of a 1 followed by n zeros, and so requires $n + 1$ bits of memory storage. To be able to represent very large numbers with a fixed number of bits, and to optimize arithmetic operations for the design of the calculator, floating-point numbers are used in calculators and computers.

Floating-Point Numbers

Floating-point numbers are numbers in which the location of the decimal point may move so that only a limited number of digits are required to represent large or small numbers, which eliminates leading or trailing zeros, but its main advantage for calculators and computers is that it greatly increases the range of numbers that can be represented using a fixed number of bits. For example, a number x may be represented as $x = (-1)^s \times F \times b^E$, where s is the sign, F is the significand or fraction, b is the base used in the floating-point hardware, and E is a signed exponent. A fixed number of bits are then used to represent each number inside the calculator. The registers in a CPU, which is designed for efficient floating-point operations, have three fields that correspond to the sign, significand, and exponent, and can be manipulated separately.

Two types of errors can appear when a calculator returns an answer. One type is avoidable and is caused by inadequate algorithms. The other type is unavoidable and is the result of using finite approximations for infinite objects. For example, the infinitely repeating decimal representation for 2/3 is displayed as .6666666667 on a 10-decimal-place calculator. A system called binary-coded decimal (or BCD) is used on some calculators and computers as a way to deal with rounding. Each decimal digit, 0, 1, 2, 3, . . .,9, is represented by its four-bit binary equivalent: 0000, 0001, 0010, 0011,. . .,1001. So rather than convert each base-10 number into the equivalent base-2 number, the individual digits of the base-10 number are each represented with zeros and ones. When arithmetic is performed using BCD numbers, the methods for carrying and rounding follow base-10 conventions.

One way to improve results that are subject to rounding errors is to use extra digits for keeping track of intermediate results, and then do one rounding before the result is returned using the smaller number of digits that the user sees. For example, some advanced scientific calculators allow the user to input numbers using up to 12 decimal places, and return results in this same format, but 15-digit numbers are actually used during calculation.

Reverse Polish Notation and Algebraic Logic System

The Polish logician Jan Lukasiewicz demonstrated a way of writing mathematical expressions unambiguously without using parentheses in 1951. For example, given the expression $(2 + 3) \times (7 - 1)$, each operator can be written before the corresponding operands: $\times + 2\ 3 - 7\ 1$. Or each operator can be written after its operands: $2\ 3 + 7\ 1 - \times$. The latter method has come to be known as reverse polish notation (RPN) (14). Arithmetic expressions are converted to RPN before they are processed by computers because RPN simplifies the evaluation of expressions. In a non-RPN expression containing parentheses, some operators cannot be applied until after parenthesized subexpressions are first evaluated. Reading from left to right in an RPN expression, every time an operator is encountered it can be applied immediately, which means there is less memory and bookkeeping required to evaluate RPN expressions. Some calculators allow users to input expressions using RPN. This saves the calculator the step of converting the expression to RPN before processing it. It also means less keystrokes for the user bacause parentheses are never needed with RPN. Algebraic logic system (ALS) calculators require numbers and operators to be entered in the order they would appear in an algebraic expression. Parentheses are used to delimit subexpressions in ALS.

User Memory

On many calculators, the user can store numbers in special memory locations or storage register and then perform arithmetic operations on the stored values. This process is called register arithmetic. On RPN calculators, memory locations are arranged in a structure called a stack. For each operation that is performed, the operands are taken from the stack and then the result is returned to the stack. Each time a new number is placed on the stack, the previous items that were on the stack are each advanced one level to make room for the new item. Whenever an item is removed from the stack, the remaining items shift back. A stack is a data structure that is similar to a stack of cafeteria trays, where clean trays are added to the top, and as trays are needed, they are removed from the top of the stack. This scheme for placing and removing items is called last-in–first-out or LIFO.

ALGORITHMS

An algorithm is a precise, finite set of steps that describes a method for a computer (or calculator) to solve a particular problem. Many computer algorithms are designed with knowledge of the underlying hardware resources in mind, so that they can optimize the performance of the computer. Numerical algorithms for calculators take into account the way that numbers are represented in the calculator.

Square-Root Algorithm

A simple approximation method is used by calculators to find square roots. The basic steps to finding $y = x^{1/2}$ are to first guess the value of y, calculate y^2, and then find $r = x - y^2$. Then if the magnitude of r is small enough return y as the answer. Otherwise, increase or decrease y (depending on whether r is positive or negative, respectively) and repeat the process. The number of intermediate calculations required can be reduced by avoiding finding y^2 and $x - y^2$ for each value of y. This can be done by first finding the value of the largest place digit of y, then the next largest place digit, and so on. For example, if calculating $54756^{1/2}$, first find 200, then 30, and then 4 to construct the answer $y = 234$. This method is similar to a method once taught in schools for finding square roots by hand(15).

Trigonometric Function Algorithms

The algorithms for computing trigonometric functions depend on using trigonometric identities and relationships to reduce arbitrarily difficult problems to more manageable problems. First, the input angle θ is converted to an angle in radians, which is between 0 and 2π (or in some calculators, between 0 and π/4). Next θ is expressed as a sum of smaller angles. These smaller angles are chosen to be angles whose tangents are powers of 10: $\tan^{-1}(1) = 45^\circ$, $\tan^{-1}(0.1)$, $\tan^{-1}(0.01)$, etc. A process called pseudodivision is used to express θ in this way: First $\tan^{-1}(1)$ is repeatedly subtracted from θ until an overdraft (or carry) occurs, then the angle being subtracted from is restored to the value it had right before the overdraft occurred, then the process is repeated by subtracting $\tan^{-1}(0.1)$ until an overdraft occurs, and so forth, until we are left with a remaining angle r, which is small enough for the required level of accuracy of the calculator. Then θ can be expressed as

$$\theta = q_0 \tan^{-1}(1) + q_1 \tan^{-1}(0.1) + \cdots + r \tag{1}$$

Vector geometry is the basis for the formulas used to compute the tangent of θ once it has been broken up into the sum of smaller angles. Starting with a vector with angle θ_1 and then rotating it counter-clockwise by an additional angle of θ_2, Fig. 7 illustrates the following relationships:

$$X_2 = X_1 \cos\theta_2 - Y_1 \sin\theta_2$$
$$Y_2 = Y_1 \cos\theta_2 + X_1 \sin\theta_2$$

Dividing both sides of these equations by cos θ_2 we obtain:

$$X_2/\cos\theta_2 = X_1 - Y_1 \tan\theta_2 = X_2' \tag{2}$$

$$Y_2/\cos\theta_2 = Y_1 + X_1 \tan\theta_2 = Y_2' \tag{3}$$

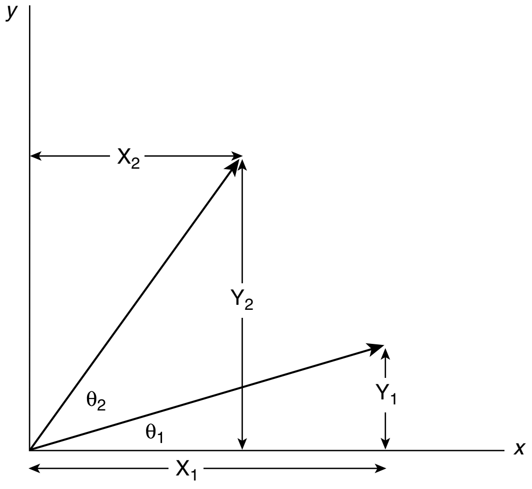

Figure 7.

As $Y_2/X_2 = \tan(\theta_1 + \theta_2)$, then by Equations 2 and 3, we can see that $Y_2'/X_2' = \tan(\theta_1 + \theta_2)$. Equations 2 and 3 can be used repeatedly to construct the tangent of θ, because θ has been broken down into a series of smaller angles, shown in Equation (1). The initial X_1 and Y_1 correspond to the small residual angle r. As r is a very small angle (in radians), $\sin(r)$ is close to r and $\cos(r)$ is close to 1, so if these values are close enough for our overall accuracy requirements, we can let Y_1 be r and X_1 be 1. Note Equations 2 and 3 involve finding tangents, but because we expressed θ as a sum of angles of the form $\tan^{-1}(10^{-k})$, $\tan(\tan^{-1}(10^{-k})) = 10^{-k}$, so each evaluation of Equations 2 or 3 will simply involve addition, subtraction, and multiplication by powers of 10. As the only multiplication involved is by powers of 10, the calculations can be accomplished more quickly and simply using a process called pseudomultiplication, which involves only addition and the shifting of contents of registers to simulate decimal point shifts that correspond to multiplication by powers of 10. The iterative process of using Equations 2 and 3 generates an X and Y, which are proportional to the sine and cosine of the original angle θ. Then elementary operations can be used to find the values of the various trigonometric functions for θ (16).

Logarithm Algorithms

Logarithms are found using a process similar to the approximation process used to compute trigonometric functions (17). It is a basic property of logarithms that $\ln(a_1 \times a_2 \times \ldots \times a_n) = \ln(a_1) + \ln(a_2) + \ldots + \ln(a_n)$. To find the logarithm of a number x, x is first expressed as product of factors whose logarithms are known. The number x will be stored in the calculator using scientific notation $x = M \times 10^k$, where M is called the mantissa and M is greater than or equal to 1 and less than 10. As $\ln = (M \times 10^k) = \ln(M) + k \times \ln(10)$, the problem of finding $\ln(x)$ is reduced to the problem of finding $\ln(M)$. Let a_j be numbers whose natural logarithms are known. Let $P = 1/M$. Then $-\ln(P) = \ln(M)$. Then express P as $P = P_n/r$, where $P_n = a_0^{k0} \times a_1^{k1} \times \ldots \times a_j^{kj}$ and r is a number close to 1. Note that $\ln(P) = \ln(P_n) - \ln(r)$, so now $\ln(M) = \ln(r) - \ln(P_n)$ and for r close to 1, $\ln(r)$ is close to 0. Also note that $M = 1/P = r/P_n$ implies that $M \times P_n = r$. So to find ln(M), we can first find P_n such that $M \times P_n$ is close to 1, where P_n is a product of specially chosen numbers a_j whose logarithms are known. To optimize this routine for a calculator's specialized microprocessor, values that give good results are $a_j = (1 + 10^{-j})$. Thus, for example, a_0, a_1, a_2, a_3, and a_4 would be 2, 1.1, 1.01, 1.001, and 1.0001. It turns out that M must first be divided by 10 to use these a_j choices. This choice of the a_j terms allows intermediate multiplications by each a_j to be accomplished by an efficient, simple shift of the digits in a register, similar to the pseudomultiplication used in the trigonometric algorithm.

CALCULATOR DESIGN CHOICES AND CHALLENGES

The requirements for a handheld calculator to be small, portable, inexpensive, and dedicated to performing computational tasks have driven many design choices. Custom integrted circuits and the CMOS process have been used because of low power requirements. Calculator software has been designed to use mostly ROM and very little RAM because of part cost and power constraints. Specialized algorithms have been developed and refined to be optimized for calculator CPUs. As calculators become more complicated, ease-of-use becomes an important design challenge. As memory becomes less expensive and calculators have more storage space, the keypad and display become bottlenecks when it comes to transferring large amounts of data. Improved input/output devices such as pen input, better displays, and character and voice recognition could all help to alleviate bottlenecks and make calculators easier to use.

A desktop PC does not fit the needs of personal portability. Desktop or laptop PCs are not very convenient to use as a calculator for quick calculations. Also, a PC is a generic platform rather than a dedicated appliance. The user must take the time to start up an application to perform calculations on a PC so a PC does not have the back-of-the-envelope type of immediacy of a calculator. Handheld PCs and palmtop PCs also tend to be generic platforms, only in smaller packages. So they are as portable as calculators, but they still do not have dedicated calculating functionality. The user must go out of their way to select and run a calculator application on a handheld PC. The keypad of a handheld PC has a QWERTY keyboard layout, and so it does not have keys dedicated to calculator functions like sine, cosine, and logarithms. Handheld organizers and personal digital assistants (PDAs) are closer to the calculator model, because they are personal, portable, battery-operated electronic devices that are dedicated to particular functionality, but they currently emphasize organizer functionality rather than mathematics functionality.

COMMUNICATION CAPABILITY

Some calculators have already had communication capability for many years, using infrared as well as serial cable and other types of cable ports. These have allowed calculators to communicate with other calculators, computers, printers, and overhead display devices that allow an image of the calculator screen to be enlarged and projected for a roomful of people, data collection devices, bar code readers, external memory storage, and other peripheral devices. Protocols are standard formats for the exchange of electronic data that allow different types of devices to communicate with each other. For example, Kermit is a file transfer protocol developed at Columbia University. By coding this protocol into a calculator, the calculator can communicate with any of a number of different types of computers by running a Kermit program on the computer. By programming appropriate protocols into calculators, they could work with modems and gain access to the Internet. Calculations could then be performed remotely on more powerful computers, and answers could be sent back to the calculator. Or calculators could be used for the delivery of curriculum material and lessons over the Internet.

TECHNOLOGY IN EDUCATION

Curriculum materials have changed with the increased use of graphing calculators in mathematics and science classrooms. Many precalculus and calculus textbooks and science workbooks now contain exercises that incorporate the use of calculators, which allows the exercise to be more complicated than the types of problems that could be easily solved with pencil and paper in a few minutes. With the use of calculators, more realistic and thus more interesting and extensive problems can be used to teach mathematics and science concepts. Calculators are becoming a requirement in many mathematics classes and on some standardized tests, such as the Scholastic Aptitude Test taken by most U.S. high-school seniors who plan to attend college. Educational policy has, in turn, influenced the design of graphing calculators. In the United States, the National Council of Teachers of Mathematics promoted the use of the symbolic, graphic, and numeric views for teaching mathematics. These views are reflected in the design of graphing calculators, which have keys dedicated to entering a symbolic expression, graphing it, and showing a table of function values. Figure 8 shows a graphing calculator display of the symbolic, graphic, and numeric views of sin(x) (18).

FUTURE NEED FOR CALCULATORS

Technical students and professionals will always need to do some back-of-the-envelope-type calculations quickly and conveniently. The key-per-function model of a calculator fits in nicely with this need. So does a device that is dedicated, personal, portable, low cost, and has long battery life. Users' expectations will be influenced by improvements in computer speed and memory size. Also, video game users have higher expectations for interactivity, better controls, color, animation, quick responses, good graphic design, and visual quality. For the future, calculators can take advantage of advances in computer technology and the decreasing cost of electronic components to move to modern platforms that have the benefits of increased speed, more memory, better displays, color displays, more versatile input devices (such as pen and voice), and more extensive communication capability (such as wireless communication).

FAULT-TOLERANT COMPUTING

INTRODUCTION

Fault-tolerant computing can be defined as the process by which a computing system continues to perform its specified tasks correctly in the presence of faults. These faults could be transient, permanent, or intermittent faults. A fault is said to be transient if it occurs for a very short duration of time. Permanent faults are the faults that continue to exist in the system, and intermittent faults repeatedly appear for a period of time. They could be either hardware or software faults caused by errors in specification, design, or implementation, or faults caused by manufacturing defects. They also could be caused by external disturbances or simply from the aging of the components.

The goal of fault-tolerant computing is to improve the dependability of a system where dependability can be defined as the ability of a system to deliver service at an acceptable level of confidence. Among all the attributes of dependability, reliability, availability, fault coverage, and safety commonly are used to measure the dependability of a system. Reliability of a system is defined as the probability that the system performs its tasks correctly throughout a given time interval. Availability of a system is the probability that the system is available to perform its tasks correctly at time *t*. Fault coverage, in general, implies the ability of the system to recover from faults and to continue to operate correctly given that it still contains a sufficient complex of functional hardware and software. Finally, the safety of a system is the probability that the system either will operate correctly or switch to a safe mode if it operates incorrectly in the event of a fault.

The concept of improving dependability of computing systems by incorporating strategies to tolerate faults is not new. Earlier computers, such as the Bell Relay Computer built in 1944, used ad hoc techniques to improve reliability. The first systematic approach for fault-tolerant design to improve system reliability was published by von Neumann in 1956. Earlier designers improved the computer system reliability by using fault-tolerance techniques to compensate for the unreliable components that included vacuum tubes and electromechanical relays that had high propensity to fail. With the advent of more reliable transistor technology, the focus shifted from improving reliability to improving performance. Although component reliability has drastically improved over the past 40 years, increases in device densities have led to the realization of complex computer systems that are more prone to failures. Furthermore, these systems are becoming more pervasive in all areas of daily life, from medical life support systems where the effect of a fault could be catastrophic to applications where the computer systems are exposed to harsh environments, thereby increasing their failure rates. Researchers in industry and academe have proposed techniques to reduce the number of faults. However, it has been recognized that such an approach is not sufficient and that a shift in design paradigm to incorporate strategies to tolerate faults is necessary to improve dependability. Moreover, advances in technologies, such as very large-scale integration (VLSI), have led to manufacturing processes that are not only complex but also sensitive, which results in lower yields. Thus, it is prudent to develop novel fault-tolerance techniques for yield enhancement.

Research in this area in the last 50 years has resulted in numerous highly dependable systems that span a wide range of applications from commercial transactions systems and process control to medical systems and space applications. However, the *ever increasing* complexity of computer systems and the *ever increasing* need for error-free computation results, together with advances in technologies, continue to create interesting opportunities and unique challenges in fault-tolerant computing.

PRINCIPLES OF FAULT-TOLERANT COMPUTER SYSTEMS

Although the goal of fault-tolerant computer design is to improve the dependability of the system, it should be noted that a fault-tolerant system does not necessarily imply a highly dependable system and that a highly dependable system does not necessarily imply a fault-tolerant system.

Any fault-tolerance technique requires the use of some form of redundancy, which increases both the cost and the development time. Furthermore, redundancy also can impact the performance, power consumption, weight, and size of the system. Thus, a good fault-tolerant design is a *trade-off* between the level of dependency provided and the amount of redundancy used. The redundancy could be in the form of hardware, software, information, or temporal redundancy.

One of the most challenging tasks in the design of a fault-tolerant system is to evaluate the design for the dependability requirements. All the evaluation methods can be divided into two main groups, namely the qualitative and the quantitative methods. Qualitative techniques, which typically are subjective, are used when certain parameters that are used in the design process cannot be quantified. For example, a typical user should not be expected to know about fault-tolerance techniques used in the system to use the system effectively. Thus, the level of transparency of the fault-tolerance characteristics of the system to the user could determine the effectiveness of the system.

As the name implies, in the quantitative methods, numbers are derived for a certain dependability attribute of the system and different systems can be compared with respect to this attribute by comparing the numerical values. This method requires the development of models. Several probabilistic models have been developed based on combinatorial techniques and Markov and semi-Markov stochastic processes. Some disadvantages of the combinatorial models are that it is very difficult to model complex systems and

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

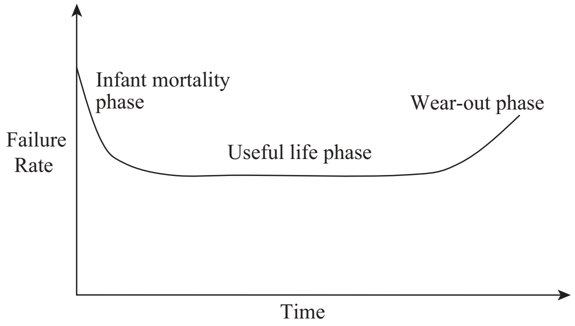

Figure 1. Bathtub curve.

difficult to model systems where repairing a faulty module is feasible.

Fundamental to all these models is the failure rate, defined as the expected number of failures per a time interval. Failure rates of most electronic devices follow a bathtub curve, shown in Fig. 1. Usually, the useful life phase is the most important phase in the life of a system, and during this time, the failure rate is assumed to be constant and denoted typically by λ. During this phase, reliability of a system and the failure rate are related by the following equation, which is known as the exponential failure law.

$$R(t) = e^{-\lambda t}$$

Figure 2 shows the reliability function with the constant failure rate. It should be noted that the failure rate λ is related to the mean time to failure (MTTF) as MTTF = 1/λ where MTTF is defined as the expected time until the occurrence of the first failure of the system.

Researchers have developed computer-aided design (CAD) tools based on quantitative methods, such as CARE III (the NASA Langley Research Center), SHARPE (Duke University), DEPEND (University of Illinois at Urbana-Champaign), and HIMAP (Iowa State University).

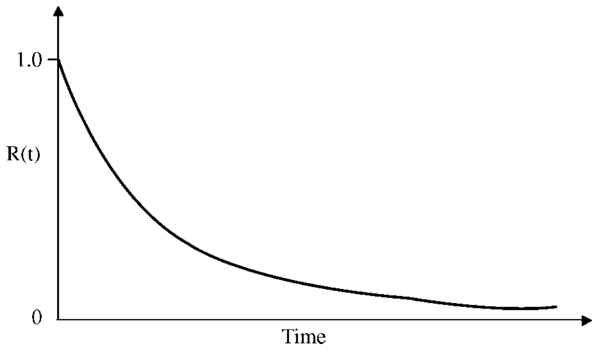

Figure 2. Reliability function with constant failure rate.

In the last several years, a considerable interest has developed in the experimental analysis of computer system dependability. In the design phase, CAD tools are used to evaluate the design by extensive simulations that include simulated fault injection; during the prototyping phase, the system is allowed to run under a controlled environment. During this time, physical fault injection is used for the evaluation purposes. Several CAD tools are available, including FTAPE developed at the University of Illinois at Urbana Champaign and Ballista developed at the Carnegie-Mellon University. In the following subsections, several common redundancy strategies for fault-tolerance will be described briefly.

Hardware Redundancy

Hardware redundancy is one of the most common forms of redundancy in which a computer system is partitioned into different subsystems or modules, and these are replicated so that a faulty module can be replaced by a fault-free module. Because each subsystem acts as a fault-containment region, the size of the fault-containment region dependes on the partitioning strategy.

Three basic types of hardware redundancy are used, namely, passive, active, and hybrid. In the passive techniques, also known as static techniques, the faults are masked or hidden by preventing them from producing errors. Fault masking is accomplished by voting mechanisms, typically majority voting, and the technique does not require any fault detection or system reconfiguration. The most common form of this type of redundancy is triple modular redundancy (TMR). As shown in Fig. 3, three identical modules are used, and majority voting is done to determine the output. Such a system can tolerate one fault. However, the voter is the single point of failure; that is, the failure of the voter leads to the compete failure of the system.

A generalization of the TMR technique is the N-modular redundancy (NMR), where N modules are used and N typically is an odd number. Such a system can mask up to $\lfloor \frac{N-1}{2} \rfloor$ faulty modules.

In general, the NMR system is a special case of an M-of-N system that consists of N modules, out of which at least M of them should work correctly in order for the system to operate correctly. Thus, system reliability of an M-of-N

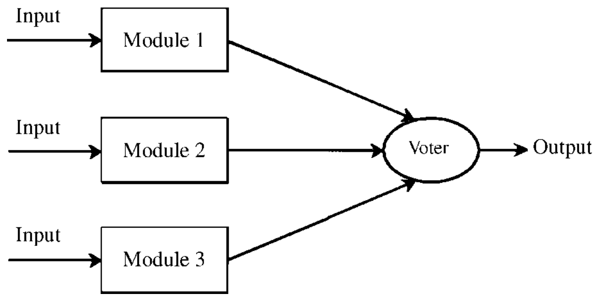

Figure 3. Basic triple modular redundancy.

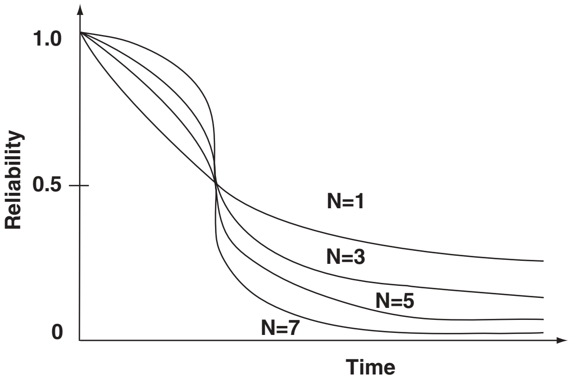

Figure 4. Reliability plots of NMR system with different values of N. Note that $N = 1$ implies a simplex system.

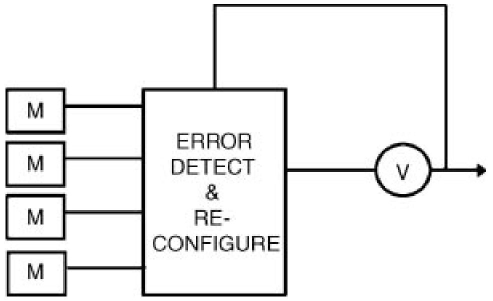

Figure 5. TMR system with hot spare.

system is given by

$$R(t) = \sum_{i=M}^{N} \binom{N}{i} R^{i}(t)\left[1 - R(t)\right]^{N-i}$$

For a TMR system, $N = 3$ and $M = 2$ and if an nonideal voter is assumed ($R_{\text{voter}}<1$), then the system reliability is given by

$$\begin{aligned} R(t) &= \sum_{i=2}^{3} \binom{3}{i} R^{i}(t)[1 - R(t)]^{3-i} \\ &= R_{voter}(t)\left(3R^{2}(t) - 2R^{3}(t)\right) \end{aligned}$$

Figure 4 shows reliability plots of simplex, TMR, and NMR when $N = 5$ and 7. It can be seen that higher redundancy leads to higher reliability in the beginning. However, the system reliability sharply falls at the end for higher redundancies.

In the active hardware redundancy, also known as dynamic hardware redundancy, some form of a reconfiguration process is performed to isolate the fault after it is detected and located. This process typically is followed by a recovery process to undo the effects of erroneous results. Unlike passive redundancy, faults can produce errors that are used to detect faults in dynamic redundancy. Thus, this technique is used for applications where consequences of erroneous results are not disastrous as long as the system begins to operate correctly within an acceptable time period. In general, active redundancy requires less redundancy than passive techniques. Thus, this approach is attractive for environments where the resources are limited, such as limited power and space. One major disadvantage of this approach is the introduction of considerable delays during the fault location, reconfiguration, and recovery processes. Some active hardware redundancy schemes include duplication with comparison, pair-and-a-spare technique, and standby sparing.

The hybrid hardware redundancy approach incorporates the desirable features of both the passive and active strategies. Fault masking is used to prevent the generation of erroneous results, and dynamic techniques are used when fault masking fails to prevent the production of erroneous results. Hybrid approaches usually are most expensive in terms of hardware. Examples of hybrid hardware redundancy schemes include self-purging redundancy, N-modular redundancy with spares, triple-duplex, sift-out modular redundancy, and the triple-triplex architecture used in the Boeing 777 primary flight computer.

Figure 5 shows a TMR system with a hot spare. The first fault is masked, and if this faulty module is replaced by the spare module, then the second fault also can be masked. Note that for a static system, masking two faults requires five modules. Reliability of the TMR system with a hot spare can be determined based on the Markov model shown in Fig. 6. Such models assume that (*1*) the system starts in the perfect state, (*2*) a single mode of failure exists, that is, only a single failure occurs at a time, and (*3*) each module follows the exponential failure law with a constant failure rate λ. A transition probability is associated with each state transition. It can be shown that if the module was operational at time t, then the probability that the module has failed at

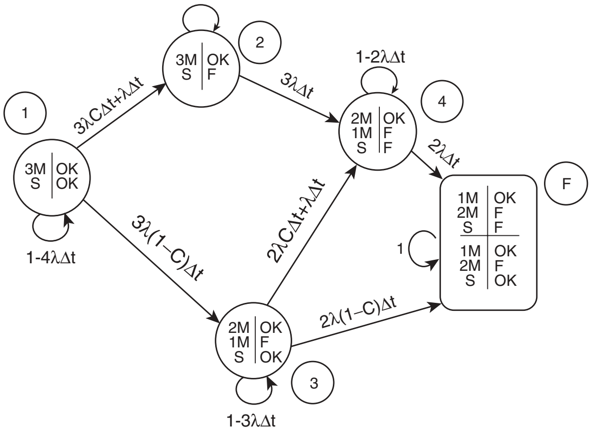

Figure 6. The Markov model of the TMR system with a hot spare.

time $t + \Delta t$ is

$$1 - e^{-\lambda \Delta t}$$

For $\lambda \Delta t < 1$,

$$1 - e^{-\lambda \Delta t} \approx \lambda \Delta t$$

The equations of the Markov model of the TMR system with a hot spare can be written in the matrix form as

$$\begin{bmatrix} P_1(t+\Delta t) \\ P_2(t+\Delta t) \\ P_3(t+\Delta t) \\ P_4(t+\Delta t) \\ P_F(t+\Delta t) \end{bmatrix} = \begin{bmatrix} 1 - 4\lambda\Delta t & 0 & 0 & 0 & 0 \\ 3\lambda C\Delta t + \lambda\Delta t & 1 - 3\lambda\Delta & 0 & 0 & 0 \\ 3\lambda(1-C)\Delta t & 0 & 1 - 3\lambda\Delta & 0 & 0 \\ 0 & 3\lambda\Delta t & 2\lambda C\Delta t + \lambda\Delta t & 1 - 2\lambda\Delta t & 0 \\ 0 & 0 & 2\lambda(1-C)\Delta t & 2\lambda\Delta t & 1 \end{bmatrix} \begin{bmatrix} P_1(t) \\ P_2(t) \\ P_3(t) \\ P_4(t) \\ P_5(t) \end{bmatrix}$$

The above discrete-time equations can be written in a compact form as

$$\mathbf{P}(t + \Delta t) = \mathbf{A}\mathbf{P}(t)$$

and the solution as

$$\mathbf{P}(n\Delta t) = \mathbf{A}^n \mathbf{P}(0)$$

where

$$P(0)| = \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

It can be seen that the system reliability $R(t)$ is given by

$$R(t) = 1 - P_F(t) = \sum_{i=1}^{4} P_i(t)$$

where $P_F(t)$ is the probability that the system has failed. The continuous-time equations can be derived from the above equations by letting Δt approach zero; that is

$$P_1'(t) = \lim_{\Delta t \to 0} \frac{P_1(t+\Delta t) - P_1(t)}{\Delta t}$$

$$P_1'(t) = \lim_{\Delta t \to 0} \frac{P_1(t+\Delta t) - P_1(t)}{\Delta t} = -4\lambda P_1(t)$$

Similarly,

$$P_2'(t) = (3C + 1)\lambda P_1(t) - 3\lambda P_2(t)$$

$$P_3'(t) = (1 - C)3\lambda P_1(t) - 3\lambda P_3(t)$$

$$P_4'(t) = 3\lambda P_2(t) - 2\lambda P_4(t) + (2C\lambda + \lambda)P_3(t)$$

$$P_F'(t) = (2\lambda - 2\lambda C)P_3(t) + 2\lambda P_4(t)$$

Using Laplace transforms

$$sP_1(s) - P_1(0) = -4\lambda P_1(s)$$

$$P_1(s) = \frac{1}{s + 4\lambda} \Rightarrow P_1(t) = e^{-4\lambda t}$$

$$sP_2(s) - P_2(0) = P_1(s)(3C + 1)\lambda - 3\lambda P_2(s)$$

$$P_2(s) = \frac{(3C+1)\lambda}{(s+3\lambda)(s+4\lambda)} = (3C+1)\left(\frac{1}{s+3\lambda} - \frac{1}{s+4\lambda}\right)$$

$$P_2(t) = (3C + 1)(e^{-3\lambda t} - e^{-4\lambda t})$$

In the similar way,

$$P_3(t) = 3(1 - C)(e^{-3\lambda t} - e^{-4\lambda t})$$

$$P_4(t) = -3(C^2 - 2C - 1)(e^{-4\lambda t} + e^{-2\lambda t} - 2e^{-3\lambda t})$$

$$R(t) = 1 - P_F(t) = \sum_{i=1}^{4} P_i(t)$$

It can be seen that when the failure rate, λ, is 0.1 failures/hour and the fault coverage is perfect ($C = 1$) then the reliability of the TMR system with a hot spare is greater than the static TMR system after one hour. Moreover, it can be noted that the system reliability can be improved by modifying the system so that it switches to simplex mode after the second failure.

Software Redundancy

Unlike hardware faults, software faults are caused by mistakes in software design and implementation. Thus, a software fault in two identical modules cannot be detected by usual comparison. Many software fault-tolerance techniques have used approaches similar to that of the hardware redundancy. Most of these schemes assume fault independence and full fault coverage and fall under the software replication techniques, including *N*-version programming, recovery blocks, and *N* self-checking programming.

The basic idea of *N*-version programming is to design and code *N* different software modules; the voting is performed, typically majority voting, on the results produced by these modules. Each module is designed and implemented by a separate group of software engineers, based on the same specifications. Because the design and implementation of each module is done by an independent group, it is expected that a mistake made by a group will not be repeated by another group. This scheme complements *N*-modular hardware redundancy. A TMR system where all three processors are running the same copy of the software module will be rendered useless if a software fault will affect all the processors in the same way. *N*-version programming can avoid the occurrence of such a situation. This scheme is prone to faults from specification mistakes. Thus, a proven methodology should be employed to verify the correctness of the specifications.

In an ultra- reliable system, each version should be made as diverse as possible. Differences may include software developers, specifications, algorithms, programming languages, and verification and validation processes. Usually it is assumed that such a strategy would make different versions fail independently. However, studies have shown that although generally this is true, instances have been reported where the failures were correlated. For example, certain types of inputs, such as division by zero, that need special handling and potentially are overlooked easily by different developers could lead to correlated failures.

In the recovery block schemes, one version of the program is considered to be the primary version and the remaining *N*-1 versions are designated as the secondary versions or spares. The primary version normally is used if it passes the acceptance tests. Failure to pass the acceptance tests prompts the use of the first secondary version. This process is continued until one version is found that passes the acceptance tests. Failure of the acceptance tests by all the versions indicates failure of the system. This approach is analogous to the cold standby sparing approach of the hardware redundancy, and it can tolerate up to *N*-1 faults.

In *N* self-checking programming, *N* different versions of the software, together with their acceptance tests, are written. The output of each program, together with its acceptance tests results, are input to a selection logic that selects the output of the program that has passed the acceptance tests.

Information Redundancy

Hardware redundancy is very effective but expensive. In information redundancy, redundant, information is added to enable fault detection, and sometimes fault tolerance, by correcting the affected information. For certain systems, such as memory and bus, error-correcting codes are cost effective and efficient. Information redundancy includes all error-detecting codes, such as various parity codes, *m-of-n* codes, duplication codes, checksums, cyclic codes, arithmetic codes, Berger codes, and Hamming error-correcting codes.

Time Redundancy

All the previous redundancy methods require a substantial amount of extra hardware, which tends to increase size, weight, cost, and power consumption of the system. Time redundancy attempts to reduce the hardware overhead by using extra time. The basic concept is to repeat execution of a software module to detect faults. The computation is repeated more than once, and the results are compared. An existence of discrepancy suggests a fault, and the computations are repeated once more to determine if the discrepancy still exists. Earlier, this scheme was used for transient fault detection. However, with a bit of extra hardware, permanent faults also can be detected. In one of the schemes, the computation or transmission of data is done in the usual way. In the second round of computation or transmission, the data are encoded and the results are decoded before comparing them with the previous results. The encoding scheme should be such that it enables the detection of the faults. Such schemes may include complementation and arithmetic shifts.

Coverage

The coverage probability *C* used in the earlier reliability-modeling example was assumed to be a constant. In reality, of course, it may well vary, depending on the circumstances. In that example (TMR with a spare), the coverage probability is basically the probability that the voting and switching mechanism is functional and operates in a timely manner. This probability in actuality may be dependent on the nature of the fault, the time that it occurs, and whether it is the first or the second fault.

In systems in which the failure rate is dominated by the reliability of the hardware modules being protected through redundancy, the coverage probability may be of relatively minor importance and treating it as a constant may be adequate. If extremely high reliability is the goal, however, it is easy to provide sufficient redundancy to guarantee that a system failure from the exhaustion of all hardware modules is arbitrarily small. In this case, failures from imperfect coverage begin to dominate and more sophisticated models are needed to account for this fact.

It is useful to think of fault coverage as consisting of three components: the probability that the fault is detected, the probability that it is isolated to the defective module, and the probability that normal operation can be resumed successfully on the remaining healthy modules. These probabilities often are time dependent, particularly in cases in which uninterrupted operation is required or in which loss of data or program continuity cannot be tolerated. If too much time elapses before a fault is detected, for example, erroneous data may be released with potentially unacceptable consequences. Similarly, if a database is corrupted before the fault is isolated, it may be impossible to resume normal operation.

Markov models of the sort previously described can be extended to account for coverage effects by inserting additional states. After a fault, the system transitions to a state in which a fault has occurred but has not yet been detected, from there to a state in which it has been detected but not yet isolated, from there to a state in which it has been isolated but normal operation has not yet resumed successfully, and finally to a successful recovery state. Transitions out of each of those states can be either to the next state in the chain or to a failed state, with the probability of each of these transitions most likely dependent on the time spent in the state in question. State transition models in which the transition rates are dependent on the state dwelling-time are called semi-Markov processes. These models can be analyzed using techniques similar to those illustrated in the earlier Markov analysis, but the analysis is complicated by the fact that differences between the transition rates that pertain to hardware or software faults and those that are associated with coverage faults can be vastly different. The mean time between hardware module failures, for example, typically is on the order of thousands of hours, whereas the time between the occurrence of a fault and its detection may well be on the order of microseconds. The resulting state-transition matrix is called "stiff", and any attempt to solve it numerically may not converge. For this reason, some of the aforementioned reliability models use a technique referred to as behavioral decomposition. Specifically, the model is broken down into its component parts, one subset of models used to account for coverage failures and the second incorporating the outputs of those models into one accounting for hardware and software faults.

FAULT TOLERANT COMPUTER APPLICATIONS

Incorporation of fault tolerance in computers has tremendous impact on the design philosophy. A good design is a trade-off between the cost of incorporating fault tolerance and the cost of errors, including losses from downtime and the cost of erroneous results.

Over the past 50 years, numerous fault-tolerant computers have been developed. Historically, the applications of the fault-tolerant computers were confined to military, communications, industrial, and aerospace applications where the failure of a computer could result in substantial financial loses and possibly loss of life. Most of the fault-tolerant computers developed can be classified into five general categories.

General-Purpose Computing

General-purpose computers include workstations and personal computers. These computers require a minimum level of fault tolerance because errors that disrupt the processing for a short period of time are acceptable, provided the system recovers from these errors. The goal is to reduce the frequency of such outages and to increase reliability, availability, and maintainability of the system.

Because the attributes of each of the main components, namely the processor, memory, and input/output, are unique, the fault-tolerant strategies employed for these components are different, in general. For example, the main memory may use a double-error detecting code on data and on address and control information, whereas cache may use parity on both data and address information. Similarly, the processor may use parity on data paths and control store and duplication and comparison of control logic, whereas input/output could use parity on data and control information.

Moreover, it is well known that as feature sizes decrease, the systems are more prone to transient failures than other failures and it is desirable to facilitate rapid recovery. One of the most effective approaches for rapid error recovery for transient faults is instruction retry, in which the appropriate instruction is retried once the error is detected. The instruction retry concept has been extended to a wide variety of other systems, including TMR systems and Very Large Instruction Word (VLIW) architectures.

Long-Life Applications

Applications in which manual intervention is impractical or impossible, such as unmanned space missions, demand systems that have a high probability of surviving unattended for long periods of time. Typical specifications require a 95% or better probability that the system is still functional at the end of a five- or ten-year mission. Computers in these environments are expected to use the hardware in an efficient way because of limited power availability and constraint on weight and size. Long-life systems sometimes can allow extended outages, provided the system becomes operational again. The first initiative for the development of such computers was taken by NASA for the Orbiting Astronomical Observatory, in which basic fault masking at the transistor level was used. Classic examples of systems for long-life applications include the Self-Testing And Repairing (STAR) computer, the Fault-Tolerant Space-borne Computer (FTSC), the JPL Voyager computers, and the Fault-Tolerant Building Block Computer (FTBBC).

The STAR computer was the first computer that used dynamic recovery strategies that used extensive instrumentation for fault detection and signal errors. Galileo Jupiter system is a distributed system based on 19 microprocessors with 320 kilobytes of ROM. Block redundancy is used for all the subsystems, and they operate as standby pairs, except the command and data subsystem that operate as an active pair. Although special fault protection software is used to minimize the effects of faults, fault identification and isolation are by ground intervention.

Critical-Computation Applications

In these applications, errors in computations can be catastrophic, affecting such things as human safety. Applications include a certain type of industrial controllers, aircraft flight control systems, and military applications. A typical requirement for such a system is to have reliability of 0.9999999 at the end of 3-hour time period.

An obvious example of a critical-computation application is the space shuttle. Its computational core employs software voting in a five-computer system. The system is responsible for guidance, navigation, and preflight checkouts. Four computers are used as a redundant set during mission-critical phases, and the fifth computer performs noncritical tasks and also act as a backup for the primary four-computer system. The outputs of the four computers are voted at actuators while each computer compares its output with the outputs of the other three computers. A disagreement is voted by the redundancy-management circuitry of each computer, and it will isolate its computer if the vote is positive. Up to two computer failures can be tolerated in the voting mode operation. A second failure will force the system to function as a duplex system, that uses comparison and self-tests, and it can tolerate one more failure in this mode. The fifth computer contains the flight software package developed by another vendor to avoid common software error.

Another interesting system that was developed recently is the flight control computer system of Boeing 777. In avionics, system design diversity is an important design criterion to tolerate common-mode failures, such as design flaws. One of the specifications includes mean time between maintenance actions to be 25,000 hours. The system can tolerate certain Byzantine faults, such as disagreement between the replicated units, power and component failures, and electromagnetic interference. The system uses triple-triplex redundancy, in which design diversity is incorporated by using three dissimilar processors in each triplex node. Each triplex node is isolated physically and electrically from the other two nodes. However, recent studies suggest that a single-point of failure exists in the software system. Instead of using different teams to generate different versions of the source code in Ada Boeing decided to use the same source code but three different Ada compilers to generate the object code.

High-Availability Applications

The applications under this category include time-shared systems, such as banking and reservation systems, where providing prompt services to the users is critical. In these applications, although system-wide outages are unacceptable, occasional loss of service to individual users is acceptable provided the service is restored quickly so that the downtime is minimized. In fact sometimes the downtime needed to update software and upgrade hardware may not be acceptable, and so well-coordinated approaches are used to minimize the impact on the users. Some examples of early highly available commercial systems include the NonStop Cyclone, Himalaya K10000, and Integrity S2, all products of Tandem Computers now part of Hewlett Packard; the Series 300 and Series 400 systems manufactured by Sequoia Systems, now owned by Radisys Corporation; and the Stratus XA/R Series 300 systems of the Stratus family.

system that was designed to prevent a single hardware or software failure from disabling the entire system. The processors are independent and use Tandem's GURADIAN 90 fault-tolerant operating system with load balancing capabilities. The NonStop Cyclone system employs both hardware and software fault-tolerant strategies. By extensively using hardware redundancy in all the subsystems—multiple processors, mirrored disks, multiple power supplies, redundant buses, and redundant input/output controllers—a single component failure will not disable the system. Error propagation is minimized by making sure that fault detection, location, and isolation is done quickly. Furthermore, Tandem has incorporated other features that also improve the dependability of the system. For example, the system supports on-site replaceable, hot-pluggable cards known as field replaceable units (FRUs) to minimize any downtime.

In the newer S-series, NonStop Himalaya servers (Figure 8), the processor and I/O buses are replaced by proprietary network architecture called the ServerNet that incorporates numerous data integrity schemes. Furthermore, redundant power and cooling fans are provided to ensure continuity in service. A recent survey suggests that more than half of the credit card and automated teller machine transactions are processed by NonStop Himalaya computers.

Stratus Technologies, Inc. has introduced fault-tolerant servers with the goal of providing high availability at lower complexity and cost. For example, its V series server systems that are designed for high-volume applications use TMR hardware scheme to provide at least 99.999% probability of surviving all hardware faults. These systems use Intel Xeon Processors and run on a Stratus VOS operating system that provides a highly secured environment. A single copy manages a module that consists of tightly coupled processors.

The Sequoia computers were designed to provide a high level of resilience to both hardware and software faults and to do so with a minimum of additional hardware. To this end, extensive use was made of efficient error detection and correction mechanisms to detect and isolate faults combined with the automatic generation of periodic system-level checkpoints to enable rapid recovery without loss of data or program continuity. Checkpoints are established typically every 40 milliseconds, and fault recovery is accomplished in well under a second, making the occurrence of a fault effectively invisible to most users.

Recently Marathon Technologies Corporation has released software solutions, *everRun FT* and *everRun HA,* that enable any two standard Windows servers to operate as a single, fully redundant Windows environment, protecting applications from costly downtime due to failures within the hardware, network, and data.

Maintenance Postponement Applications

Applications where maintenance of computers is either costly or difficult or perhaps impossible to perform, such as some space applications, fall under this category. Usually the breakdown maintenance costs are extremely high for the systems that are located in remote areas. A maintenance crew can visit these sites at a frequency that is cost-effective. fault-tolerance techniques are used between these visits to ensure that the system is working correctly. Applications where the systems may be remotely located include telephone switching systems, certain renewable energy generation sites, and remote sensing and communication systems. One of the most popular systems in the literature in this group is AT&T's Electronic Switching System (ESS). Each subsystem is duplicated. While one set of these subsystems perform all the functions, the other set acts as a backup.

PRINCIPLES OF FAULT-TOLERANT MULTIPROCESSORS AND DISTRIBUTED SYSTEMS

Although the common perception is that the parallel systems are inherently fault-tolerant, they suffer from high failure rates. Most of the massively parallel systems are built based on performance requirements. However, their dependability has become a serious issue; numerous techniques have been proposed in the literature, and several vendors have incorporated innovative fault-tolerance schemes to address the issue. Most of these schemes are hierarchical in nature incorporating both hardware and software techniques. Fault-tolerance techniques are designed for each of the following levels such that the faults that are not detected at lower levels should be handled at higher levels.

At the technology and circuit levels, decisions are made to select the appropriate technology and circuit design techniques that will lead to increased dependability of the modules. At the node level, architecture involves design of VLSI chips that implement the processor, whereas at the internode architecture level, considerations are given to how the nodes are connected and effective reconfiguration in the presence of faulty processors, switches, and links. At the operating system level, recovery of the system is addressed, which may involve checkpointing and rollback after a certain part of the system has been identified faulty and allocating tasks of the faulty processor to the remaining operating processor. Finally, at the application level, the user uses mechanisms to check the results.

A couple of most popular approaches to fault tolerance in multiprocessor systems are static or masking redundancy and dynamic or standby redundancy

Static Redundancy

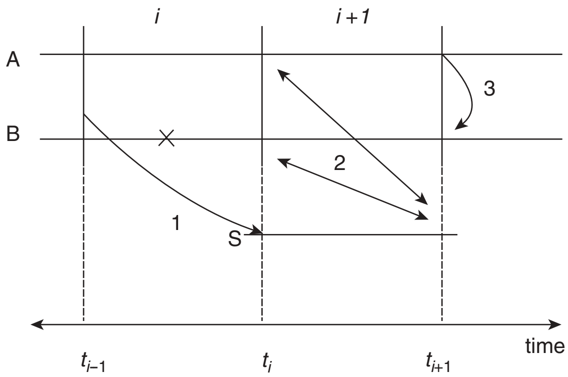
Static redundancy is used in multiprocessor system for reliability and availability, safety, and to tolerate nonclassic faults. Although redundancy for reliability and availability uses the usual NMR scheme, redundancy for safety usually requires a trade-off between reliability and safety. For example, one can use a k-out-of-n system where a voter produces the output y only if at least k modules agree on the output y. Otherwise the voter asserts the unsafe flag. The reliability refers to the probability that the system produces correct output, and safety refers to the probability that the system either produces the correct output or the error is detectable. Thus, high reliability implies high safety. However, the reverse is not true.

Voting of the NMR system becomes complicated when nonclassic faults are present. In systems requiring ultrahigh reliability, a voting mechanism should be able to handle arbitrary failures, including the malicious faults where more than one faulty processor may collaborate to disable the system. The Byzantine failure model was proposed to handle such faults.

Dynamic Redundancy

Unlike static redundancy, dynamic redundancy in multiprocessor systems includes built-in fault detection capability. Dynamic redundancy typically follows three basic steps: (*1*) fault detection and location, (*2*) error recovery, and (*3*) reconfiguration of the system. When a fault is detected and a diagnosis procedure locates the fault, the system is usually reconfigured by activating a spare module; if the spare module is not available, then the reconfigured system may have to operate under a degraded mode with respect to the resources available. Finally, error recovery is performed in which the spare unit takes over the functionality of the faulty unit from where it left off. Although various approaches have been proposed for these steps, some of them have been successfully implemented on the real systems. For example, among the recovery strategies, the most widely adopted strategy is the rollback recovery using checkpoints. The straightforward recovery strategy is to terminate execution of the program and to re-execute the complete program from the beginning on all the processors, which is known as the global restart. However, this leads to severe performance degradation. Thus, the goal of all the recovery strategies is to perform effective recovery from the faults with minimum overheads. The rollback recovery using checkpoints involves storing on adequate amount of processor state information at discrete points during the execution of the program so that the program can be rolled back to these points and restarted from there in the event of a failure. The challenge is when and how these checkpoints are created. For interacting processes, inadequate checkpointing may lead to a domino effect where the system is forced to go to a global restart state. Over the years, researchers have proposed strategies that effectively address this issue.

Although rollback recovery schemes are effective in most systems, they all suffer from substantial inherent latency that may not be acceptable for real-time systems. For such systems, forward recovery schemes are typically used. The basic concept common to all the forward recovery schemes is that when a failure is detected, the system discards the current erroneous state and determines the correct state without any loss of computation. These schemes are either based on hardware or software redundancy. The hardware based schemes can be classified further as static or dynamic redundancy. Several schemes based on dynamic redundancy and checkpointing that avoid rollback have been proposed in the literature. Like rollback schemes, when a failure is detected, the roll-forward checkpointing schemes (RFCS) attempt to determine the faulty module and the correct state of the system is restored once the fault diagnosis is done, although the diagnostic methods may differ. For example, in one RFCS, the faulty processing module is identified by retrying the computation on a spare processing module. During this retry, the duplex modules continue to operate normally. Figure 9 shows execution of two copies, A and B of a task. Assume that B fails in the checkpointing interval i. The checkpoints of A and B will not match at the end of the checkpointing interval i at time t_i. This mismatch will trigger concurrent retry of the checkpoint interval i on a spare module, while A and B continue to execute into the checkpointing interval i+1. The previous checkpoint taken



1: Copy state and executable code to spare
2: Compare states A and S and B and S
3: Copy state from A to B
X: A fault

Figure 9. A RFCS scheme.

at t_{i-1} together with the executable code is loaded into the spare, and the checkpoint interval i in which the fault occurred is retired on the spare module. When the spare module completes the execution at time t_{i+1} the state of the spare module is compared with the states of A and B at time t_i and B is identified faulty. State of A copied to B. A rollback is required when both A and B have failed. In this scheme, one fault is tolerated without paying the penalty of the rollback scheme. Several version of this scheme have been proposed in the literature.

FAULT-TOLERANCE IN VLSI CIRCUITS

The advent of VLSI circuits has made it possible to incorporate fault-tolerant techniques that were too expensive to implement earlier. For example, it has enabled schemes to provide redundant processors and fault detection and location capabilities within the chip. This is mainly from increasing packaging densities and decreasing cost and power consumption. However, VLSI also has several disadvantages. Some of these disadvantages include a higher percentage of internal faults compared with previous small-scale integration (SSI) and large-scale integration (LSI) during the manufacturing phase leading to low yield; increased complexity of the system has led to considerable increase in design mistakes, and imperfections can lead to multiple faults from smaller feature sizes. Furthermore, VLSI circuits are more prone to common-mode failures, and decreased feature sizes and lower operating voltages have made the circuits more susceptible to external disturbances, such as a particles and variations in the supply voltages, respectively, which lead to an increase in transient faults. Thus, the main motivations for incorporating fault-tolerance in VLSI circuits is yield enhancement and to enable real-time and compile-time reconfiguration with the goal of isolating a faulty functional unit, such as a processor or memory cells, during field operation.

Strategies for manufacture-time and compile-time reconfigurations are similar since they do not affect the normal operation of the system and no real-time constraints are imposed on reconfiguration time. Real-timer reconfiguration schemes are difficult to design since the reconfiguration has to be performed without affecting the operation of the system. If erroneous results are not acceptable at all, then static or hybrid techniques are typically used; otherwise, cheaper dynamic techniques would suffice. The effectiveness of any reconfiguration scheme is measured by the probability that a redundant unit can replace a faulty unit and the amount of reconfiguration overhead involved.

Numerous schemes have been proposed for all three types of reconfiguration in the literature. One of the first schemes that was proposed for an array of processing elements allowed each processing element to be converted into a connecting element for signal passing so that a failed processor resulted in converting other processors in the corresponding row and column to connecting elements and they ceased to perform any computation. This simple scheme is not practical for multiple faults since an entire row and column must be disabled for each fault. This problem has been addressed by several reconfiguration schemes that either use spare columns and rows or redundant processing elements are dispersed throughout the chip, such as the interstitial redundancy scheme.

Advances in nanometer-scale geometries have made devices prone to new types of defects that greatly limit the yields. Furthermore, the existing external infrastructure, such as automatic test equipment (ATE), are not capable of dealing with the new defect levels that nanometer-scale technologies create in terms of fault diagnosis, test time, and handling & the amount of test data generated. In addition, continual development of ATE facilities that can deal with the new manufacture issues is not realistic. This has considerably slowed down the design of various system-on-a-chip efforts. For example, although the embedded memory typically occupies half of the IC area, their defect densities tend to be twice that of logic. Thus, to achieve and maintain cost advantages requires improving memory yields. As described, one commonly used strategy to increase yield is to incorporate redundant elements that can replace the faulty elements during the repair phase. The exiting external infrastructure cannot perform these tasks in a cost-effective way. Thus, a critical need exists for an on-chip (internal) infrastructure to resolve these issues effectively. The semiconductor industry has attempted to address this problem by introducing embedded intellectual property blocks called the infrastructure intellectual property (IPP). For embedded memory, the IPP may consist of various types of test and repair capabilities.

TRENDS AND FUTURE

In the last few years, several developments have occurred that would define the future activities in the fault-tolerance area in general.

Conventional fault-tolerance techniques do not render themselves well in the area of mobile computing. For example, most schemes for checkpointing coordination and message logging schemes are usually complex and difficult to control because of the mobility of the hosts. Similarly, in the area of reconfigurable computing, including field programmable gate arrays (FPGAs), new fault-tolerance strategies are being developed based on the specific architectures.

Recent advances in nanoscience and nanometer-scale devices, such as carbon nanotubes and single electron transistors, will drastically increase device density and at the same time reduce power needs, weight, and size. However, these nanosystems are expected to suffer from high failure rates, both transient and permanent faults, because of the probabilistic behavior of the devices and lack of maturity in the manufacturing processes that will reduce the process yield. In fact, it is expected that the fault densities will be orders of magnitude greater than the current technology. This new circuit design paradigm is needed to address these issues. However, this will be an evolving area as the device fabrication processes are being scaled-up from the laboratory to the manufacturing level.

A good viable alternative approach for fault-tolerance would be to mimic biological systems. There is some activity in this area, but it is still in its infancy. For example, an approach to design complex computing systems with inherent fault-tolerance capabilities based on the embryonics was recently proposed. Similarly, a fault detection/location and reconfiguration strategy was proposed last year that was based on cell signaling, membrane trafficking, and cytokinesis.

Furthermore, there is an industry trend in space and aerospace applications to use commercial off-the-shelf (COTS) components for affordability. Many COTS have dependability issues, and they are known to fail when operated near their physical limits, especially in military applications. Thus, innovative fault-tolerance techniques are needed that can strike an acceptable balance between dependability and cost.

Moreover, although the hardware and software costs have been dropping, the cost of computer downtime has been increasing because of the increased complexity of the systems. Studies suggest that the state-of-the-art fault-tolerant techniques are not adequate to address this problem. Thus, a shift in the design paradigm may be needed. This paradigm shift is driven in large part by the recognition that hardware is becoming increasingly reliable for any given level of complexity, because, based on empirical evidence, the failure rate of an integrated circuit increases roughly as the 0.6th power of the number of its equivalent gates. Thus, for a given level of complexity, the system fault rate *decreases* as the level of integration increases. If, say, the average number of gates per device in a system is increased by a factor of 1000, the fault rate for that system decreases by a factor of roughly 16. In contrast, the rapid increase in the complexity of software over the years, because of the enormous increase in the number and variety of applications implemented on computers, has not been accompanied by a corresponding reduction in software bugs. Significant improvements have indeed been made in software development, but these are largely offset by the increase in software complexity and in the increasing opportunity for software modules to interact in unforeseen ways as the number of applications escalate. As a result, it is expected that the emphasis in future fault-tolerant computer design will shift from techniques for circumventing hardware faults to mechanisms for surviving software bugs.

FIBER-OPTIC COMMUNICATION NETWORKS

INTRODUCTION

The continuing growth of traffic and demand for bandwidth has changed dramatically the telecommunication market and industry, and has created new opportunities and challenges. The proliferation of DSL and cable modems for residential homes and Ethernet links for businesses have spurred the need to upgrade network backbones with newer and faster technologies. It is estimated that Internet traffic doubles every 12 months driven by the popularity of Web services and the leveraged business model for data centers and centralized processing. The Telecom Deregulation Act of 1996 brought competition to the marketplace and altered the traditional traffic profile. Competition brought about technological advances that reduced the cost of bandwidth and allowed the deployment of data services and applications that in turn fueled higher demand for bandwidth. Coupled with the fact that most networks were optimized for carrying voice traffic, the telecommunication providers have had to change their business models and the way they build networks. As a result, voice and data traffic are now carried over separate networks, which doubles the cost and renders service delivery and network operation and management inefficient.

Optical networking seems to be the fix for all problems and limitations despite the downturn in the telecommunications industry in general and optical networking in particular, because all-optical or photonic switching is the only core networking technology that is capable of supporting the increasing amount of traffic and the demands for higher bandwidth, brought about by emerging applications such as grid computing and tele-immersion. Needless to say that optical fibers offer far more bandwidth than copper cables and are less susceptible to electromagnetic interference. Several fibers are bundled easily into a fiber cable and support transmissions with ultra-low bit error rates. As a result, optical fibers are currently used to alleviate the bandwidth bottleneck in the network core, whereas traditional copper cables are limited to the last mile. Advances in *wavelength-division multiplexing* (WDM) have provided abundant capacity in effect dividing the optical fiber into several channels (or wavelengths) where each wavelength can support upwards of 10 Gbps. In the first generation of optical networks, deployed primarily to support SONET/SDH, these wavelengths are provisioned manually and comprise static connections between source and destination nodes. However, as the wavelength data rate increases, the intermediate electronic processing at every node becomes problematic and limits the available bandwidth. The second generation of optical networks integrates intelligent switching and routing at the optical layer to achieve very high data throughput. All optical transparent connections, or *lightpaths*, are dynamically provisioned and routed where wavelength conversion and fiber delay lines can be used to provide spatial and temporal reuse of channels. These networks are referred to as *wavelength-routed networks* (WRNs) where several optical switching technologies exist to leverage the available wavelengths among various traffic flows while using a common signaling and control interface such as *generalized multi-protocol label switching* (GMPLS).

The rest of this article first discusses the SONET transport, which is used heavily in the core networks and presents some of the proposed enhancements for reducing SONET's inefficiencies when supporting Ethernet traffic. The WRNs are introduced, and the concepts of lightpath, traffic grooming, and waveband switching are discussed later in this article. Several switching technologies are then presented highlighting their advantages and disadvantages as well as their technical feasibility. Finally, the various control and signaling architectures in optical networks are discussed, emphasizing the interaction between the IP and optical layers as well as path protection and restoration schemes.

CURRENT TRANSPORTS

A *Synchronous Optical Network* (SONET) (1) has been the predominant transport technology used in today's wide area networks, and forms the underlying infrastructure for most voice and data services. SONET was designed to provide carrier-class service (99.999%) reliability, physical layer connectivity, and self-healing. Time-division multiplexing (TDM) standards are used to multiplex different signals that are transported optically and switched electronically using timeslots to identify destinations. SONET is deployed generally in ring networks to provide dedicated point-to-point connections between any two source and destination node pairs. Two common ring architectures with varying degrees of protection exist: *unidirectional path switched rings* (UPSRs) and *bi-directional line switched rings* (BLSRs). These rings are often built using *add/drop multiplexers* (ADMs) to terminate connections and multiplex/demultiplex client signals onto/from the SONET frames, which implies that the optical signal undergoes optical–electro–optical (O–E–O) conversions at every intermediate hop.

The fundamental frame in traditional and optical SONET is the *Synchronous Transport Signal level-1* (STS-1), which consists of 810 bytes often depicted as a 90-column by 9-row structure. With a frame length of 125 μs (or 8000 frames per second), STS-1 has a bit rate of 51.84 Mbps. The STS-1 frame can be divided into two main areas: the transport overhead and the synchronous payload envelope (SPE). A SONET connection is provisioned by the *contiguous concatenation* (CC) of STS-1 frames to achieve the desired rate. SONET framing has proven inefficient for transporting bursty data traffic, because additional protocols, such as asynchronous

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Table 1. Wasted Bandwidth

Application	Data rate	NG-SONET	SONET
Ethernet	10 Mbps	12%	80%
Fast Ethernet	100 Mbps	1%	33%
Gigabit Ethernet	1 Gbps	5%	58%

transfer mode (ATM), are required to adapt the various traffic flows, such as constant bit rate (voice) and unspecified bit rate (data) connections, to the SPE containers. The layering of ATM on SONET has worked adequately but proved to be inefficient when carrying data traffic; the ATM layering incurs about 15% overhead. In addition, because of the SPE fixed-size, SONET connections are provisioned to support the peak data rates, which often leads to over-allocation especially when the traffic load is low.

A more recent approach is the *next-generation SONET* (NG-SONET) specification (2), which provides carriers with the capabilities of optimizing the bandwidth allocation and using any unused and fragmented capacity across the ring network, to better match the client data rate as shown in Table 1.

The new protocols required in NG-SONET are the *generic framing procedure* (GFP), *virtual concatenation* (VC), and *link capacity adjustment scheme* (LCAS). GFP is an encapsulation mechanism used to adapt different services to the SONET frames. The GFP specification provides for single-and multi-bit header error correction capabilities and channel identifiers for multiplexing client signals and data packets onto the same SONET SPE. VC is the main component of NG-SONET. It is used to distribute traffic into several smaller containers, which are not necessarily contiguous, but can be concatenated into virtual groups (VCGs) to form the desired rate. The benefits of VC include:

1. Better network utilization: Low-order data connections can be provisioned in increments of 1.5-Mbps virtual tributary (VT-1.5) instead of STS-1 frames.
2. Noncontiguous frame allocation: This facilitates the provisioning of circuits and improves the network utilization as available, but fragmented capacity can be allocated rather than wasted.
3. Load balancing and service resiliency: Through the use of diverse paths, the source can balance the traffic load among different paths, which provides some degree of resiliency; a fiber cut will only affect some VCs, thereby degrading the service without complete interruption.

LCAS is a two-way handshake protocol that allows for dynamic provisioning and reconfiguration of VCGs to enlarge or shrink incrementally the size of a SONET connection. The basic approach is to have the Network Management System instruct the source node to resize an existing connection. The source and destination nodes coordinate the addition, deletion, and sequencing of the new or existing VC by using the H4 control bytes in the frame headers.

WAVELENGTH-ROUTED NETWORKS

Wavelength-division multiplexing offers an efficient way to exploit the enormous bandwidth of an optical fiber; WDM allows the transmission of multiple optical signals simultaneously on a single fiber by dividing the fiber transmission spectrum into several nonoverlapping wavelengths (or channels), with each wavelength capable of supporting a single communication channel operating at peak electronic processing speed. With the rapid advance and use of dense WDM (DWDM) technology, 100 or more wavelength channels can be multiplexed onto a single fiber, each operating at 10 to 100 Gbps, leading to Tbps aggregate bandwidth.

WDM optical network topologies can be divided into three basic classes based on their architecture: *(1)* point-to-point, *(2)* broadcast-and-select star, and *(3)* Wavelength-routed. In point-to-point and broadcast-and-select networks, no routing function is provided, and as such, they are simple but inflexible and only suitable for small networks. (WRNs), on the other hand, support true routing functionality and hence are highly efficient, scalable, and more appropriate for wide area networks (3). A wavelength-routed optical network is shown in Fig. 1. The network can be built using switching nodes, wavelength routers, optical cross-connects (OXCs), or optical add–drop multiplexers (OADMs) connected by fiber links to form an arbitrary physical topology. Some routing nodes are attached to access stations where data from several end users (e.g., IP, and ATM users) can be multiplexed or groomed on to a single optical channel. The access station also provides optical-to-electronic conversion and vice versa to interface the optical network with the conventional electronic network using transceivers.

Lightpath

In a WRN, end users communicate with one another via optical channels, which are referred to as lightpaths. A lightpath is an optical path (data channel) established between the source node and the destination node by using

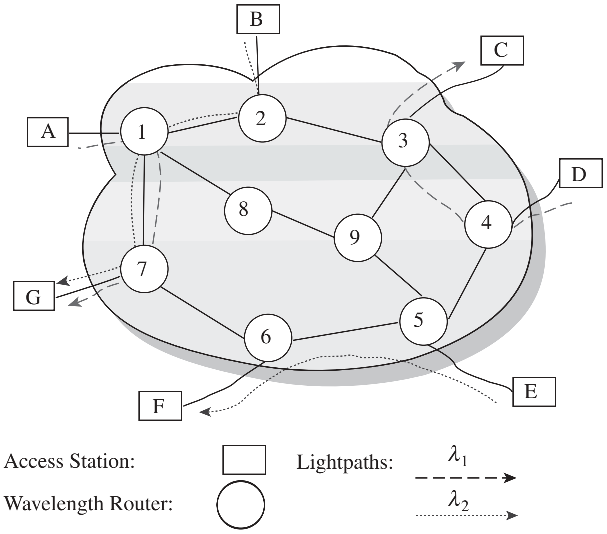

Figure 1. Structure of WRNs.

a dedicated wavelength along multiple intermediate links. Because of the limited number of wavelength channels, wavelength reuse is necessary when the network has to support a large number of users. Wavelength reuse allows the same wavelength to be reused in spatially disjoint parts of the network. In particular, any two lightpaths can use the same wavelength as long as they do not share any common links. For example, Fig. 1 shows the lightpaths A->1->7->G and D->4->3->C, which can use the same wavelength λ_1. However, two or more lightpaths traversing the same fiber link must be on different wavelengths so that they do not interfere with one another. Hence, the lightpaths A->1->7->G and B->2->1->7->G cannot use the same wavelength simultaneously because they have common links.

Without wavelength conversion, a lightpath is required to be on the same wavelength channel throughout its path in the network. This is known as the wavelength-continuity constraint. Another important constraint is the wavelength-capacity constraint, which is caused by the limited number of wavelength channels and transmitters/receivers in a network. Given these two constraints, a challenging and critical problem in WRNs is to determine the route that the lightpath should traverse and which wavelength should be assigned. This is commonly referred to as the routing and wavelength assignment (RWA) problem, which has been shown to be NP-complete for static traffic demands.

Optical Cross-Connects

A key node in WRNs is the OXC, which allows dynamic setup and tear down of lightpaths as needed (i.e., without having to be provisioned statically). The OXCs can connect (i.e., switch) any input wavelength channel from an input fiber port to any one of the output fiber ports in optical form. An OXC consists of optical switches preceded by wavelength demultiplexers and followed by wavelength multiplexers. Thus, in an OXC, incoming fibers are demultiplexed into individual wavelengths, which are switched to corresponding output ports and are then multiplexed onto outgoing fibers. By appropriately configuring the OXCs along the physical path, lightpaths can be established between any pair of nodes (4).

Wavelength Conversion

The function of a wavelength converter is to convert signals from an input wavelength to a different output wavelength. Wavelength conversion is proven to be able to improve the channel utilization in WRNs because the wavelength-continuity constraint can be relaxed if the OXCs are equipped with wavelength converters. For example, in Fig. 1, if node 4 has wavelength converters, lightpath E->5->4->3->C can be established using a different wavelength on link 5->4 and 4->3 (e.g., using wavelength λ_1 on links E->5->4, and a different wavelength, say λ_2, on links 4->3->C).

Wavelength conversion can be implemented by *(1)* (O–E–O) wavelength conversion and *(2)* all-optical wavelength conversion. When using O–E–O wavelength conversion, the optical signal is first converted into the electronic domain. The electronic signal is then used to drive the input of a tunable laser, which is tuned to the desired output wavelength. This method can only provide opaque data transmission (i.e., data bit rate and data format dependent), which is very complex while consuming a huge amount of power. On the other hand, no optical-to-electronic conversion is involved in the all-optical wavelength conversion techniques and the optical signal remains in the optical domain throughout the conversion process. Hence, all-optical wavelength conversion using techniques such as wave-mixing and cross-modulation are more attractive. However, all-optical technologies for wavelength conversion are still not mature, and all-optical wavelength converters are likely to remain very costly in the near future. Therefore, a lot of attention has been focused on compromising schemes such as limited number, limited range, and sparse wavelength conversion to achieve high network performance (5,6).

Traffic Grooming

Although WDM transmission equipment and OXCs enable the establishment of lightpaths operating at a high rate (currently at 10 Gb/s, or OC-192, expected to grow to 40 Gb/s, or OC-768), only a fraction of end users are expected to have a need for such high bandwidth that uses a full wavelength. Most users typically generate lower speed traffic, such as OC-12 (622 Mbps), OC-3 (155 Mbps), and OC-1 (51.84 Mbps), using SONET framing. Hence, the effective packing of these sub-wavelength tributaries onto high-bandwidth full-wavelength channels (i.e., by appropriate routing or wavelength and time-slot assignment) is a very important problem and is known as the traffic grooming problem. For example, 64 OC-3 circuits can be groomed onto a single OC-192 wavelength.

Traffic grooming has received considerable attention recently (7,8). In WDM SONET, an ADM is used to multiplex (combine) low-speed SONET streams into a higher speed traffic stream before transmission. Similarly, an ADM receives a wavelength from the ring and demultiplexes it into several low-speed streams. Usually, an ADM for a wavelength is required at a particular node only when the wavelength must be added or dropped at that particular node. However, the cost of ADMs often makes up a significant portion of the total cost, and as such, an objective of traffic grooming is to achieve efficient utilization of network resources while minimizing the network cost and the number of ADMs required. Similarly, in mesh network topologies, the number of electronic ADMs and the network cost can be reduced by carefully grooming the low-speed connections and using OXCs for bypass traffic.

Waveband Switching

The rapid advance in dense WDM technology and worldwide fiber deployment have brought about a tremendous increase in the size (i.e., number of ports) of OXCs, as well as the cost and difficulty associated with controlling such large OXCs. In fact, despite the remarkable technological advances in building photonic cross-connect systems and associated switch fabrics, the high cost (both capital and operating expenditures) and unproven reliability of large switches (e.g., with 1000 ports or more) have not justified their deployment. Recently, *waveband switching* (WBS) in conjunction with new *multigranular optical cross-connects* (MG-OXCs) have been proposed to reduce this cost and complexity (9–11). The main idea of WBS is to group several wavelengths together as a band, switch the band using a single port whenever possible (e.g., as long as it carries only bypass or express traffic), and demultiplex the band to switch the individual wavelengths only when some traffic needs to be added or dropped. A complementary hardware is an MG-OXC that not only can switch traffic at multiple levels such as fiber, waveband, and individual wavelength (or even sub wavelength), but also it can add and drop traffic at multiple levels, as well as multiplex and demultiplex traffic from one level to another. By using WBS in conjunction with MG-OXCs, the total number of ports required in such a network to support a given amount of traffic is much lower than that in a traditional WRN that uses ordinary OXCs (that switch traffic only at the wavelength level). The reason is that 60% to 80% of traffic simply bypasses the nodes in the backbone, and hence, the wavelengths carrying such transit traffic do not need to be individually switched in WBS networks (as opposed to WRNs wherein every such wavelength still has to be switched using a single port). In addition to reducing the port count, which is a major factor contributing to the overall cost of switching fabrics, the use of bands can reduce complexity, simplify network management, and provide better scalability.

WBS is different from wavelength routing and traditional traffic grooming in many ways. For example, techniques developed for traffic grooming in WRNs, which are useful mainly for reducing the electronic processing and/or the number of wavelengths required, cannot be applied directly to effectively grouping wavelengths into wavebands. This restriction is because in WRNs, one can multiplex just about any set of lower bit rate (i.e., subwavelength) traffic such as OC-1s into a wavelength, which is subject only to the wavelength-capacity constraint. However, in WBS networks, at least one more constraint exists: Only the traffic carried by a fixed set of wavelengths (typically consecutive) can be grouped into a band.

SWITCHING

Similar to the situation in electronic network, three underlying switching technologies for optical networks exist: *optical circuit switching* (usually referred to as *wavelength routing* in the literature), *optical packet switching, and optical burst switching* as shown in Fig. 2.

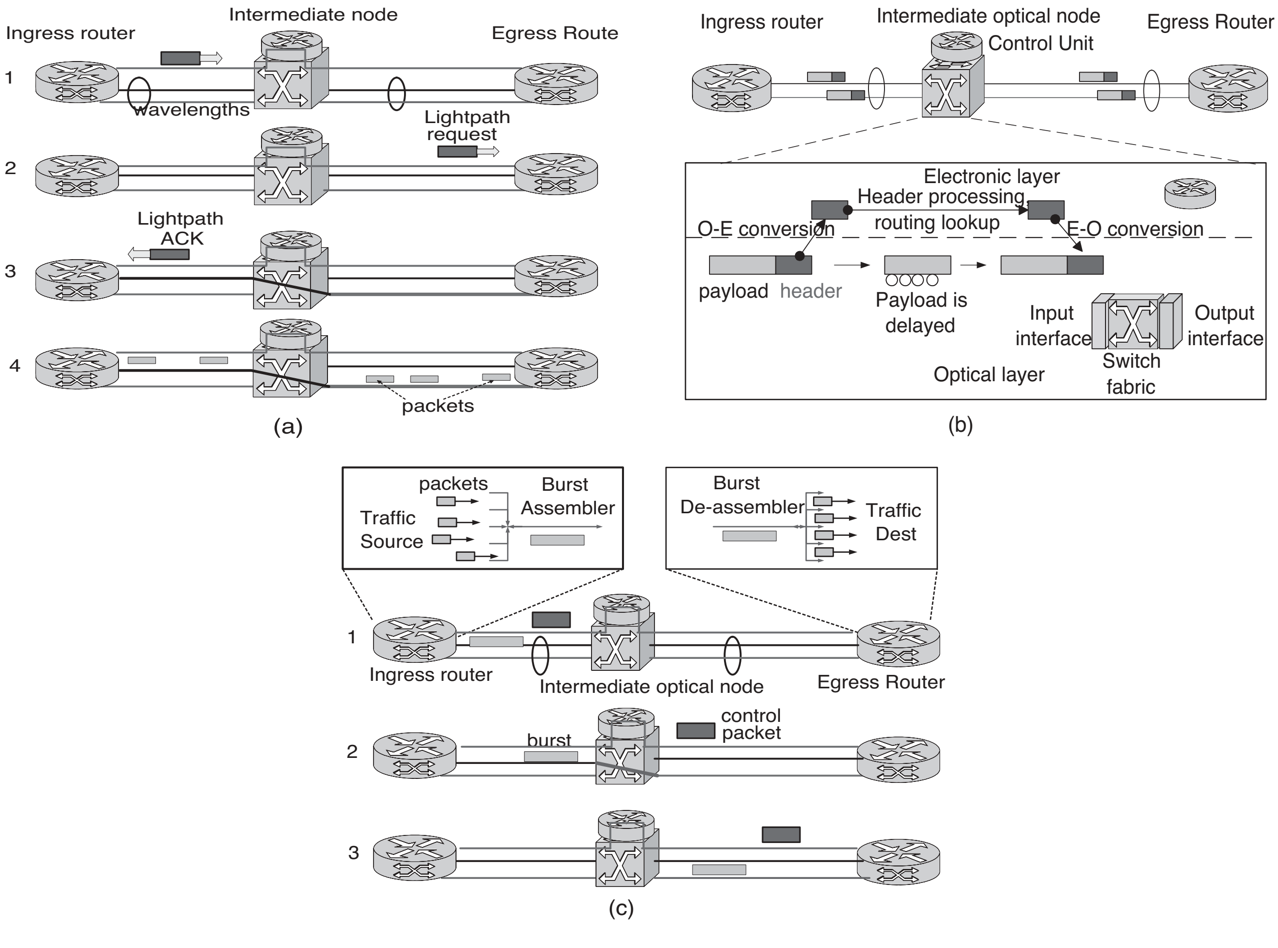

Figure 2. Optical switching: (a) OCS, (b) OPS, and (c) OBS.

Optical Circuit Switching

Optical circuit switching (OCS) takes a similar approach as in the circuit-switched telecommunication networks. To transport traffic, lightpaths are set up among client nodes (such as IP routers or ATM switches) across the optical network, with each lightpath occupying one dedicated wavelength on every traversed fiber link. The lightpaths are treated as logical links by client nodes, and the user data are then transported over these lightpaths. Figure 2(a) illustrates the lightpath setup procedure and the data packet's transport.

The major advantage of OCS is that data traffic is transported purely in the optical domain, and the intermediate hop-by-hop electronic processing is eliminated, in addition to other benefits such as protocol transparency, quality of service (QoS) support, and traffic engineering. In addition, OCS is only suitable for large, smooth, and long duration traffic flows but not for bursty data traffic. However, OCS does not scale well; to connect N client nodes, $O(N^2)$ lightpaths are needed. Moreover, the total number of lightpaths that can be set up over an optical network is limited, because of the limited number of wavelengths per fiber and dedicated use of wavelengths by lightpaths. These issues have driven the research community to study alternative switching technologies.

Optical Packet Switching

To address the poor scalability and inefficiency of transporting bursty data traffic using OCS, optical packet switching (OPS) has been introduced and well studied with a long history in the literature. OPS has been motivated by the (electronic) packet switching used in IP networks where data packets are statistically multiplexed onto the transmission medium without establishing a dedicated connection. The major difficulty of OPS is that the optical layer is a dumb layer, which is different from the intelligent electronic layer. Specifically, the data packet cannot be processed in the optical layer, but it has to be processed in the electronic layer to perform routing and forwarding functionality. To reduce processing overhead and delay, only the packet header is converted from the optical layer to the electronic layer for processing (12).

As illustrated in Fig. 2(b), the OPS node typically has a control unit, input and output interfaces, and a switch fabric. The input interface receives incoming packets from input ports (wavelengths) and performs wavelength division multiplexing in addition to many other functionalities, such as 3R (reamplification, reshaping, and retiming) regeneration to restore incoming signal quality, packet delineation to identify the beginning/end of the header and payload of a packet, and optical–to–electronic (O–E) conversion of the packet header. The control unit processes the packet header, looks up the routing/forwarding table to determine the next hop, and configures the switch fabric to switch the payload, which has been delayed in fiber delay lines (FDLs) while the header is being processed. The updated packet header is then converted back to the optical layer and combined with the payload at the output interface, which performs wavelength-division multiplexing, 3R regeneration, and power equalization before transmitting the packet on an output port wavelength to the next hop.

Packet loss and contention may occur in the control unit when multiple packets arrive simultaneously. In this case, the packet headers are buffered generally and processed one-by-one. Furthermore, the contention may also happen on the payloads when multiple packets from different input ports need to be switched to the same output wavelength. Note that a payload contention results in a packet header contention but not vice versa. The payload contentions can be resolved in the optical layer using FDLs, wavelength conversion, or deflection routing. FDLs delay a payload for deterministic periods of time, and thus, multiple payloads going to the same output port simultaneously can be delayed with different periods of time to resolve the contention. Wavelength conversion can switch multiple payloads to different output wavelengths. Deflection routing deflects a contending payload to an alternative route at a different output port. Note that deflection routing should be attempted last because it may cause contentions on the alternative paths and may lead to unordered packet reception (13).

OPS may take a *synchronous or asynchronous* approach. The former approach is more feasible technically (most research efforts have focused on this approach), where packets are of fixed length (like ATM cells) and the input/output interfaces perform packet synchronization in addition to other functions. In the asynchronous approach, the packets are of variable length and the packet processing in the input/output interface is asynchronous as well. This task is highly demanding with existing technologies and is expected to be viable in the very long term. A recent development of OPS is the *optical label switching*, which is a direct application of *multi-protocol label switching* (MPLS) technology. MPLS associates a label to a forwarding equivalence class (FEC), which as far as the optical network is concerned, can be considered informally as a pair of ingress/egress routers. The packet header contains a label instead of the source/destination address, and the data forwarding is performed based on the label, instead of the destination address. A major benefit of label switching is the speedup for the routing/forwarding table lookup, because the label is of fixed length and is easier to handle than the variable length destination address prefix.

Optical Burst Switching

Although OPS may be beneficial in the long run, it is difficult to build a cost-effective OPS nodes using the current technologies, primarily caused by the lack of "optical" random access memory and the strict synchronization requirement (the asynchronous OPS is even more difficult). Optical burst switching (OBS) has been proposed as a novel alternative to combine the benefit of OPS and OCS while eliminating their disadvantages (14–16). Through statistical multiplexing of bursts, OBS significantly improves bandwidth efficiency and scalability over OCS. In addition, when compared with OPS, the "optical" random access memory and/or fiber delay lines are not required in OBS (although having them would result in a better performance), and the synchronization is less strict. Instead of processing, routing, and forwarding each packet, OBS assembles multiple packets into a burst at the ingress router and the burst is switched in the network core as one unit. In other words, multiple packets are *bundled* with only one control packet (or header) to be processed, resulting in much less control overhead. The burst assembly at the ingress router may employ some simple scheme, for example, assembling packets (going to the same egress router) that have arrived during a fixed period into one burst or simply assembling packets into one burst until a certain burst length is reached, or uses more sophisticated schemes, for example, capturing an higher layer protocol data unit (PDU), for example, a TCP segment, into a burst.

Different OBS approaches primarily fall into three categories: *reserve-a-fixed-duration* (RFD), *tell-and-go* (TAG), or *in-band-terminator* (IBT). Figure. 2(c) illustrates a RFD-based protocol, called *just enough time* (JET), where each ingress router assembles incoming data packets that are destined to the same egress router into a burst, according to some burst assembly scheme (14). For each burst, a control packet is first sent out on a control wavelength toward the egress router and the burst follows the control packet (on a separate data wavelength) after an offset time. This offset time can be made no less than the total processing delay to be encountered by the control packet, to reduce the need for fiber delay lines, and at the same time much less than the round-trip propagation delay between the ingress and the egress routers. The control packet, which goes through optical-electronic-optical conversion at every intermediate node, just as the packet header in OPS does, attempts to reserve a data wavelength for just enough time (specifically, between the time that the burst arrives and departs), to accommodate the succeeding burst. If the reservation succeeds, the switch fabric is configured to switch the data burst. However, if the reservation fails, because no wavelength is available at the time of the burst arrival on the outgoing link, the burst will be dropped (retransmissions are handled by higher layers such as TCP). When a burst arrives at the egress router, it is disassembled into data packets that are then forwarded toward their respective destinations.

In the IBT-based OBS, the burst contains an IBT (e.g., silence of a voice circuit) and the control packet may be sent in-band preceding the burst or out-of-band over a control wavelength (before the burst). At an intermediate node, the bandwidth (wavelength) is reserved as soon as the control packet is received and released when the IBT of the burst is detected. Hence, a key issue in the IBT-based OBS is to *detect optically* the IBT. The TAG-based OBS is similar to circuit switching; a *setup* control packet is first sent over a control wavelength to reserve bandwidth for the burst. The burst is then transmitted without waiting for the acknowledgment that the bandwidth has been reserved successfully at intermediate nodes. A *release* control packet can be sent afterward to release the bandwidth, or alternatively the intermediate nodes automatically release the bandwidth after a timeout interval if they have not received a *refresh* control packet from the ingress router.

Similar to OPS, the contentions may happen in OBS when multiple bursts need to go to the same output port, or when multiple control packets from different fibers arrive simultaneously. The contention resolution techniques in OPS can be employed for OBS. Nevertheless, compared with OPS, the contention in OBS (particularly in terms of control packets) is expected to be much lighter because of the packet bundling. As far as the performance is concerned, the RFD-based OBS (e.g., using JET) can achieve higher bandwidth utilization and lower burst dropping than the IBT and TAG-based OBS, because it reserves the bandwidth for just enough time to switch the burst, and can reserve the bandwidth well in advance to reduce burst dropping.

Comparison of Optical Switching Technologies

A qualitative comparison of OCS, OPS, and OBS is presented in Table 2 where it is evident that OBS combines the benefits of OCS and OPS while eliminating their shortcomings. However, today's optical networks primarily employ OCS because of its implementation feasibility using existing technologies. OBS will be the next progression in the evolution of optical networks, whereas OPS is expected to be the long-term goal.

CONTROL AND SIGNALING

Optical networks using WDM technology provide an enormous network capacity to satisfy and sustain the exponential growth in Internet traffic. However, all end-user communication today uses the IP protocol, and hence, it has become clear that the IP protocol is the common convergence layer in telecommunication networks. It is therefore important to integrate the IP layer with WDM to transport end-user traffic over optical networks efficiently.

Control Architecture

General consensus exists that the optical network control plane should use IP-based protocols for dynamic provisioning and restoration of lightpaths within and across optical networks. As a result, it has been proposed to reuse or adapt the signaling and routing mechanisms developed for IP traffic engineering in optical networks, to create a common control plane capable of managing IP routers as well as optical switches.

Table 2. Comparison of OCS, OPS, and OBS

Technology	Bandwidth utilization	Setup latency	Implementation difficulty	Overhead	Adaptivity to bursty traffic and fault	Scalability
OCS	Low	High	Low	Low	Low	Poor
OPS	High	Low	High	High	High	Good
OBS	High	Low	Medium	Low	High	Good

Two general models have been proposed to operate an IP over an optical network. under the *domain services* model, the optical network primarily offers high bandwidth connectivity in the form of lightpaths. Standardized signaling across the *user network interface* (UNI) is used to invoke the services of the optical network for lightpath creation, deletion, modification, and status query, whereas the *network-to-network interface* (NNI) provides a method of communication and signaling among subnetworks within the optical network. Thus, the domain service model is essentially a client (i.e., IP layer)–server (i.e., optical layer) network architecture, wherein the different layers of the network remain isolated from each other (17). This is also known as the *overlay* model and is well suited for an environment that consists of multiple administrative domains, which is prevalent in most carrier networks today. On the other hand, in the *Unified Services* model, the IP and optical networks are treated as a single integrated network from a control plane view. The optical switches are treated just like any other router, and in principle, no distinction exists between UNIs and NNIs for routing and signaling purposes. This model is also known as the *peer-to-peer* model, wherein the services of the optical network are obtained in a more seamless manner as compared with the overlay model. It allows a network operator to create a single network domain composed of different network elements, thereby allowing them greater flexibility than in the overlay model. The peer model does, however, present a scalability problem because of the amount of information to be handled by any network element within an administrative domain. In addition, nonoptical devices must know the features of optical devices and vice versa, which can present significant difficulties in network operation. A third *augmented* model has also been proposed (18), wherein separate routing instances in the IP and optical domains exist but information from one routing instance is passed through the other routing instance. This model is also known as the *hybrid* model representing a middle ground between the overlay and the peer models; the hybrid model supports multiple administrative domains as in the overlay model, and supports heterogeneous technologies within a single domain as in the peer model.

Signaling

The Generalized Multi-Protocol Label Switching (GMPLS) framework (19) has been proposed as the control plane for the various architectures. Similar to traditional MPLS, GMPLS extends the IP layer routing and signaling information to the optical layer for dynamic path setup. In its simplest form, labels are assigned to wavelengths to provide mappings between the IP layer addresses and the optical wavelengths. Several extensions have been added for time slots and sets of contiguous wavelengths to support subwavelength and multiwavelength bandwidth granularities.

GMPLS signaling such as *resource reservation* (RSVP) and *constraint route label distribution* (CR-LDP) protocols map the IP routing information into preconfigured *labeled switched paths* (LSPs) in the optical layer. These LSPs are generally set up on a hop-by-hop basis or specified explicitly when traffic engineering is required. GMPLS labels can be stacked to provide a hierarchy of LSP bundling and explicit routing. Despite their similar functionalities, RSVP and CR-LDP operate differently. RSVP uses PATH and RESV messages to signal LSP setup and activation. PATH messages travel from source to destination nodes and communicate classification information. RESV messages travel from destination to source nodes to reserve the appropriate resources. RSVP uses UDP/IP packets to distribute labels, and as such, it can survive hardware or software failures caused by IP rerouting. CR-LDP on the other hand assumes that the network is reliable and uses TCP/IP packets instead. It has much lower overhead than RSVP, but it cannot survive network failures quickly. The advantages and disadvantages of RSVP and CR-LDP have long been discussed and compared in the literature without a clear winner. It seems, however, that RSVP is the industry's preferred protocol because it is coupled more tightly with IP-based signaling protocols.

Protection and restoration in GMPLS involve the computation of primary and backup LSPs and fault detection and localization. Primary and backup LSP computations consider traffic engineering requirements and network constraints. LSP protection includes dedicated and shared mechanisms with varying degrees of restoration speeds. In dedicated protection (1+1), data are transmitted on the primary and backup LSPs simultaneously, and as a result, 1+1 protection offers fast restoration and recovery from failures. In shared protection (*m:n*), *m* backup LSPs are preconfigured to provide protection for *n* primary LSPs. Data traffic is switched onto the backup LSPs at the source only after a failure has been detected. As a result, *m:n* schemes are slower than dedicated protection but use considerably less bandwidth. Fault detection and management are handled by the *link management protocol* (LMP), which is also used to manage the control channels and to verify the physical connectivity.

SUMMARY

Optical networks can sustain a much higher throughput than what can be achieved by pure electronic switching/routing techniques despite the impressive progress made in electronics and electronic switching. As such, optical networking holds the key to a future of unimagined communication services where true broadband connectivity and converged multimedia can be realized. Other anticipated services such as grid computing, video on demand, and high-speed Internet connections will require large amounts of bandwidth over wide-scale deployments that will permeate optical networking undoubtedly well into the last mile. However, exploiting the phenomenal data capacity of optical networks is anything but trivial. Both traditional architectures, such as SONET, and emerging paradigms, such as WRNs, require complex architectures and protocols while providing various degrees of statistical multiplexing. Although SONET is well entrenched and understood, it is very expensive and its static nature limits its scalability and, therefore, its reach into the last mile. WRNs, on the other hand, provide far more efficient and dynamic topologies that support a significantly larger number of all-optical connections.

Clearly, WRNs present several technological challenges, the most pressing of which is how to exploit this vast optical bandwidth efficiently while supporting bursty data traffic. Techniques such as waveband switching and traffic grooming help the realization of WRNs by reducing the overall cost. Switching technologies such as OBS and OPS provide statistical multiplexing and enhance the elasticity of WRNs in support of varying traffic volumes and requirements. Common and standardized signaling interfaces such as GMPLS allow for dynamic provisioning and ease of operation and maintenance. As a result, optical networks are more scalable and flexible than their electronic counterparts and can support general-purpose and special-purpose networks while providing a high degree of protection and restoration against failures.

Given today's available technologies, optical networks are realized using OCS techniques that are less scalable and efficient than OBS and OPS when supporting data traffic. However, as optical technologies mature, the next generation of optical networks will employ OBS and OPS techniques that are far more efficient at leveraging network resources. As such, much of the current research is focused on developing switching techniques that are fast and reliable, routing protocols that are scalable and have fast convergence, and signaling protocols that exploit network-wide resources efficiently while integrating the optical and data layers seamlessly.

HIGH-LEVEL SYNTHESIS

INTRODUCTION

Over the years, digital electronic systems have progressed from vacuum-tube to complex integrated circuits, some of which contain millions of transistors. Electronic circuits can be separated into two groups, digital and analog circuits. Analog circuits operate on analog quantities that are continuous in value and in time, whereas digital circuits operate on digital quantities that are discrete in value and time (1). Examples of analog and digital systems are shown in Fig. 1.

Digital electronic systems (technically referred to as digital logic systems) represent information in digits. The digits used in digital systems are the 0 and 1 that belong to the binary mathematical number system. In logic, the 0 and 1 values could be interpreted as True and False. In circuits, the True and False could be thought of as High voltage and Low voltage. These correspondences set the relations among logic (True and False), binary mathematics (0 and 1), and circuits (High and Low).

Logic, in its basic shape, deals with reasoning that checks the validity of a certain proposition—a proposition could be either True or False. The relation among logic, binary mathematics, and circuits enables a smooth transition of processes expressed in propositional logic to binary mathematical functions and equations (Boolean algebra), and to digital circuits. A great scientific wealth of information exists that strongly supports the relations among the three different branches of science that lead to the foundation of modern digital hardware and logic design.

Boolean algebra uses three basic logic operations: AND, OR, and NOT. Truth tables and symbols of the logic operators AND, OR, and NOT are shown in Fig. 2. Digital circuits implement the logic operations AND, OR, and NOT as hardware elements called “gates” that perform logic operations on binary inputs. The AND-gate performs an AND operation, an OR-gate performs an OR operation, and an Inverter performs the negation operation NOT. The actual internal circuitry of gates is built with transistors; two different circuit implementations of inverters are shown in Fig. 3. Examples of AND, OR, and NOT gates of integrated circuits (ICs—also known as chips) are shown in Fig. 4. Besides the three essential logic operations, four other important operations exist: the NOR (NOT-OR), NAND (NOT-AND), Exclusive-OR (XOR), and Exclusive-NOR (XNOR).

A logic circuit is usually created by combining gates together to implement a certain logic function. A logic function could be a combination of logic variables (such as A, B, and C) with logic operations; logic variables can take only the values 0 or 1. The created circuit could be implemented using a suitable gate structure. The design process usually starts from a specification of the intended circuit; for example, consider the design and implementation of a three-variable majority function. The function *F(A, B, C)* will return a 1 (High or True) whenever the number of 1s in the inputs is greater than or equal to the number of 0s. The truthtable of *F* is shown in Fig. 5(a). The terms that make the function *F* return a 1 are F(0, 1, 1), F(1, 0, 1), F(1, 1, 0), or F(1, 1, 1). This could be alternatively formulated as in the following equation:

$$F = A'BC + AB'C + ABC' + ABC$$

In Figure 5(b), the implementations using a standard *AND–OR–Inverter* gate structure are shown. Some other specifications might require functions with more number of inputs and accordingly a more complicated design process.

The complexity of the digital logic circuit that corresponds to a Boolean function is directly related to the complexity of the base algebraic function. Boolean functions may be simplified by several means. The simplification step is usually called optimization or minimization as it has direct effects on the cost of the implemented circuit and its performance. The optimization techniques range from simple (manual) to complex (automated using a computer).

The basic hardware design steps can be summarized in the following list:

1. Specification of the required circuit.
2. Formulation of the specification to derive algebraic equations.
3. Optimization of the obtained equations
4. Implementation of the optimized equations using suitable hardware (IC) technology.

The above steps are usually joined with an essential verification procedure that ensures the correctness and completeness of each design step.

Basically, three types of IC technologies can be used to implement logic functions on Ref. 2 these are full-custom, semi-custom, and programmable logic devices (PLDs). In full-custom implementations, the designer cares about the realization of the desired logic function to the deepest details, including the gate-level and the transistor-level optimizations to produce a high-performance implementation. In semi-custom implementations, the designer uses some ready logic-circuit blocks and completes the wiring to achieve an acceptable performance implementation in a shorter time than full-custom procedures. In PLDs, the logic blocks and the wiring are ready. In implementing a function on a PLD, the designer will only decide of which wires and blocks to use; this step is usually referred to as programming the device.

The task of manually designing hardware tends to be extremely tedious, and sometimes impossible, with the

increasing complexity of modern digital circuits. Fortunately, the demand on large digital systems has been accompanied with a fast advancement in IC technologies. Indeed, IC technology has been growing faster than the ability of designers to produce hardware designs. Hence, a growing interest has occurred in developing techniques and tools that facilitate the process of hardware design.

The task of making hardware design simpler has been inspired largely by the success story in facilitating the programming of traditional computers done by software designers. This success has motivated eager hardware designers to follow closely the footsteps of software designers, which leads to a synergy between these two disciplines that creates what is called hardware/software codesign.

SOFTWARE DESIGN

A computer is composed basically from a computational unit made out of logic components whose main task is to perform arithmetic and logic operations; this is usually called the arithmetic and logic unit (ALU). The computations performed by the ALU are usually controlled by a neighboring unit called the control unit (CU). The ALU and the CU construct the central processing unit (CPU) that is usually attached to a storage unit, memory unit, and input and output units to build a typical digital computer. A simplified digital computer is shown in Fig. 6.

To perform an operation using the ALU, the computer should provide a sequence of bits (machine instruction) that include signals to enable the appropriate operation, the inputs, and the destination of the output. To run a whole program (sequence of instruction), the computations are provided sequentially to the computer. As the program sizes grow, dealing with 0s and 1s becomes difficult. Efforts to facilitate dealing with computer programs concentrated on the creation of translators that hides the complexity of dealing with programming using 0s and 1s. An early proposed translator produced the binary sequence of bits (machine instructions) from easy-to-handle instructions written using letters and numbers called assembly language instructions. The translator performing the above job is called an assembler (see Fig. 7).

Before long, the limitations of assembly instructions became apparent for programs consisting of thousands of

Figure 7. The translation process of high-level programs.

instructions. The solution came in favor of translation again; this time the translator is called a compiler. Compilers automatically translate sequential programs, written in a high-level language like C and Pascal, into equivalent assembly instructions (see Fig. 7). Translators like assemblers and compilers helped software designers ascend to higher levels of abstraction. With compilers, a software designer can code with a fewer number of lines that are easy to understand. Then, the compiler will do the whole remaining job of translation to hide all the low-level complex details from a software designer.

TOWARD AUTOMATED HARDWARE DESIGN

Translation from higher levels of abstraction for software has motivated the creation of automated hardware design (synthesis) tools. The idea of hardware synthesis sounds very similar to that for software compilation. A designer can produce hardware circuits by automatically synthesizing an easy-to-understand description of the required circuit, to provide a list of performance-related requirements.

Several advantages exist to automating part or all of the hardware design process and to moving automation to higher levels of abstraction. First, automation assures a much shorter design cycle and time to market for the produced hardware. Second, automation allows for more exploration of different design styles because different designs can be synthesized and evaluated within a short time. Finally, with well-developed design automation tools, they may outperform human designers in generating high-quality designs.

HARDWARE DESIGN APPROACHES

Two different approaches emerged from the debate over ways to automate hardware design. On the one hand, the capture-and-simulate proponents believe that human designers have good design experience that cannot be automated. They also believe that a designer can build a design in a bottom-up style from elementary components such as transistors and gates. Because the designer is concerned with the deepest details of the design, optimized and cheap designs could be produced. On the other hand, the describe-and-synthesis advocates believe that synthesizing algorithms can outperform human designers. They also believe that a top-down fashion would be better suited for designing complex systems. In describe-and-synthesize methodology, the designers first describe the design. Then, computer aided design (CAD) tools can generate the physical and electrical structure. This approach describes the intended designs using special languages called hardware description languages (HDLs). Some HDLs are very similar to traditional programming languages like C and Pascal (3).

Both design approaches may be correct and useful at some point. For instance, circuits made from replicated small cells (like memory) are to perform efficiently if the cell is captured, simulated, and optimized to the deepest-level components (such as transistors). Another complicated heterogeneous design that will be developed and mapped onto a ready prefabricated device, like a PLD where no optimizations are possible on the electronics level, can be described and synthesized automatically. However, modern synthesis tools are well equipped with powerful automatic optimization tools.

HIGH-LEVEL HARDWARE SYNTHESIS

Hardware synthesis is a general term used to refer to the processes involved in automatically generating a hardware design from its specification. High-level synthesis (HLS) could be defined as the translation from a behavioral description of the intended hardware circuit into a structural description similar to the compilation of programming languages (such as C and Pascal) into assembly language. The behavioral description represents an algorithm, equation, and so on, Whereas a structural description represents the hardware components that implement the behavioral description. Despite the general similarity between hardware and software compilations, hardware synthesis is a multilevel and complicated task. In software compilation, you translate from a high-level language to a low-level language, Whereas in hardware synthesis, you step through a series of levels.

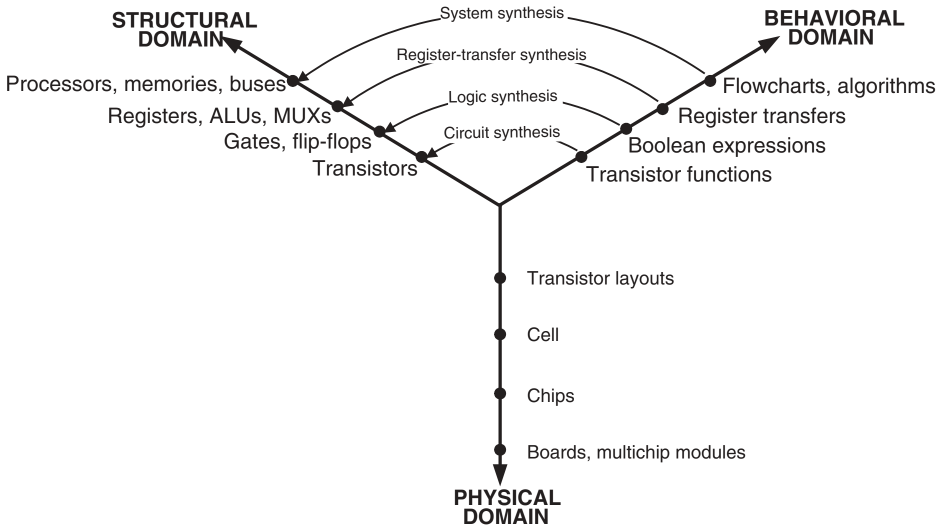

Figure 8. Gajski's Y-chart.

To explain more on behavior, structure, and their correspondences, Fig. 8 shows Gajski's Y-chart. In this chart, each axis represents a type of description (behavioral, structural, and physical). On the behavioral side, the main concern is for algorithms, equations, and functions but not for implementations. On the structural side, implementation constructs are shown; the behavior is implemented by connecting components with known behavior. On the physical side, circuit size, component placements, and wire routes on the developed chip (or board) are the main focus.

The chained synthesis tasks at each level of the design process include system synthesis, register-transfer synthesis, logic synthesis, and circuit synthesis. System synthesis starts with a set of processes communicating though either shared variables or message passing. It generates a structure of processors, memories, controllers, and interface adapters from a set of system components. Each component can be described using a register-transfer language (RTL). RTL descriptions model a hardware design as circuit blocks and interconnecting wires. Each of these circuit blocks could be described using Boolean expressions. Logic synthesis translates Boolean expressions into a list of logic gates and their interconnections (netlist). The used gates could be components from a given library such as NAND or NOR. In many cases, a structural description using one library must be converted into one using another library (usually referred to as technology mapping). Based on the produced netlist, circuit synthesis generates a transistor schematic from a set of input–output current, voltage and frequency characteristics, or equations. The synthesized transistor schematic contains transistor types, parameters, and sizes.

Early contributions to HLS were made in the 1960s. The ALERT (4) system was developed at IBM (Armonk NY) ALERT automatically translates behavioral specifications written in APL (5) into logic-level implementations. The MIMOLA system (1976) generated a CPU from a high-level input specification (6). HLS has witnessed & considerable growth since the early 1980s, and currently, it plays a key role in modern hardware design.

HIGH-LEVEL SYNTHESIS TOOLS

A typical modern hardware synthesis tool includes HLS logic synthesis, placement, and routing steps as shown in Fig. 9. In terms of Gajski's Y-chart vocabulary, these modern tools synthesize a behavioral description into a

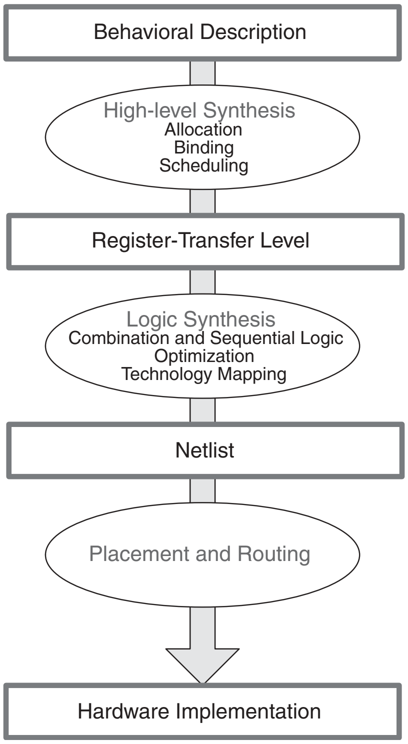

Figure 9. The process of describe-and-synthesize for hardware development.

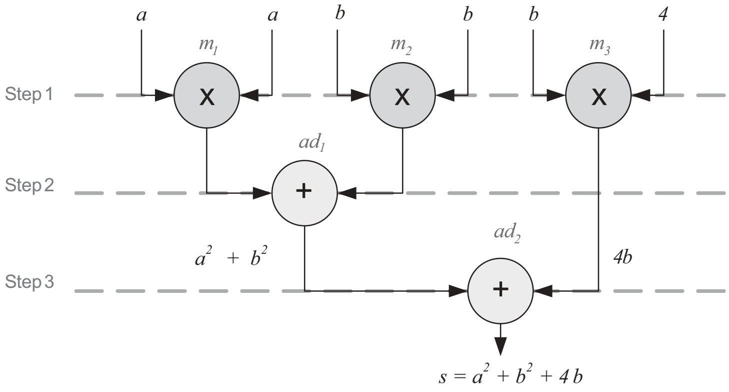

Figure 10. A possible allocation, binding, and scheduling of $s = a^2 + b^2 + 4b$.

structural network of components. The structural network is then synthesized even more, optimized, placed physically in a certain layout, and then routed through. The HLS step includes, first, allocating necessary resources for the computations needed in the provided behavioral description (the allocation stage). Second, the allocated resources are bound to the corresponding operations (the binding stage). Third, the operations order of execution is scheduled (the scheduling stage). The output of the high-level synthesizer is an RT-level description. The RT-level description is then synthesized logically to produce an optimized netlist. Gate netlists are then converted into circuit modules by placing cells of physical elements (transistors) into several rows and connecting input/output (I/O) pins through routing in the channels between the cells. The following example illustrates the HLS stages (allocation, binding, and scheduling).

Consider a behavioral specification that contains the statement, $s = a^2 + b^2 + 4b$. The variables a and b are predefined. Assume that the designer has allocated two multipliers (m_1 and m_2) and one adder (ad) for s. However, to compute s, a total of three multipliers and two adders could be used as shown in the dataflow graph in Fig. 10.

A possible binding and schedule for the computations of s are shown in Fig. 11. In the first step, the multiplier m_1 is bound with the computation of a^2, and the multiplier m_2 is bound with the computation of b^2. In the second step, m_1 is reused to compute ($4b$); also the adder (ad) is used to perform ($a^2 + b^2$). In the third and last step, the adder is reused to add ($4b$) to ($a^2 + b^2$). Different bindings and schedules are possible. Bindings and schedules could be carried out to satisfy a certain optimization, for example, to minimize the number of computational steps, routing, or maybe multiplexing.

HARDWARE DESCRIPTION LANGUAGES

HDLs, like traditional programming languages, are often categorized according to their level of abstraction. Behavioral HDLs focus on algorithmic specifications and support constructs commonly found in high-level imperative programming languages, such as assignment, and conditionals.

Verilog (7) and VHDL (Very High Speed Integrated Circuit Hardware Description Language) (8) are by far the most commonly used HDLs in the industry. Both of these HDLs support different styles for describing hardware, for example, behavioral style, and structural gate-level style, VHDL became IEEE Standard 1076 in 1987. Verilog became IEEE Standard 1364 in December 1995.

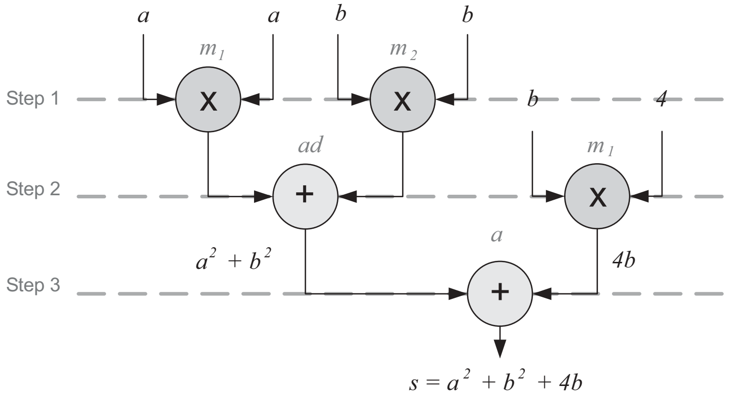

Figure 11. Another possible allocation, binding, and scheduling of $s = a^2 + b^2 + 4b$.

```
Module Half_Adder (a, b, c, s);
      input a, b;
      output c, s; //Output sum and carry.

      and Gate1 (c, a, b);     //an AND gate with two inputs a and b
                               //and one output c

      xor Gate2 (s, a, b)      //a XOR gate with two inputs a and b
                               //and one output s
endmodule
```

Figure 12. A Verilog description of a half-adder circuit.

The Verilog language uses the module construct to declare logic blocks (with several inputs and outputs). In Fig. 12, a Verilog description of a half-adder circuit is shown.

In VHDL, each structural block consists of an interface description and architecture. VHDL enables behavioral descriptions in dataflow and algorithmic styles. The half-adder circuit of Fig. 12 has a dataflow behavioral VHDL description as shown in Fig. 13; a structural description is shown in Fig. 14.

Efforts for creating tools with higher levels of abstraction lead to the production of many powerful modern hardware design tools. Ian Page and Wayne Luk (9) developed a compiler that transformed a subset of Occam into a netlist. Nearly 10 years later, we have witnessed the development of Handel-C (9), the first commercially available high-level language for targeting programmable logic devices (such as field-programmable gate arrays—FPGAs).

```
entity Half_Adder is
      port (
            a: in STD_LOGIC;
            b: in STD_LOGIC;
            c: out STD_LOGIC;
            s: out STD_LOGIC);
end Half_Adder

architecture behavioral of Half_Adder is
begin

s <= (a xor b) after 5 ns;
c <= (a and b) after 5 ns;

end behavioral;
```

Figure 13. A behavioral VHDL description of a `Half_Adder`.

Handel-C is a parallel programming language based on the theories of communicating sequential processes (CSPs) and Occam with a C-like syntax familiar to most programmers. This language is used for describing computations that are to be compiled into hardware. A Handel-C program is not compiled into machine code but into a description of gates and flip-flops, which is then used as an input to FPGA design software. Investments for research into rapid development of reconfigurable circuits using Handel-C have been largely made at Celoxica (oxfordshire, united kingdom)(10). The Handel-C compiler comes packaged with the Celoxica DK Design Suite.

Almost all ANSI-C types are supported in Handel-C. Also, Handel-C supports all ANSI-C storage class specifiers and type qualifiers except volatile and register, which have no meaning in hardware. Handel-C offers additional types for creating hardware components, such as memory, ports, buses, and wires. Handel-C variables can only be initialized if they are global or if they are declared as *static* or constant. Figure 15 shows C and Handel-C types and objects in addition to the design flow of Handel-C. Types are not limited to width in Handel-C because, when targeting hardware, no need exists to be tied to a certain width. Variables can be of different widths, thus minimizing the hardware usage. For instance, if we have a variable a that can hold a value between 1 and 5, then it is enough to use 3 bits only (declared as *int* 3 a).

The notion of time in Handel-C is fundamental. Each assignment happens in exactly one clock cycle; everything

```
entity Half_Adder is
      port (
            a, b: in bit;
            c, s: out bit;);
end Half_Adder

architecture structural of Half_Adder is
      component AND2    port (x, y: in bit; o: out bit);
      component EXOR2   port (x, y: in bit; o: out bit);

begin

Gate1 : AND2 port map (a, b, c);
Gate2 : EXOR2 port map (a, b, s);

end structural;
```

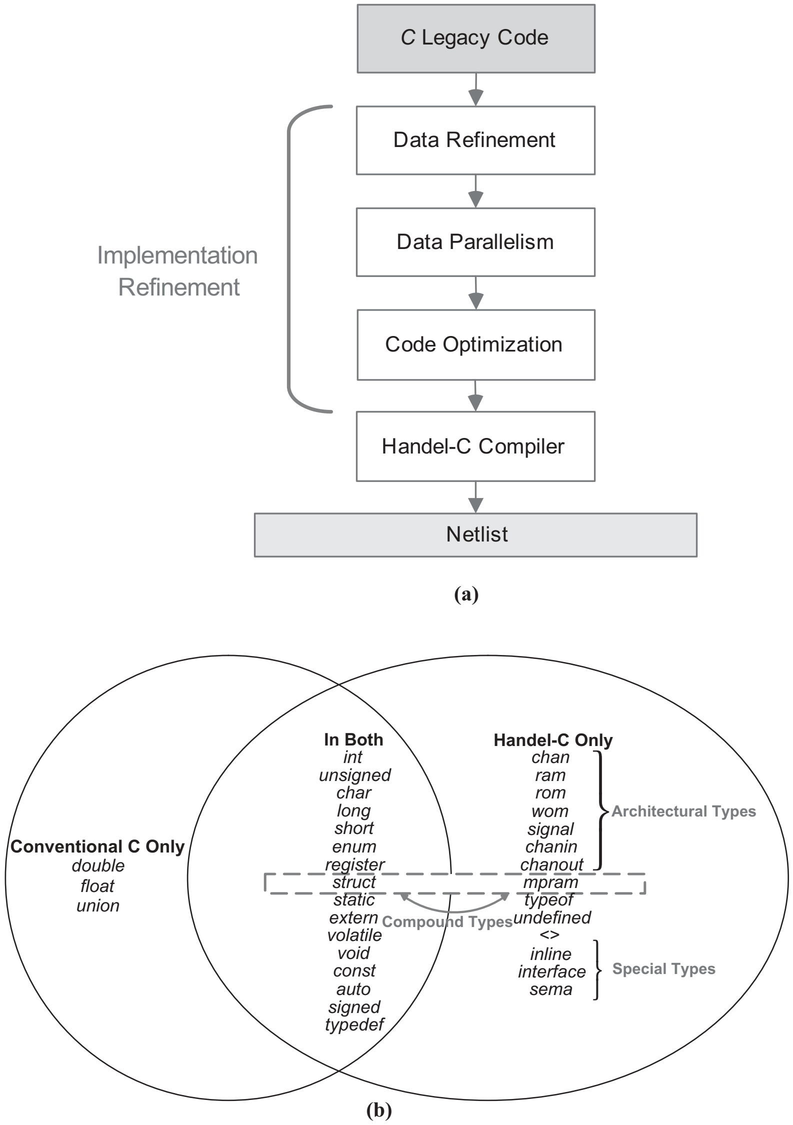

Figure 15. C and Handel-C types and objects. Handel-C types can be classified into common logic types, architectural types, compound types, and special types.

else is "free." An essential feature in Handel-C is the *par* construct, which executes instructions in parallel. Figure 16 provides an example showing the effect of using *par*.

Building on the work carried out in Oxford's Hardware Compilation Group by Page and Luk, Saul at Oxford's Programming Research Group (12) introduced a different codesign compiler, Dash FPGA-Based Systems. This compiler provides a cosynthesis and cosimulation environment for mixed FPGA and processor architectures. It compiles a C-like description to a solution containing both processors and custom hardware.

Luk and McKeever (13) introduced Pebble, a simple language designed to improve the productivity and effectiveness of hardware design. This language improves productivity by adopting reusable word-level and bit-level descriptions that can be customized by different parameter values, such as design size and the number of pipeline stages. Such descriptions can be compiled without flattening into various VHDL dialects. Pebble improves design effectiveness by supporting optional constraint descriptions, such as placement attributes, at various levels of abstraction; it also supports runtime reconfigurable designs.

Todman and Luk (14) proposed a method that combines declarative and imperative hardware descriptions. They investigated the use of Cobble language, which allows abstractions to be performed in an imperative setting. Designs created in Cobble benefit from efficient bit-level implementations developed in Pebble. Transformations are suggested to allow the declarative Pebble blocks to be used in cobble's imperative programs.

Weinhardt (15) proposes a high-level language programming approach for reconfigurable computers. This approach automatically partitions the design between hardware and software and synthesizes pipelined circuits from parallel *for* loops.

The computation finishes in a single time step

Figure 16. Parallel execution using a *par* statement.

Najjar et al. (16) presented a high-level, algorithmic language and optimizing compiler for the development of image-processing applications on RC-systems. SA-C, a single assignment variant of the C programming language, was designed for this purpose.

A prototype HDL called Lava was developed by Satnam Singh at Xilinx, Inc. (San Jose, CA) and Mary Sheeran and Koen Claessen at Chalmers University in Sweden (17). Lava allows circuit tiles to be composed using powerful higher order combinators. This language is embedded in the Haskell lazy functional programming language. Xilinx's implementation of Lava is designed to support the rapid representation, implementation, and analysis of high-performance FPGA circuits.

Besides the above advances in the area of high-level hardware synthesis, the current market has other tools employed to aid programmable hardware implementations. These tools include the Forge compiler from Xilinx, the System*C* language, the Nimble compiler for Agileware architecture from Nimble Technology (now Actuate Corporation, San Mateo, CA) and Superlog.

Forge is a tool for developing reconfigurable hardware, mainly FPGAs. Forge uses Java with no changes to syntax. It also requires no hardware design skills. The Forge design suite compiles into Verilog, which is suitable for integration with standard HLS and simulation tools.

SystemC is based on a methodology that can be used effectively to create a cycle-accurate model of a system consisting of software, hardware, and their interfaces in C++. SystemC is easy to learn for people who already use C/C++. SystemC produces an executable specification, while inconsistencies and errors are avoided. The executable specification helps to validate the system functionality before it is implemented. The momentum in building the SystemC language and modeling platform is to find a proper solution for representing functionality, communication, and software and hardware implementations at various levels of abstraction.

The Nimble compiler is an ANSI-C-based compiler for a particular type of architecture called Agileware. The Agileware architecture consists of a general-purpose CPU and a dynamically configurable data path coprocessor with a memory hierarchy. It can parallelize and compile the code into hardware and software without user intervention. Nimble can extract computationally intensive loops, turn them into data flow graphs, and then compile them into a reconfigurable data path.

Superlog is an advanced version of Verilog. It adds more abstract features to the language to allow designers to handle large and complex chip designs without getting too much into the details. In addition, Superlog adds many object-oriented features as well as advanced programming construct to Verilog.

Other famous HLS and hardware design tools include Altera's Quartus (San Jose, CA), Xilinx's ISE,and Mentor Graphics's HDL Designer, Leonardo Spectrum, Precision Synthesis, and ModelSim (Wilsonville, OR).

HIGHER LEVEL HARDWARE DESIGN METHODOLOGIES

The area for deriving hardware implementations from high-level specifications has been witnessing a continuous growth. The aims always have been to reach higher levels of abstraction through correct, well-defined refinement steps. Many frameworks for developing correct hardware have been brought out in the literature (18–20).

Hoare and colleagues (20) in the Provably Correct Systems project (ProCoS) suggested a mathematical basis for the development of embedded and real-time computer systems. They used FPGAs as back-end hardware for realizing their developed designs. The framework included novel specification languages and verification techniques for four levels of development:

- Requirements definition and design.
- Program specifications and their transformation to parallel programs.
- Compilation of programs to hardware.
- Compilation of real-time programs to conventional processors.

Aiming for a short and precise specification of requirements, ProCoS has investigated a real-time logic to formalize dynamic systems properties. This logic provides a calculus to verify a specification of a control strategy based on finite state machines (FSMS). The specification language SL is used to specify program components and to support transformation to an Occam-like programming language PL. These programs are then transformed into hardware or machine code. A prototype compiler in SML has been produced, which converts a PL-like language to a netlist suitable for placement and routing for FPGAs from Xilinx.

Abdallah (19), at London South Bank University, created a step-wise refinement approach to the development of correct hardware circuits from formal specifications. A functional programming notation is used for specifying algorithms and for reasoning about them. The specifications are realized through the use of a combination of function decomposition strategies, data refinement techniques, and off-the-shelf refinements basedupon higher order functions. The off-the-shelf refinements are inspired by the operators of CSP and map easily to programs in Handel-C. The Handel-C descriptions are then compiled directly into hardware.

The development of hardware solutions for complex applications is no more a complicated task with the emergence of various HLS tools. Many areas of application have benefited from the modern advances in hardware design, such as automotive and aerospace industries, computer graphics, signal and image processing, security, complex simulations like molecular modeling, and DNA matching.

The field of HLS is continuing its rapid growth to facilitate the creation of hardware and to blur more and more the border separating the processes of designing hardware and software.

INSTRUCTION SETS

A computer system's instruction set reflects the most primitive set of commands directly accessible to the programmer or compiler. Instructions in the instruction set manipulate components defined in the computer's instruction set architecture (ISA), which encompasses characteristics of the central processing unit (CPU), register set, memory access structure, and exception handling mechanisms.

In addition to defining the set of commands that a computer can execute, an instruction set specifies the format of each instruction. An instruction is divided into various fields that indicate the basic command (opcode) and the operands to the command. Instructions should be chosen and encoded so that frequently used instructions or instruction sequences execute quickly. Often there is more than one implementation of an instruction set architecture, which enables computer system designers to exploit faster technology and components while maintaining object code compatibility with previous versions of the computer system.

INSTRUCTION SET BASICS

Instructions contain an opcode—the basic command to execute, including the data type of the operands—and some number of operands, depending on hardware requirements. Historically, some or all of the following operands have been included: one or two data values to be used by the operation (source operands), the location where the result of the operation should be stored (destination operand), and the location of the next instruction to be executed. Depending on the number of operands, these are identified as one-, two-, three-, and four-address instructions. The early introduction of the special hardware register, the program counter, quickly eliminated the need for the fourth operand.

Types of Instructions

There is a minimum set of instructions that encompasses the capability of any computer:

- Add and subtract (arithmetic operations).
- Load and store (data movement operations).
- Read and write (input/output operations).
- An *unconditional* branch or jump instruction.
- A minimum of two *conditional* branch or jump instructions [e.g., BEQ (branch if equal zero) and BLT (branch if less than zero) are sufficient].
- A halt instruction.

Early computers could do little more than this basic instruction set. As machines evolved and changed, greater hardware capability was added, e.g., the addition of multiplication and division units, floating point units, multiple registers, and complex instruction decoders. Instruction sets expanded to reflect the additional hardware capability by combining frequently occurring instruction sequences into a single instruction. The expanding CISCs continued well into the 1980s until the introduction of RISC machines changed this pattern.

Classes of Instruction Set Architectures

Instruction sets are often classified according to the method used to access operands. ISAs that support memory-to-memory operations are sometimes called SS architectures (for Storage–Storage), whereas ISAs that support basic arithmetic operations only in registers are called RR (Register–Register) architectures.

Consider an addition, $A = B + C$, where the values of A, B, and C have been assigned memory locations 100, 200, and 300, respectively. If an instruction set supports three-address memory-to-memory instructions, a single instruction,

```
Add A, B, C
```

would perform the required operation. This instruction would cause the contents of memory locations 200 and 300 to be moved into registers in the arithmetic logic unit (ALU), the add performed in the ALU, and then the result stored into location 100.

However, it is unlikely that an instruction set would provide this three-address instruction. One reason is that the instruction requires many bytes of storage for all operand information and, therefore, is slow to load and interpret. Another reason is that later operations might need the result of the operation (for example, if $B + C$ were a subexpression of a later, more complex expression), so it is advantageous to retain the result for subsequent instructions to use.

A two-address register-to-memory alternative might be as follows:

```
Load   R1, B  ; R1 := B
Add    R1, C  ; R1 := R1 + C
Store  A, R1  ;  A := R1
```

whereas a one-address alternative would be similar, with the references to Rl (register 1) removed. In the latter scheme, there would be only one hardware register available for use and, therefore, no need to specify it in each instruction. (Example hardwares are the IBM 1620 and 7094.)

Most modern ISAs belong to the RR category and use general-purpose registers (organized either independently or as stacks) as operands. Arithmetic instructions require that at least one operand is in a register while "load" and "store" instructions (or "push" and "pop" for stack-based

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

machines) copy data between registers and memory. ISAs for RISC machines require both operands to be in registers for arithmetic instructions. If the ISA defines a register file of some number of registers, the instruction set will have commands that access, compute with, and modify all of those registers. If certain registers have special uses, such as a stack pointer, instructions associated with those registers will define the special uses.

The various alternatives that ISAs make available, such as

- both operands in memory,
- one operand in a register and one in memory,
- both operands in registers,
- implicit register operands such as an accumulator, and
- indexed *effective address* calculation, for $A[i]$ sorts of references,

are called the *addressing modes* of an instruction set. Addressing modes are illustrated below with examples of addressing modes supported by specific machines.

Issues in Instruction Set Design

There are many tradeoffs in designing an efficient instruction set. The code density, based on the number of bytes per instruction and number of instructions required to do a task, has a direct influence on the machine's performance. The architect must decide what and how many operations the ISA will provide. A small set is sufficient, but it leads to large programs. A large set requires a more complex instruction decoder. The number of operands affects the size of the instruction. A typical, modern instruction set supports 32-bit words, with 32-bit address widths, 32-bit operands, and dyadic operations, with an increasing number of ISAs using 64-bit operands. Byte, half-word, and double-word access are also desirable. If supported in an instruction set, additional fields must be allocated in the instruction word to distinguish the operand size.

The number of instructions that can be supported is directly affected by the size of the opcode field. In theory, $2^n - 1$ (a 0 opcode is never used), where n is the number of bits allocated for the opcode, is the total number of instructions that can be supported. In practice, however, a clever architect can extend that number by using the fact that some instructions, needing only one operand, have available space that can be used as an "extended" opcode. See the representative instruction sets in below for examples of this practice.

Instructions can either be fixed size or variable size. Fixed-size instructions are easier to decode and execute but either severely limit the instruction set or require a very large instruction size, i.e., wasted space. Variable-size instructions are more difficult to decode and execute but permit rich instruction sets. The actual machine word size influences the design of the instruction set. Small machine word size (see below for an example machine) requires the use of multiple words per instruction. Larger machine word sizes make single word instructions feasible. Very large machine word sizes permit multiple instructions per word (see below).

GENERAL PURPOSE ISAs

In this section, we discuss the most common categories of an instruction set. These categories include complex encoding, simplified encoding (often called load/store or reduced instruction sets), and wide instruction word formats. In the 1980s, CISC architectures were favored as best representing the functionality of high-level languages; however, later architecture designers favored RISC designs for the higher performance attained by using compiler analysis to detect instruction level parallelism. Another architectural style, VLIW, also attempts to exploit instruction level parallelism by providing multiple function units.

CISC

The CISC instruction set architecture is characterized by complicated instructions, many of which require multiple clock cycles to complete. CISC instructions typically have two-operand instructions in which one source also serves as a destination. CISC operations often involve a memory word as one operand, and they have multiple addressing modes to access memory, including indexed modes. Because the complexity of the instructions vary, instructions may have different lengths and vary in the number of clock cycles required to complete them. This characteristic makes it difficult to pipeline the instruction sequence or to execute multiple instructions in parallel.

RISC

RISC architectures were developed in response to the prevailing CISC architecture philosophy of introducing more and more complex instructions to supply more support for high-level languages and operating systems. The RISC philosophy is to use simple, fixed-size instructions that complete in a single cycle to yield the greatest possible performance (throughput and efficiency) for the RISC processor.

RISC designs may achieve instruction execution rates of more than one instruction per machine cycle. This result is accomplished by using techniques such as:

- Instruction pipelines
- Multiple function units
- Load/store architecture
- Delayed load instructions
- Delayed branch instructions

On any machine, a series of steps is required to execute an instruction. For example, these steps may be fetch instruction, decode instruction, fetch operand(s), perform operation, and store result. In a RISC architecture, these steps are *pipelined* to speed up overall execution time.

If all instructions require the same number of cycles for execution, a *full* pipeline will generate an instruction per cycle. If instructions require different numbers of cycles for execution, the pipeline will necessarily delay cycles while waiting for resources. To minimize these delays, RISC instruction sets include *prefetch* instructions to help ensure the availability of resources at the necessary point in time. The combination of pipelined execution with multiple internal function units allows a RISC processor sometimes to achieve multiple instruction execution per clock cycle.

Memory accesses require additional cycles to calculate operand address(es), fetch the operand(s), and store result(s) back to memory. RISC machines reduce the impact of these instructions by requiring that all operations be performed only on operands held in registers. Memory is then accessed only with load and store operations.

Load instructions fetch operands from memory to registers, to be used in subsequent instructions. As memory bandwidth is generally slower than processor cycle times, an operator is not immediately available to be used. The ideal solution is to perform one or more instructions, depending on the delay required for the load, which are *not* dependent on the data being loaded. This method effectively uses the pipeline, eliminating wasted cycles. The burden of generating effective instruction sequences is generally placed on a compiler, and of course, it is not always possible to eliminate all delays.

Lastly, branch instructions cause delays because the branch destination must be calculated and then that instruction must be fetched. As with load instructions, RISC designs typically use a delay on the branch instruction so they do not take effect until the one or two instructions (depending on the RISC design) immediately following the branch instruction have been executed. Again, the burden falls on the compiler to identify and move instructions to fill the one (or two) delay slots caused by this design. If no instruction(s) can be identified, a NOP (no op) has to be generated that reduces performance.

VLIW Instruction Sets

VLIW architectures are formed by using many parallel, pipelined functional units but with only a single execution thread controlling them all. The functional units are connected to a large memory and register banks using crossbars and/or busses. These elements are controlled by a single instruction stream. Each instruction has fields that control the operation of each functional unit, which enables the VLIW processor to exploit fine-grained instruction level parallelism (ILP).

Figure 1 shows a "generic" VLIW computer, and Fig. 2 shows an instruction word for such a machine.

To optimize code for a VLIW machine, a compiler may perform *trace* or *hyperblock scheduling* to identify the parallelism needed to fill the function units. Indirect memory references, generated by array indexing and pointer dereferencing can cause difficulties in the trace. These memory references must be disambiguated wherever possible to generate the most parallelism.

SPECIALIZED INSTRUCTION SETS

The discussion so far has focused on instruction sets for most general-purpose machines. Often the basic instruction set is augmented for efficient execution of special functions.

Vector Instruction Sets

Vector architectures, such as the original Cray computers, supplement the conventional scalar instruction set with a vector instruction set. By using vector instructions, operations that would normally be executed in a loop are expressed in the ISA as single instructions. In addition to the normal fetch–decode–execute pipeline of a scalar processor, a vector instruction uses additional vector pipelines to execute the vector instructions. In a vector instruction, the vector register's set of data is pipelined through the appropriate function unit.

Categories of vector instructions include:

- Vector–vector instructions, where all operands of the instruction are vectors. An example is an add with vector registers as operands and a vector register as result.
- Vector–scalar instructions, where the content of a scalar register is combined with each element of the vector register. For example, a scalar value might be

P_1			P_2			P_3			P_4		
F+	Fx	ALU	F+	Fx	ALU	F+	Fx	ALU	F+	Fx	ALU

Figure 2. A VLIW instruction word.

multiplied by each element of a vector register and the result stored into another vector register.

- Vector–memory instructions, where a vector is loaded from memory or stored to memory.
- Vector reduction instructions, in which a function is computed on a vector register to yield a single result. Examples include finding the minimum, maximum, or sum of values in a vector register.
- Scatter–gather instructions, in which the values of one vector register are used to control vector load from memory or vector store to memory. Scatter uses an indirect addressing vector register and a base scalar register to form an effective address. Values in a data vector register corresponding to the indirect addressing vector register are stored to the calculated effective memory addresses. Similarly, a gather uses the indirect address register combined with a scalar base register to form a set of effective addresses. Data from those addresses are loaded into a vector data register.

SIMD Instruction Sets

Single instruction multiple data (SIMD) machines were popular in the late 1980s as a means of realizing massively parallel operations with relatively simple control.

Instruction sets for SIMD machines built in the 1980s such as the CM-2, DAP, and MasPar MP series are conceptually similar to vector instruction sets. SIMD instructions also operate on aggregate data. However, rather than processing multiple pairs of operands through a functional pipeline, the SIMD machine had a single instruction controller directing many identical processors, each operating in lockstep through the instruction stream. The instructions could be SS, as in the CM-2, or RR, as in the MasPar machines. As there was just one instruction stream, only the instruction controller could execute branch instructions. Conditional operation on the array of processors was accomplished through *contextualization,* meaning each processor had its own unique "context" that determined whether it executed the current instruction.

Instructions exist in a SIMD instruction set to evaluate an expression and set the context to the result of the expression evaluation. Thus, processors that evaluate the expression to true will execute subsequent instructions, whereas those that evaluate the expression to false will not. Naturally, some instructions execute regardless of the context value, so that "context" can be set and reset during computation. SIMD instruction sets usually include reduce instructions, as described above for vector machines. In addition, some SIMD machines had scan instructions, which set up variable-length vectors across the processor array on which reduced operations could be performed.

Digital Signal Processor (DSP) Instruction Sets

The architecture of a DSP is optimized for pipelined data flow. Many DSPs for embedded applications support only fixed point arithmetic; others have both fixed and floating point units; still others offer multiple fixed point units in conjunction with the floating point processor. All of these variations, of course, affect the instruction set of the DSP, determining whether bits in the instruction word are needed to specify the data type of the operands. Other distinguishing characteristics of DSP instruction sets include:

- A multiple-accumulate instruction (MAC), used for inner product calculations
- Fast basic math functions, combined with a memory access architecture optimized for matrix operations
- Low overhead loop instructions
- Addressing modes that facilitate (Fast Fourier Transform)-like memory access
- Addressing modes that facilitate table look-up.

Configurable Instruction Sets

Research into future generations of processors generalizes the notion of support for specialized operations. New designs call for *configurable hardware* to be available so new instructions can be synthesized, loaded into the configurable logic, and thus dynamically extend the processor's instruction set. The Xilinx Virtex2 Pro illustrates this concept. In conjunction with a PowerPC RISC processor, the Virtex2 Pro Integrated Circuit contains an embedded field programmable gate array (FPGA). By designing circuits for the FPGA portion of the device, a programmer can augment the instruction set of the RISC processor with arbitrary functionality. Control signals to activate the custom instructions are generated by memory-mapped writes to a communications bus that connects the RISC processor with the FPGA. Such architectures provide virtually unlimited, application-dependent extensibility to an ISA.

REPRESENTATIVE INSTRUCTION SETS

In this section, we describe six representative instruction sets in greater detail. These are the IBM System 360, the PDP-11 mini-computer, the Pentium (Intel Architecture—IA-32), the PowerPC, the IA-64 Itanium, and the Cray X1 supercomputer.

The IBM System 360

The IBM System 360, introduced in April 1964 with first delivery in April 1965, was the first of the third-generation (integrated circuit) computers. The general acceptance of a 32-bit word and 8-bit byte comes from this machine. The system 360 consisted of a series of models, with models 30, 40, 50, 65, and 75 being the best known. The model 20, introduced in November 1964, had a slightly different architecture from the others.

The 360 (any of the models) was a conventional mainframe computer, incorporating a rich, complex instruction set. The machine had 16 general-purpose registers (8 on the smaller models) and 4 floating-point registers. Instructions

Table 1. IBM System 360 Addressing Modes

addr mode	byte 1	byte 2		bytes 3–4	bytes 5–6	Notes
RR	opcode	Rl	R2		unused	Rl changes
		DS & DD	DS		unused	R2 is unchanged
					unused	
RX	opcode	Rl	X	storage ref	unused	memory is base + disp. + X
		DS or DD			unused	
					unused	
RS	opcode	Rl	R2	storage ref	unused	Rl & R2 specify
		DS or DD	DS or DD		unused	a register range
					unused	
SI	opcode	immed. data		storage ref	unused	
					unused	
SS	opcode	op1	op2	storage ref1	storage ref2	
		len	len	DD	DS	

mainly had two addresses, but 0, 1, and 3 were also permitted in some cases.

There are five addressing modes, using 2-, 4-, and 6-byte instructions. Table 1 shows these five modes. The notation in the table is (*1*) R1, R2, and X are general-purpose registers selected from the available set of 16; (*2*) R1 is either a data source (DS) *and* destination (DD) (in RR instructions) or, DS *or* DD, depending on the opcodes (other modes); (*3*) X is an index added to the specified storage reference; (*4*) a storage reference is a standard 360 memory reference consisting of a 4-bit base address and a 12-bit displacement value; (*5*) immed(iate) data are the second instruction data value and is the *actual* data value to be used, i.e., not a register or memory reference; and (*6*) op1 len and op2 len are the lengths of the of the instruction result destination and data source, respectively (op2 len is only needed for packed-decimal data).

Table 2 contains a list of 360 op codes along with the type (RR, RX, RS, SI, SS) of each operation.

DEC PDP-11

The DEC PDP-11 was a third-generation computer, introduced around 1970. It was a successor to the highly successful (also) third-generation PDP-8, introduced in 1968, which was a successor to second-generation PDP machines.

The PDP-11, and the entire PDP line, were minicomputers, where minicomputer is loosely defined as a machine with a smaller word size and memory address space, and a slower clock rate, than cogenerational mainframe computers. The PDP-11 was a 16-bit word machine, with 8 general-purpose registers (R0–R7), although R6 and R7 were “reserved” for use as the stack pointer (SP) and program counter (PC), respectively.

Instructions required one word (16 bits) immediately followed by one or two words used for some addressing modes. Instructions could be *single* operand instructions with a 10-bit opcode specifying the operation to be performed and a 6-bit destination of the result of the operation; or *double* operand instructions with a 4-bit opcode specifying the operation to be performed and two 6-bit data references for the data source and destination, respectively. Each data reference consists of a 3-bit register subfield and a 3-bit addressing mode subfield.

Instruction operands could be either a single byte or a word (or words using indirection and indexing). When the operand was a byte, the leading bit in the op code field was 1; otherwise, that bit was 0.

There are eight addressing modes, as in Table 3. The PDP-11 instruction set is given in Table 4.

Pentium Processor

The Intel Pentium series processor became the most prevalent microprocessor in the 1990s. The Pentium follows the ISA of the 80x86 (starting with 8086). It uses advanced techniques such as speculative and out-of-order execution, once used only in supercomputers, to accelerate the interpretation of the x86 instruction stream.

The original 8086 was a 16-bit CISC architecture, with 16-bit internal registers. Registers had fixed functions. Segment registers were used to create an address larger than 16 bits, so the address space was broken into 64K byte chunks. Later members of the x86 family (starting with the 386) were true 32-bit machines, with 32-bit registers and a 32-bit address space. Additional instructions in the later x86 instruction set made the register set more general purpose.

The general format of an “Intel Architecture” (IA-32) instruction is shown in Fig. 3. The instructions are a variable number of bytes with optional prefixes, an opcode, an addressing-form specifier consisting of the ModR/M and Scale/Index/Base fields (if required), address displacement of 0 – 4 bytes, and an immediate data field of 0 to 4 bytes. The instruction prefixes can be used to override default registers, operand size, and address size or to specify certain actions on string instructions. The opcode is either one or two bytes, although occasionally a third byte is encoded in the next field. The ModR/M and SIB fields have a complex encoding. In general, their purpose is to specify registers (general purpose, base, or index), addressing modes, scale factor, or additional opcode information.

Prefixes	opcode	ModR/M	SIB	Displacement	Immediate

The register specifiers may select MMX registers. The displacement is an address displacement. If the instruction requires immediate data, it is found in the final byte(s) of the instruction.

A summary of the Intel Architecture instruction set is given in Table 5. The arithmetic instructions are two-operand, where the operands can be two registers, register and memory, immediate and register, or immediate and memory. The Jump instructions have several forms depending on whether the target is in the same segment or a different segment.

MMX Instructions. The Pentium augments the ×86 instruction set with several multimedia instructions to operate on aggregate small integers. The MMX multimedia extensions have many SIMD-like characteristics. An MMX instruction operates on data types ranging from 8 to 64 bits. With 8-bit operands, each instruction is similar to a SIMD instruction in that during a single clock cycle, multiple instances of the instruction are being executed on different instances of data. The arithmetic instructions PADD/PSUB and PMULLW/PMULHW operate in parallel on either 8 bytes, four 16-bit words, or two 32-bit double words.

The MMX instruction set includes a DSP-like MAC instruction, PMADDWD, which does a multiply-add of four signed 16-bit words and adds adjacent pairs of 32-bit results. The PUNPCKL and PUNKCKH instructions help with interleaving words, which is useful for interpolation. The arithmetic instructions in the MMX instruction set allow for saturation to avoid overflow or underflow during calculations.

The MMX instructions use the Pentium floating point register set, thus requiring the FP registers to be saved and restored when multimedia instruction sequences occur in conjunction with floating point operations.

PowerPC RISC Processor

The PowerPC (PPC) family of 32- and 64-bit processors, jointly developed by IBM, Motorola, and Apple, follows the RISC architecture and instruction set philosophy. In common with other RISC processors, the PPC uses register operands for all arithmetic and logical instructions, along with a suite of load/store instructions to explicitly access data from memory. A complex instruction pipeline with multiple internal function units is used to achieve execution of more than one instruction per clock cycle.

The PPC CPU contains 32, 32-bit or 64-bit general-purpose registers; 32, 64-bit floating point registers; a 32-bit condition register; a 32- or 64-bit link register; and a 32- or 64-bit count register. The condition register can be set by arithmetic/logical instructions and is used by branch instructions. The link register is used to form an effective

Table 3. Addressing Modes of the PDP-11

address mode	Name	Form	Meaning
0	register	Rn	operand is in register n
1	indirect register[a]	(Rn)	address of operand is in register n
2	autoincrement	(Rn)+	address of operand is in register n n (Rn):=(Rn)+2 after operand is fetched[b]
3	indirect autoincrement	@(Rn)+	register n contains the address of the *address* of the operand: (Rn):=(Rn)+2 after operand is fetched
4	autodecrement	−(Rn)	(Rn):=(Rn)−2 *before* operand is fetched[c] address of operand is in register n
5	indirect autodecrement	@−(Rn)	(Rn):=(Rn)−2 before operand is fetched register n contains the address of the *address* of the Operand
6	index	X(Rn)	address of operand is in X+(Rn); address of X is in the PC; (PC):=(PC)+2 after X is fetched
7	indirect index	@X(Rn)	X+(Rn) is the *address* of the address of the operand; address if X is in the PC; (PC):=(PC)+2 after X is fetched

[a] "Indirect" is also called "deferred."

[b] If the instruction is a byte instruction and the register is *not* the SP or PC, (Rn):=(Rn)+l.

[c] If the instruction is a byte instruction and the register is *not* the SP or PC, (Rn):=(Rn)−l.

address for memory access. The count register is used for fixed iteration loops and can be automatically decremented by checking its value within a branch instruction.

Each instruction fits into a 32-bit word. The 32-bit instruction contains a 6-bit opcode (for register-to-register mode), three 5-bit register operand specifiers, and 11 remaining opcode-specific modifier bits. In register-immediate mode, only one source operand is in a register, and the 5 bits for the second source register are concatenated with the 11-bit modifier field to yield a 16-bit constant. Other instruction formats use a more complex encoding, as shown below:

Reg - Reg	$\texttt{opcode}_6$	$\texttt{rd}_5$	$\texttt{rs1}_5$	$\texttt{rs2}_5$	$\texttt{opex1}_{11}$

Reg - Imm	$\texttt{opcode}_6$	$\texttt{rd}_5$	$\texttt{rs1}_5$	$\texttt{const}_{16}$

Branch	$\texttt{opcode}_6$	$\texttt{opex1}_6$	$\texttt{rs1}_5$	$\texttt{const}_{14}$	$\texttt{opex2}_2$

Jump	$\texttt{opcode}_6$	$\texttt{const}_{24}$	$\texttt{opex}_2$

Reg-reg is the register–register format used for the arithmetic and logical instructions. Reg-Imm is the register–immediate format in which the second operand is a 16-bit constant. The branch format specifies a relative branch distance in a 14-bit constant, and the Jump format uses a 24-bit constant to hold the jump or call target. “rd” is the register number of the destination, “rs1” is the first source operand, “rs2” is the second source operand register, “const” is a constant, and “opex1” and “opex2” are extensions of the opcode. The subscript shows the number of bits for each field.

The core PPC instruction set contains three categories of instructions: arithmetic/logical for both fixed and floating point, load/store for both fixed and floating point, and branch instructions. In addition, there are specialized instructions to control caches and synchronize memory accesses. Arithmetic and logical operations must use either both source operands in registers or one operand in a register and one operand as a 16-bit constant value. Load/store instructions access memory and can occur in one of three addressing modes:

- Register indirect with index, where the effective address from which to load or store is calculated by adding rsl to rs2.

Table 5. Intel architecture instruction set summary

Command	Opcode	Command	Opcode
ASCII Adjust after Addition	AAA	Load Global Descriptor Table Register	LGDT
ASCII Adjust AX before Division	AAD	Load Pointer to GS	LGS
ASCII Adjust AX after Multiply	AAM	Load Interrupt Descriptor Table Register	LIDT
ASCII Adjust AL after Subtraction	AAS	Load Local Descriptor Table Register	LLDT
ADD with Carry	ADC	Load Machine Status	LMSW
Add	ADD	Assert LOCK Num. Signal Prefix	LOCK
Logical AND	AND	Load String Operand	LOD*
Adjust RPL Field of Selector	ARPL	Loop Count (with condition)	LOOP*
Check Array Against Bounds	BOUND	Load Segment Limit	LSL
Bit Scan Forward	BSF	Load Task Register	LTR
Bit Scan Reverse	BSR	Move Data, Registers	MOV*
Byte Swap	BSWAO	Unsigned Multiply	MUL
Bit Test	BT	Two's Complement Negation	NEG
Bit Test and Complement	BTC	No Operation	NOP
Bit Test and Reset	BTR	One's Complement Negation	NOT
Bit Test and Set	BTS	Logical Inclusive OR	OR
Call Procedure (m same segment)	CALL	Output to Port	OUT*
Call Procedure (in different segment)	CALL	Pop Word/Register(s) from Stack	POP
Convert Byte to Word	CWB	Push Word/Register(s) onto Stack	PUSH
Convert Doubleword to Qword	CDQ	Rotate thru Carry Left	RCL
Clear Carry Flag	CLC	Rotate thru Carry Right	RCR
Clear Direction Flag	CLD	Read from Model Specific Register	RDMSR
Clear Interrupt Flag	CLI	Read Performance Monitormg Counters	RDPMC
Clear Task-Switched Flag in CRO	CLTS	Read Time-Stamp Counter	RDTSC
Complement Carry Flag	CMC	Input String	REP INS
Conditional Move	CMOVcc	Load String	REP LODS
Compare to Operands	CMP	Move String	REP MOVS
Compare String Operands	CMP[S[W/D]]	Output String	REP OUTS
Compare/Exchange	CMPXCHG	Store String	[REP] STOS
Compare/Exchange 8 Bytes	CMPXCHG8B	Compare String	REP[N][E] CMPS
CPU Identification	CPUID	Scan String	[REP] [N][E] SCANS
Convert Word to Doubleword	CWD	Return from Procedure	RET
Convert Word to Doubleword	CWDE	Rotate Left	ROL
Decimal Adjust AL after Addition	DAA	Rotate Right	ROR
Decimal Adjust AL after Subtraction	DAS	Resume from System Management Mode	RSM
Decrement by 1	DEC	Store AH into Flags	SAHF
Unsigned Divide	DIV	Shift Arithmetic Left	SAL
Make Stack Frame for Proc.	ENTER	Shift Arithmetic Right	SAR
Halt	HLT	Subtract with Borrow	SBB
Signed Divide	IDIV	Jziyte oet on Condition	SETcc
Signed Multiply	IMUL	Store Global Descriptor Tabel Register	SGTD
Input From Port	IN	Shift Left [Double]	SHL[D]
Increment by 1	INC	Shift Right [Double]	SHR[D]
Input from DX Port	INS	Store Interrupt Descriptor Table Register	SIDT
Interrupt Type n	INT n	Store Local Descriptor Table	SLDT
Single-Step Interrupt 3	INT	Store Machine Status Word	SMSW
Interrupt 4 on Overflow	INTO	Set Carry Flag	STC
Invalidate Cache	INVD	Set Direction Flag	SDC
Invalidate TLB Entry	INVLPG	Set Interrupt Flag	STI
Interrupt Return	IRET/IRETD	Store Task Register	STR
Jump if Condition is Met	Jcc	Integer Subtract	SUB
Jump on CX/ECX Zero	JCXZ/JECXZ	Logical Compare	TEST
Unconditional Jump (same segment)	JMP	Undefined Instruction	UD2
Load Flags into AH Register	LAHF	Verify a Segment for Reading	VERR
Load Access Rights Byte	LAR	Wait	WAIT
Load Pointer to DS	LDS	Writeback and Invalidate Data Cache	WVINVD
Load Effective Address	LEA	Write to Model-Specific Register	WRMSR
High Level Procedure Exit	LEAVE	Exchange and Add	XCHG
Load Pointer to ES	LES	Table Look-up Translation	XLAT[B]
Load Pointer to FS	LFS	Logical Exclusive OR	XOR

- Register indirect with immediate index, in which the effective address is calculated by adding rs1 to the constant.
- Register indirect, in which the effective address is in rs1.

Branch instructions also have three categories of addressing modes:

- Immediate. The 16-bit constant is used to compute a relative or absolute effective address.
- Link register indirect. The branch address is in the link register.
- Count register indirect. The branch address is in the count register.

Like the Pentium, some PowerPC models offer a SIMD-like extended instruction set for aggregate operation on byte (or larger) data. The extensions are variously referred to as Altivec (Motorola) or VMX (IBM). There are 162 specialized SIMD instructions that operate on a set of 32, 128-bit registers. Each register can be used as either 16, 8-bit registers; 8, 16-bit registers; or 4 single precision floating-point registers. Unlike the Pentium, the SIMD instruction set operates on a completely different set of registers than the normal instruction set, and thus, the general-purpose registers do not need to be saved or restored when SIMD instructions are executed.

IA-64 Itanium Processor

As discussed, modern microprocessors achieve performance by executing multiple instructions in parallel. In most cases, the parallelism is hidden from the instruction set architecture view of the microprocessor. In contrast, the Intel and HP Itanium processor is a 64-bit architecture (Intel Architecture IA-64) that follows an explicitly parallel instruction computing (EPIC) model. The EPIC model exposes opportunities for ILP in the instruction set, allowing the compiler and the underlying microarchitecture to communicate about potentially parallel operations. This architecture incorporates ideas from CISC, RISC, and VLIW.

The IA-64 architecture provides a very large set of 64-bit registers, including 128 general registers: 128, 82-bit floating-point registers; and 128 application registers. In addition, there are 64, 1-bit predicate registers (called condition registers in other architectures) and 8, 64-bit branch registers. The 1-bit registers NaT (not-a-thing) and NatVal (not-a-thing-value) are used to signal potential exception conditions. There is a NaT register for each general register and a NatVal for each floating-point register. Other miscellaneous registers are used for memory mapping, system control, performance counters, and communicating with the operating system.

The 128-bit instruction word is called a "bundle" and contains three 41-bit instructions plus a 5-bit "template" that is used to help decode and route instructions within the instruction pipeline. The template bits also can signal the end of a group of instructions that can be executed in parallel. This instruction format is an outgrowth of the VLIW architectures described above.

The 128 general registers are divided into two groups. A set of 32 static registers is used similarly to RISC processors. The remaining 96 registers are called "stacked" registers and implement a register stack that is used to store parameters and results of procedure calls. Registers from the stacked set are allocated with an explicit "alloc" instruction.

IA-64 provides instructions to rename registers, which makes the registers appear to rotate. This mechanism is provided for the general registers, floating-point registers, and the predicate registers. The RRB (register rotation base) is used to specify a register number offset. Rotate instructions are used by the compiler to support "software pipelining," a technique whereby multiple loop iterations execute concurrently. By rotating a set of registers, a set of active loop iterations all refer to different registers and can execute in parallel. The general registers 32–127, floating point registers 32–127, and predicate registers 16–63 can be rotated. The RRB register is used to specify an offset to the subset of rotating registers. A reference to any register in the range of the rotating registers is offset by the value of the RRB. Thus, if the RRB has a current value of 15, a reference to GR[40] would actually refer to GR[55]. The effective register number is computed using modulo arithmetic, so that the register values appear to rotate.

The compiler creates "instruction groups" of instructions that can be executed in parallel. The size of the group is variable, with a stop bit in the template indicating the end of a group. Often, the amount of parallelism is limited by conditional execution ("if" statements or "if" expressions in most programming languages). The IA-64 architecture supports parallelism through conditional execution by using predicate bits in the instruction word: The instruction is executed only if the specified predicate bit is true. This feature is remniscent of SIMD-style processors, with a "context" bit determining whether a processor executes the instruction. Conditional branching is also provided in the instruction set by allowing each instruction to branch based on a different predicate register.

The IA-64 has unique instructions that allow operations such as loads and stores to memory to be executed *speculatively*. A speculative operation is executed before it would normally be executed in the sequential instruction stream. For example, consider the instruction sequence

1. Branch conditional to 3.
2. Load from memory.
3. Other instruction.

Speculative execution of the load instruction means that the load (instruction 2) is executed before the branch (instruction 1) completes. A set of speculation check instructions then determine whether the speculative load (or store) is kept or discarded.

Similarly, suppose the instruction sequence includes a store followed later in the instruction stream by a load. The load may be executed speculatively before the store even if the compiler cannot guarantee that the load and store refer to different addresses. A check instruction follows the store to determine whether the store and load refer to the same or different addresses. If they refer to the same address (called “aliasing”), the speculatively loaded value is discarded, and the most recently stored value is used. If they refer to distinct locations, the loaded value is immediately available in the register for use by other instructions.

Speculative operations cause the CPU to perform additional work. However, if they enable the CPU to not wait when values are needed, they improve execution rates. In some cases, however, speculative operations may cause exception conditions that, under normal sequential operation, would not have occurred. For example, if a load were performed speculatively before a branch, and the address to be loaded were illegal, then a true exception should not be raised because the load may never be executed. The NaT and NatVal registers record exceptions that occur during speculative execution. If the speculative operation is retained, an exception is raised; otherwise, the speculative operation is aborted.

Another unique aspect of the IA-64 architecture is the ability to emulate other instruction sets. There are special instructions in the instruction set to direct the IA-64 to operate in IA-32 mode, and an IA-32 instruction to return to IA-64 mode. The application register set is used to facilitate emulation of other instruction set architectures.

Although it is not feasible to include the entire IA-64 instruction set in a summary article, the core set of IA-64 instructions[1] are as follows:

- Load/store, memory operations.
- Logical, compare, shift, arithmetic operations.
- Aggregate operations on small integers, similar to the MMX (see above or Altivec).
- Floating-point operations, both simple and aggregate.
- Branch operations, including multiway branches and loop control branches.
- Cache management operations.

Cray X1 Computer

The Cray X1 was announced in November 2002, although five early production systems had already been shipped. The X1 combines vector processing (from the Cray C90, T90, and SV1) and massively parallel processing (MPP, from the Cray T3D and T3E) into a single unified architecture.

A single stream processor (SSP) is a RISC processor, consisting of a superscalar processing unit and a two-pipe vector processing unit, which is the basic component of the system. Four SSPs are combined to form a multistream processor (MSP). Four MSPs form a *node*. Cache memory is fully shared by the four SSPs in an MSP; memory is fully shared by the four MSPs of a node.

A maximum of 1024 nodes can be joined in a X1 system. A hypercube network combines nodes into groups of 128. A three-dimensional-torus network connects the hypercubes to form a *global shared nonuniform memory access* (NUMA) machine.

The X1 has two execution modes. In SSP mode, each SSP runs independently of the others, executing its instruction stream. In MSP mode, the MSP automatically distributes parallel parts of multistreaming applications to its SSPs. SSPs support vectorization; MMPs support multistreaming. The entire system support both the distributed (MPI, shmem) and the shared memory (UPC, coarray FORTRAN) parallel paradigms.

Table 6 shows the register types for the Cray X1 processors.

Although both the address and the scalar registers are general purpose and can be used for memory reference instructions, immediate loads, integer functions, and conditional branches, they each have specific uses as well. The address registers *must* be used for memory base addresses,

Table 6. Cray X1 Register Types

register type	designator	number	size in bits	comment
address	a	64	64-bits	general purpose
scalar	s	64	64-bits	general purpose
vector	V	31	32- or 64-bits	max. 64 elements in each
vector length	vl	1		max. elements a vector register can hold
mask	m	8	varies	control vector ops on per-element basis; only first four used in instuctions
vector carry	vc	1	varies	used w/64-bit vector add w/carry and subtract w/borrow inst.
bit matrix mult.	bmm	1	64 x 64-bit	loaded from a vector register
control	c	64		mostly kernel mode; only cO–c4, c28–c31 are user accessible
program counter	pc	1	64-bit	byte addr. of next instruction to fetch; invisible to user but content referenced in some instruction descriptions
performance ctrs	32	64-bits		accessible via c31

[1] Most of these instructions can be predicated.

field name	g	i	j	k	t	f
bit length	6	6	6	6	2	6
use	opcode	dest.	source	source	size+	opcode

Figure 4. Cray XI instruction format.

indirect jump addresses and returns, vector element indexing, vector length computations for the vector length register, reading and writing the vector length register and control registers, receiving results of mask analysis instructions [first(), last(), pop()], supplying the span for vector span() and cidx(), and 8- and 16-bit accesses. The scalar registers *must* be used for scalar bit matrix multiplications, floating-point operations, and scalar operands to vector operations.

The Cray X1 has fixed 32-bit instructions. All instructions (other than branch instructions) have six fields, although all fields may not be used by all instructions. The instruction format is shown in Fig. 4.

The g-field opcode is more of a general class such as "a-register integer instructions," "a-register halfword instructions," and "s-register logical instructions". The f-field opcode, when used, specifies the specific instruction in the general class such as "a-register integer add" and "a-register integer subtract". The source and destination fields, i, j, and k, can be any of the address, scalar, or vector registers or, when appropriate, a mask register. Additionally, the source may also be an "immediate" value. Immediates can be 6 bits, 8 bits (using the t-field), or 16 bits (using the t- and f-fields plus 2 bits from the j-field). The t-field is used for various flags; for example, "11" is used in register logical oprations to indicate that the second source operand is a register (rather than "immediate") and "01" and "00" are used to flag "64-bit" and "32-bit", respectively, in register move and conversion operations.

Branch instructions use only three fields: g, i, and k. The g-field contains the opcode, the i-field contains the location of the value to be tested for the condition, and the k-field is an immediate of 20 bits, which when combined with the program counter, yields the branch address.

The Cray X1 has a rich ISA for scalar and vector instructions. An overview of the vector instructions is given here.

The vector instruction set is too rich to be included here..

The vector instruction set is organized into five categories:

- Elemental vector operations
- Vector memory references
- Elemental vector functions
- Mask operations
- Other vector instructions

The *elemental vector operations* are vector versions of most scalar integer and floating-point functions and memory references. These operations process each vector element independently, under control of a mask register and the vector length register. The semantics of these operations is similar to a loop stepping through each element of a vector.

Vector registers are loaded and stored from a sequence of properly aligned byte addresses. The address sequence is computed from a base address register and either a scalar stride value or a vector of 64-bit offset values. The five *vector memory reference* instructions are **strided load, strided store, gather,** and two **scatters,** one with distinct offsets and one with arbitrary offsets.

The *elemental vector functions* include **arithmetic** operations, **bitwise** operations (and, or, etc.), **logical left shift, logical right shift,** and **arithmetic right shift,** several floating point to integer **convert** instructions, **compare** instructions ([not] equal, [not] less than, [not] greater than), **merge, square root, leading zero count, population count, bit matrix multiply,** and **arithment absolute value.** Most of these operations permit a scalar register, in place of a vector register, for one data source.

Mask operations operate directly on mask registers to set values and otherwise manipulate these registers. Instructions include **bitwise** operations (and, xor, etc.), **set leading n bits, clear remainder, find lowest/highest set bit index,** and **count number of bits set,** among others. Any mask register can be used in the mask operation instructions, but only the first four, m0–m3, can be used in vector instructions.

The *other vector operations* category contains those instructions that do not fit easily into the other four categories. These are **set vector length, retrieve vector length, read vector element, write vector element, load bit matrix,** and **declare vector state dead.** This last instruction undefines all vector registers, the vector carry register vc, and the mask registers. Mask register m0 remains defined if it has all of its bits set; otherwise, it too becomes undefined.

INTERCONNECTION NETWORKS FOR PARALLEL COMPUTERS

The interconnection network is responsible for fast and reliable communication among the processing nodes in any parallel computer. The demands on the network depend on the parallel computer architecture in which the network is used. Two main parallel computer architectures exist (1). In the *physically shared-memory parallel computer, N* processors access *M* memory modules over an interconnection network as depicted in Fig. 1(a). In the *physically distributed-memory parallel computer,* a processor and a memory module form a processor–memory pair that is called *processing element* (PE). All *N* PEs are interconnected via an interconnection network as depicted in Fig. 1(b). In a *message-passing system,* PEs communicate by sending and receiving single messages (2), while in a *distributed-shared-memory system,* the distributed PE memory modules act as a single shared address space in which a processor can access any memory cell (3). This cell will either be in the memory module local to the processor, or be in a different PE that has to be accessed over the interconnection network.

Parallel computers can be further divided into SIMD and MIMD machines. In *single-instruction-stream multiple-data-stream* (SIMD) parallel computers (4), each processor executes the same instruction stream, which is distributed to all processors from a single control unit. All processors operate synchronously and will also generate messages to be transferred over the network synchronously. Thus, the network in SIMD machines has to support synchronous data transfers. In a *multiple-instruction-stream multiple-data-stream* (MIMD) parallel computer (5), all processors operate asynchronously on their own instruction streams. The network in MIMD machines therefore has to support asynchronous data transfers.

The interconnection network is an essential part of any parallel computer. Only if fast and reliable communication over the network is guaranteed will the parallel system exhibit high performance. Many different interconnection networks for parallel computers have been proposed (6).

One characteristic of a network is its topology. In this article we consider only point-to-point (non-bus-based) networks in which each network link is connected to only two devices. These networks can be divided into two classes: direct and indirect networks. In direct networks, each switch has a direct link to a processing node or is simply incorporated directly into the processing node. In indirect networks, this one-to-one correspondence between switches and nodes need not exist, and many switches in the network may be attached only to other switches. Direct and indirect network topologies are discussed in the following section.

The mechanism to transfer a message through a network is called *switching.* A section below is devoted to switching techniques. Switching does not take into consideration the actual route that a message will take through a network. This mechanism is termed *routing,* and will be discussed in turn. In indirect networks, active switch boxes are used to transfer messages. Switch box architectures are discussed in a final section.

NETWORK TOPOLOGIES

Direct Networks

Direct networks consist of physical interconnection links that connect the nodes (typically PEs) in a parallel computer. Each node is connected to one or more of those interconnection links. Because the network consists of links only, routing decisions have to be made in the nodes. In many systems, dedicated router (switch) hardware is used in each node to select one of the interconnection links to send a message to its destination. Because a node is normally not directly connected to all other nodes in the parallel computer, a message transfer from a source to a destination node may require several steps through intermediate nodes to reach its destination node. These steps are called *hops.*

Two topology parameters that characterize direct networks are the degree and the network diameter. The *degree* Γ of a node is defined as the number of interconnection links to which a node is connected. Herein, we generally assume that direct network links are bidirectional, although this need not always be the case. Networks in which all nodes have the same degree *n* are called *n-regular* networks. The network *diameter* Φ is the maximum distance between two nodes in a network. This is equal to the maximum number of hops that a message needs to be transferred from any source to any destination node. The degree relates the network topology to its hardware requirements (number of links per node), while the diameter is related to the transfer delay of a message (number of hops through the network). The two parameters depend on each other. In most direct network, a higher degree implies a smaller diameter because with increasing degree, a node is connected to more other nodes, so that the maximum distance between two nodes will decrease.

Many different direct network topologies have been proposed. In the following, only the basic topologies are studied. Further discussion of other topologies can be found in Refs. 7–9.

In a *ring network* connecting *N* nodes, each node is connected to only two neighbors ($\Gamma = 2$), with PE *i* connected to PEs $i - 1 \bmod N$ and $i + 1 \bmod N$. However, the network has a large diameter of $\Phi = \lfloor N/2 \rfloor$ (assuming bidirectional links). Thus, global communication performance in a ring network will decrease with increasing number of nodes.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

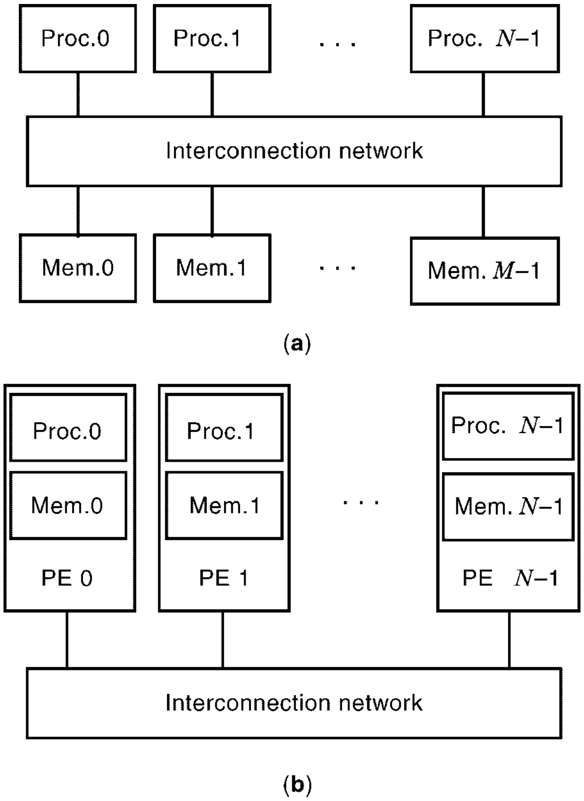

Figure 1. (a) Physically shared-memory and (b) distributed-memory parallel computer architecture.

A direct network quite commonly used in parallel computers is the mesh network. In a *two-dimensional mesh,* the nodes are configured in an $M_X \times M_Y$ grid (with M_X nodes in the X direction and M_Y nodes in the Y direction), and an internal node is connected to its nearest neighbors in the north, south, east, and west directions. Each border node is connected to its nearest neighbors only. A 4 × 4 two-dimensional mesh connecting 16 nodes is depicted in Fig. 2(a). Because of the mesh edges, nodes have different degrees. In Fig. 2(a), the internal nodes have degree $\Gamma = 4$, while edge nodes have degree $\Gamma = 3$ and $\Gamma = 2$ (for the corner nodes). Because the edge nodes have a lower degree than internal nodes, the (relatively large) diameter of a two-dimensional mesh is $\Phi = (M_X - 1) + (M_Y - 1)$.

To decrease the network diameter, the degree of the edge nodes can be increased to $\Gamma = 4$ by adding edge links. The topology of a two-dimensional *torus network* is created by connecting the edge nodes in columns and rows, as depicted in Fig. 2(b). All nodes of this two-dimensional torus network have degree $\Gamma = 4$, and the network diameter is reduced to $\Phi = \lfloor M_X/2 \rfloor + \lfloor M_Y/2 \rfloor$.

The disadvantage of two-dimensional mesh networks is their large diameter, which results in message transfers over many hops during global communication, especially in larger networks. To further reduce the diameter, higher-dimensional meshes can be used. Figure 3(a) depicts a three-dimensional mesh with open edge connections connecting 27 nodes. Internal nodes have degree $\Gamma = 6$, while edge nodes have degree of $\Gamma = 5$, $\Gamma = 4$, or $\Gamma = 3$, depending on their position. The network diameter is equal to $\Phi = (M_X - 1) + (M_Y - 1) + (M_Z - 1)$, with M_i equal to the number of nodes in the i direction. This diameter can be further reduced if edge connections are added.

In a *hypercube network* that connects N nodes, each node has degree $\Gamma = n = \log_2 N$, where n is called the *hypercube dimension* (8). Each link corresponds to a cube function (10). The *cube$_k$ function* on an address (node number) complements the kth bit of that address. To describe the hypercube topology, the Hamming distance H can be used. The *Hamming distance H* between two binary numbers is defined in Ref. 11 as the number of bits in which the two numbers differ. Thus, two nodes are directly connected in a hypercube if their Hamming distance is $H = 1$ (the node numbers differ in exactly one bit). The number of hops that a message will take through the network is therefore equal to the Hamming distance between its source and destination addresses. In Fig. 3(b), a four-dimensional hypercube that connects 16 nodes is depicted. The diameter of a hypercube network is $\Phi = n$, because in the worst case, a source and a destination address of a message can differ in all n bits, so that all n cube functions have to be executed in order to transfer that message.

One disadvantage of a hypercube network concerns scalability. To increase the number of nodes a hypercube can interconnect, the degree of each node has to be incremented by at least one. Thus, to obtain the next larger hypercube, the number of nodes has to be doubled. To alleviate this scalability problem, *incomplete hypercubes*

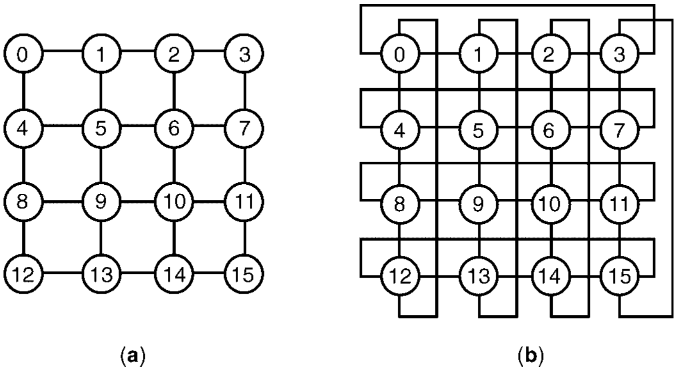

Figure 2. (a) Two-dimensional mesh network connecting 16 nodes, (b) torus network connecting 16 nodes. Because of the edge connections, the torus network has a uniform degree of four, while nodes in the mesh network have different degrees, depending on their location.

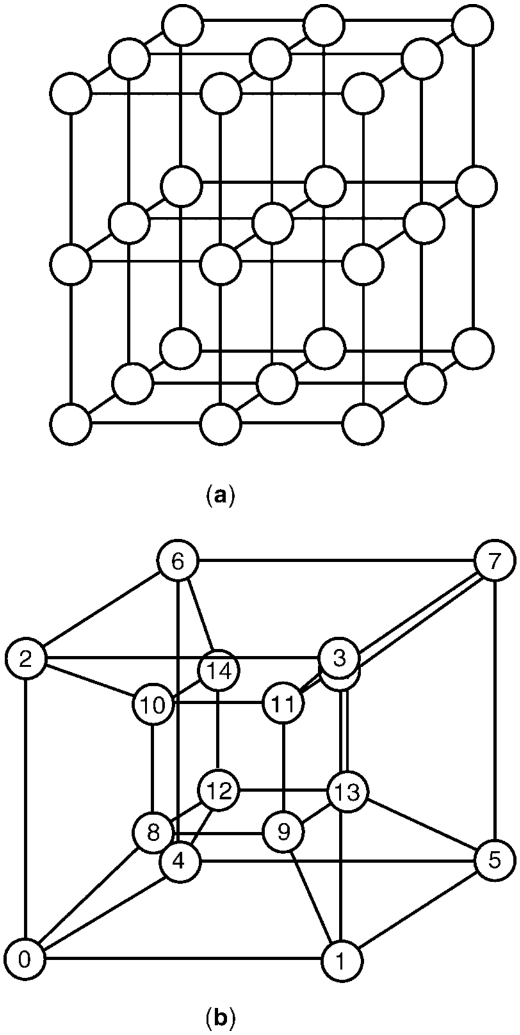

Figure 3. (a) Three-dimensional mesh connecting 27 nodes, (b) four-dimensional hypercube network connecting 16 nodes. In hypercube networks, the nodes that are directly connected have a Hamming distance of $H = 1$.

were introduced, in which any number of nodes can be interconnected (12).

To relate the different direct network topologies, the k-ary n-cube classification was introduced (13). A *k-aryn-cube network* connects $N = k^n$ nodes, where n is equal to the number of different dimensions the network consists of, while k is the network radix, which is equal to the number of nodes in each dimension. For example, a k-ary 1-cube is equivalent to a k-node ring network, a k-ary 2-cube is equivalent to a k^2-node torus network, and a 2-ary n-cube is equivalent to a 2^n-node n-dimensional hypercube. Figure 3(a) depicts a 3-ary 3-cube (assuming appropriate edge connections not shown in the figure), and Fig. 3(b) a 2-ary 4-cube. The diameter (Φ) is $n \times \lfloor k/2 \rfloor$.

Indirect Networks

In indirect networks, each processing node is connected to a network of switches over one or more (often bidirectional) links. Typically, this network consists of one or more stages of switch boxes; a network stage is connected to its successor and predecessor stage via a set of interconnection links. Depending on the number of stages, the number of switch boxes per stage, and the interstage interconnection topology, indirect networks provide exactly one path (*single-path networks*) or multiple paths (*multipath networks*) from each source to each destination.

Many different indirect network topologies have been proposed. This section is a brief introduction to multistage cube and fat-tree networks. Further discussion of these and other topologies can be found in Refs. 14–17.

One important indirect single-path network topology is the *generalized-cube network* topology (10), based on the cube interconnection function. A generalized-cube network that connects $N = 2^n$ sources with N destinations consists of $s = \log_B N$ stages of $B \times B$ switch boxes. The stages are numbered from $s - 1$ (stage next to the sources) to 0 (stage next to the destination). Each stage consists of N/B switch boxes; two consecutive stages are connected via N interconnection links. In Fig. 4(a), an 8 × 8 generalized-cube network comprising 2 × 2 switch boxes is shown, while Fig. 4(b) depicts a 16 × 16 generalized-cube network with 4 × 4 switches.

Consider the link labeling depicted in Fig. 4(a). The labels at the input (and output) side of each switch box differ in exactly one bit, which is bit k in stage k. Thus, if a message is routed straight through a switch box, its link number is not changed. If a message goes from the upper input to the lower output (or from the lower input to the upper output) at stage k, it moves to an output link that differs in bit k (the cube$_k$ operation transforms the link number). Each stage corresponds to a specific cube function, and all n cube-functions can be applied to a message on its way through the network.

A simple distributed routing algorithm can be used to transfer messages through the network. As routing information, each message header contains its destination address (*destination-tag routing*). If a message enters a switch box in stage k, this switch box will examine the kth bit of the message destination address. This bit determines the switch box output port to which the message is destined. If the bit is 0, the message is destined to the upper output port; if it is 1 to the lower output port. This scheme can be easily extended to $B \times B$ switch boxes, using the kth digit of the radix B representation of the destination address to select one of the B switch output links.

In shared memory parallel computers, many messages are requests for memory data, which results in reply messages that send data back to the original source. Thus, a read request sent through the network to the memory has to include the destination address (memory address) and also the source address (the node number to with the data is to be sent back). Thus, when destination-tag routing is used, the source address has to be added to the message header. This overhead can be avoided by using the XOR-routing algorithm. During *XOR routing,* an n-bit routing tag T that is formed by XOR-ing the source and the destination address ($T = S \oplus D$) is added to each message as a message header. If a message enters a switch box in stage k, this switch box will examine the kth bit of the message

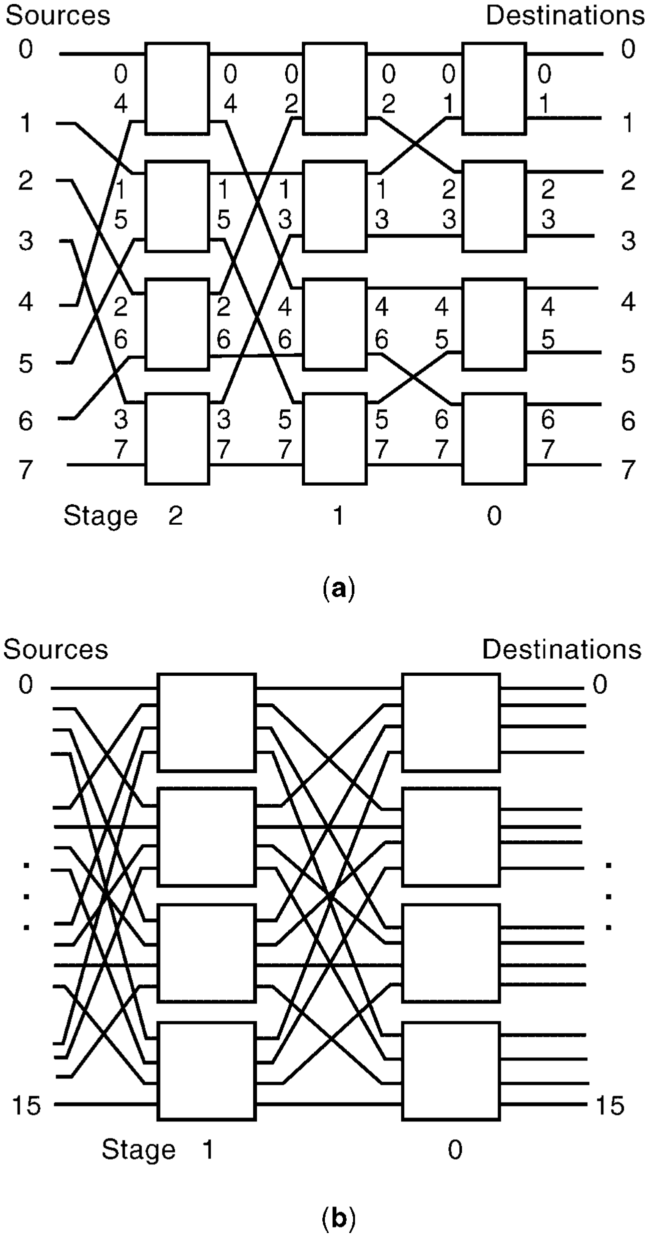

Figure 4. (a) 8 × 8 generalized-cube network comprising 2 × 2 switch boxes, (b) 16 × 16 generalized-cube network comprising 4 × 4 switch boxes. The link labels at the input (and output) side of each switch box in (a) differ in exactly one bit (bit k in stage k).

routing tag T. If this bit is 0 (the corresponding source address bit is equal to the destination address bit), the message will be routed straight through that switch box (e.g., if it arrived at the upper input, it will be routed to the upper output). If the routing bit is 1, the switch will be set to exchange (e.g., if the message arrived at the upper input, it will be routed to the lower output). Once a message has arrived at its destination, the destination can determine the message's source address by XORing its own address with the message's routing tag T. XOR routing works in networks comprising 2 × 2 switch boxes only. A similar scheme can be used in hypercube networks.

Many different single-path multistage networks have been proposed in the literature, among them the SW-banyan, omega, indirect binary n-cube, delta, baseline, butterfly, and multistage shuffle-exchange networks. In Ref. 10 it was shown (by reordering switches and/or renumbering links) that instances of these networks are typically equivalent to the generalized-cube network topology.

A generalized topology of a multipath indirect network is the three-stage network. This network consists of three stages of switches. Each switch box in the first and third network stages is connected to all switches in the network middle stage. A 16 × 16 multipath network comprising 4 × 4 switches is depicted in Fig. 5. The number of switches in the middle stage determines the number of distinct paths from each source to each destination (in Fig. 5, there are four distinct paths between any source and destination).

Another multipath indirect network topology that is used in parallel computers is the fat-tree network (18). The *binary fat-tree* network has the topology of a binary tree in which the leaves are connected to the processing elements and the root and intermediate tree nodes are switch boxes. All interconnection links are bidirectional. Unlike in an ordinary tree, the number of links between internal tree nodes is increasing when ascending the tree from the leaves to its root. Figure 6(a) depicts a binary fat-tree network that interconnects eight nodes. A cluster of processors is connected to the same switch box in the lowest switch level of the network (the switch level closest to the processors). This network provides only a single path that connects processors within a cluster. For all other connections, there exist multiple paths. To route a message between two nodes, the message first ascends in the network, rising to the lowest common ancestor of the source and destination, and then descends to the destination. This indirect topology thus rewards local communication by providing shorter paths between nearer nodes.

A different network topology that is similar to a fat tree is shown in Fig. 6(b). As in the binary fat-tree network, only a single path connects two processors within a cluster. However, each switch box on the lower switch level is connected to all switches on the next higher level. Thus, the number of switches in the higher switch level determines the number of different paths between two processors in different processor clusters. More switch levels can be added to the network, which will increase the number of distinct paths among processors in different clusters. However, with each switch level, the message transfer delay will increase, because more switches have to be traversed by a message if the message is routed through higher switch levels.

SWITCHING TECHNIQUES

The mechanism to transfer a message through a network is called *switching*. Switching does not take into consideration the actual route that a message will take through a network (this mechanism is termed routing and will be discussed in the next section). The four fundamental and

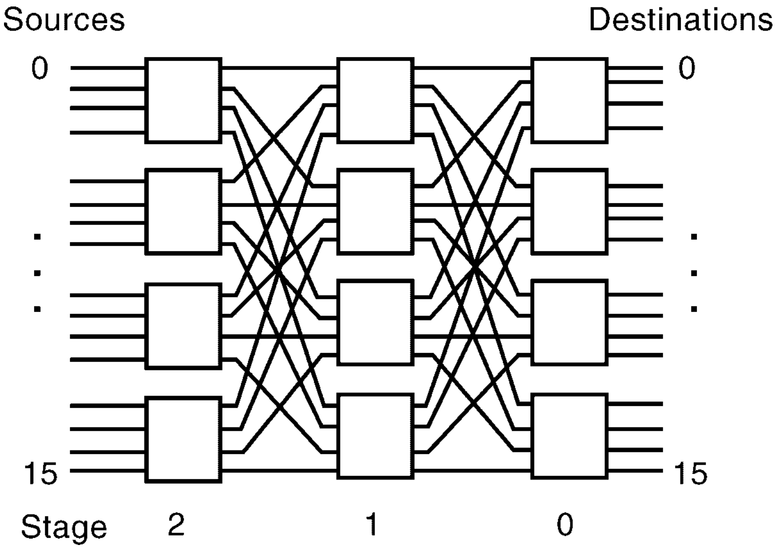

Figure 5. 16 × 16 three-stage multipath indirect network comprising 4 × 4 switch boxes. This network provides four link-disjoint paths from any source to any destination.

most-used switching techniques in interconnection networks are circuit switching, packet switching, wormhole routing, and virtual cut-through.

In a *circuit-switched* network, a complete connection through the network (from the source to the destination) is established before any data are sent. Network resources such as network links and switch ports are exclusively reserved for this connection. Once the connection is established, data are sent over the reserved network links and ports. After all data are sent, the established connection is disconnected to free the reserved resources for new connections. The connection establishment and disconnection can either be controlled centrally through a central network controller, or decentralized through messages that are sent through the network during connection establishment and disconnection. If a connection cannot be established because needed network resources are unavailable, the connection is refused (data cannot be transmitted) and the source has to try to establish the connection again.

In a *packet-switched* network, a message is divided into one or more data packets and routing information is added to each packet. These packets are sent through the network without the establishment of an overall connection between the source and destination. Network resources are reserved only when needed by a packet. Thus, network resources forming the path of a given packet that are not occupied by the given packet can be used to transfer other packets while the given packet is still in the network. This is impossible under circuit switching. The packet-switching technique is also called *store-and-forward packet-switching,* because a packet will be forwarded to the next node only if it was completely received by the current node. Therefore, nodes need enough space to buffer at least one complete packet. If a network resource such as a node's output port that a packet needs to use is unavailable (used by another message), the packet waits in its buffer within the node until the resource becomes available.

Wormhole routing is a switching technique similar to packet switching and is currently most often used in direct networks. In a wormhole-routed network, a message is divided into several *flow-control digits* (*flits*) (19). The first flit of a message (*header flit*) contains the message's routing information, and the last flit (*tail flit*) indicates its end. A message will be sent, flit by flit, in a pipelined fashion

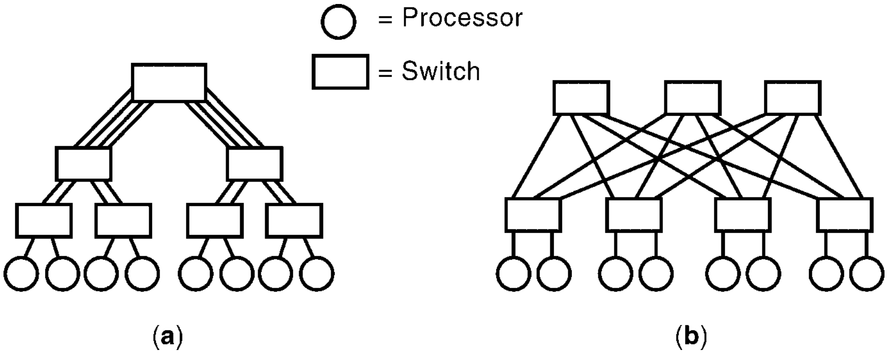

Figure 6. (a) Binary fat-tree network and (b) generalized fat-tree network connecting eight processors. This topology results in fast local communication, while the performance of global communication depends on the network size.

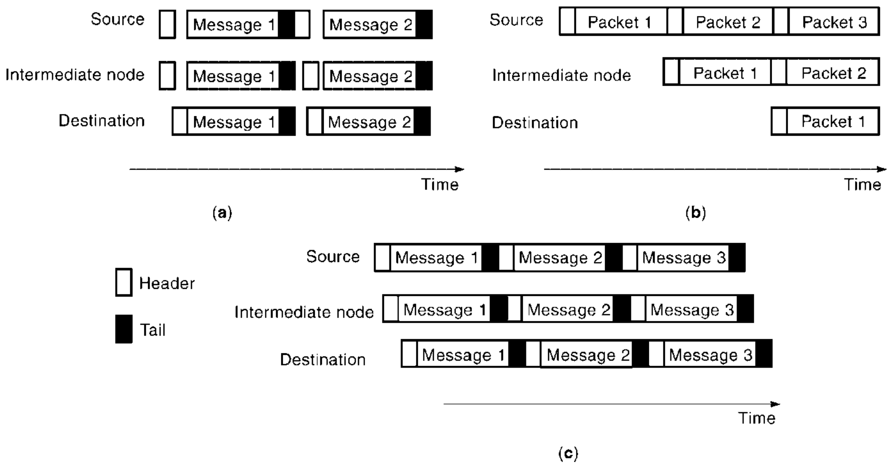

Figure 7. Data transport through an intermediate node in (a) a circuit-switching network, (b) a store-and-forward packet-switching network, and (c) a wormhole- routing network. Circuit switching and wormhole routing result in a shorter message transmission time, while packet-switching networks tend to have fewer message blockings.

through the network. The header flit will reserve network resources exclusively for its message, and the tail flit will release each resource after it has passed it. Thus, the message will traverse a network like a worm through a hole. Depending on the message length (number of flits) and the length of the path the message takes through the network (number of intermediate nodes), the tail flit will be submitted to the network either while the head is still in the network, or when part of the message is already received by the destination.

If a header flit cannot acquire a network resource (e.g., an output port of an intermediate node), it has to be temporarily buffered in that node (normally at the input port of that node). This will stop the worm from advancing through the network. To minimize the network hardware, normally each input port of a node has the capability of buffering one or two flits only. Therefore, once a worm has stopped advancing through the network, each flit of the worm will wait in the node it currently resides in, without releasing any network resources. Thus, while a worm is blocked in a network, it will block the corresponding network resources from being used by other messages. This can result in deadlocks within the network, and the routing algorithm used in the network has to handle those situations (see the next section).

The *virtual-cut-through* (VCT) switching technique combines characteristics of store-and-forward packet switching and wormhole routing. Each data packet is divided into flits again and sent through the network, as is done during wormhole routing. However, each node has the capability to buffer a whole packet. If a flit reaches an empty node buffer and is not blocked, it will either be directly routed through the node or be buffered in that buffer for one flit cycle and then routed through the node (depending on the implementation). If a message is blocked and cannot be forwarded to the next node, all the flits of that message will be received one by one and buffered in that blocked node. Thus, under a light network load, VCT behaves similarly to wormhole routing. Under heavier loads, when blocking occurs more frequently, the message worm will be completely buffered in the blocked node, similarly to store-and-forward packet switching. This way, the message does not block resources of several nodes and will therefore block fewer messages in the network.

In Fig. 7, the data transport from a source to a destination through an intermediate node over time is shown for a circuit-switching, a store-and-forward packet-switching, and a wormhole-routing network (in the circuit-switching example, line propagation delays are neglected). It can be seen that circuit-switching and wormhole-routing networks behave similarly over time, while the packet transmission in a store-and-forward packet-switching network takes longer. As long as the header and tail parts of a message are much shorter than the message itself, the transmission time for a message in a wormhole-routing and circuit-switching network is virtually independent of the length of the path the message has to take through the network. Pipelining of the message bits or flits on the network interconnection links can further reduce the transmission time. On the contrary, in a store-and-forward packet-switching network, the transmission time of a message is proportional to the length of the path through the network. This has to be weighted against the fact that blocked messages will normally block fewer other messages in a store-and-forward packet-switching network than in a wormhole-routing network, while in a circuit-switching network, connections might be refused due to internal blocking. As noted earlier, the behavior of virtual cut-through depends on the network load.

The main disadvantage of wormhole-routing networks is that a blocked message may spread over several nodes in the network and will then block several network links, which become unavailable for other messages. As an example, consider Fig. 8(a). Two interconnected wormhole switches are shown that have a flit buffer at each input port. Assume that a message is currently routed through switch 2 from port D to port E. This message blocks another message that enters switch 1 at port A, which is destined to port E as well. The head flit will wait in the flit buffer at input port C. However, this message blocks a third message

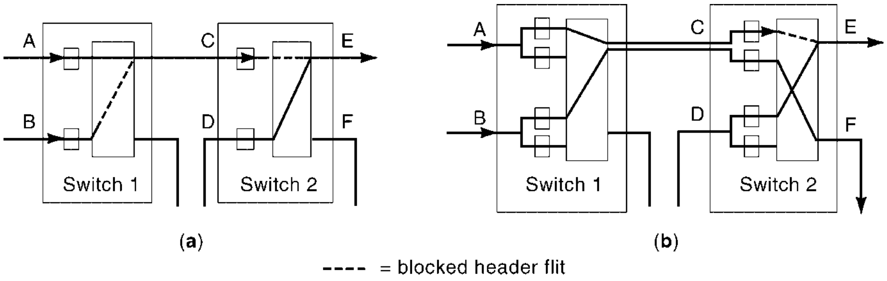

Figure 8. (a) Conventional wormhole-routing network, (b) wormhole-routing network with virtual channels. The virtual channels enhance the network performance substantially because fewer messages are blocked.

entering switch 1 at port B that is destined to port F. In this example, two messages are blocked because port E is currently unavailable.

To alleviate this problem, *virtual channels* were introduced (20). As depicted in Fig. 8(b) each switch now has two parallel flit buffers per input port, resulting in two virtual channels that are multiplexed over one physical interconnection link. In this case, the message entering switch 1 at input port A is still blocked at input port C because it is destined to the busy output port E. However, the third message is able to use the second virtual channel at input port C, so that it can proceed to the idle output port F.

The concept of virtual channels enhances the performance of wormhole-routing networks substantially, especially when the data traffic consists of a mixture of short and long messages. Without virtual channels, long messages can block short messages for quite some time. However, short messages often result from time-critical operations such as synchronization, so that a short latency is crucial for those messages. Because message latency also includes blocking time, virtual channels result in a decreased latency because there is less message blocking in the network.

ROUTING TECHNIQUES FOR DIRECT NETWORKS

The network mechanism that selects certain network resources (e.g., a specific output port of a switch) in order to transfer a message from a source to a destination is termed *routing*. Routing can either be done through a centralized network controller, or, as it is most often the case, decentralized in the individual network switches.

Routing algorithms can be either deterministic or adaptive. During *deterministic routing,* the path to be taken through the network is determined by the source and destination addresses only. The network load and the availability of network resources do not influence the routing of a message. *Adaptive routing protocols* take the availability of network links into account as well. To support adaptive routing, multiple paths between a source and a destination have to be present in the network.

Routing deadlock occurs when a set of messages has a cyclic dependency on resources (buffers or links). Because of the problem of deadlocks in direct networks, most routing algorithms have been proposed for direct networks to avoid deadlock situations. This section therefore focuses on routing algorithms for direct networks, and only a few basic algorithms are outlined here. Basic routing algorithms for indirect networks are covered in the subsection "Indirect Networks" of the section on "Network Topologies" above.

Deterministic Routing

The most common deterministic routing strategy used in direct networks is dimension-order routing in which a message traverses the network by successively traveling over an ordered set of dimensions of path. Two examples of dimension-ordered routine are *XY* routing and *e*-cube routing.

The *XY routing algorithm* used for mesh networks routes a message always in the *X* direction first. Once it has reached its destination column, the message will be routed in the *Y* direction (of course, this method also works if messages are routed in the *Y* direction first and then in the *X* direction). This routing strategy results in deadlock-free message delivery because cyclic dependences cannot occur (21). Consider the mesh network in Fig. 9(a), and assume *XY* routing (*X* dimension first, then *Y* dimension). A message from source 2 destined to node 7 will be routed through the intermediate nodes 1 and 4 as shown in the figure. If one of the network links on that path is blocked (e.g., the link between nodes 4 and 7), the message is blocked as well. An alternative path of the same length exists through nodes 5 and 8, but this path cannot be taken because of the *XY* routing algorithm. Thus, on the one hand, *XY* routing restricts the number of paths a message can take (and therefore increases the possibility of message

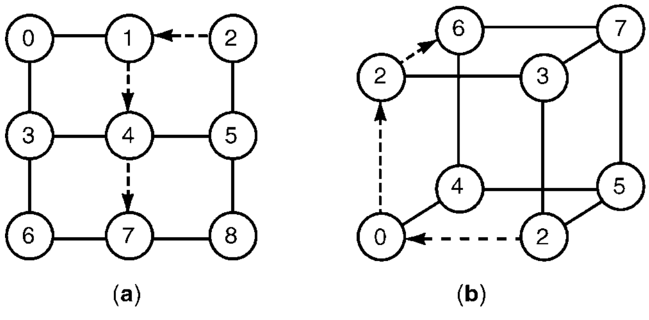

Figure 9. (a) *XY* routing in a mesh with $N = 9$, (b) *e*-cube routing in a hypercube with $N = 8$. Messages are routed in a dimension-ordered fashion.

blocking), but, on the other hand, guarantees deadlock freedom in the network (for a detailed explanation, see Ref. 19).

Similarly to the *XY* routing strategy in mesh networks, a message in a hypercube network under the *e-cube algorithm* will always traverse the dimensions of the network in the same order (e.g., cube_0, then cube_1, then cube_2, . . .). In Fig. 9(b), the transfer of a message from source node 1 to destination node 6 (over intermediate nodes 0 and 2) is shown in a hypercube with $N = 8$ using the e-cube algorithm. If a network resource on this path is blocked, the message has to wait, even though alternative paths exist (e.g., over intermediate nodes 5 and 7). However, cyclic dependences cannot occur when the e-cube algorithm is used, so that deadlocks are avoided [for a detailed explanation, see (21)].

The *e*-cube algorithm, initially proposed for hypercube networks, can be generalized for *k*-ary *n*-cubes (21). The original *e*-cube algorithm cannot guarantee deadlock freedom in these networks because of inherent cycles due to the wrap-around edge connections (see the subsection "Direct Networks" under "Network Topologies" above). Thus, in order to avoid deadlocks, the routing algorithm is not allowed to used certain edge connections. This results in some message paths that are longer than in the network with unrestricted routing, but deadlock freedom is guaranteed.

Adaptive Routing

Adaptive routing protocols can be characterized by three independent criteria: progressive versus backtracking, profitable versus misrouting, and complete versus partial adaptation (22).

Once a routing decision is made in a *progressive protocol,* it cannot be reversed. The path has to be taken even if the message might end up being blocked. In a *backtracking protocol,* routing decisions can be reversed if they lead to the blocking of a message. Thus, if a message reaches a blocked network resource (e.g., a temporarily unavailable network link), the message will track back its path taken so far to try to find an alternative route that is not blocked. This method is mainly used in circuit-switching or packet-switching direct networks with bidirectional links between nodes that enable the backtracking. Backtracking protocols are not well suited for wormhole-routing networks, because a message can be spread over several nodes, which makes it difficult to backtrack the worm.

A *profitable protocol* (also called *minimal routing protocol*) will always choose a network resource (e.g., a node output) that guides the message closer to its destination. If a message encounters a blocked link, it can only use other links that result in the same path length through the network. If those links are blocked as well, the message has to wait. This results in a minimal length of the path a message will take through a network. This routing restriction is omitted in *misrouting protocols* (also called *nonminimal routing protocols*) so that a misroute is preferred over message blocking. Thus, the length of the path a message will take can be longer than the minimum path from the source to its destination.

The two above-mentioned criteria define classes of paths that the routing algorithm can choose from. *Completely adaptive routing protocols* can use any path out of a class, while *partially adaptive* ones can only use a subset of those paths (to avoid deadlock situations). Examples of a progressive and a backtracking completely adaptive routing protocol are now given.

A very simple adaptive progressive routing protocol with a profitable path choice is the *idle algorithm*. It is based on a deterministic routing scheme (e.g., *XY* or *e*-cube routing). If the deterministic routing scheme encounters a blocked node output port, the adaptive protocol will choose a different output port that will bring the message closer to its destination. This way, a message either reaches its destination or is blocked when no other output port is available that would bring the message closer to its destination. The resulting path will always be of minimal length, and the network performance will be increased over the deterministic routing scheme because a message is allowed to take alternative paths. However, this routing protocol is not deadlock-free. Thus, if a deadlock occurs, it has to be detected by the routing algorithm (e.g., through timeouts) and dissolved. Each occurring deadlock will decrease the network performance, though, so that it is more efficient to use an adaptive routing protocol that is inherently deadlock-free.

A backtracking routing algorithm allows a message to reverse routing steps to avoid the blocking of the message. Deadlocks cannot occur, because messages will rather backtrack than wait. To avoid a livelock situation (i.e., when a message is routed indefinitely through the network without ever reaching its destination), information about path segments already taken has to be added to the message or stored in the network nodes in a distributed fashion.

A simple backtracking algorithms is the *exhaustive profitable backtracking protocol*. This protocol performs a depth-first search of the network, considering profitable network links only. If a shortest path that is not blocked exists between a source and a destination, this routing algorithm will find it. The *k-family routing protocol* speeds up the path search through a two-phase algorithm. As long as the distance of a message from its destination is larger then the parameter *k*, a profitable search heuristic is used that considers a subset of all available shortest paths only. If the distance is lower than *k*, then the exhaustive profitable search is used, which considers all available shortest paths (22).

Both routing protocols forbid misrouting, so that a nonblocked path through the network cannot always be found. *Exhaustive misrouting backtracking protocols* will always find an existing nonblocked path in a network, because messages can be misrouted. However, the search itself can degrade the network performance, especially when a nonblocked path does not exist. In this case, the routing algorithm will search the whole network before it recognizes that a path does not exist. Thus, a message may stay inside the network for quite a while and will use network resources during the search that are then unavailable for other messages.

To alleviate this search problem, the *two-phase misrouting backtracking protocol* can be used. This protocol divides

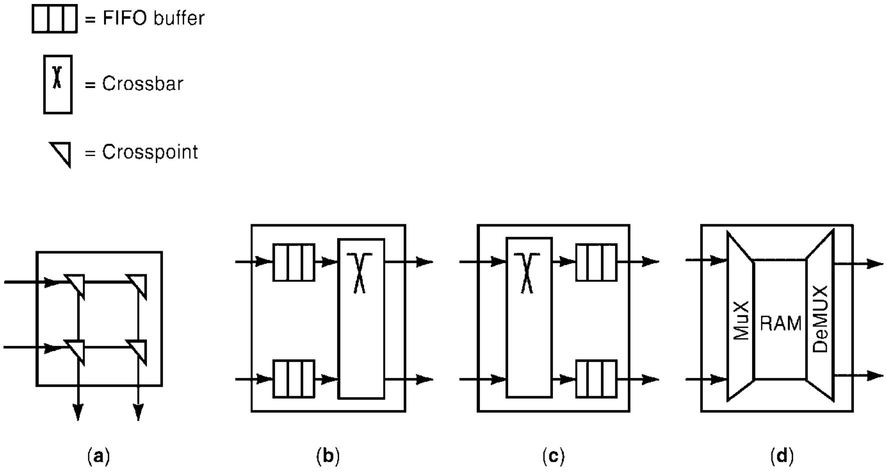

Figure 10. 2 × 2 (a) crossbar, (b) input-buffered, (c) output-buffered, and (d) central-memory-buffered switch box architectures. The placement of the buffers within a switch box has a major effect on the network performance and on the buffer requirements.

the search into two phases, similarly to the k-family routing protocol. Each phase is determined by the current distance between the message and its destination. If the distance is larger than a parameter d, then the protocol will use an exhaustive profitable search. If the message is closer to its destination than d, then the protocol switches to an exhaustive misrouting search. Because the second phase can route the message further away from its destination again, the search may switch between the two phases multiple times.

SWITCH BOX ARCHITECTURES

The architecture of the switch boxes depends on the underlying switching mechanism (see the section "Switching Techniques" above) and has a large effect on network performance. This section discusses architectural issues with respect to switch boxes and their effect on network performance.

When a connection is established in a circuit-switching network, each switch box is set in a specific switching state. For example, in the 2 × 2 switch boxes that are sometimes used to construct multistage indirect networks, there are four distinct settings for each switch: straight, exchange, upper broadcast, and lower broadcast. The *straight* setting connects the upper input port with the upper output port, and the lower input port with the lower output port. In the *exchange* setting, the upper input port is connected to the lower output port, while the lower input port is connected to the upper output port. Finally, in the *broadcast* setting, one of the input ports is connected to both switch output ports (in the *lower broadcast* the lower input port is chosen; in the *upper broadcast,* the upper input port). If during the connection establishment for a message transmission a switch box within the network already uses a setting that is different from the requested one, the connection cannot be established and will be refused. One way to implement 2 × 2 and larger switches is the *crossbar* [see Fig. 10(a)]. A $B \times B$ crossbar consists of B inputs, B outputs, and B^2 crosspoints that can connect the horizontal line with the corresponding vertical one.

In packet-switching (and wormhole-routing) networks, packets (or flits) can be blocked within the network and have to be temporarily buffered inside a switch box. The placement of these buffers within a switch box has a major effect on the network performance and on the buffer requirements. The method that results in the lowest hardware requirement is *input buffering,* where a first-in-first-out (FIFO) buffer for storing multiple packets is placed at each input port of a switch box [see Fig. 10(b)]. During each network cycle, each buffer must be able to store up to one packet and dequeue up to one packet. A packet reaching a switch box input port that cannot be transferred to an output port because that port is currently busy will be stored in that input buffer. Although these buffers are easy to implement, they have the major disadvantage of *head-of-line* (HOL) blocking because of their FIFO discipline. If the packet at the head of an input buffer is blocked, it will block all other packets in that buffer, although some of those packets might be destined to an idle switch box output port. This blocking reduces the switch box throughput significantly, especially in larger switches.

To eliminate the HOL-blocking effect, *output buffering* can be employed, where FIFO buffers reside at each switch box output port [see Fig. 10(c)]. Because, during each network cycle, up to B packets can be destined to one specific output port in a $B \times B$ switch box (one from each switch box input), an output buffer must be able to store up to B packets and dequeue up to one packet during each network cycle. Because in an output buffer only packets are stored that are destined to the same output port of that switch box, HOL blocking cannot occur. If buffers with an infinite length are assumed, a maximum switch throughput of 100% can be achieved.

To achieve high performance with output buffered switch boxes, considerable buffer space is needed. To reduce this buffer requirement, a central memory can be used. In *central-memory-buffered switch boxes,* there are no dedicated buffers at either the switch input or the output ports.

Packets arriving at a switch box input port are buffered in a central memory that is shared among all switch inputs [see Fig. 10(d)]. The central memory is divided into virtual FIFO queues of variable length (one for each output port) in which the packets are stored corresponding to their destination. The bandwidth requirement for the central memory is even higher than that for a buffer in an output buffered switch box, because during each network cycle, up to B packets have to be stored in the memory and up to B packets have to be read out of a $B \times B$ switch box. Because the length of each virtual queue is variable, virtual queues that are only lightly utilized require less memory and heavily utilized virtual queues can have more space (23). Thus, the buffer space can be very efficiently utilized, so that a smaller overall buffer space is needed as than for switch boxes with dedicated output buffers at each output port.

CONCLUSIONS

This article is a brief introduction to some of the concepts involved in the design of interconnection networks for parallel machines. See the references cited for more details. A reading list provides further sources of information.

LCD DESIGN TECHNIQUES

Liquid crystal displays (LCDs) play a crucial role in almost all technology scenarios based on human interfaces as being the preferred device for visual information rendering in a wide variety of application domains. With respect to a few popular examples, LCDs are extensively used for video output in personal computers, portable phones, photo and video cameras, as well as diverse home entertainment multimedia appliances. The impact of LCD performance on an important share of the worldwide consumer electronics market justifies the effort devoted to clever design of LCD-based equipment. Broadly, LCD designers have to cope with two classes of realization issues, concerning both the choice of the LCD technology and the implementation of the LCD driving electronics. The technology selection is in many ways independent of the targeted display, being either a high-end PC monitor or a cellular phone display panel. Conversely, several display driving methodologies are available at a given display technology, each one posing tradeoffs among ease of implementation, realization cost, and overall optical performance. In general, the term *driving scheme* encompasses all features cooperating with the generation of the electrical signals applied to the display panel in order to build up the desired image. The generated picture commonly acts as an individual video frame out of an arbitrarily complex frame sequence: Hence, all mechanisms used for producing a “static” picture (i.e., refreshed continuously and invariably over the display) can be extended straightforwardly to video streaming (where the frame information varies over subsequent frames). Usually, a display driver can be programmed to sort the best matching display between driving scheme and display application. The definition of a driving scheme includes the panel scanning pattern as a major component. However, a driving scheme is also made of a combination of measures put into action in order to mitigate the effects of perceptible visual artifacts. An outstanding example of such techniques is the driving polarity inversion, which will be extensivley referred to in the following parts in conjunction with the presentation of the most dangerous optical artifacts.

Panel technology and driving mode directly affect the design of the driver electronics, which motivates the interest in LCD-specialized design flows. LCD engineers are provided with customized evaluation tools that can be used to assess the impact of vital design choices as early as possible throughout the product lifecycle. Joint LCD-driver simulation environments, for instance, are highly recommended to achieve the optimal driving-scheme/display match.

THE LCD ARENA

To date, the market of LCDs puts forward a huge amount of typologies, including monochromatic, color, passive-matrix, active-matrix, and organic-material-based panels. Nonetheless, all LCDs are built on liquid crystals, i.e., materials capable of modifying their microscopic spatial orientation under the effect of comparatively small electric fields (1). The observation that a light beam directed toward the liquid crystal cell is differently diverted depending on the particular orientation of the crystals themselves triggered off the pervasive development of LCD technologies over the past few decades. LC cells are not, by themselves, spontaneous light sources, but their operation depends on the reflection or absorption of light originating from some sort of external source. The way the display interacts with such source, as well as the techniques deployed for pixel addressing and image generation over the panel, allow LCDs to be classified and several well-known families to be distinguished. Figure 1 represents a broad classification of those families, as discussed in the next subsection.

The Twisted Nematic Technology

The working principle of displays based on the twisted nematic (TN) technologies (2,3) is depicted in Fig. 2, where the structure of a single LCD cell is shown. The indium tin oxide (ITO) layers are those used to realize the cell driving electrodes. Basically, the light beam reaching the cell is allowed to pass through the output polarizer provided that it is properly twisted by the spatial orientation of the liquid crystal in the nematic layer inside the cell. Applying a proper voltage at the boundaries of the cell can alter such orientation, so that the cell would in turn shield the nontwisted light beam. The cell organization is replicated to construct matrix-like panels where each cell represents a pixel. Pixel ON/OFF states, corresponding to dark/bright pixel in black-and-white displays, can be selectively driven by applying specific voltage patterns at any pixel location. The voltage control is realized via an array of connection electrodes accessible by the driving circuits external to the display. The TN technology has been used first in passive-matrix LCDs, although a significant evolution in the LCD design philosophy must be ascribed to the introduction of active-matrix driving modes. Passive-matrix and active-matrix LCDs essentially differ in the nature of their electrodes and in the way individual pixels are addressed.

Super Twisted Nematic Technology. In practice, pure TN technology has been replaced by super twisted nematic (STN) technology. By doping the nematic layer with an optically active material, the STN technology is characterized by a greater twist-angle impressed to the light beam by the LC layer, which achieves higher optical contrast, increases the chromatic yield, and produces faster-responding displays. The introduction of STN technology has played a particularly important role for passive-matrix-addressed displays, where under some fixed optical conditions, the multiplex ratio, i.e., the number of lines to be addressed in the pixel matrix for image generation, can be only increased if the response of the liquid crystal is faster.

Figure 1. Overview of the most relevant liquid crystal display technologies and implementation techniques.

Color Super Twisted Nematic Displays. For color generation, each LC cell is physically replicated three times per pixel. Light passing through individual cells that belong to the same pixel (the so-called subpixels) is then selectively filtered through red, green, and blue channels, respectively. It is important to stress the absolute independence of subpixels from the voltage generation point of view, so the resulting color display can be simply thought of as an extended pixel-matrix with respect to its pure gray-scale counterpart. It is the spatial integration capability of the human eye over adjacent subpixel locations to ensure that individual channels out of the same pixels are concretely perceived as a single color by the observer.

Transmission-Voltage Curves

The light-transmitting capability of liquid crystals is usually characterized by plotting the LC cell transmission as a function of the applied voltage to form the electro-optical characteristic of the liquid crystal (Fig. 3). In the LC jargon, the expressions *threshold* and *saturation voltage* are used also to define the voltage below which the cell light transmission is none, and that above which the light transmission cannot be increased further (no matter the magnitude of the applied voltage), equaling 100%, respectively. Figure 3 also explains a major difference between TN and STN technologies: STN liquid transmission-voltage curves are generally steeper than the corresponding TN curves, so ON/OFF state transitions are appreciably faster.

Transmissive and Reflective LCDs

A first, coarse classification of LCDs distinguishes between transmissive panels, where the light source is positioned beyond the display with respect to the observer and the light beam is filtered depending on the orientation of the liquid crystal at a particular point in time, and reflective panels, where the *external* environmental light is reflected by a mirror located behind the display LC panel and afterward filtered by the crystals. Reflective displays obviously promote low-power operation since a built-in light source is not required; yet their optical performance tends to degrade when they are used in dim areas. For that reason, they are commonly avoided for indoor applications. Transflective LCDs offer a tradeoff between the performance of both types; they are increasingly penetrating into the market of displays for mobile appliances, offering guarantees of good performance under almost all illumination conditions.

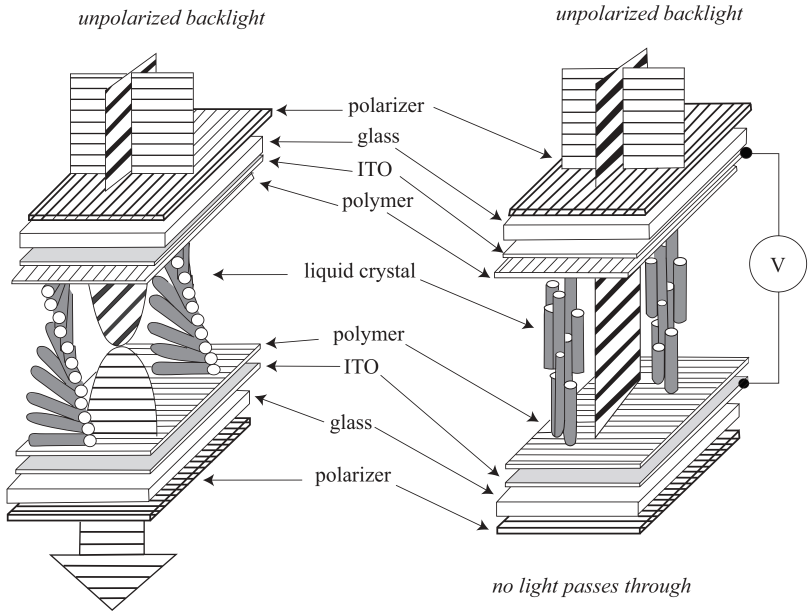

Figure 2. Building principle of a liquid crystal cell for display realization: light transmission and shielding depending on the applied voltage is also shown.

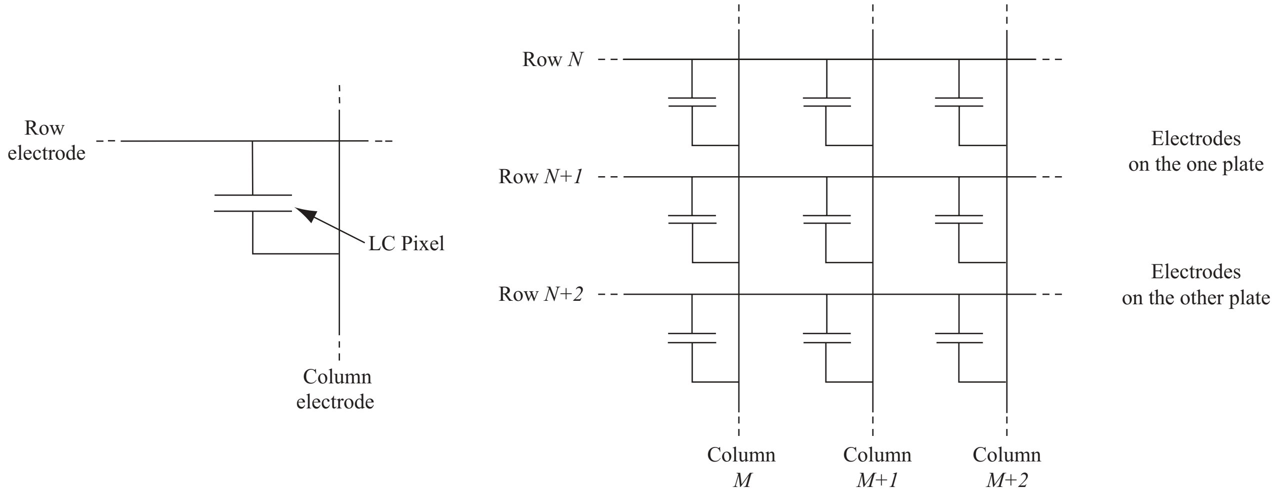

Figure 4. Pixel model and display matrix for PMLCDs.

LCD Addressing Modes

Passive-Matrix Displays. In passive-matrix LCDs (PMLCD), the electrodes are implemented by thin metal-oxide stripes layered over the surfaces of the LC panel. In particular, the mash of electrode stripes laid on one side of the panel is orthogonal to those placed on the other side. LC cells (i.e., individual pixels of the display) correspond to crossing points between electrodes belonging to different sides. On the whole, the display can be viewed as a pixel matrix, with each pixel being equivalent to a capacitor connected between electrode stripes from different plates (Fig. 4). Constructing a proper voltage between the electrodes that address that particular cell drives the pixel states ON or OFF. During each frame scan, i.e., over the time needed by the driving electronics to address all other rows and columns in the display, the ON/OFF states of the pixels must be maintained. The effectiveness of the approach rests on the inherent persistency of the human visual system, which ensures correctness of optical perception as long as the display scan period and the time each pixel's state is held are properly synchronized. Flickering would otherwise affect the perceived image: This is generally avoided by taking special measures at the driving scheme level. Inter-electrode crosstalk is another common but undesirable side effect of passive-matrix addressing, which manifests as halos around the displayed picture.

Active-Matrix Displays. The development of active-matrix addressing decreased most image quality flaws by associating a dedicated transistor switch at each pixel in the display. The switch allows the pixel to be driven ON/OFF without being affected by the electrical activities of the other pixels in the row. In other words, the pixel control is no longer committed to a combined row/column electrical driving performed on a frame basis: The pixel state can be held independently of the frame refresh period or the persistency interval, just as long as the switching transistor state is maintained. From the technological perspective, the increased complexity of active-matrix LCDs (AMLCDs) is abundantly compensated by the tremendous gain in the optical quality as much as by important savings in the display power consumption. In a fact, AMLCDs currently represent the mainstream solution in the market of displays, especially when wide-area panels are regarded.

Thin-film transistor (TFT) displays embody a popular implementation of the active-matrix addressing principle. In TFT displays, the switching transistors are integrated within thin plastic layers deposited over the internal surfaces of the glass panels, and they directly delimit the liquid crystal core. TFT displays can be diversely realized. The low temperature polysilicon TFT is a new technology allowing large-size panels with easy integration of the driver circuits. Integration of the driving circuits is also possible with the high temperature polysilicon TFT, which is a MOS-IC-like process applicable to small-size panels. Finally, large-area panels are based on the amorphous silicon TFT technology, which is the most mature and most popular technology.

Thanks to the constructive procedure of AMLCDs, parasitic capacitive effects are minimized with respect to PMLCDs. Furthermore, TFT displays are much brighter than PMLCDs, their viewing angle reaches up to 45 degrees with respect to the display axis, and their response time is one order of magnitude shorter than that of PMLCDs. On the other hand, constructive data for TFT displays demonstrate in what sense complexity is a major point: For instance, even a small 132 × 176-pixel color display requires up to 70,000 transistors for active-matrix addressing!

Advanced Technologies

Over the past few years, the poor performance exhibited by PMLCDs in appliances featuring video streaming facilities motivated display manufacturers to massively migrate toward active-matrix TFT panels. Currently, not only do AMLCDs represent the favorite solution for large display realization, but they are pervasively exploited in portable devices as well, such as last-generation high-end video cellular phones. Alternative technologies with respect to liquid crystals are also starting to creep into the market of displays. A particular class of devices based on organic light-emitting diodes (OLEDs) currently yields competitive performance, especially when flexibility (OLED displays can be significantly small and thin) and low power operation turn out to be important factors. In OLEDs, a layer of specific organic polymers placed between the driving electrodes is responsible for the light emission without external sources. For the time being, the use of OLEDs in portable battery-operated displays is only hindered by the comparatively short lifecycle of the embedded organic materials.

PASSIVE-MATRIX LCDS

Scanning Modes

The *driving voltage* applied to a PMLCD's pixel to modify the crystals orientation is something more than a mere constant voltage through the LC cell. In fact, PMLCDs are operatively sensitive to the *root-mean-square value* (rms) of some properly arranged steering voltage waveforms (4). The rms is the physical quantity actually responsible for the light transmission as readable from a transmission-voltage curve. Therefore, the driving-scheme designer chiefly focuses on alternative ways of constructing the desired rms value over the available driving time slots. The maximum allowable time length of such a driving window is an important constraint, as it is directly related to the avoidance of undesired visual artifacts that affect correct image displaying. Most driving schemes imply tradeoffs between performance and design factors, such as output image contrast, color gamut, visual artifact occurrence, driver hardware complexity, and power dissipation. In particular, hardware parameters, such as the number and type of the driving voltages to be built up or the complexity of the digital switching logic used for waveform generation, are directly involved.

The basic scanning mode is the Alt&Pleshko approach, which is essentially a simple one-row-at-a-time addressing scheme: Proper voltage pulses are sequentially sent over the row electrodes to select individual rows until the whole display has been scanned over a frame. During each row pulse, the column electrodes are driven according to the pixel data in order to construct the desired rms value at every location. Currently, the importance of the Alt&Pleshko technique has nothing to do with implementation, but is only limited to providing a better understanding of more sophisticated solutions derived from it. However, it is worth citing the so-called improved Alt&Pleshko technique, where non-negative column voltages and lower supply voltages are exploited to reduce power consumption and driver circuit area.

Significant progress in LCD driving rests on multiple-line-addressing (or multiple-row-addressing) methods (equally referred to as MLA or MRA techniques). With MLA, p rows are concurrently driven through sets of p orthogonal digital row functions (scan signals) $F_i(t)$. As a result, the total frame scanning period is automatically reduced. In typical settings, the scan signals are piecewise constant analog voltage waveforms; i.e., their repetition period is slotted into predefined equal-length intervals during which they take constants values F_i. The number of the time slots over a scan signal repetition period is usually fixed to be equal to p, although different choices are viable. Orthogonality requires that:

$$\begin{cases} \overline{F_i \cdot F_j} = \dfrac{1}{T} \cdot \displaystyle\int_o^T F_i \cdot F_j \cdot dt = F^2, & i = j \\ \overline{F_i \cdot F_j} = 0, & i \neq j \end{cases} \qquad (1)$$

The column functions (data signals) are constructed by combining the scan signals properly. Their value at a given time depends on the ON/OFF states of the pixels they are meant to activate, as follows:

$$G_j(t) = \frac{1}{\sqrt{N}} \sum_1^p \mathrm{a_{ij} F_i(t)} \quad i, j = 1, \ldots, p \qquad (2)$$

Orthogonality of the scan signals ensures that individual pixels remain unaffected by the state of the others along the same column. The advantages of MLA include the power savings achievable because of the moderate supply voltages required by the technique and the possibility of reducing the frame frequency without fearing "frame response." In the LC jargon, frame response is referred to as the relaxation of the liquid crystal directors over a frame time, which leads to contrast lowering and image flickering. By means of MLA, the LC is pushed several times within a frame so that virtually no relaxation occurs: The image contrast can be preserved, the flicker restrained, and the artifacts like smearing on moving objects (e.g., while scrolling) are suppressed by eventually adopting faster responding LC material. On the downside, all of this technology comes at the expense of an increase in the number of driving voltages to be generated (three row voltages and p + 1 column voltages are needed) and of more complex driver realizations.

Alternative MLA Schemes

The sets of the orthogonal scan signals used in MLA are assigned through matrices. Each signal is described along the rows, whereas each column shows the constant normalized value (+1, −1, or 0) assumed by the resulting waveform at the corresponding time slot. Theoretically, the matrices can be rectangular, where the number of rows indicates the number of concurrently addressed display rows (p), and the number of columns indicates the number of MLA scans needed to cover the whole panel (being in turn equal to the number of time slots composing each orthogonal signal). Different types of matrices that meet the orthogonality constraints are available and used diversely in practical implementations of MLA schemes (5). A first class is the set of Walsh functions, coming up as 2^s orthogonal functions derived from Hadamard matrices. The class of the so-called "Walking –1" functions is also used extensively: They are

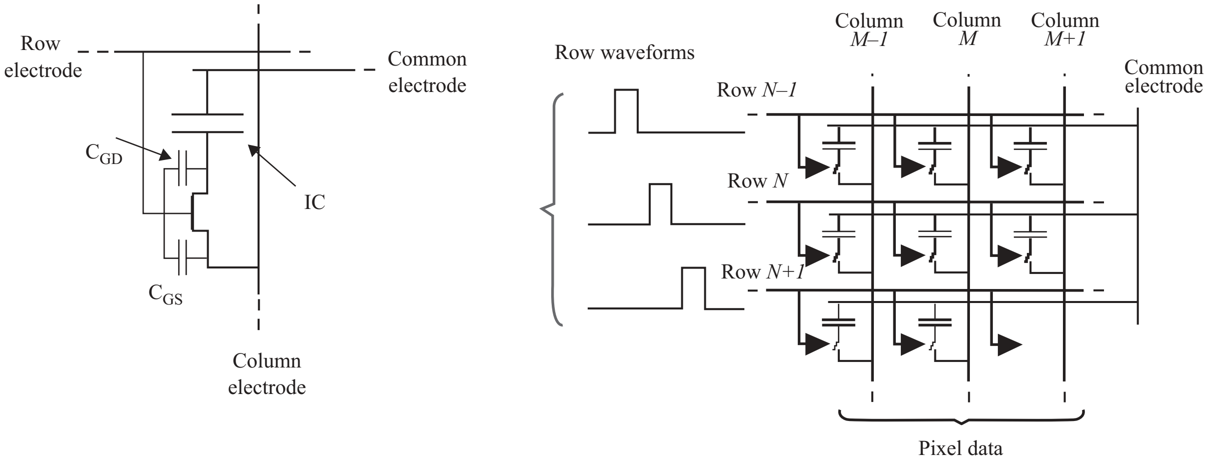

Figure 5. Pixel model and display matrix addressing for AMLCDs.

built up of p−1 positive pulses (+1) and 1 negative pulse (−1) shifting right or left from one function to the other. Hadamard and Walking –1 matrices, like many other standardized patterns, only contain 1 and −1 entries. However, since the number of nonzero entries in the matrix columns plus one corresponds to the number of column voltage levels used for waveform generation, it is desirable to introduce zeroes in the matrices. In this respect, conference matrices with one zero per row represent a smart solution.

Once the matrix structure has been chosen, the value of p must be also set, i.e., the number of rows addressed in parallel. The choice is dictated by optical performance considerations: It is widely agreed that for p up to 8, frame response is effectively suppressed, so that p is usually set to 2, 3, or 4 in commercial mobile display drivers (for ease of reference, 2-MLA, 3-MLA, or 4-MLA, respectively). For 2-MLA and 4-MLA, either Walsh or Walking –1 functions can be taken, whereas 3-MLA works with 4 × 4 conference matrices (the 0 entry corresponding to one nonselected row out of 4). Also, a particularly interesting solution exists, sometimes referred to as virtual-3-MLA, which is brought in as a modification of the 4-MLA scheme. In fact, virtual-3-MLA is identical to 4-MLA when the driver operation is regarded, but the fourth *rowdriver output* out of every set of four rows is *not* connected to the display but is just left open. On the display side, row number 4 is connected to the fifth driver row output, and so on for the remaining ones. It can be calculated that with virtual-3-MLA, only two voltage levels are required to construct the data signals, which represents significant improvement, making the driver less complex and reducing the power dissipation.

The rationale of MLA does not entail any built-in measure to guarantee optical uniformity in the' brightness of the pixels. Extended features are commonly then added up on top of the basic MLA scheme. The drive pattern switching is a popular example consisting of the periodical interchange of the set of used orthogonal functions; the change usually is scheduled to occur before every p-row addressing sequence.

ACTIVE-MATRIX LCDS

Addressing Concept

In AMLCDs, each pixel within the display matrix can be accessed only when the corresponding switch is closed. Pixel driving is realized by means of three separate electrodes, as shown in Fig. 5, where a circuit model of the pixel has been worked out. The concept of AMLCD driving is theoretically simple with respect to PMLCD: Adjacent rows are addressed sequentially by applying a positive pulse to the row electrodes. The row electrodes are connected directly to the switches gates and then are used to switch ON/OFF at the same time for all pixels along a given row. In turn, the column electrodes are used to build up the voltage throughout the LC cell according to the pixel data. In practical scenarios, row-interlaced patterns are used in place of the rudimentary row-sequential addressing, with beneficial effects with respect to the driver overall power consumption. Even if the addressing principle is straightforward, various dedicated countermeasures usually are exploited to target AMLCD-specific drawbacks, which complicate the realization of the driving schemes.

Effects of NonIdealities in Active-Matrix Addressing

Parasitic gate-source and gate-drain capacitances of the switching transistors have been explicitly drawn in Fig. 5. They are responsible for several undesired consequences that affect the display dynamic operation. The gate-drain capacitance, for instance, brings in an appreciable overshoot that distorts the driving voltage throughout the pixel cell at the switching point of the row driving pulses. The mechanism is shown in Fig. 6 for a typical voltage waveform: The effect is known as “kickback effect” and is practically caused by some extra charge loaded into the pixel capacitance. The overshoot, unless mitigated purposely, results in some sort of visible display flickering. A common technique used to fight the kickback effect is described as “common electrode modulation”: In essence, the common electrode is driven so as to compensate for the additional

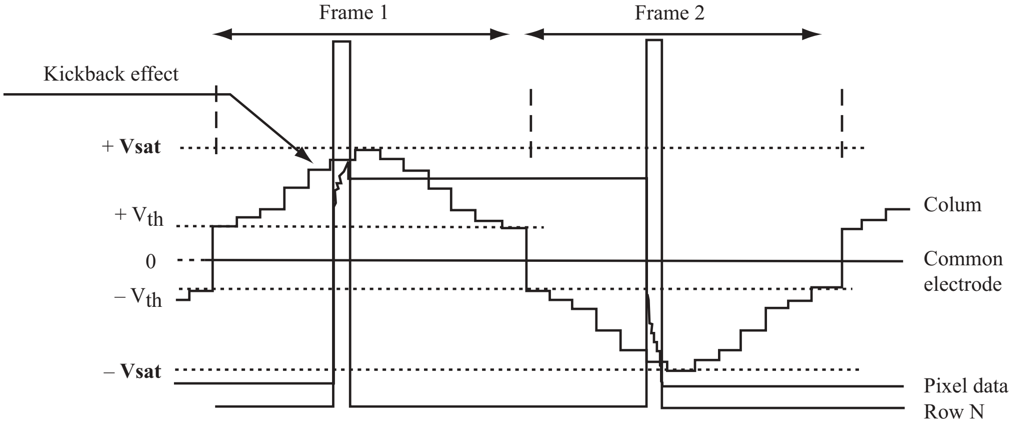

Figure 6. Driving waveforms affected by the "kickback effect" in AMLCDs panels.

spurious charge injection affecting the pixel capacitance at critical time points within the frame.

The kickback phenomenon is not the sole effect of the active-matrix nonidealities. The quality of the display is also influenced by the sensitivity of the LC capacitance to the applied voltage and by different forms of leakage currents, generally depending on either the liquid crystal itself or the technology of the active devices. The LC capacitance variability often nullify the advantages of common electrode modulation. On the other hand, leakage determines a loss in contrast and compromises the visual uniformity of the displayed pictures, as well as inducing vertical crosstalk among pixels. Both LC capacitance variations and leakage can be controlled by using a storage capacitor. The storage capacitor is connected between the switch drain and the row electrode of the previous or next display row (or to a separate electrode), so as to work in parallel with the pixel's real capacitance. Kickback correction is then made more effective, as the increase in the overall capacitance makes the cell less sensitive to any parasitic current. Another specific measure against leakage currents in the active device is the driving voltage polarity inversion, which is a technique that belongs to a broad class of polarity inversion methods used extensively to mitigate different forms of optical artifacts.

GRAY TONES AND COLOR GENERATION TECHNIQUES

The concept of ON/OFF pixel driving is suitable for mere black- and- white displays. Extending this principle to gray-scale panels requires that different gray-levels be constructed throughout a sequence of black/white states driven over consecutive frames. *Frame rate control* (FRC) serves this purpose: Sequences of N frames (N-FRC) are grouped together to compose a superframe. Over each superframe, the sequence of black- and- white states created consecutively at each pixel are perceived as homogeneous gray tones thanks to the persistency of the human visual system (3). Proper operation only requires that the superframe frequency, forced to equal the frame frequency divided by N, be above a minimum admissible value: Over a 50-Hz superframe frequency usually is agreed on for flicker-free image visualization. A refinement of the FRC method is *frame length control*, where different gray tones are generated over a superframe by varying the time–length ratio between adjacent frames in the superframe (and thereof the duration of individual black/white phases).

FRC is a very basic gray shading solution, so that cooperating schemes usually are combined in industrial drivers to enhance the color gamut: A common design choice is to modulate the data signal pulses to enrich the color resolution (*pulse width modulation*, PWM). As for the hardware, joint PWM-FRC is costly in terms of extra chip complexity, but it successfully cuts off the power consumption. The programmable gray shades are defined by means of a gray-scale table (GST), which specifies the sequence of ON/OFF state scheduled to produce a given tone. An important concern in designing the color generation mechanism is the smart configuration of such table: For instance, when applying a mixed FRC-PWM approach, pure-FRC color tones (i.e., gray tones obtained without in-frame shade modulation) should be avoided strictly in the GST to prevent awkward perceptible artifacts.

Generalization of the gray shading techniques to color displays is straightforward, as color channels are created by diverse color filtering at each subpixel, without any extra complexity on the driver side.

OPTICAL PERFROMANCE IN LCD DRIVING

Frequency Dependence of the Electro-Optical Characteristic

When thinking of optical performance, the main aspect to be considered is the non-negligible dependence of the LCD electro-optical transmission curve on the frequency of the applied signals, which can be modeled in different ways based on the particular view one may want to stress. At the physical level, the frequency dependence of the LC characteristic can be ascribed to frequency drifts of the threshold voltage. More deeply, threshold frequency variations can be traced back to frequency shifts of the liquid crystal dielectric constant, which will most likely show discrepancies between the programmed rms voltage across LC cells and the actual driving level. Extensive data are categorized by LCD manufacturers, which helps in selecting the most suitable LC technology. In a fact, the dynamic operation of an LCD is jointly determined by the cross-correlation among several constructive and material-dependent parameters (6,7). Not only must LC-specific factors be regarded, but also information about the display module arrangement is equally important. As an example, desired versus actual voltage mismatching may also arise from the capacitive coupling between row and column electrodes, for both individual pixels and between adjacent pixels.

For design purposes, all frequency dependencies can be translated into an input–output frequency-selective relationship between the LCD applied driving waveforms and the effective voltage signals controlling the LC cells. This approach is the most common, which also suits the electrical modeling of the LC cell as a simplified passive RC network. By studying the display response, several design rules can be worked out to serve as a reference when designing the driver architecture. First and foremost, it is desirable that the frequency band of the drive signals be narrow to prevent uneven frequency filtering and optical distortion. MLA guarantees band collimation since most of the spectrum becomes concentrated around p times the frame frequency. However, experimental results show that when other schemes (such as PWM) are mounted on top of MLA, frequency multiplication may turn out to reinforce more than to suppress artifacts. Polarity inversion is another established methodology for bandwidth reduction, which entails that the signs of both the row and the column signals be periodically inverted, with an inversion period set on a superframe, frame, or block-of-N-lines basis. Dot inversion also is possible in AMLCDs, where the inversion takes place from one pixel location to the adjacent one. Whatever inversion is used, the lowest frequency of the spectrum is upshifted, and the DC offset in the driving signals is suppressed. The latter is another important result, since the DC component is a primary cause of LC degeneration and of panel lifetime reduction.

Keeping the waveform frequency spectrum under control also is vital with respect to energy awareness. Curbing the chip power consumption is possible when frame/superframe frequencies are low enough: In fact, the superframe frequency can be made even lower than 50 Hz if phase mixing is supported.

Phase Mixing. Phase mixing exploits the spatial low-pass filtering capability of the human eye to construct the same gray level in adjacent pixels (blocks of pixels) by driving the same number of ON/OFF states (phases) but throughout different sequences over the superframe. If individual ON/OFF states out of the GST are referred to as *phases* for each gray tone, *phase mixing* implies scheduling different phases during the same frame for each pixel out of a region of adjacent ones. Phase mixing better distributes the voltage switching activities over the columns and produces a lowering of global frequency. To yield the best optical performance, phase mixing is typically applied on an RGB-subpixel basis (subpixel blocks instead of pixel blocks) and the phase pattern (which phases are driven at which position) is switched from one pixel (respectively, subpixel) block to another. The designer wanting to implement phase mixing arranges a phase mixing table holding the basic phase sequencing for pixel blocks within the display matrix together with the related phase switching rule (which phase follows a given one at any location). The setting of the phase switching table has a strong impact on the chip functionalities, so that it must be granted particular care.

Flicker

The meaning of flicker in the scope of LCD artifacts is familiar; however, the reasons why flicker affects display visualization and the countermeasures needed to remove it might be less clear. Flicker generally stems from an incorrect distribution of the driving waveforms frequency spectrum: As it is, time-uneven or amplitude-unbalanced contributions to the rms value over a frame are likely to bring about flicker. Hence, common solutions to suppress flicker are part of those general measures used to regulate the frequency spectrum of the voltage waveforms: Lowering the frame frequency, using MLA-based driving (for flicker caused by uneven rms contribution over a frame), and embedding some smart phase-mixing scheme (for flicker caused by uneven rms contributions over a superframe) currently are deployed in industrial PMLCD modules. As for AMLCDs, flicker always represents a crucial concern because of the kickback effect unless dedicated measures are taken, like the common electrode modulation technique or the use of an additional storage capacitor as described above.

Crosstalk

By crosstalk we define all pattern-dependent effects of mutual interference among the gray-scale values of pixels (3,8). Those effects tend to grow worse with increasing display size, higher resolution, and faster responding LC, all of which unfortunately are features that the display market's evolution is more and more heading toward. Diverse mechanisms are responsible for crosstalk, although they can be connected generally to the frequency-selectiveness of the LC response.

Static Crosstalk Artefacts. It is commonly agreed that *static* crosstalk is defined as all sorts of crosstalk-related visual artifacts affecting the displaying of single (in this sense, *static*) pictures. Therefore, frame switching over time such as in video streaming is not considered. Static crosstalk appears as differences in the brightness of theoretically equal gray-scale pixels and manifests in multiple manners. Simply stated, at least three types can be distinguished: vertical crosstalk, horizontal crosstalk, and block shadowing. Vertical crosstalk usually hinges on different frequency contents of different column waveforms. It is growing more and more important with the increasing steepness of the LC transmission-voltage curve as required for acceptable contrast in visualization. Horizontal crosstalk occurs when differences in the LC dielectric constant for black- and-white pixels induce spatially asymmetrical capacitive coupling between rows and columns. The amount of perceptible artifacts depends on the width of dark/bright horizontal blocks along a row. Finally, when current spikes result from symmetrically and simultaneously changing column waveforms in areas where sizable blocks of darker pixels determine different coupling between rows and columns, vertical block shadowing is likely.

Dynamic Crosstalk Artefacts. In conjunction with static artifacts, LCD modules supporting video streaming may be affected by dynamic crosstalk. The exact characterization of dynamic crosstalk often turns out to be difficult, since many cooperative causes contribute to it. Loosely speaking, dynamic crosstalk—also called "splicing"—can be associated with uneven voltage contributions to the perceived rms value *on switching from one frame to anothe*r. This view of the problem generally allows for quantifying the impact of improper driving schemes and for putting into action concrete measures to oppose splicing.

Crosstalk Minimization. The problem of reducing crosstalk has been attacked diversely. Apart from technological advances in the display manufacturing, either dedicated and more sophisticated hardware in the driver integrated circuits (such as built-in voltage-correction facilities) or specialization of the addressing schemes have been devised. Beyond the particular features of the huge amount of available alternatives, it is, however, possible to outline some basic design guidelines that help to identify the very essential concepts underneath crosstalk suppression.

Uniformity of the rms contributions over time, for instance, can be pursued through smart selection of the MLA driving mode (e.g., virtual-3-MLA) or the adoption of specific schemes such as the so-called self-calibrating driving method (SCDM), described in the literature. Both such approaches actually eliminate static crosstalk and significantly reduce, although do not entirely suppress, dynamic crosstalk. In particular, virtual-3-MLA also makes the overall optical performance insensitive to asymmetries or inaccuracies in the column voltage levels and contemporarily allows for reducing the number of such levels, which is unquestionably beneficial with respect to static artifacts. Similar results can be attained by using rectangular instead of square phase mixing tables and by enabling drive pattern switching. However, joint application of those methods should be supported by extensive back-end performance evaluation activities to diagnose potential side effects that may stem from their reciprocal interaction at particular image patterns. High-accuracy simulations usually serve this goal.

The above-mentioned polarity inversion modes commonly are also employed as good measures to alleviate static crosstalk artifacts along with all other shortcomings of the nonlinear response of LC cells. However, an important point must be made in selecting the most appropriate inversion strategies. For instance, although separate row or column inversion effectively reduces the impact of horizontal and vertical crosstalk, respectively, vertical or horizontal crosstalk is likely to manifest if either is used independently of each other, with limited advantages in terms of power consumption. Simultaneous suppression of both vertical and horizontal crosstalk is possible with dot inversion in AMLCDs at the cost of extra driving energy. Finally, frame inversion promotes low power operation, but its efficiency in crosstalk reduction is minimal.

The selection of unconventional FRC and PWM schemes, at particular choices of the number of frames in the superframe and of the signal modulation pulses in the scan signals, frequently leads to some controllable reshaping of the frequency spectrum with favorable effects on static crosstalk. It must be noted, however, that all spectral manipulations are only effective when they match concretely the frequency characteristic of the particular liquid: Early assessment of possible drawbacks is mandatory, and customized top-level simulators are valuable in this respect.

Useful suggestions can be also drawn when looking into the technology side of the matter. Interactions between display module parameters and static crosstalk can be tracked down easily: It is well established that static crosstalk is hampered when the resistivity of the ITO tracks is lowered, when a less frequency-dependent liquid is used, or when the deviations in the LC cell capacitances are restrained (the cell capacitance basically depends on the inter-cell gap).

As a final remark, from a theoretical perspective, the phenomenology behind static crosstalk is more easily kept under control when compared with dynamic effects. Experimental verification or system-level simulations are often the sole viable approaches to work into the issues of dynamic artifacts.

Gray-Tone Visualization Artifacts. When GSTs are too simplistic, artifacts altering the visualization of particular color patterns may develop. For instance, with patterns characterized by (although not limited to) the incremental distribution over the pixels of the full gray-tone gamut itself from one side of the display to the other, spurious vertical dim lines may occur. Popular solutions rest essentially on some clever redefinition of the GST, e.g., by the elimination of FRC-only gray tones, the usage of redundancies in the PWM scheme for generating identical gray levels, or the shift of every gray tone one level up with respect to the default GST. A key factor is that the color alteration only affects some particular and well-known gray tones, so that the problem usually can be confined. Because problematic gray tones commonly cause static crosstalk artifacts, their removal yields an added value with respect to crosstalk suppression.

LCD DRIVER DESIGN OVERVIEW

Architectural Concept

In a display module, the driver electronics is responsible for the generation of the proper panel driving waveforms depending on the pixel RGB levels within the image to be displayed. Therefore, optimal driver design is imperative for the realization of high-quality display-based appliances. Display drivers generally are developed as application-specific integrated circuits (ASICs). When considering the hardware architecture, drivers targeting PMLCDs and AMLCDs can be treated jointly in that they share the same building units.

At the architecture level, analog subsystems play a central role in generating the high level voltages required for driving the rows and the columns, and they usually occupy most of the electronics on-chip area. On the other hand, digital blocks do not commonly require any massive area effort: Yet, a deal of vital functions takes place in digital logic. The digital part accommodates all units involved in instruction decoding (the driver is usually fed with commands from an on-board microcontroller) and interface-data handling as well as with display specific functionalities responsible for orthogonal function and scan signal generation, timing, and switching scheduling. Finally, many display drivers also are equipped and shipped with some sort of built-in video memory for local pixel data storage; this facilitates the independence of operation from the host system.

LCD Driver Design Flow

A typical industrial LCD driver design flow includes all those steps needed for mixed analog–digital, very-large-scale-of-integration ASIC design, usually structured throughout the following milestones:

1. Project proposal: analysis of system level requirements based on the application needs.
2. Feasibility study: architecture definition based on system level requirements, preliminary evaluation based on a dedicated LCD module simulator, and project planning.
3. Project start approval.
4. Architecture implementation: block level design of both analog and digital parts (design front-end). Analog circuit design and digital register-transfer-level description and coding are included. Top-level simulation can be also performed at this stage, usually by means of behavioral modeling for the analog parts.
5. Analog and digital place & route and timing verification (design back-end). Cosimulation of functional testbenches with hardware description, including back-annotated timing information, is frequently employed at this stage. Top-level verification and checks follow.
6. Prototype-based on-chip evaluation.

All the steps outlined above describe some very general design phases that are common to the implementations of both active-matrix and passive-matrix addressing display drivers.

Front-End Driving Scheme Selection and Performance Evaluation: Simulation Tools

When regarding the structure of a typical LCD design flow, entailing the availability of testable prototypes at the very end of the design chain, the interest in tools devoted to early stage evaluation of the driver-display module performance should become plain. As a matter of fact, although the hardware development environments comprise mostly standard analog and digital ASIC design tools (those for circuit design, register-transfer-level description and synthesis, technology mapping, cell place & route, and chip verification), specialized tools should be featured to simulate all functional interactions between the front-end driver and the back-end panel. Indeed, merely relying on the chip prototype evaluation phase for performance assessment is often impractical because of the severe costs associated with hardware redesigns on late detection of operational faults. Proprietary simulation tools are likely to be embedded into advanced industrial LCD design flows, and they usually allow for:

1. Functional simulation of the hardware-embedded or software-programmable driving schemes.
2. Functional simulation of all targeted color generation modes.
3. Functional simulations of all embedded measures to prevent visual artifact generation (for testing and evaluation purposes).
4. Highly reconfigurable input modes (such as single-picture display mode, or multiframe driving mode for video streaming evaluation).
5. Sophisticated LCD-modeling engine (including the frequency model of the LC cell response).
6. Reconfigurability with respect to all significant physical display parameters (such as material conductivity, material resistivity, LC cell geometry, and electrode track lengths).
7. Multiple and flexible output formats and performance figures.

The availability of an LCD circuit model is a particularly important aspect, as it opens the possibility of performing reliable evaluation of the module dynamic operation within different frequency ranges.

Display Modeling for LCD Design. Any simulation engine used for driver-display joint modeling cannot function without some form of electrical characterization of an LC cell to work as the electrical load of the driving circuits. A satisfactorily accurate model of the frequency behavior of the LC cell broadly used in practice (9) treats the cell as a simplified RC network whose resistances and capacitances can be calculated as functions of some very basic process and material parameters for the liquid crystal, the polyimide layers, and the connection tracks (e.g., LC conductivity and ITO sheet resistivity). The resulting typical frequency response of the LC cell turns out to be that of a 2-pole, 1-zero network. Consequently, apart from the claim that the driving signals bandwidth be narrow for crosstalk minimization, their lowest frequency bound must be also high enough to prevent distortion induced by the first pole's attenuation.

LOGIC DESIGN

INTRODUCTION

Over the years, digital electronic systems have progressed from vacuum tube to complex integrated circuits, some of which contain millions of transistors. Electronic circuits can be separated into two groups, digital and analog circuits. Analog circuits operate on analog quantities that are continuous in value and in time, whereas digital circuits operate on digital quantities that are discrete in value and time (1).

Analog signals are continuous in time besides being continuous in value. Most measurable quantities in nature are in analog form, for example, temperature. Measuring around the hour temperature changes is continuous in value and time, where the temperature can take any value at any instance of time with no limit on precision but on the capability of the measurement tool. Fixing the measurement of temperature to one reading per an interval of time and rounding the value recorded to the nearest integer will graph discrete values at discrete intervals of time that easily could be coded into digital quantities. From the given example, it is clear that an analog-by-nature quantity could be converted to digital by taking discrete-valued samples at discrete intervals of time and then coding each sample. The process of conversion is usually known as analog-to-digital conversion (A/D). The opposite scenario of conversion is also valid and known as digital-to-analog conversion (D/A). The representation of information in a digital form has many advantages over analog representation in electronic systems. Digital data that are discrete in value, discrete in time, and limited in precision could be efficiently stored, processed, and transmitted. Digital systems are said practically to be more noise immune as compared with analog electronic systems because of the physical nature of analog signals. Accordingly, digital systems are more reliable than their analog counterpart. Examples of analog and digital systems are shown in Fig. 1.

A BRIDGE BETWEEN LOGIC AND CIRCUITS

Digital electronic systems represent information in digits. The digits used in digital systems are the *0* and *1* that belong to the *binary* mathematical number system. In logic, the *1* and *0* values correspond to *True* and *False*. In circuits, the *True* and *False* could be thought of as *High* voltage and *Low* voltage. These correspondences set the relationships among logic (*True* and *False*), *binary* mathematics (*0* and 1), and circuits (*High* and *Low*).

Logic, in its basic shape, deals with reasoning that checks the validity of a certain proposition—a proposition could be either *True* or *False*. The relationship among logic, *binary* mathematics, and circuits enables a smooth transition of processes expressed in propositional logic to *binary* mathematical functions and equations (*Boolean* algebra) and to digital circuits. A great scientific wealth exists that strongly supports the relationships among the three different branches of science that lead to the foundation of modern digital hardware and logic design.

Boolean algebra uses three basic logic operations *AND, OR*, and *NOT*. The *NOT* operation if joined with a proposition *P* works by negating it; for instance, if *P* is *True*, then *NOT P* is *False* and vice versa. The operations *AND* and *OR* should be used with two propositions, for example, *P* and *Q*. The logic operation *AND*, if applied on *P* and *Q*, would mean that *P AND Q* is *True* only when both *P* and *Q* are *True*. Similarly, the logic operation *OR*, if applied on *P* and *Q*, would mean that *P OR Q* is *False* only when *P* and *Q* are *False*. Truth tables of the logic operators *AND, OR*, and *NOT are* shown in Fig. 2(a). Fig. 2(b) shows an alternative representation of the truth tables of *AND, OR*, and *NOT in* terms of *0s* and *1s*.

COMBINATIONAL LOGIC CIRCUITS

Digital circuits implement the logic operations *AND, OR*, and *NOT* as hardware elements called "gates" that perform logic operations on binary inputs. The *AND-gate* performs an *AND* operation, an *OR-gate* performs an *OR* operation, and an *Inverter* performs the negation operation *NOT*. Figure 2(c) shows the standard logic symbols for the three basic operations. With analogy from electric circuits, the functionality of the *AND* and *OR* gates are captured as shown in Fig. 3. The actual internal circuitry of gates is built using transistors; two different circuit implementations of inverters are shown in Fig. 4. Examples of *AND, OR, NOT* gates integrated circuits (*ICs*) are shown in Fig. 5. Besides the three essential logic operations, four other important operations exist—the *NOR* (*NOT-OR*), *NAND* (*NOT-AND*), Exclusive-*OR* (*XOR*), and Exclusive-*NOR* (*XNOR*).

A combinational logic circuit is usually created by combining gates together to implement a certain logic function. A combinational circuit produces its result upon application of its input(s). A logic function could be a combination of logic variables, such as *A, B, C*, and so on. Logic variables can take only the values *0* or *1*. The created circuit could be implemented using *AND-OR-Inverter* gate-structure or using other types of gates. Figure 6(a) shows an example combinational implementation of the following logic function *F*(*A, B, C*):

$$F(A,B,C) = ABC + A'BC + AB'C'$$

F(*A, B, C*) in this case could be described as a standard sum-of-products (*SOP*) function according to the analogy that exists between *OR* and addition (+), and between *AND* and product (.); the *NOT* operation is indicated by an apostrophe "'" following the variable name. Usually, standard representations are also referred to as canonical representations.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

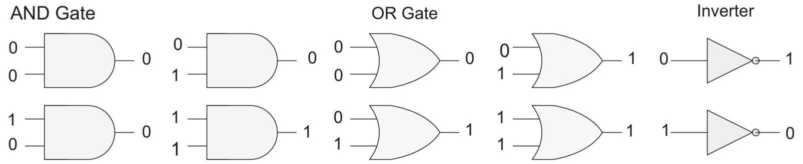
(b)



(c)

Figure 2. (a) Truth tables for AND, OR, and Inverter. (b) Truth tables for AND, OR, and Inverter in binary numbers. (c) Symbols for AND, OR, and Inverter with their operation.

In an alternative formulation, consider the following function *E*(*A,B,C*) in a product-of-sums (*POS*) form:

$$E(A,B,C) = (A + B' + C).(A' + B + C)(A + B + C')$$

The canonical *POS* implementation is shown in Fig. 6(b). Some other specifications might require functions with more inputs and accordingly with a more complicated design process.

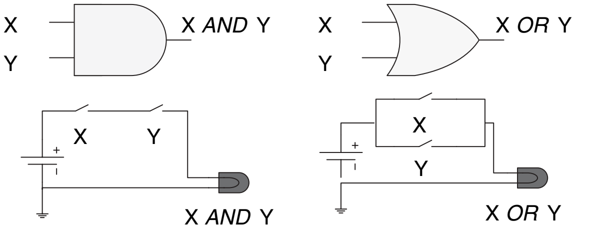


Figure 3. A suggested analogy between *AND*and *OR* gates and electric circuits.

The complexity of a digital logic circuit that corresponds to *a Boolean* function is directly related to the complexity of the base algebraic function. *Boolean* functions may be simplified by several means. The simplification process that produces an expression with the least number of terms with the least number of variables is usually called minimization. The minimization has direct effects on reducing the cost of the implemented circuit and sometimes on enhancing its performance. The minimization (optimization) techniques range from simple (manual) to complex (automated). An example of manual optimization methods is the *Karnough* map (*K*-map).

K-MAPS

A *K*-map is similar to a truth table as it presents all the possible values of input variables and their corresponding output. The main difference between *K*-maps and truth tables is in the cells arrangement. In a *K*-map, cells are arranged in a way so that simplification of a given algebraic expression is simply a matter of properly grouping the cells.

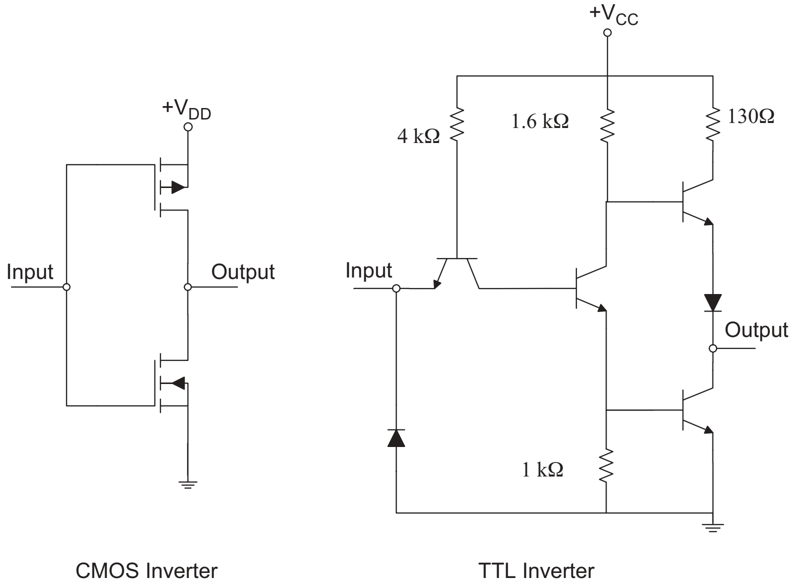

Figure 4. Complementary metal-oxide semiconductor (*CMOS*) and transistor-transistor logic (*TTL*) inverters.

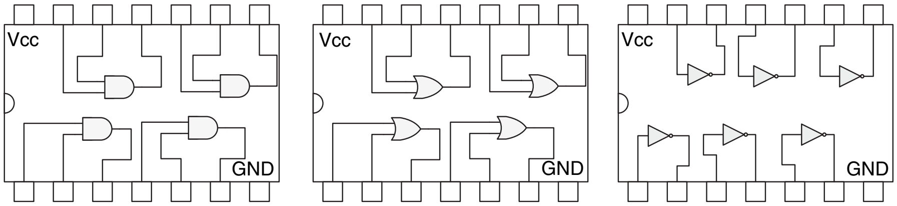

Figure 5. The 74LS21 (*AND*), 74LS32 (*OR*), and 74LS04 (*Inverter) TTL* ICs.

K-maps can be used for expressions with different numbers of input variables: three, four, or five. In the following examples, maps with only three and four variables are shown to stress the principle. Methods for optimizing expressions with more than five variables can be found in the literature. The *Quine–McClusky* method is an example that can accommodate several variables larger than five (2).

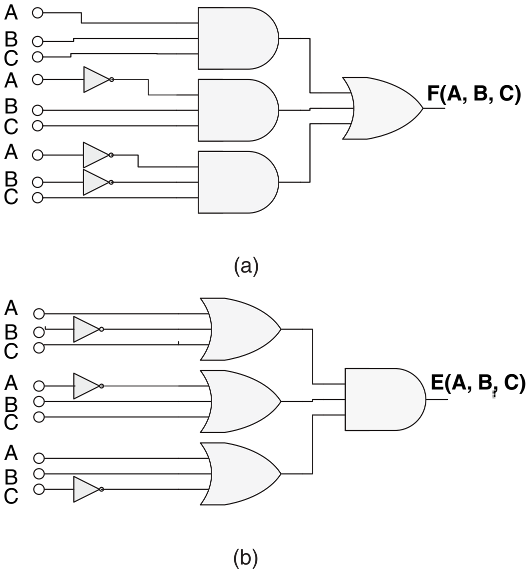

Figure 6. AND–OR–Inverter implementation of the function (a) SOP: F(A, B, C) = ABC + A′BC + AB′C′. (b) POS: E(A, B, C) = (A + B′ + C).(A′ + B + C)(A + B + C′).

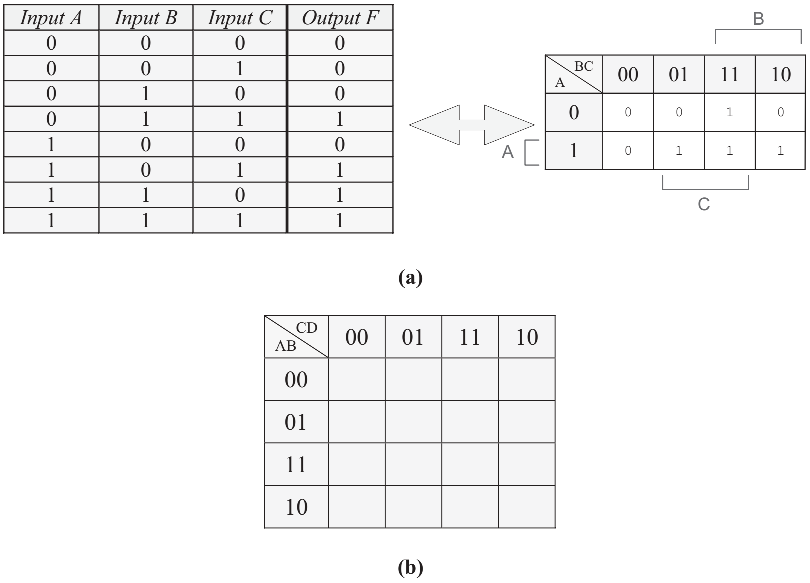
A three-variable *K*-map is an array of *8* (or *2*^{3}) cells. Figure 7(a) depicts the correspondence between a three-input (*A*, *B*, and *C*) truth table and a *K*-map. The value of a given cell represents the output at certain binary values of *A, B*, and *C*. In a similar way, a four-variable *K*-map is arranged as shown in Fig. 7(b). *K*-maps could be used for expressions in either *POS* or *SOP* forms. Cells in a *K*-map are arranged so that they satisfy the *Adjacency* property, where only a single variable changes its value between adjacent cells. For instance, the cell *000*, that is the binary value of the term *A′B′C′*, is adjacent to cell *001* that corresponds to the term *A′B′C*. The cell *0011* (*A′B′CD*) is adjacent to the cell *0010* (*A′B′C′D*).

MINIMIZING *SOP* EXPRESSIONS

The minimization of an algebraic *Boolean* function *f* has the following four key steps:

1. Evaluation
2. Placement
3. Grouping
4. Derivation



Input A	*Input B*	*Input C*	*Output F*
0	0	0	0
0	0	1	0
0	1	0	0
0	1	1	1
1	0	0	0
1	0	1	1
1	1	0	1
1	1	1	1

11				
10				

(b)

Figure 7. (a) The correspondence between a three-input (*A, B*, and *C*) truth table and a *K-map*. (b) An empty four-variable *K*-map.

The minimization starts by evaluating each term in the function *f* and then by placing a *1* in the corresponding cell on the *K*-map. A term *ABC* in a function *f* (A, *B, C*) is evaluated to *111*, and another term *AB 'CD* in a function *g(A, B, C, D)* is evaluated to *1011*. An example of evaluating and placing the following function *f* is shown in Fig. 8(a):

$$f(A,B,C) = A'B'C' + A'B'C + ABC' + AB'C'$$

After placing the *1s* on a *K*-map, grouping filled-with-*1s* cells is done according to the following rules [see Fig. 8(b)]:

- A group of adjacent filled-with-*1s* cells must contain several cells that belong to the set of powers of two (1, 2, 4, 8, or 16).

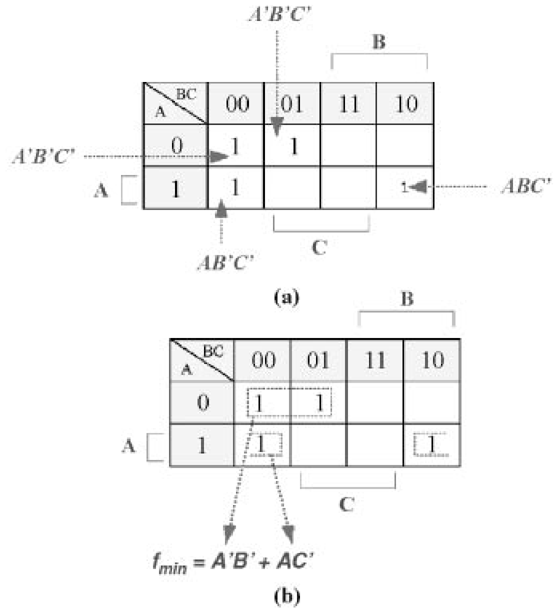

Figure 8. (a) Terms evaluation of the function *f*(*A, B, C*) = *A'B'C'* + *A'B'C* + *ABC'* + *AB'C'*.(b) Grouping and derivation.

- A group should include the largest possible number of filled-with-*1s* cells.
- Each *1* on the *K*-map must be included in at least one group.
- *Cells* contained in a group could be shared within another group as long as overlapping groups included noncommon *1s*.

After the grouping step, the derivation of minimized terms is done according to the following rules:

- Each group containing *1s* creates one product term.
- The created product term includes all variables that appear in only one form (completed or uncomplemented) across all cells in a group.

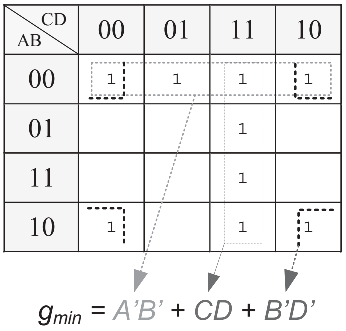
After deriving terms, the minimized function is composed of their sum. An example derivation is shown in Fig. 8(b). Figure 9 presents the minimization of the following function:

$$\begin{aligned} g(A,B,C,D) = {} & AB'C'D' + A'B'C'D' + A'B'C'D' + A'B'CD \\ & + AB'CD + A'B'CD' + A'BCD + ABCD \\ & + AB'CD' \end{aligned}$$

COMBINATIONAL LOGIC DESIGN

The basic combinational logic design steps could be summarized as follows:

1. Specification of the required circuit.
2. Formulation of the specification to derive algebraic equations.
3. Optimization (minimization) of the obtained equations.
4. Implementation of the optimized equations using a suitable hardware (*IC*) technology.



AB \ CD	00	01	11	10
00	1	1	1	1
01			1	
11			1	
10	1		1	1

$g_{min} = A'B' + CD + B'D'$

Figure 9. Minimization steps of the following function: $g(A, B, C, D) = AB'C'D' + A'B'C'D' + A'B'C'D' + A'B'CD + AB'CD + A'B'B'CD' + A'BCD + ABCD + AB'CD'$.

The above steps are usually joined with an essential verification procedure that ensures the correctness and completeness of each design step.

As an example, consider the design and implementation of a three-variable majority function. The function $F(A, B, C)$ will return a *1* (*High* or *True*) whenever the number of *1s* in the inputs is greater than or equal to the number of *0s*.

The above specification could be reduced into a truth table as shown in Fig. 7(a). The terms that make the function F return a *1* are the terms $F(0, 1, 1)$, $F(1, 0, 1)$, $F(1, 1, 0)$, or $F(1, 1, 1)$. This truth table could be alternatively formulated as in the following equation:

$$F = A'BC + AB'C + ABC' + ABC$$

Following the specification and the formulation, a *K*-map is used to obtain the minimized version of F (called $F_{\min}$). Figure 10(a) depicts the minimization process. Figure 10(b) shows the implementation of $F_{\min}$ using standard *AND-OR-NOT* gates.

COMBINATIONAL LOGIC CIRCUITS

Famous combinational circuits that are widely adopted in digital systems include encoders, decoders, multiplexers, adders, some programmable logic devices (*PLDs*), and so on. The basic operation of multiplexers, half-adders, and simple *PLDs* (*SPLDs*) is described in the following lines.

A multiplexer (*MUX*) selects one of n input lines and provides it on a single output. The select lines, denoted S, identify or address one of the several inputs. Figure 11(a) shows the block diagram of a 2-to-1 multiplexer. The two inputs can be selected by one select line, S. If the selector $S = 0$, input line d_0 will be the output O, otherwise, d_1 will be produced at the output. An *MUX* implementation of the majority function $F(A, B, C)$ is shown in Fig. 11(b).

A half-adder inputs two binary digits to be added and produces two binary digits representing the sum and carry. The equations, implementation, and symbol of a half-adder are shown in Fig. 12.

Simple *PLDs* (*SPLDs*) are usually built from combinational logic blocks with prerouted wiring. In implementing a function on a *PLD*, the designer will only decide of which wires and blocks to use; this step is usually referred to as programming the device. Programmable logic array (*PLA*) and the programmable array logic (*PAL*) are commonly used *SPLDs*. A *PLA* has a set of programmable *AND* gates, which link to a set of programmable *OR* gates to produce an output [see Fig. 13(a)]. A *PAL* has a set of programmable *AND* gates, which link to a set of fixed *OR* gates to produce an output [see Fig. 13(b)]. The *AND-OR* layout of a *PLA*/*PAL* allows for implementing logic functions that are in an *SOP* form. A *PLA* implementation of the majority function $f(A, B, C)$ is shown in Fig. 13(c).

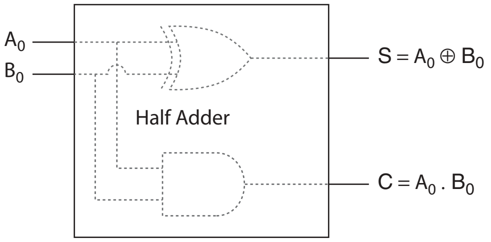

Figure 12. The equations, implementation, and symbol of a half-adder. The used symbol for a *XOR* operation is "⊕".

SEQUENTIAL LOGIC

In practice, most digital systems contain combinational circuits along with memory; these systems are known as sequential circuits. In sequential circuits, the present outputs depend on the present inputs and the previous states stored in the memory elements. Sequential circuits are of two types: synchronous and asynchronous. In a synchronous sequential circuit, a clock signal is used at discrete instants of time to synchronize desired operations. A clock is a device that generates a train of pulses as shown in Fig. 14. Asynchronous sequential circuits do not require synchronizing clock pulses; however, the completion of an operation signals the start of the next operation in sequence.

In synchronous sequential circuits, the memory elements are called flip-flops and are capable of storing only one bit. Arrays of flip-flops are usually used to accommodate for bit-width requirements of binary data. A typical synchronous sequential circuit contains a combinational part, sequential elements, and feedback signals coming from the output of the sequential elements.

FLIP-FLOPS

Flip-flops are volatile elements, where the stored bit is stored as long as power is available. Flip-flops are designed using basic storage circuits called latches. The most common latch is the *SR* (Set to 1 - Reset to 0) latch. An *SR* latch

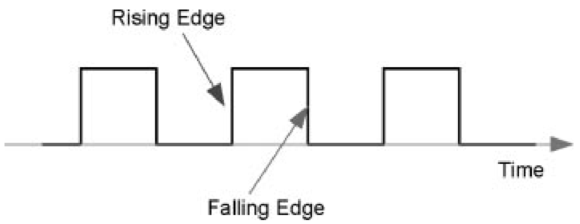

Figure 14. Clock pulses.

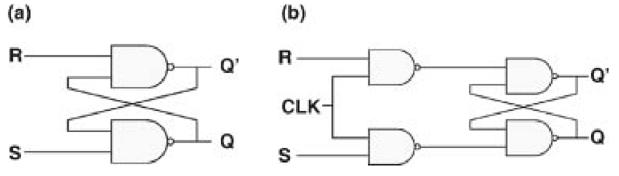

Figure 15. (a) An *SR* latch. (b) An *RS* flip-flop.

could be formed with two cross-coupled *NAND* gates as shown in Fig. 15. The responses to various inputs to the *SR* latch are setting *Q* to *1* for an *SR* input of *01* (*S* is active low; i.e., *S* is active when it is equal to *0*), resetting *Q* to *0* for an *SR* input of *10* (*R* here is also active low), and memorizing the current state for an *SR* input of *11*. The *SR* input of *00* is considered invalid.

A flip-flop is a latch with a clock input. A flip-flop that changes state either at the positive (rising) edge or at the negative (falling) edge of the clock is called an edge-triggered flip-flop (see Fig. 14). The three famous edge-triggered flip-flops are the *RS, JK*, and *D* flip-flops.

An *RS* flip-flop is a clocked *SR* latch with two more *NAND* gates [see Fig. 15(b)]. The symbol and the basic operation of an *RS* flip-flop are illustrated in Fig. 16(a). The operation of an *RS* flip-flop is different from that of an *SR* latch and responds differently to different values of *S* and *R*. The *JK* and *D* flip-flops are derived from the *SR* flip-flop.

However, the *JK* and *D* flip-flops are more widely used (2). The *JK* flip-flop is identical to the *SR* flip-flop with a single difference, where it has no invalid state [see Fig. 16(b)]. The *D* flip-flop has only one input formed with an *SR* flip-flop and an inverter [see Fig. 16(c)]; thus, it only could set or reset. The *D* flip-flop is also known as a transparent flip-flop, where output will have the same value of the input after one clock cycle.

SEQUENTIAL LOGIC DESIGN

The basic sequential logic design steps are generally identical to those for combinational circuits; these are Specification, Formulation, Optimization, and the Implementation of the optimized equations using a suitable hardware (*IC*) technology. The differences between sequential and combinational design steps appear in the details of each step.

The specification step in sequential logic design usually describes the different states through which the sequential circuit goes. A typical example for a sequential circuit is a counter that undergoes eight different states, for instance, zero, one, two, three up to seven. A classic way to describe the state transitions of sequential circuits is a state diagram. In a state diagram, a circle represents a state and an arrow represents a transition. The proposed example assumes no inputs to control the transitions among states. Figure 17(a) shows the state diagram of the specified counter. The number of states determines the minimum number of flip-flops to be used in the circuit. In the case of the *8*-states counter, the number of flip-flops should be *3*; in accordance with the formula, *8* equals 2^3. At this stage, the states could be coded in binary. For instance, the stage representing count *0* is coded to binary *000*; the stage of count *1* is coded to binary *001*, and so on.

The state diagram is next to be described in a truth table style, usually known as a state table, from which the formulation step could be carried forward. For each flip-flop, an input equation is derived [see Fig. 17(b)]. The equations are then minimized using *K*-maps [see Fig. 17(c)]. The minimized input equations are then implemented using a suitable hardware (*IC*) technology. The minimized equations are then to be implemented [see Fig. 17(d)].

MODERN LOGIC DESIGN

The task of manually designing hardware tends to be extremely tedious, and sometimes impossible, with the increasing complexity of modern digital circuits. Fortunately, the demand on large digital systems has been accompanied with a fast advancement in *IC* technologies. Indeed, *IC* technology has been growing faster than the ability of designers to produce hardware designs. Hence, there has been a growing interest in developing techniques and tools that facilitate the process of logic design.

Two different approaches emerged from the debate over ways to automate hardware logic design. On one hand, the capture-and-simulate proponents believe that human designers have good design experience that cannot be automated. They also believe that a designer can build

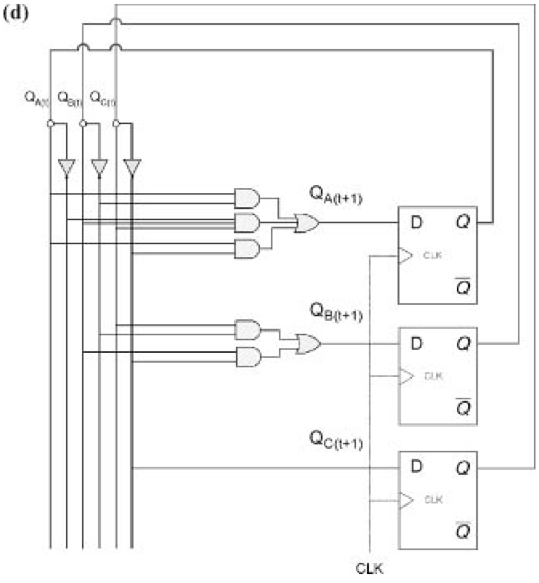

Figure 17. (*Continued*)

a design in a bottom-up style from elementary components such as transistors and gates. As the designer is concerned with the deepest details of the design, optimized and cheap designs could be produced. On the other hand, the describe-and-synthesize advocates believe that synthesizing algorithms can out-perform human designers. They also believe that a top-down fashion would be better suited for designing complex systems. In describe-and-synthesize methodology, the designers first describe the design. Then, computer-aided design (*CAD*) tools can generate the physical and electrical structure. This approach describes the intended designs using special languages called hardware description languages (*HDLs*). Some *HDLs* are very similar to traditional programming languages like *C*, *Pascal*, and so on. (3). *Verilog*(4) and *VHDL* (Very High Speed Integrated Circuit Hardware Description Language) (5) are by far the most commonly used *HDLs* in industry.

Hardware synthesis is a general term used to refer to the processes involved in automatically generating a hardware design from its specification. High-level synthesis (*HLS*) could be defined as the translation from a behavioral description of the intended hardware circuit into a structural description. The behavioral description represents an algorithm, equation, and so on, whereas a structural description represents the hardware components that implement the behavioral description.

The chained synthesis tasks at each level of the design process include system synthesis, register-transfer synthesis, logic synthesis, and circuit synthesis. System synthesis starts with a set of processes communicating though either shared variables or message passing. Each component can be described using a register-transfer language (*RTL*). *RTL* descriptions model a hardware design as circuit blocks and interconnecting wires. Each of these circuit blocks could be described using *Boolean* expressions. Logic synthesis translates *Boolean* expressions into a list of logic gates and their interconnections (netlist). Based on the produced netlist, circuit synthesis generates a transistor schematic from a set of input–output current, voltage and frequency characteristics, or equations.

The logic synthesis step automatically converts a logic-level behavior, consisting of logic equations and/or finite state machines (*FSMs*), into a structural implementation (3). Finding an optimal solution for complex logic minimization problems is very hard. As a consequence, most logic synthesis tools use heuristics. A heuristic is a technique whose result can hopefully come close to the optimal solution. The impact of complexity and of the use of heuristics on logic synthesis is significant. Logic synthesis tools differ tremendously according to the heuristics they use. Some computationally intensive heuristics require long run times and thus powerful workstations producing high-quality solutions. However, other logic synthesis tools use fast heuristics that are typically found on personal computers producing solutions with less quality. Tools with expensive heuristics usually allow a user to control the level of optimization to be applied.

Continuous efforts have been made, paving the way for modern logic design. These efforts included the development of many new techniques and tools. An approach to logic minimization using a new sum operation called multiple valued *EXOR* is proposed in Ref. 6 based on neural computing.

In Ref. 7, Tomita et al. discuss the problem of locating logic design errors and propose an algorithm to solve it. Based on the results of logic verification, the authors introduce an input pattern for locating design errors. An algorithm for locating single design errors with the input patterns has been developed.

Efforts for creating tools with higher levels of abstraction in design lead to the production of many powerful modern hardware design tools. Ian Page and Wayne Luk(8) developed a compiler that transformed a subset of *Occam* into a netlist. Nearly ten years later we have seen the development of *Handel-C*, the first commercially available high-level language for targeting programmable logic devices (such as field programmable gate arrays (9).

A prototype *HDL* called Lava was developed by Satnam Singh at *Xilinx* and by Mary Sheeran and Koen Claessen at Chalmers University in Sweden (10). Lava allows circuit tiles to be composed using powerful high-order combinators. This language is embedded in the *Haskell* lazy functional programming language. *Xilinx* implementation of *Lava* is designed to support the rapid representation, implementation, and analysis of high-performance *FPGA* circuits.

Logic design has an essential impact on the development of modern digital systems. In addition, logic design techniques are a primary key in various modern areas, such as embedded systems design, reconfigurable systems (11), hardware/software co-design, and so on.

LOGIC SYNTHESIS

The design process for an electronics system begins when an idea is transformed into a set of specifications to be verified by the future system. These specifications become the basis for a series of steps or design tasks that eventually will produce a circuit that represents the physical expression of the original idea. The process of generating a final circuit from the initial specifications is known as circuit synthesis.

The design flow for a digital system is composed of a series of stages in which system models are established in accordance with different criteria. Each stage corresponds to a level of abstraction.

To illustrate how these levels of abstraction may be classified, we might, for example, consider three levels: the system level, the RT (register transfer) level, and the logic level. In the system level, the architecture and algorithms necessary to verify the required performance are specified. The RT level represents the system specification as an RT model, in this case establishing an architecture for data flow between registers subject to functional transformations. Finally, the logic level determines the system's functionality using logic equations and descriptions of finite state machines (FSMs). The data handled is logic data with values such as 0, 1, X, Z, etc.

Design tasks in each of the levels usually are supported by different computer aided design (CAD) tools. In each level, the design process basically involves two stages: (*1*) description of the system at the corresponding level and (*2*) verification of the description's behavior via simulation. The synthesis process consists of obtaining the system structure from a description of the behavior. Depending on the level of abstraction in which the work is being carried out, the synthesis will be high level synthesis, logic synthesis, etc. This article addresses logic synthesis, which involves the generation of a circuit at the logic level based on an RT level design specification. The automation of the synthesis process has allowed the development of several tools that facilitate the tasks involved. Automatic synthesis tools offer several advantages when implementing an electronic circuit. First, automation allows the design flow to be completed in less time, which is relevant particularly today because of the high competitiveness and the requirements to solve demands in a short period of time. Second, automatic synthesis also makes the exploration of design space more viable because it enables different requirements, such as cost, speed, and power, to be analyzed. Third, a fundamental aspect of the whole design process is its robustness, that is, its certainty that the product is free from any errors attributable to the designer. In this regard, the use of automatic synthesis tools guarantees the "correct construction" of the system being designed.

The following section of this article deals with aspects associated with logic design such as data types, system components, and modes of operation. Next, the hardware description languages will be presented as tools to specify digital systems. Two standard languages (VHDL and Verilog) will be examined in detail, and the use of VHDL for synthesis will be explained to illustrate specific aspects of logic synthesis descriptions. The article ends with an illustrative example of the principal concepts discussed.

LOGIC DESIGN ORGANIZATION: DATAPATH AND CONTROL UNIT

The RT level is the level of abstraction immediately above the logic level (1,2). In contrast with the logic level, generally concerned with bitstreams, the RT level handles "data." Data is a binary word of *n* bits. Data are processed through arithmetic or logic operations that normally affect one or two data: A + B, NOT(A), and so on.

Data are stored in "registers," which constitute the electronic component for storing *n* bits. Source data must be "read" from its registers and the result of the operation is then "written" in another register to be stored there. The data operation is performed in a "functional unit" (for example, an arithmetic-logic unit). The writing operation is sequential and, in a synchronous system, for example, is therefore executed while the clock is active. The operations of the functional unit and the reading of the register are combinational functions.

Data is transmitted from the source registers toward the functional unit and from there to the target register via "buses," which are basically "*n*" cables with an associated protocol to allow their use.

The core operation is data transfer between registers—hence the name given to this level. It includes both reading and writing operations. Description techniques suitable at the logic level (FSMs and switching theory) are not sufficient at the RT level. One of the simplest ways to describe these operations is as follows:

$$\text{writing}: \quad R_{\text{target}} < \; = DataA * DataB$$

$$\text{reading}: \quad DataOut = [R_{source}]$$

where "*" is the operation between *DataA* and *DataB*.

Because a digital system is very complex at the RT level, it is advisable to split up its tasks into actions that affect the data (storage, transport, calculation, etc.) and control actions (sequencing, decision taking, etc.). Digital system structures at the RT level, therefore, have two units: the data path unit and the control unit.

The data path encompasses all of the functional units that store and process data and the buses that interconnect them. For example, Fig. 1 shows an *n*-bit serial adder with a start signal (*Start*) and an end-of-operation signal (*End*), in which both input data enter consecutively via the parallel bus *Din*. The data path unit contains the three *n*-bit registers where *A* and *B* data and the result of the addition (*SUM*) are stored. It also has an *n*-module counter (*CNT*) to count the number of bits, a full-adder and a 1-bit register

S2	TRUE	W_B	S3
S3	$\overline{Cy}$	UP, W, SR_A, SR_B, SR_S	S3
	Cy	UP, W, SR_A, SR_B, SR_S	S4
S4	TRUE	End	S0

Figure 1. Binary Serial Adder: (a) data path, and control unit; (b) ASM chart; and (c) FSMD microprogram.

(i.e., bistable) to carry out the series addition. These components have specific operation selection inputs, which, in this case, are as follows: clear (*CL*, *CLD*), shift right (*SRA*, *SRB*, *SRS*), count up (*UP*), and parallel write (*WA*, *WB*, *W*).

The set of register transfers that can be executed in one single clock cycle is called the micro-operation (μop), and is the basic operation performed by a digital system. However, from a broader perspective, a digital system executes essentially an instruction or a specific macro-operation belonging to a set of instructions of the digital system. For an instruction to be executed, several clock cycles—or several μops—usually are required. Therefore, a sequence of μops must be obtained for each instruction so that, when the sequence is executed, the instruction can be delivered. The set of μops sequences for all instructions constitutes the digital system‘s control microprogram.

Evidently, the data path design should allow execution of all the μop of the control microprogram. The purpose of the control unit is to execute the control microprogram, and therefore it has the following functions: (*1*) to control which μop must be performed in each clock cycle, (*2*) to generate the system control outputs (i.e., *End* in Fig. 1) and the data path operation selection signals that execute the μop (i.e., in the example in Fig. 1, it will activate *SRA* to shift the DA register, it will activate *UP* to make CNT count, etc.), and (*3*) to evaluate the compliance of the control conditions: in Fig. 1, *Start* and *Cy*.

The control microprogram might be seen as a sequence of actions from two perspectives: first, as a data flow expressed by the RT operations of each μop and, second, as a control signal activation sequence, whether those signals are digital system outputs (for example, End) or signals from the registers (for example, SRA). The two perspectives should be coherent. To describe the control microprogram, graphic techniques are employed, such as ASM (algorithmic state machine) charts or techniques associated with the computer languages generically known as hardware description languages (HDL), of which a great number have been developed (ABEL, AHPL, DDL, Verilog, VHDL, etc.). The most relevant of these languages will be addressed in more detail in the article.

The ASM chart is a very intuitive, useful, and simple technique to describe control microprograms, especially for synchronous digital systems. Each rectangular box identifies a μop—a state of the program or, in other words, the actions executed within the corresponding clock cycle, whether they affect data (RT operations) or control (activating control signals). Figure 1(b) shows the ASM chart that describes both the data flow and the control instructions for our example. In this case, the actions to be executed in the S2 state are DB < = Din (data view) and WB = 1 (control view). An alternative description of the control microprogram, now using a very simplified HDL, which corresponds to what is known as the finite state machine with data path(FSMD) (3) is shown in Fig. 1(c).

The data path in Fig. 1 is very simple and its design is specific. Designing more complex systems is far more difficult. In general, for the best chance of success, the data path should specify the following aspects in as much detail as possible: the functional blocks available (for both registers and processing), the data flow sequencing structures (parallel/pipeline level), and the interconnection architecture (one, two, three, or more buses). The better these elements are specified, the easier and more efficient it will be to synthesize the data path from the description at the most abstract level.

The control unit design can be obtained with the techniques employed habitually in FSM design, and the control unit therefore can be implemented with random logic, using bistables and gates. However, because of implementation restrictions, it is preferable to synthesize the control unit from the RT level. Automatic synthesis from the ASM control microprogram description is easier if it is used one bistable per state in the design of the control unit:

- every Yes state leads to a D-type bistable,
- every decision (i.e., if Cy then S4 else S3, in S3 on Fig. 1(b)) requires a 1:2 demultiplexer with Cy as the selection signal,
- and OR gates join signals that are activated (with 1) in different parts, for example, bistable input D3 is ORing between the q2 output of bistable 2 and the 0 (NOT Cy) output of the demultiplexer controlled by Cy.

Because the ROM-register or PLA-register structures are general FSM design structures, they facilitate control unit synthesis from the RT description. In this case, the microprogram is “written” in ROM (or PLA). In this technique, known as microprogrammed control, the register is a pointer to the μop that is executed and transmitted (together with other control inputs) to ROM/PLA, whereas the ROM/PLA content produces the code for the following μop via a subset of outputs and the values for the control unit output signals via the remaining ROM/PLA outputs. The control microprogram, written in ROM/PLA, constitutes the firmware. Firmware engineering studies ways to optimize the size and the performance of the ROM/PLA-register solution by limiting the data path operation.

HARDWARE DESCRIPTION LANGUAGES

Most automatic synthesis tools divide the synthesis process up into hierarchically organized stages that transfer a specific system description to another description with a greater level of detail. The initial system description usually is expressed in a high level programming language (Pascal, C, etc.) or a an HDL (VHDL, Verilog, etc.).

Hardware specifications can be represented in different ways. Tables and graphs produce representations of greater visual clarity, but do not handle large sizes efficiently. In these cases, language-based descriptions are more versatile than tables and are more machine-readable than graphs.

Specific hardware description languages should be used because high level programming languages (such as C, C++, etc.), although feasible, are not efficient. Their inefficiency stems from the fact that, because they do not possess elements suitable to describe hardware (for example, integrated procedural and nonprocedural paradigms), they require more code lines than specific HDL to describe the same function. As a result, the descriptions they generate are more difficult to understand. Furthermore, in languages designed to describe software, the compiler or translator adapts the descriptions to the machine that will execute the program (resources, architecture, etc.), whereas in HDLs the specification represents the machine that is executing the algorithm, its resources, and so an.

VHDL was created in the early 1980s as part of a U.S. Department of Defence project called VHSIC (Very High Speed Integrated Circuits). The project required a language that could be used to describe the systems being designed and would perform two specific functions: first, allow the designs to be self-documenting and, second, serve as a means of simulating the circuits being studied. In 1985, the DATC (Design Automation Technical Committee) of the IEEE (Institute of Electrical and Electronics Engineers) expressed an interest in VHDL as a result of its need to describe circuits via a language that was independent of the design tools and that could cover the different levels of abstraction in the design process. VHDL provided a solution to the problem of compatibility between designs and the different CAD platforms. Considering that, at that time, VHDL was a language that met all the DATC‘s requirements, the VASG (VHDL Analysis and Standardization Group) was created to begin the process of standardization. Subsequently, in December 1987, the standard designated IEEE 1076-1987 officially appeared for the first time (4). The language has been revised to ensure its development over time. VHDL was created specifically to describe digital systems (5–7), but today a new language called VHDL-AMS (VHDL-Analog Mixed Signal) is available to describe analog and mixed signal circuits.

The VHDL standardization process coincided with that of Verilog, a logic simulation language for the Verilog-XL simulator owned by Cadence Design Systems. Verilog was freed in 1990, allowing the creation of the OVI (Open Verilog International) organism and marking the beginning of the language‘s standardization process. The first standard version appeared in 1995 and was designated IEEE 1364-1995 (8). Later, the Accellera organism (9) was created when OVI and VI (VHDL International) merged to promote new standards and to develop those already in existence. VHDL and Verilog, like most high level programming languages, are imperative languages. These languages are based on a declarative syntax in which the desired problem is expressed through a set of instructions that does not detail the method of solution: That is to say, the sequence of instructions is not relevant. But VHDL and Verilog also allow a procedural syntax (where the desired action is described via a sequence of steps in which the order of execution is important) to be applied for certain specific instructions such as function, procedure, and process.

A VHDL description is composed of a series of design units that allow the different elements that define a circuit to be specified. The basic design unit is called an entity. The entity allows the circuit‘s interfaces (for example, input and output ports) to be defined. Through this unit, the circuit communicates with its surroundings. The entity represents the system as a black box interface accessible only via the ports. Inside that black box, another design unit—called architecture—is described. Architecture enables the behavior of a circuit or its structure to be specified. Because any system can be described in several ways, a circuit can be modeled by several architectures, but for any specific design, only one entity exists.

Architecture specification has two areas: a declarative area and the architecture body. In the former, those elements to be used in the description are declared, including the components that describe the circuit diagram, internal signals, functions and procedures, the data types to be used, and so on. But it is in the architecture body that the system is described. The instructions included in the architecture body are concurrent: That is, the instructions are executed simultaneously. These instructions serve to instance and interconnect components, execute procedures, assign values to signals via conditional or unconditional assignation instructions, and so on.

This type of description can be used to specify the circuit both structurally (schematically) and functionally (describing the system‘s equations). Procedural syntax is required to specify an algorithm, which, in VHDL, is possible through processes, functions, and procedures. A process is a concurrent instruction (because it is used within the body of an architecture) that contains sequential instructions that are executed one after another according to the established programming flow. These instructions are typical of any procedural programming language, such as loop instructions, “if . . . then . . . else” instructions, variable assignation instructions, and jumps and subroutine returns. Functions and procedures also have a procedural syntax; the difference between the two is that functions can return one value but procedures can return more than one value.

In VHDL, the user is responsible to define data types, operators, attributes, and functions. Specific instructions exist to create new data types or even to use previously defined types to create new ones. In this respect, the overload capacity of the operators and the functions is very useful: Different operators or functions can be created with the same name, distinguishable only by their parameters.

In the standard Verilog language, the basic design unit is the module. A module contains the definition of all the elements that constitute the system. It is headed by a list of input/output gates equivalent to the entity in VHDL. Inside the module internal signals (*wire*), inputs (*input*) and outputs (*output*) are defined. The module also describes the functions/structure of the system.

Certain similarities exist between the VHDL and Verilog languages: They both have a set of concurrent instructions as the basis for their descriptions. The instructions within the Verilog module are concurrent instructions and are executed when events occur at the inputs. For algorithmic descriptions, a sequentially executed program flow must be represented, and therefore a set of sequential instructions exists, composed of *always*, *initial* instructions (equivalent to processes in VHDL), procedures (*task*), and functions. *Always* and *initial* instructions are concurrent instructions (specified within a module) that contain sequential instructions. The difference between *always* and *initial* is that the latter only is executed once during the simulation whereas the former is executed each time an event occurs at input signals.

Perhaps the most important difference to be found between the VHDL and Verilog languages is their respective philosophies. Verilog is a language that originated in logic level descriptions (it was created as a logic simulator language), which makes it very suitable to generate descriptions at this level, because it contains elements that facilitate specifications (data types, primitives, specification of timing parameters, etc.). In this language, the user employs the facilities available but is not able to define new elements. In contrast, in VHDL, the user defines the elements to be used (data types, operators, etc.).

All these characteristics of the VHDL and Verilog languages make them easily adaptable to system modeling involving different description techniques (structural, functional, algorithmic). Therefore, languages are very powerful as logic synthesis languages because they cover different levels of abstraction for digital systems. These are alive languages and have update mechanisms to adapt to new requirements. Indeed, although originally designed for documentation and for simulation, today the use of these two languages is extended to other areas of application, such as high level synthesis, electrical level circuit modeling, and performance analysis.

For other applications, more suitable languages are emerging. For example, in the late 1990s the Vera language for system verification was developed. This language is oriented toward verification tasks (hardware verification language, HVL). Its features include constructions that facilitate functional verification, such as testbench creation, simulation, and formal verification. Vera has had great influence in the development of new languages such as SystemVerilog (standard IEEE 1800-2005). SystemVerilog is an extension of Verilog that includes C constructions, interfaces, and other descriptive elements. The aim of the language is to cover description levels with a greater degree of abstraction to include synthesis and, above all, verification applications; therefore, it is known as a system level design/verification language (hardware design and verification language).

To describe system specifications at a higher level, languages are required that allow those specifications to be defined without undertaking a priori decision with regard to their implementation. To meet this challenge, the SystemC language was created. It was approved as a standard language in December 2005 under the designation IEEE 1666-2005. Basically, it is composed of a C++ library aimed to facilitate hardware description from C++. The level of abstraction addressed by this language is required to specify systems that contain a global description: That is, both hardware-related aspects and those aspects associated with the software to be executed on the hardware are described. Therefore, it is a very suitable language to generate specifications in the field of hardware–software codesign environments. In such environments, the baseline is to produce system descriptions that do not pre-establish the nature of the system‘s eventual implementation (either in hardware or software). It is the codesign tools that will decide which functions will be implemented in hardware and which in software. Languages employed in this type of system are usually object-oriented programming languages.

VHDL FOR SYNTHESIS

One of the new applications for HDLs is circuit synthesis (1,2,10–12). When VHDL or Verilog are used for synthesis, certain restrictions must be imposed on the language. Basically, two factors are involved. First, the way the language handles time is decisive. Because both languages were designed for simulation, time is well defined. Simulation is controlled by events; the simulator clock runs in accordance with the status of the queued events. But synthesis tools are not controlled by events. The tool determines the timing of the tasks. In other words, it is not possible to predict when the operations will be executed because the synthesis tool schedules the tasks. The differences that exist between simulation modeling and synthesis modeling should also be taken into account. In simulation modeling, the designer can specify delays in signal assignments and in the execution of processes. In synthesis modeling, the designer can establish no absolute conditions on time whatsoever, because it depends on how the circuit has been implemented, on the technology employed, and on the objectives and restrictions that have been established. These factors will determine delays. Restrictions must be imposed on the language to limit signal assignments, beginnings, and ends of processes. Descriptions tend to be generated with syntax that is more declarative than procedural. The second decisive factor to restrict HDLs when they are used for synthesis is that certain instructions only make sense when they form part of a simulation. For example, with VHDL, file type and file object are only significant from a computing point of view, but these terms are meaningless in terms of circuits.

Moreover, the way hardware codes should be written is different from the way they should be written for programming or simulation. It would be possible to have codes that, although complying with synthesis restrictions, produce inefficient or even functionally incorrect designs. The specific rules depend on each individual synthesis tool. In most of these tools, the restrictions imposed are very similar.

This section examines, from a practical point of view, a series of guidelines that should be followed to obtain a VHDL code that is suitable not only for synthesis but also is efficient in terms of results.

Prohibited or Nonrecommendable Sentences

Some VHDL data types are not useful, or not supported for synthesis. These data types include physical types (such as time, voltage, etc.), real number types, and floating point types. Arithmetical operations that are supported by synthesis include add, subtract, and product operations. As a rule, synthesis tools do not support division or more complicated operations. For supported operations, synthesis tools implement predesigned structures that vary with the restrictions imposed on the design. The use of other structures generates a detailed description.

Another restrictive condition is the use of time. Usually, synthesis tools prohibit expressly the use of delayed signal assignations. Others simply ignore them. But the synthesis tool evidently will attempt to implement a circuit‘s functionality, and the explicit declaration of these delays makes no sense, which explains why multiple assignations to a signal are not allowed within a single sentence. Neither is it allowed, within a process, to have several assignations for the same signal all of which must be executed at the same moment. Similarly, “WAIT for XX ns” sentences are not allowed because it would be very difficult to implement such sentences (with reasonable accuracy) in hardware, which would also be a nonrecommendable design practice. The use of WAIT is very much restricted and, as will be shown, it can only be used to synchronize a process with a clock edge.

The initialization of signals or variables in the declaration sentence is not taken into account by the synthesis tool, but no error is produced. Therefore, these sentences should be used with great care, because they may cause different behavior in simulations before and after synthesis.

Design Issues

As mentioned, the way the code is written can be used to obtain designs with the same functionality but that differ greatly in terms of complexity and performance. The following is a list of recommendations to build the code to obtain efficient results:
