2. $d(\mathbf{x}, \mathbf{y}) = d(\mathbf{y}, \mathbf{x})$ for all $\mathbf{x}, \mathbf{y} \in F_2^n$.
3. $d(\mathbf{x}, \mathbf{z}) \geq d(\mathbf{x}, \mathbf{y}) + d(\mathbf{y}, \mathbf{z})$ for all $\mathbf{x}, \mathbf{y}, \mathbf{z} \in F_2^n$.

For any code C, one of the most important parameters is its *minimum distance*, defined by

$$d = \min\{d(\mathbf{x}, \mathbf{y}) | \mathbf{x} \neq \mathbf{y}, \mathbf{x}, \mathbf{y} \in C\}$$

The *Hamming weight* of a vector $\mathbf{x}$ in F_2^n is the number of nonzero components in $\mathbf{x} = (x_0, x_1, \ldots, x_{n-1})$. That is,

$$w(\mathbf{x}) = |\{i | x_i \neq 0, 0 \leq i \leq n - 1\}| = d(\mathbf{x}, \mathbf{0})$$

Note that because $d(\mathbf{x}, \mathbf{y}) = d(\mathbf{x} - \mathbf{y}, \mathbf{0}) = w(\mathbf{x} - \mathbf{y})$ for a linear code C, it follows that

$$d = \min\{w(\mathbf{z}) | \mathbf{z} \in C, \mathbf{z} \neq \mathbf{0}\}$$

Therefore, finding the minimum distance of a linear code is equivalent to finding the minimum nonzero weight among all codewords in the code.

If $w(\mathbf{c}) = i$, then $\mathbf{c}H^{tr}$ is the sum of i columns of H. Hence, an alternative description of the minimum distance of a linear code is as follows: the smallest d such that d linearly dependent columns exist in the parity-check matrix. In particular, to obtain a binary linear code of minimum distance of at least three, it is sufficient to select the columns of a parity-check matrix to be distinct and nonzero.

Sometimes we include d in the notation and refer to an $[n, k]$ code with minimum distance d as an $[n, k, d]$ code. If t components are corrupted during transmission of a codeword, we say that t errors have occurred or that an error $\mathbf{e}$ of weight t has occurred [where $\mathbf{e} = (e_0, e_1, \dots, e_{n-1}) \in F_2^n$, where $e_i = 1$ if and only if the ith component was corrupted, that is, if $\mathbf{c}$ was sent, $\mathbf{c} + \mathbf{e}$ was received].

The *error-correcting capability* of a code is defined as

$$t = \left\lfloor \frac{d-1}{2} \right\rfloor$$

where $\lfloor x \rfloor$ denotes the largest integer $\leq x$.

A code with minimum distance d can correct all errors of weight t or less, because if a codeword $\mathbf{c}$ is transmitted and an error $\mathbf{e}$ of weight $e \leq t$ occurs, the received vector $\mathbf{r} = \mathbf{c} + \mathbf{e}$ is closer in Hamming distance to the transmitted codeword $\mathbf{c}$ than to any other codeword. Therefore, decoding any received vector to the closest codeword corrects all errors of weight $\leq t$.

The code can be used for error detection only. The code can detect all errors of weight $< d$ because if a codeword is transmitted and the error has weight $< d$, then the received vector is not another codeword.

The code also can be used for a combination of error-correction and error-detection. For a given $e \leq t$, the code can correct all errors of weight $\leq e$ and in addition can detect all errors of weight at most $d - e - 1$. This is caused by the fact that no vector in F_2^n can be at distance $\leq e$ from one codeword and at the same time at a distance $\leq d - e - 1$ from another codeword. Hence, the algorithm in this case is to decode a received vector to a codeword at distance $\leq e$ if such a codeword exists and otherwise detect an error.

If C is an $[n, k]$ code, the *extended code* C^{ext} is the $[n + 1, k]$ code defined by

$$c^{\text{ext}} = \left\{ (c_{\text{ext}}, c_0, c_1, \dots c_{n-1}) \middle| (c_0, c_1, \dots, c_{n-1}) \in C, \right.$$
$$\left. c_{\text{ext}} = \sum_{i=0}^{n-1} c_i \right\}$$

That is, each codeword in C is extended by one parity bit such that the Hamming weight of each codeword becomes even. In particular, if C has odd minimum distance d, then the minimum distance of C^{ext} is $d + 1$. If H is a parity-check matrix for C, then a parity check matrix for C^{ext} is

$$\begin{pmatrix} 1 & \mathbf{1} \\ 0^{tr} & H \end{pmatrix}$$

where $\mathbf{1} = (11\dots1)$.

For any linear $[n, k]$ code C, the *dual code* $C^{\perp}$ is the $[n, n - k]$ code defined by

$$C^{\perp} = \{\mathbf{x} \in F_2^n | (\mathbf{x}, c) = 0 \text{ for all } \mathbf{c} \in C\}$$

where $(\mathbf{x}, \mathbf{c}) = \sum_{i=0}^{n-1} x_i c_i$. We say that $\mathbf{x}$ and $\mathbf{c}$ are *orthogonal* if $(\mathbf{x}, \mathbf{c}) = 0$. Therefore $C^{\perp}$ consists of all n-tuples that are orthogonal to all codewords in C and vice versa; that is, $(C^{\perp})^{\perp} = C$. It follows that $C^{\perp}$ has dimension $n - k$ because it consists of all vectors that are solutions of a system of equations with coefficient matrix G of rank k. Hence, the parity-check matrix of $C^{\perp}$ is a generator matrix of C, and similarly the generator matrix of $C^{\perp}$ is a parity-check matrix of C. In particular, $GH^{tr} = O$ [the $k \times (n - k)$ matrix of all zeros].

Example. Let C be the $[n, n - 1, 2]$ even-weight code where

$$G = \begin{pmatrix} 1 & 0 & \dots & 0 & 1 \\ 0 & 1 & \dots & 0 & 1 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \dots & 1 & 1 \end{pmatrix}$$

and

$$H = (\,1 \quad 1 \quad \dots \quad 1 \quad 1\,)$$

Then $C^{\perp}$ has H and G as its generator and parity-check matrices, respectively. It follows that $C^{\perp}$ is the $[n, 1, n]$ *repetition code* consisting of the two codewords $(00 \cdots 000)$ and $(11 \cdots 111)$.

Example. Let C be the $[2^m - 1, 2^m - 1 - m, 3]$ code, where H contains all nonzero m-tuples as its columns. This is known as the *Hamming code*. In the case when $m = 3$, a parity-check matrix already is described in Equation (1). Because all columns of the parity-check matrix are distinct and nonzero, the code has minimum distance of at least 3. The minimum distance is indeed 3 because three columns exist whose sum is zero; in fact, the sum of any two columns of H equals another column in H for this particular code.

The dual code $C^{\perp}$ is the $[2^m - 1, m, 2^{m-1}]$ *simplex code*, all of whose nonzero codewords have weight 2^{m-1}. This follows because the generator matrix has all nonzero vectors as its columns. In particular, taking any linear combination of rows, the number of columns with odd parity in the corresponding subset of rows equals 2^{m-1} (and the number with even parity is $2^{m-1} - 1$).

The extended code of the Hamming code is a $[2^m, 2^m - 1 - m, 4]$ code. Its dual code is a $[2^m, m + 1, 2^{m-1}]$ code that is known as the first-order Reed–Muller code.

SOME BOUNDS ON CODES

The *Hamming bound* states that for any (n, M, d) code, we have

$$M \sum_{i=0}^{e} \binom{n}{i} \leq 2^n$$

where $e = \lfloor (d-1)/2 \rfloor$. This follows from the fact that the M spheres

$$S_{\mathbf{c}} = \{\mathbf{x} | d(\mathbf{x}, \mathbf{c}) \le e\}$$

centered at the codewords $\mathbf{c} \in C$ are disjoint and that each sphere contains

$$\sum_{i=0}^{e} \binom{n}{i}$$

vectors.

If the spheres fill the whole space, that is,

$$\bigcup_{\mathbf{c} \in C} S_{\mathbf{c}} = F_2^n$$

then C is called *perfect*. The binary *linear* perfect codes are as follows:

- the $[n, 1, n]$ repetition codes for all odd n
- the $[2^m - 1, 2^m - 1 - m, 3]$ Hamming codes H_m for all $m \ge 2$
- the [23, 12, 7] Golay code G_{23}

We will return to the Golay code later.

GALOIS FIELDS

Finite fields, also known as Galois fields, with p^m elements exist for any prime p and any positive integer m. A Galois field of a given order p^m is unique (up to isomorphism) and is denoted by F_{p^m}.

For a prime p, let $F_p = \{0, 1, \ldots, p-1\}$ denote the integers modulo p with the two operations addition and multiplication modulo p.

To construct a Galois field with p^m elements, select a polynomial $f(x)$ with coefficients in F_p, which is irreducible over F_p; that is, $f(x)$ cannot be written as a product of two polynomials with coefficients from F_p of degree ≥ 1 (irreducible polynomials of any degree m over F_p exist).

Let

$$F_{p^m} = \{a_{m-1}x^{m-1} + a_{m-2}x^{m-2} + \ldots + a_0 | a_0, \ldots, a_{m-1} \in F_p\}$$

Then F_{p^m} is a finite field when addition and multiplication of the elements (polynomials) are done modulo $f(x)$ and modulo p. To simplify the notations, let α denote a zero of $f(x)$, that is, $f(\alpha) = 0$. If such an α exists, formally it can be defined as the equivalence class of x modulo $f(x)$. For coding theory, $p = 2$ is by far the most important case, and we assume this from now on. Note that for any $a, b \in F_{2^m}$,

$$(a+b)^2 = a^2 + b^2$$

Example. The Galois field F_{2^4} can be constructed as follows. Let $f(x) = x^4 + x + 1$ that is an irreducible polynomial over F_2. Then $\alpha^4 = \alpha + 1$ and

$$F_{2^4} = \{a_3\alpha^3 + a_2\alpha^2 + a_1\alpha + a_0 | a_0, a_1, a_2, a_3 \in F_2\}$$

Computing the powers of α, we obtain

$$\alpha^5 = \alpha \cdot \alpha^4 = \alpha(\alpha + 1) = \alpha^2 + \alpha$$
$$\alpha^6 = \alpha \cdot \alpha^5 = \alpha(\alpha^2 + \alpha) = \alpha^3 + \alpha^2$$
$$\alpha^7 = \alpha \cdot \alpha^6 = \alpha(\alpha^3 + \alpha^2) = \alpha^4 + \alpha^3 = \alpha^3 + \alpha + 1$$

and, similarly, all higher powers of α can be expressed as a linear combination of $\alpha^3, \alpha^2, \alpha$, and 1. In particular, $\alpha^{15} = 1$. We get the following table of the powers of α. In the table the polynomial $a_3\alpha^3 + a_2\alpha^2 + a_1\alpha + a_0$ is represented as $a_3a_2a_1a_0$.

i	α^i	i	α^i	i	α^i
0	0001	5	0110	10	0111
1	0010	6	1100	11	1110
2	0100	7	1011	12	1111
3	1000	8	0101	13	1101
4	0011	9	1010	14	1001

Hence, the elements $1, \alpha, \alpha^2, \ldots, \alpha^{14}$ are all the nonzero elements in F_{2^4}. Such an element α that generates the nonzero elements of F_{2^m} is called a *primitive element* in F_{2^m}. An irreducible polynomial $g(x)$ with a primitive element as a zero is called a primitive polynomial. Every finite field has a primitive element, and therefore, the multiplicative subgroup of a finite field is cyclic.

All elements in F_{2^m} are roots of the equation $x^{2^m} + x = 0$. Let β be an element in F_{2^m}. It is important to study the polynomial $m(x)$ of smallest degree with coefficients in F_2, which has β as a zero. This polynomial is called the *minimal polynomial* of β over F_2.

First, observe that if $m(x) = \sum_{i=0}^{\kappa} m_i x^i$ has coefficients in F_2 and β as a zero, then

$$m(\beta^2) = \sum_{i=0}^{\kappa} m_i \beta^{2i} = \sum_{i=0}^{\kappa} m_i^2 \beta^{2i} = \left(\sum_{i=0}^{\kappa} m_i \beta^i\right)^2 = (m(\beta))^2 = 0$$

Hence, $m(x)$ has $\beta, \beta^2, \ldots, \beta^{2^{\kappa-1}}$ as zeros, where κ is the smallest integer such that $\beta^{2^\kappa} = \beta$. Conversely, the polynomial with exactly these zeros can be shown to be a binary irreducible polynomial.

Example. We will find the minimal polynomial of all the elements in F_{2^4}. Let α be a root of $x^4 + x + 1 = 0$; that is, $\alpha^4 = \alpha + 1$. The minimal polynomials over F_2 of α^i for $0 \le i \le 14$ are denoted $m_i(x)$. Observe by the above argument that $m_{2i}(x) = m_i(x)$, where the indices are taken modulo 15. It follows that

$$\begin{aligned}
m_0(x) &= (x+\alpha^0) = x+1\\
m_1(x) &= (x+\alpha)(x+\alpha^2)(x+\alpha^4)(x+\alpha^8) = x^4+x+1\\
m_3(x) &= (x+\alpha^3)(x+\alpha^6)(x+\alpha^{12})(x+\alpha^9)\\
&= x^4+x^3+x^2+x+1\\
m_5(x) &= (x+\alpha^5)(x+\alpha^{10}) = x^2+x+1\\
m_7(x) &= (x+\alpha^7)(x+\alpha^{14})(x+\alpha^{13})(x+\alpha^{11}) = x^4+x^3+1\\
m_9(x) &= m_3(x)\\
m_{11}(x) &= m_7(x)\\
m_{13}(x) &= m_7(x)
\end{aligned}$$

To verify this, one simply computes the coefficients and uses the preceding table of F_{2^4} in the computations. For example,

$$\begin{aligned}
m_5(x) &= (x+\alpha^5)(x+\alpha^{10}) = x^2 + (\alpha^5+\alpha^{10})x + \alpha^5\cdot\alpha^{10}\\
&= x^2+x+1
\end{aligned}$$

This also leads to a factorization into irreducible polynomials,

$$\begin{aligned}
x^{2^4}+x &= x\prod_{j=0}^{14}(x+\alpha^j)\\
&= x(x+1)(x^2+x+1)(x^4+x+1)\\
&\quad (x^4+x^3+x^2+x+1)(x^4+x^3+1)\\
&= xm_0(x)m_1(x)m_3(x)m_5(x)m_7(x)
\end{aligned}$$

In fact, in general it holds that $x^{2^m}+x$ is the product of all irreducible polynomials over F_2 of degree that divides m.

Let $C_i = \{i\,2^j \mod n | j = 0, 1, \ldots\}$, which is called the *cyclotomic coset* of i (mod n). Then, the elements of the cyclotomic coset C_i (mod 2^m-1) correspond to the exponents of the zeros of $m_i(x)$. That is,

$$m_i(x) = \prod_{j\in C_i}(x-\alpha^j)$$

The cyclotomic cosets (mod n) are important in the next section when cyclic codes of length n are discussed.

CYCLIC CODES

Many good linear codes that have practical and efficient decoding algorithms have the property that a cyclic shift of a codeword is again a codeword. Such codes are called cyclic codes.

We can represent the set of n-tuples over F_2^n as polynomials of degree $< n$ in a natural way. The vector

$$\mathbf{c} = (c_0, c_1, \ldots, c_{n-1})$$

is represented as the polynomial

$$c(x) = c_0 + c_1x + c_2x^2 + \cdots + c_{n-1}x^{n-1}.$$

A *cyclic shift*

$$\sigma(\mathbf{c}) = (c_{n-1}, c_0, c_1, \ldots, c_{n-2})$$

of $\mathbf{c}$ is then represented by the polynomial

$$\begin{aligned}
\sigma(c(x)) &= c_{n-1} + c_0x + c_1x^2 + \cdots + c_{n-2}x^{n-1}\\
&= x(c_{n-1}x^{n-1} + c_0 + c_1x + \cdots + c_{n-2}x^{n-2})\\
&\quad + c_{n-1}(x^n+1)\\
&\equiv xc(x) \pmod{x^n+1}
\end{aligned}$$

Example. Rearranging the columns in the parity-check matrix of the [7, 4] Hamming code in Equation (1), an equivalent code is obtained with parity-check matrix

$$H = \begin{pmatrix} 1 & 0 & 0 & 1 & 0 & 1 & 1\\ 0 & 1 & 0 & 1 & 1 & 1 & 0\\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{pmatrix} \tag{2}$$

This code contains 16 codewords, which are represented next in polynomial form:

$$\begin{array}{lrr}
1000110 \leftrightarrow & x^5+x^4+1 = & (x^2+x+1)g(x)\\
0100011 \leftrightarrow & x^6+x^5+x = & (x^3+x^2+x)g(x)\\
1010001 \leftrightarrow & x^6+x^2+1 = & (x^3+x+1)g(x)\\
1101000 \leftrightarrow & x^3+x+1 = & g(x)\\
0110100 \leftrightarrow & x^4+x^2+x = & xg(x)\\
0011010 \leftrightarrow & x^5+x^3+x^2 = & x^2g(x)\\
0001101 \leftrightarrow & x^6+x^4+x^3 = & x^3g(x)\\
0010111 \leftrightarrow & x^6+x^5+x^4+x^2 = & (x^3+x^2)g(x)\\
1001011 \leftrightarrow & x^6+x^5+x^3+1 = & (x^3+x^2+x+1)g(x)\\
1100101 \leftrightarrow & x^6+x^4+x+1 = & (x^3+1)g(x)\\
1110010 \leftrightarrow & x^5+x^2+x+1 = & (x^2+1)g(x)\\
0111001 \leftrightarrow & x^6+x^3+x^2+x = & (x^3+x)g(x)\\
1011100 \leftrightarrow & x^4+x^3+x^2+1 = & (x+1)g(x)\\
0101110 \leftrightarrow & x^5+x^4+x^3+x = & (x^2+x)g(x)\\
0000000 \leftrightarrow & 0 = & 0\\
1111111 \leftrightarrow & x^6+x^5+x^4+x^3+x^2+x+1 & \\
 & = & (x^3+x^2+1)g(x)
\end{array}$$

By inspection it is easy to verify that any cyclic shift of a codeword is again a codeword. Indeed, the 16 codewords in the code are $\mathbf{0}$, $\mathbf{1}$ and all cyclic shifts of (1000110) and (0010111). The unique nonzero polynomial in the code of lowest possible degree is $g(x) = x^3+x+1$, and $g(x)$ is called the *generator polynomial* of the cyclic code. The code consists of all polynomials $c(x)$, which are multiples of $g(x)$. Note that the degree of $g(x)$ is $n-k=3$ and that $g(x)$ divides x^7+1 because

$$x^7+1 = (x+1)(x^3+x+1)(x^3+x^2+1).$$

Therefore the code has a simple description in terms of the set of code polynomials as

$$C = \{c(x)|c(x) = u(x)(x^3+x+1),\quad deg(u(x)) < 4\}$$

This situation holds in general for any cyclic code.

For any cyclic $[n, k]$ code C, we have

$$C = \{c(x)|c(x) = u(x)g(x),\quad deg(u(x)) < k\}$$

for a polynomial $g(x)$ of degree $n-k$ that divides x^n+1.

We can show this as follows: Let $g(x)$ be the generator polynomial of C, which is the nonzero polynomial of smallest degree r in the code C. Then the cyclic shifts $g(x)$, $xg(x)$, $\cdots$, $x^{n-r-1}g(x)$ are codewords as well as any linear combination $u(x)g(x)$, where $\deg(u(x)) < r$. These are the only 2^{n-r} codewords in the code C, because if $c(x)$ is a codeword, then

$$c(x) = u(x)g(x) + s(x), \text{where} \quad deg(s(x)) < deg(g(x))$$

By linearity, $s(x)$ is a codeword and therefore $s(x) = 0$ because $\deg(s(x)) < \deg(g(x))$ and $g(x)$ is the nonzero polynomial of smallest degree in the code. It follows that C is as described previously. Since C has 2^{n-r} codewords, it follows that $n - r = k$; i.e., $\deg(g(x)) = n - k$.

Finally, we show that $g(x)$ divides $x^n + 1$. Let $c(x) = c_0 + c_1x + \cdots + c_{n-1}x^{n-1}$ be a nonzero codeword shifted such that $c_{n-1} = 1$. Then the cyclic shift of $c(x)$ given by $\sigma(c(x)) = c_{n-1} + \ c_0x + c_1x + \cdots + c_{n-2}x^{n-1}$ also is a codeword and

$$\sigma(c(x)) = xc(x) + (x^n + 1)$$

Because both codewords $c(x)$ and $\sigma(c(x))$ are divisible by $g(x)$, it follows that $g(x)$ divides $x^n + 1$.

Because the generator polynomial of a cyclic code divides $x^n + 1$, it is important to know how to factor $x^n + 1$ into irreducible polynomials. Let n be odd. Then an integer m exists such that $2^m \equiv 1 \pmod{n}$ and an element $\alpha \in F_{2^m}$ exists of order n [if ω is a primitive element of F_{2^m}, then α can be taken to be $\alpha = \omega^{(2^m-1)/n}$].

We have

$$x^n + 1 = \prod_{i=0}^{n-1}(x + \alpha^i)$$

Let $m_i(x)$ denote the minimal polynomial of α^i; that is, the polynomial of smallest degree with coefficients in F_2 and having α^i as a zero. The generator polynomial $g(x)$ can be written as

$$g(x) = \prod_{i \in I}(x + \alpha^i)$$

where I is a subset of $\{0, 1, \ldots, n - 1\}$, called the *defining set* of C with respect to α. Then $m_i(x)$ divides $g(x)$ for all $i \in I$. Furthermore, $g(x) \prod_{j=1}^{l} m_{i_j}(x)$ for some i_1, $i_2, \ldots, i_l$.

Therefore we can describe the cyclic code in alternative equivalent ways as

$$\begin{aligned} C &= \{c(x) | m_i(x) \text{divides } c(x), \text{for all } i \in I\} \\ C &= \{c(x) | c(\alpha^i) = 0, \text{for all } i \in I\} \\ C &= \{\mathbf{c} \in F_q^n | \mathbf{c}H^{tr} = 0\} \end{aligned}$$

where

$$H = \begin{pmatrix} 1 & \alpha^{i_1} & \alpha^{2i_1} & \cdots & \alpha^{(n-1)i_1} \\ 1 & \alpha^{i_2} & \alpha^{2i_2} & \cdots & \alpha^{(n-1)i_2} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & \alpha^{i_l} & \alpha^{2i_l} & \cdots & \alpha^{(n-1)i_l} \end{pmatrix}$$

The encoding for cyclic codes usually is done in one of two ways. Let $u(x)$ denote the information polynomial of degree $< k$. The two ways are as follows:

1. Encode into $u(x)g(x)$.
2. Encode into $c(x) = x^{n-k}u(x) + s(x)$, where $s(x)$ is the polynomial such that
   - $s(x) \equiv x^{n-k}u(x) \pmod{g(x)}$ [thus $g(x)$ divides $c(x)$],
   - $\deg(s(x)) < \deg(g(x))$.

The last of these two methods is systematic; that is, the last k bits of the codeword are the information bits.

BCH CODES

An important task in coding theory is to design codes with a guaranteed minimum distance d that correct all errors of Hamming weight $\lfloor \frac{d-1}{2} \rfloor$. Such codes were designed independently by Bose and Ray-Chaudhuri (1) and by Hocquenghem (2) and are known as BCH codes. To construct a BCH code of *designed distance d*, the generator polynomial is chosen to have $d - 1$ "consecutive" powers of α as zeros

$$\alpha^b, \alpha^{b+1}, \ldots, \alpha^{b+d-2}$$

That is, the defining set I with respect to α contains a set of $d - 1$ consecutive integers (mod n). The parity-check matrix of the BCH code is

$$H = \begin{pmatrix} 1 & \alpha^b & \alpha^{2b} & \cdots & \alpha^{(n-1)b} \\ 1 & \alpha^{b+1} & \alpha^{2(b+1)} & \cdots & \alpha^{(n-1)(b+1)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & \alpha^{b+d-2} & \alpha^{2(b+d-2)} & \cdots & \alpha^{(n-1)(b+d-2)} \end{pmatrix}$$

To show that this code has a minimum distance of at least d, it is sufficient to show that any $d - 1$ columns are linear independent. Suppose a linear dependency between the $d - 1$ columns corresponds to $\alpha^{i_1b}, \alpha^{i_2b}, \ldots, \alpha^{i_{d-1}b}$. In this case the $(d - 1) \times (d - 1)$ submatrix obtained by retaining these columns in H has determinant

$$\begin{aligned} &\begin{vmatrix} \alpha^{i_1b} & \alpha^{i_2b} & \cdots & \alpha^{i_{d-1}b} \\ \alpha^{i_{1(b+1)}} & \alpha^{i_{2(b+1)}} & \cdots & \alpha^{i_{d-1}(b+1)} \\ \vdots & \vdots & \ddots & \vdots \\ \alpha^{i_1(b+d-2)} & \alpha^{i_2(b+d-2)} & \cdots & \alpha^{i_{d-1}(b+d-2)} \end{vmatrix} \\ = \quad & \alpha^{b(i_1+i_2+\ldots+i_{d-2})} \begin{vmatrix} 1 & 1 & \cdots & 1 \\ \alpha^{i_1} & \alpha^{i_2} & \cdots & \alpha^{i_{d-1}} \\ \vdots & \vdots & \vdots & \vdots \\ \alpha^{(d-2)i_1} & \alpha^{(d-2)i_2} & \cdots & \alpha^{(d-2)i_{d-1}} \end{vmatrix} \\ = \quad & \alpha^{b(i_1+i_2+\ldots+i_{d-2})} \prod_{k<r}(\alpha^{i_k} - \alpha^{i_r}) \neq 0 \end{aligned}$$

because the elements $\alpha^{i_1}, \alpha^{i_2}, \cdots, \alpha^{i_{d-1}}$ are distinct (the last equality follows from the fact that the last determinant is a Vandermonde determinant). It follows that the BCH code has a minimum Hamming distance of at least d.

If $b = 1$, which is often the case, the code is called a *narrow-sense* BCH code. If $n = 2^m - 1$, the BCH code is called a *primitive* BCH code. A binary single error-correcting primitive BCH code is generated by $g(x) = m_1(x)$. The zeros of $g(x)$ are α^{2^i}, $i = 0, 1, \ldots, m - 1$. The parity-check matrix is

$$H = (\,1 \quad \alpha^1 \quad \alpha^2 \quad \ldots \quad \alpha^{2^m-2}\,)$$

This code is equivalent to the Hamming code because α is a primitive element of F_{2^m}.

To construct a binary double-error-correcting primitive BCH code, we let $g(x)$ have α, α^2, α^3, α^4 as zeros. Therefore, $g(x) = m_1(x)m_3(x)$ is a generator polynomial of this code. The parity-check matrix of a double-error-correcting BCH code is

$$H = \begin{pmatrix} 1 & \alpha^1 & \alpha^2 & \ldots & \alpha^{2^m-2} \\ 1 & \alpha^3 & \alpha^6 & \ldots & \alpha^{3(2^m-2)} \end{pmatrix}$$

In particular, a binary double-error correcting BCH code of length $n = 2^4 - 1 = 15$, is obtained by selecting

$$\begin{aligned} g(x) &= m_1(x)m_3(x) \\ &= (x^4 + x + 1)(x^4 + x^3 + x^2 + x + 1) \\ &= x^8 + x^7 + x^6 + x^4 + 1 \end{aligned}$$

Similarly, a binary triple-error correcting BCH code of the same length is obtained by choosing the generator polynomial

$$\begin{aligned} g(x) &= m_1(x)m_3(x)m_5(x) \\ &= (x^4 + x + 1)(x^4 + x^3 + x^2 + x + 1)(x^2 + x + 1) \\ &= x^{10} + x^8 + x^5 + x^4 + x^2 + x + 1 \end{aligned}$$

The main interest in BCH codes is because they have a very fast and efficient decoding algorithm. We will describe this later.

AUTOMORPHISMS

Let C be a binary code of length n. Consider a permutation π of the set $\{0, 1, \ldots, n - 1\}$; that is, π is a one-to-one function of the set of coordinate positions onto itself.

For a codeword $\mathbf{c} \in C$, let

$$\pi(\mathbf{c}) = (c_{\pi(0)}, c_{\pi(1)}, \ldots, c_{\pi(n-1)})$$

That is, the coordinates are permuted by the permutation π. If

$$\{\pi(\mathbf{c}) | \mathbf{c} \in C\} = C$$

then π is called an *automorphism* of the code C.

Example. Consider the following (nonlinear code):

$$C = \{101, 011\}$$

The actions of the six possible permutations on three elements are given in the following table. The permutations, which are automorphisms, are marked by a star.

$\pi(0)$	$\pi(1)$	$\pi(2)$	$\pi((101))$	$\pi((011))$	
0	1	2	101	011	⋆
0	2	1	110	011	
1	0	2	011	101	⋆
1	2	0	011	110	
2	0	1	110	101	
2	1	0	101	110	

In general, the set of automorphisms of a code C is a group, the *Automorphism group* Aut(C). We note that

$$\sum_{i=0}^{n-1} x_i y_i = \sum_{i=0}^{n-1} x_{\pi(i)} y_{\pi(i)}$$

and so $(\mathbf{x}, \mathbf{y}) = 0$ if and only if $(\pi(\mathbf{x}), \pi(\mathbf{y})) = 0$. In particular, this implies that

$$\mathrm{Aut}(C) = \mathrm{Aut}(C^{\perp})$$

That is, C and $C^{\perp}$ have the same automorphism group.

For a *cyclic* code C of length n, we have by definition $\sigma(\mathbf{c}) \in C$ for all $\mathbf{c} \in C$, where $\sigma(i) \equiv i - 1 \pmod{n}$. In particular, $\sigma \in \mathrm{Aut}(C)$. For n odd, the permutation δ defined by $\delta(j) = 2j \pmod{n}$ also is contained in the automorphism group. To show this permutation, it is easier to show that $\delta^{-1} \in \mathrm{Aut}(C)$. We have

$$\begin{aligned} \delta^{-1}(2j) &= j & &\text{for } j = 0, 1, \ldots, (n-1)/2 \\ \delta^{-1}(2j+1) &= (n+1)/2 + j & &\text{for } j = 0, 1, \ldots, (n-1)/2 - 1 \end{aligned}$$

Let $g(x)$ be a generator polynomial for C, and let $\sum_{i=0}^{n-1} c_i x^i = a(x)g(x)$. Because $x^n \equiv 1 \pmod{x^n + 1}$, we have

$$\begin{aligned} \sum_{i=0}^{n-1} c_{\delta^{-1}(i)} x^i &= \sum_{j=0}^{(n-1)/2} c_j x^{2j} + \sum_{j=0}^{(n-1)/2} c_{(n+1)/2+j} x^{2j+1} \\ &= \sum_{j=0}^{(n-1)/2} c_j x^{2j} + \sum_{j=(n+1)/2}^{n-1} c_j x^{2j} \\ &= a(x^2)g(x^2) = (a(x^2)g(x))g(x), \quad (\mathrm{mod}\, x^n + 1) \end{aligned}$$

and so $\delta^{-1}(\mathbf{c}) \in C$; that is, $\delta^{-1} \in \mathrm{Aut}(C)$ and so $\delta \in \mathrm{Aut}(C)$.

The automorphism group Aut(C) is *transitive* if for each pair (i, j) a $\pi \in \mathrm{Aut}(C)$ exists such that $\pi(i) = j$. More general, Aut(C) is t-fold transitive if, for distinct $i_1, i_2, \ldots, i_t$ and distinct $j_1, j_2, \ldots, j_t$, a $\pi \in \mathrm{Aut}(C)$ exists such that $\pi(i_1) = j_1$, $\pi(i_2) = j_2, \ldots, \pi(i_t) = j_t$.

Example. Any cyclic $[n, k]$ code has a transitive automorphism group because σ repeated s times, where $s \equiv i - j \pmod{n}$, maps i to j.

Example. The (nonlinear) code $C = \{101, 011\}$ was considered previously. Its automorphism group is not transitive because there is no automorphism π such that $\pi(0) = 2$.

Example. Let C be the $[9, 3]$ code generated by the matrix

$$\begin{pmatrix} 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 \end{pmatrix}$$

This is a cyclic code, and we will determine its automorphism group. The all zero and the all one vectors in C are transformed into themselves by any permutation. The vectors of weight 3 are the rows of the generator matrix, and the vectors of weight 6 are the complements of these vectors. Hence, we see that π is an automorphism if and only if it leaves the set of the three rows of the generator matrix invariant, that is, if and only if the following conditions are satisfied:

$$\begin{aligned} \pi(0) \equiv \pi(3) \equiv \pi(6) \pmod 3 \\ \pi(1) \equiv \pi(4) \equiv \pi(7) \pmod 3 \\ \pi(2) \equiv \pi(5) \equiv \pi(8) \pmod 3 \end{aligned}$$

Note that the two permutations σ and δ defined previously satisfy these conditions, as they should. They are listed explicitly in the following table:

i	0	1	2	3	4	5	6	7	8
$\sigma(i)$	8	0	1	2	3	4	5	6	7
$\delta(i)$	0	2	4	6	8	1	3	5	7

The automorphism group is transitive because the code is cyclic but not doubly transitive. For example, no automorphism π exists such that $\pi(0) = 0$ and $\pi(3) = 1$ because 0 and 1 are not equivalent modulo 3. A simple counting argument shows that Aut(C) has order 1296: First choose $\pi(0)$; this can be done in nine ways. Then two ways exist to choose $\pi(3)$ and $\pi(6)$. Next choose $\pi(1)$; this can be done in six ways. There are again two ways to choose $\pi(4)$ and $\pi(7)$. Finally, there are 3×2 ways to choose $\pi(2)$, $\pi(5)$, $\pi(8)$. Hence, the order is $9 \times 2 \times 6 \times 2 \times 3 \times 2 = 1296$.

Example. Consider the extended Hamming code H_m^{ext}. The positions of the codewords correspond to the elements of F_{2^m} and are permuted by the affine group

$$AG = \{\pi | \pi(x) = ax + b, a, b \in F_{2^m}, a \neq 0\}$$

This is the automorphism group of H_m^{ext}. It is double transitive.

THE WEIGHT DISTRIBUTION OF A CODE

Let C be a binary linear $[n, k]$ code. As we noted,

$$d(\mathbf{x}, \mathbf{y}) = d(\mathbf{x} - \mathbf{y}, 0) = w(\mathbf{x} - \mathbf{y})$$

If $\mathbf{x}$, $\mathbf{y} \in C$, then $\mathbf{x} - \mathbf{y} \in C$ by the linearity of C. In particular, this means that the set of distances from a fixed codeword to all the other codewords is independent of which codeword we fix; that is, the code looks the same from any codeword. In particular, the set of distances from the codeword **0** is the set of *Hamming weights* of the codewords. For $i = 0, 1, \ldots, n$, let A_i denote the number of codewords of weight i. The sequence

$$A_0, A_1, A_2, \ldots, A_n$$

is called the *weight distribution* of the code C. The corresponding polynomial

$$A_C(z) = A_0 + A_1 z + A_2 z^2 + +A_n z^n$$

is known as the *weight enumerator polynomial* of C.

The polynomials $A_C(z)$ and $A_{C^\perp}(z)$ are related by the fundamental MacWilliams identity:

$$A_{C^\perp}(z) = 2^{-k}(1 + z)^n A_C\left(\frac{1 - z}{1 + z}\right)$$

Example. The $[2^m - 1, m]$ simplex code has the weight distribution polynomial $1 + (2^m - 1)z^{2^{m-1}}$. The dual code is the $[2^m - 1,\ 2^m - 1 - m]$ Hamming code with weight enumerator polynomial

$$\begin{aligned} &2^{-m}(1 + z)^{2^m - 1}\left(1 + (2^m - 1)\left(\frac{1 - z}{1 + z}\right)^{2^{m-1}}\right) \\ &\quad = 2^{-m}(1 + z)^{2^m - 1} + (1 - 2^{-m})(1 - z)^{2^{m-1}}(1 + z)^{2^{m-1} - 1} \end{aligned}$$

For example, for $m = 4$, we get the weight distribution of the [15, 11] Hamming code:

$$\begin{aligned} &1 + 35z^3 + 105z^4 + 168z^5 + 280z^6 + 435z^7 + 435z^8 + 280z^9 \\ &\quad + 168z^{10} + 105z^{11} + 35z^{12} + z^{15} \end{aligned}$$

Consider a binary linear code C that is used purely for error detection. Suppose a codeword $\mathbf{c}$ is transmitted over a binary symmetric channel with bit error probability p. The probability of receiving a vector $\mathbf{r}$ at distance i from $\mathbf{c}$ is $p^i(1 - p)^{n-i}$, because i positions are changed (each with probability p) and $n - i$ are unchanged (each with probability $1 - p$). If $\mathbf{r}$ is not a codeword, then this will be discovered by the receiver. If $\mathbf{r} = \mathbf{c}$, then no errors have occurred. However, if $\mathbf{r}$ is another codeword, then an undetectable error has occurred. Hence, the *probability of undetected error* is given by

$$\begin{aligned} P_{\text{ue}}(C, p) &= \sum_{\mathbf{c}\prime \neq \mathbf{c}} p^{d(\mathbf{c}\prime, \mathbf{c})}(1 - p)^{n - d(\mathbf{c}\prime, \mathbf{c})} \\ &= \sum_{\mathbf{c}' \neq 0} p^{w(\mathbf{c}')}(1 - p)^{n - w(\mathbf{c}')} \\ &= \sum_{i=1}^{n} A_i p^i (1 - p)^{n-i} \\ &= (1 - p)^n A_C\left(\frac{p}{1 - p}\right) - (1 - p)^n \end{aligned}$$

From the MacWilliams identity, we also get

$$P_{\text{ue}}(C^\perp, p) = 2^{-k} A_C(1 - 2p) - (1 - p)^n$$

Example. For the $[2^m - 1, 2^m - 1 - m]$ Hamming code H_m, we get

$$P_{\text{ue}}(H_m, p) = 2^{-m}(1 + (2^m - 1)(1 - 2p)^{2^{m-1}}) - (1 - p)^{2^{m-1}}$$

More information on the use of codes for error detection can be found in the books by Kløve and Korzhik (see Further Reading).

THE BINARY GOLAY CODE

The Golay code G_{23} has received much attention. It is practically useful and has a several interesting properties. The code can be defined in various ways. One definition is that G_{23} is the cyclic code generated by the irreducible polynomial

$$x^{11} + x^9 + x^7 + x^6 + x^5 + x + 1$$

which is a factor of $x^{23} + 1$ over F_2. Another definition is the following: Let H denote the [7, 4] Hamming code, and let H^* be the code whose codewords are the reversed of the codewords of H. Let

$$C = \{(\mathbf{u} + \mathbf{x}, \mathbf{v} + \mathbf{x}, \mathbf{u} + \mathbf{v} + \mathbf{x}) | \mathbf{u}, \mathbf{v} \in H^{\text{ext}}, \mathbf{x} \in (H^*)^{\text{ext}}\}$$

where H^{ext} is the [8, 4] extended Hamming code and $(H^*)^{\text{ext}}$ is the [8, 4] extended H^*. The code C is a [24, 12, 8] code. Puncturing the last position, we get a [23, 12, 7] code that is (equivalent to) the Golay code.

The weight distribution of G_{23} is given by the following table:

i	A_i
0, 23	1
7, 16	253
8, 15	506
11, 12	1288

The automorphism group Aut(G_{23}) of the Golay code is the Mathieu group M_{23}, a simple group of order $10200960 = 2^7 \times 3^2 \times 5 \times 7 \times 11 \times 23$, which is fourfold transitive.

Much information about G_{23} can be found in the book by MacWilliams and Sloane and in the *Handbook of Coding Theory* (see Further Reading).

DECODING

Suppose that a codeword $\mathbf{c}$ from the $[n, k]$ code C was sent and that an error $\mathbf{e}$ occurred during the transmission over the noisy channel. Based on the received vector $\mathbf{r} = \mathbf{c} + \mathbf{e}$, the receiver has to make an estimate of what was the transmitted codeword. Because error patterns of lower weight are more probable than error patterns of higher weight, the problem is to estimate an error $\hat{\mathbf{e}}$ such that the weight of $\hat{\mathbf{e}}$ is as small as possible. He will then decode the received vector $\mathbf{r}$ into $\hat{\mathbf{c}} = \mathbf{r} + \hat{\mathbf{e}}$.

If H is a parity-check matrix for C, then $\mathbf{c}H^{tr} = \mathbf{0}$ for all codewords $\mathbf{c}$. Hence,

$$\mathbf{r}H^{tr} = (\mathbf{c} + \mathbf{e})H^{tr} = \mathbf{c}H^{tr} + \mathbf{e}H^{tr} = \mathbf{e}H^{tr} \tag{3}$$

The vector

$$\mathbf{s} = \mathbf{e}H^{tr}$$

is known as the *syndrome* of the error $\mathbf{e}$; Equation (3) shows that $\mathbf{s}$ can be computed from $\mathbf{r}$. We now have the following outline of a decoding strategy:

1. Compute the syndrome $\mathbf{s} = \mathbf{r}H^{tr}$.
2. Estimate an error $\hat{\mathbf{e}}$ of smallest weight corresponding to the syndrome $\mathbf{s}$.
3. Decode to $\hat{\mathbf{c}} = \mathbf{r} + \hat{\mathbf{e}}$.

The hard part is, of course, step 2.

For any vector $\mathbf{x} \in F_2^n$, the set $\{\mathbf{x} + \mathbf{c} \mid \mathbf{c} \in C\}$ is a *coset* of C. All the elements of the coset have the same syndrome, namely, $\mathbf{x}H^{tr}$. There are 2^{n-k} cosets, one for each syndrome in F_2^{n-k}, and the set of cosets is a partition of F_2^n. We can rephrase step 2 as follows: Find a vector $\mathbf{e}$ of smallest weight in the coset with syndrome $\mathbf{s}$.

Example. Let C be the [6, 3, 3] code with parity-check matrix

$$H = \begin{pmatrix} 1 & 1 & 0 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 1 & 0 & 0 & 1 \end{pmatrix}$$

A *standard array* for C is the following array (the eight columns to the right):

000	000000	001011	010101	011110	100110	101101	110011	111000
110	100000	101011	110101	111110	000110	001101	010011	011000
101	010000	011011	000101	001110	110110	111101	100011	101000
011	001000	000011	011101	010110	101110	100101	111011	110000
100	000100	001111	010001	011010	100010	101001	110111	111100
010	000010	001001	010111	011100	100100	101111	110001	111010
001	000001	001010	010100	011111	100111	101100	110010	111001
111	100001	101010	110100	111111	000111	001100	010010	011001

Each row in the array is a listing of a coset of C; the first row is a listing of the code itself. The vectors in the first column have minimal weight in their cosets and are known as *coset leaders*. The choice of coset leader may not be unique. For example, in the last coset there are three vectors of minimal weight. Any entry in the array is the sum of the codeword at the top of the column and the coset leader (at the left in the row). Each vector of F_2^6 is listed exactly once in the array. The standard array can be used to decode: Locate $\mathbf{r}$ in the array and decode the codeword at the top of the corresponding column (that is, the coset leader is assumed to be the error pattern). However, this method is not practical; except for small n, the standard array of 2^n entries is too large to store (also locating $\mathbf{r}$ may be a problem). A step to simplify the method is to store a table of coset leaders corresponding to the 2^{n-k} syndromes. In the table above, this method is illustrated by listing the syndromes at the left. Again this alternative is possible only if $n - k$ is small. For carefully designed codes, it is possible to *compute* $\mathbf{e}$ from the syndrome. The simplest case is single errors: If $\mathbf{e}$ is an error pattern of weight 1, where the 1 is in the ith position, then the corresponding syndrome is in the ith column of H; hence, from H and the syndrome, we can determine i.

Example. Let H be the $m \times (2^m - 1)$ parity-check matrix where the ith column is the binary expansion of the integer i for $i = 1, 2, \ldots, 2^m - 1$. The corresponding $[2^m - 1, 2^m - 1 - m, 3]$ Hamming code corrects all single errors. Decoding is done as follows: Compute the syndrome $\mathbf{s} = (s_0, s_1, \ldots, s_{m-1})$. If $\mathbf{s} \neq \mathbf{0}$, then correct position $i = \sum_{j=0}^{m-1} s_j 2^j$.

Example. Let

$$H = \begin{pmatrix} 1 & \alpha & \alpha^2 & \cdots & \alpha^{n-1} \\ 1 & \alpha^3 & \alpha^6 & \cdots & \alpha^{3(n-1)} \end{pmatrix}$$

where $\alpha \in F_{2^m}$ and $n = 2^m - 1$. This is the parity-check matrix for the double error-correcting BCH code. It is convenient to have a similar representation of the syndromes:

$$\mathbf{s} = (S_1, S_3) \quad \text{where} \quad S_1, S_3 \in F_{2^m}$$

Depending on the syndrome, there are several cases:

1. If no errors have occurred, then clearly $S_1 = S_3 = 0$.
2. If a single error has occurred in the ith position (that is, the position corresponding to α^i), then $S_1 = \alpha^i$ and $S_3 = \alpha^{3i}$. In particular, $S_3 = S^3{}_1$.
3. If two errors have occurred in positions i and j, then

$$S_1 = \alpha^i + \alpha^j, S_3 = \alpha^{3i} + \alpha^{3j}$$

This implies that $S^3{}_1 = S_3 + \alpha^i\alpha^j S_1 \neq S_3$. Furthermore, $x_1 = \alpha^{-i}$ and $x_2 = \alpha^{-j}$ are roots of the equation

$$1 + S_1 x + \frac{S_1^3 + S_3}{S_1} x^2 = 0. \qquad (4)$$

This gives the following procedure to correct two errors:

- Compute S_1 and S_3.
- If $S_1 = S_3 = 0$, then assume that no errors have occurred.
- Else, if $S^3 = S_1^3 \neq 0$, then one error has occurred in the ith position determined by $S_1 = \alpha^i$.
- Else (if $S_3 \neq S_1^3$), consider the equation

$$1 + S_1 x + (S_1^3 + S_3)/S_1 x^2 = 0$$

- If the equation has two roots α^{-i} and α^{-j}, then errors have occurred in positions i and j.

Else (if the equation has no roots in F_{2^m}), then more than two errors have occurred.

Similar explicit expressions (in terms of the syndrome) for the coefficients of an equation with the error positions as roots can be found for t error-correcting BCH codes when $t = 3$, $t = 4$, etc., but they become increasingly complicated. However, an efficient algorithm to determine the equation exists, and we describe this is some detail next.

Let α be a primitive element in F_{2^m}. A parity-check matrix for the primitive t-error-correcting BCH code is

$$H = \begin{pmatrix} 1 & \alpha & \alpha^2 & \cdots & \alpha^{n-1} \\ 1 & \alpha^3 & \alpha^6 & \cdots & \alpha^{3(n-1)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & \alpha^{2t-1} & \alpha^{2(2t-1)} & \cdots & \alpha^{(2t-1)(n-1)} \end{pmatrix}$$

where $n = 2^m - 1$. Suppose errors have occurred in positions $i_1, i_2, \ldots, i_\tau$, where $\tau \leq t$. Let $X_j = \alpha^{i_j}$ for $j = 1, 2, \ldots, \tau$. The *error locator polynomial* $\Lambda(x)$ is defined by

$$\Lambda(x) = \prod_{j=1}^{\tau}(1 + X_j x) = \sum_{l=0}^{\tau} \lambda_l x^l$$

The roots of $\Lambda(x) = 0$ are $X^{-1}{}_j$. Therefore, if we can determine $\Lambda(x)$, then we can determine the locations of the errors. Expanding the expression for $\Lambda(x)$, we get

$$\begin{aligned}
\lambda_0 &= 1 \\
\lambda_1 &= X_1 + X_2 + \cdots + X_\tau \\
\lambda_2 &= X_1X_2 + X_1X_3 + X_2X_3 + \cdots + X_{\tau-1}X_\tau \\
\lambda_3 &= X_1X_2X_3 + X_1X_2X_4 + X_2X_3X_4 + \cdots + X_{\tau-2}X_{\tau-1}X_\tau \\
&\vdots \\
\lambda_\tau &= X_1X_2 \cdots X_\tau \\
\lambda_l &= 0 \text{ for } l > \tau
\end{aligned}$$

Hence λ_l is the lth elementary symmetric function of $X_1, X_2, \ldots, X_\tau$.

From the syndrome, we get $S_1, S_3, \ldots, S_{2t-1}$, where

$$\begin{aligned}
S_1 &= X_1 + X_2 + \cdots + X_\tau \\
S_2 &= X_1^2 + X_2^2 + \cdots + X_\tau^2 \\
S_3 &= X_1^3 + X_2^3 + \cdots + X_\tau^3 \\
&\vdots \\
S_{2t} &= X_1^{2t} + X_2^{2t} + + X_\tau^{2t}
\end{aligned}$$

Furthermore,

$$S_{2r} = X_1^{2r} + X_2^{2r} + \cdots + X_r^{2r} = (X_1^r + X_2^r + \cdots + X_r^r)^2 = S_r^2$$

for all r. Hence, from the syndrome we can determine the polynomial

$$S(x) = 1 + S_1 x + S_2 x^2 + \cdots + S_{2t} x^{2t}$$

The *Newton equations* is a set of relations between the power sums S_r and the symmetric functions λ_l, namely

$$\sum_{j=0}^{l-1} S_{l-j}\lambda_j + l\lambda_l = 0 \text{ for } l \geq 1$$

Let

$$\Omega(x) = S(x)\Lambda(x) = \sum_{l \geq 0} \omega_l x^l \qquad (5)$$

Because $\omega_l = \sum_{j=0}^{l-1} S_{l-j}\lambda_j + \lambda_l$, the Newton equations imply that

$$\omega_l = 0 \text{ for all odd } l,\ 1 \le l \le 2t - 1 \tag{6}$$

The *Berlekamp–Massey algorithm* is an algorithm that, given $S(x)$, determines the polynomial $\Lambda(x)$ of smallest degree such that Equation (6) is satisfied, where the ω_l are defined by Equation (5). The idea is, for $r = 0, 1, \ldots, t$, to determine polynomials $\Lambda^{(r)}$ of lowest degree such that

$$\omega_l^{(r)} = 0 \text{ for all odd } l, 1 \le l \le 2r - 1$$

where

$$\sum_{l \ge 0} \omega_l^{(r)} x^l = S(x)\Lambda^{(r)}(x)$$

For $r = 0$, clearly we can let $\Lambda^{(0)}(x) = 1$. We proceed by induction. Let $0 \le r < t$, and suppose that polynomials $\Lambda^{(\rho)}(x)$ have been constructed for $0 \le \rho \le r$. If $\omega_{2r+1}^{(r)} = 0$, then we can choose

$$\Lambda^{(r+1)}(x) = \Lambda^{(r)}(x)$$

If, on the other hand, $\omega_{2r+1}^{(r)} \neq 0$, then we modify $\Lambda^{(r)}(x)$ by adding another suitable polynomial. Two cases to consider are as follows: First, if $\Lambda^{(r)}(x) = 1$ [in which case $\Lambda^{(\tau)}(x) = 1$ for $0 \le \tau \le r$], then

$$\Lambda^{(r+1)}(x) = 1 + \omega_{2r+1}^{(r)} x^{2r+1}$$

will have the required property. If $\Lambda^{(r)}(x) \neq 1$, then a maximal positive integer $\rho < r$ such that $\omega_{2\rho+1}^{(\rho)} \neq 0$ exists and we add a suitable multiple of $\Lambda^{(\rho)}$:

$$\Lambda^{(r+1)}(x) = \Lambda^{(r)}(x) + \omega_{2r+1}^{(r)} (\omega_{2\rho+1}^{(\rho)})^{-1} x^{2r-2\rho} \Lambda^{(\rho)}(x)$$

We note that this implies that

$$\Lambda^{(r+1)}(x)S(x) = \sum_{l \ge 0} \omega_l^{(r)} x^l + \omega_{2r+1}^{(r)} (\omega_{2\rho+1}^{(\rho)})^{-1} \sum_{l \ge 0} \omega_l^{(\rho)} x^{l+2r-2\rho}$$

Hence for odd l we get

$$\omega_l^{(r+1)} = \begin{cases} \omega_l^{(r)} = 0 & \text{for } 1 \le l \le 2r - 2\rho - 1 \\ \omega_l^{(r)} + \omega_{2r+1}^{(r)} (\omega_{2\rho+1}^{(\rho)})^{-1} \omega_{l-2r+2\rho}^{(\rho)} & \\ = 0 + 0 = 0 & \text{for } 2r - 2\rho + 1 \le l \le 2r - 1 \\ \omega_{2r+1}^{(r)} + \omega_{2r+1}^{(r)} (\omega_{2\rho+1}^{(\rho)})^{-1} \omega_{2\rho+1}^{(\rho)} & \\ = \omega_{2r+1}^{(r)} + \omega_{2r+1}^{(r)} = 0 & \text{for } l = 2r + 1 \end{cases}$$

We now formulate these ideas as an algorithm (in a Pascal-like syntax). In each step we keep the present $\Lambda(x)$ [the superscript (r) is dropped] and the modifying polynomial $[x^{2r-2\rho-1}$ or $(\omega_{2\rho+1}^{(\rho)})^{-1} x^{2r-2\rho-1} \Lambda^{(\rho)}(x)]$, which we denote by $B(x)$.

Berlekamp–Massey Algorithm in the Binary Case

```
Input: $t$ and $S(x)$.
$\Lambda(x) := 1$;   $B(x) := 1$;
for $r := 1$ to $t$ do
begin
     $\omega$ := coefficient of $x^{2r-1}$ in $S(x)\Lambda(x)$;
     if $\omega = 0$ then $B(x) := x^2 B(x)$
       else
          $[\Lambda(x), B(x)] := [\Lambda(x) + \omega x B(x),\ \ x\Lambda(x)/\omega]$ :
end;
```

The assignment following the **else** is two assignments to be done in parallel; the new $\Lambda(x)$ and $B(x)$ are computed from the old ones.

The Berlekamp–Massey algorithm determines the polynomial $\Lambda(x)$. To find the roots of $\Lambda(x) = 0$, we try all possible elements of F_{2^m}. In practical applications, this can be efficiently implemented using shift registers (usually called the *Chien search*).

Example. We consider the [15, 7, 5] double-error correcting BCH code; that is, $m = 4$ and $t = 2$. As a primitive root, we choose α such that $\alpha^4 = \alpha + 1$. Suppose that we have received a vector with syndrome $(S_1, S_3) = (\alpha^4, \alpha^5)$. Since $S_3 \neq S^3{}_1$, at least two errors have occurred. Equation (4) becomes

$$1 + \alpha^4 x + \alpha^{10} x^2 = 0$$

which has the zeros α^{-3} and α^{-7}. We conclude that the received vector has two errors (namely, in positions 3 and 7).

Now consider the Berlekamp–Massey algorithm for the same example. First we compute $S_2 = S^2{}_1 = \alpha^8$ and $S_4 = S^2{}_2 = \alpha$. Hence

$$S(x) = 1 + \alpha^4 x + \alpha^8 x^2 + \alpha^5 x^3 + \alpha x^4.$$

The values of r, ω, $\Lambda(x)$, and $B(x)$ after each iteration of the for-loop in the Berlekamp–Massey algorithm are shown in the following table:

r	ω	$\Lambda(x)$	$B(x)$
		1	1
1	α^4	$1 + \alpha^4 x$	$\alpha^{11} x$
2	α^{14}	$1 + \alpha^4 x + \alpha^{10} x^2$	$\alpha x + \alpha^5 x^2$

Hence, $\Lambda(x) = 1 + \alpha^4 x + \alpha^{10} x^2$ (as before).

Now consider the same code with syndrome of received vector $(S_1, S_3) = (\alpha, \alpha^9)$. Because $S_3 \neq S_1^3$, at least two errors have occurred. We get

$$\Lambda(x) = 1 + \alpha x + x^2$$

However, the equation $1 + \alpha x + x^2 = 0$ does not have any roots in F_{2^4}. Hence, at least three errors have occurred, and the code cannot correct them.

REED–SOLOMON CODES

In the previous sections we have considered binary codes where the components of the codewords belong to the finite field $F_2 = \{0, 1\}$. In a similar way we can consider codes with components from any finite field F_q.

The *Singleton bound* states that for any $[n, k, d]$ code with components from F_q, we have

$$d \leq n + k - 1$$

A code for which $d = n - k + 1$ is called *maximum distance separable* (MDS). The only binary MDS codes are the trivial $[n, 1, n]$ repetition codes and $[n, n - 1, 2]$ even-weight codes. However, important nonbinary MDS codes exist (in particular, the Reed–Solomon codes, which we now will describe).

Reed–Solomon codes are t-error-correcting cyclic codes with symbols from a finite field F_q, even though they can be constructed in many different ways. They can be considered as the simplest generalization of BCH codes. Because the most important case for applications is $q = 2^m$, we consider this case here. Each symbol is an element in F_{2^m} and can be considered as an m-bit symbol.

One construction of a cyclic Reed–Solomon code is as follows: Let α be a primitive element of F_{2^m}, and let $x_i = \alpha^i$. Because $x_i \in F_{2^m}$ for all i, the minimal polynomial of α^i over F_{2^m} is just $x - x_i$. The generator polynomial of a (primitive) t-error-correcting Reed–Solomon code of length $2^m - 1$ has $2t$ consequtive powers of α as zeros:

$$\begin{aligned} g(x) &= \prod_{i=0}^{2t-1} (x - \alpha^{b+i}) \\ &= g_0 + g_1 x + \cdots + g_{2t-1} x^{2t-1} + x^{2t} \end{aligned}$$

The code has the following parameters:

Block length: $n = 2^m - 1$
Number of parity-check symbols: $n - k = 2t$
Minimum distance: $d = 2t + 1$

Thus, the Reed–Solomon codes satisfy the Singleton bound with equality $n - k = d + 1$. That is, they are MDS codes.

An alternative description of the Reed–Solomon code is

$$\{(f(x_1), f(x_2), \ldots, f(x_n))| \\ f \text{ polynomial of degree less than } k\}.$$

The weight distribution of the Reed–Solomon code is (for $i \geq d$)

$$A_i \binom{n}{i} \sum_{j=0}^{i-d} (-1)^j \binom{i}{j} \left(2^{m(i-d-j+1)} - 1\right)$$

The encoding of Reed–Solomon codes is similar to the encoding of binary cyclic codes. One decoding is similar to the decoding of binary BCH codes with one added complication. Using a generalization of the Berlekamp–Massey algorithm, we determine the polynomials $\Lambda(x)$ and $\Omega(x)$. From $\Lambda(x)$ we can determine the locations of the errors. In addition, we must determine the value of the errors (in the binary case, the values are always 1). The value of the error at location X_j easily can be determined using $\Omega(x)$ and $\Lambda(x)$; we omit further details.

An alternative decoding algorithm can sometimes decode errors of weight more than half the minimum distance. We sketch this algorithm, first giving the simplest version, which works if the errors have weight less than half the minimum distance; that is, we assume a codeword $c = (f(x_1), f(x_2), \ldots, f(x_n))$ was sent and $r = (r_1, r_2, \ldots, r_n)$ was received, and $w(r - c) < (n - k + 1)/2$. It is easy to show that if $Q(x,y)$ is a nonzero polynomial in two variables of the form

$$Q(x,y) = Q_0(x) + Q_1(x)y$$

where

$$\begin{aligned} &Q(x_i, r_i) = 0 \text{ for } i = 1, 2, \ldots, n \\ &Q_0(x) \text{ has degree at most } n - 1 - t \\ &Q_1(x) \text{ has degree at most } n - k - t \end{aligned}$$

then $Q_0(x) + Q_1(x) f(x) = 0$, and so $Q(x,y) = Q_1(x)(y - f(x))$. Moreover, such a polynomial $Q(x,y)$ does exist. An algorithm to find $Q(x,y)$ is as follows:

```
Input: $r = (r_1, r_2, \ldots r_n)$.
Solve the equations $\sum_{j=0}^{n-1} a_j x_i^j + \sum_{j=0}^{n-k-t} b_j r_i x_i^j = 0$,
  where $i = 1, 2, \ldots, n$, for the unknown $a_j$ and $b_j$;
$Q_0(x) := \sum_{j=0}^{n-1-t} a_j x^j$;
$Q_1(x) := \sum_{j=0}^{n-k-t} b_j x^j$;
```

We now recover *f(x)* from the relation

$$Q_0(x) + Q_1(x)\ f(x) = 0.$$

To correct (some) errors of weight more than half the minimum distance, the method above must be generalized. The idea is to find a nonzero polynomial *Q(x, y)* of the form

$$Q(x,y) = Q_0(x) + Q_1(x)y + Q_2(x)y^2 + \cdots + Q_l(x)y^l$$

where now, for some integer τ and s,

(x_i, r_i) for $i = 1, 2, \ldots, n$, are zeros of $Q(x,y)$ of multiplicity s
$Q_m(x)$ has degree at most $s(n - \tau) - 1 - m(k - 1)$
for $m = 0, 1, \ldots, l$

For such a polynomial one can show that if the weight of the error is at most τ, then $y - f(x)$ divides *Q(x,y)*. Therefore, we can find all codewords within distance τ from **r** by finding all factors of *Q(x,y)* of the form $y - h(x)$, where *h(x)* is a polynomial of degree less than k. In general, there may be more than one such polynomial *h(x)*, of course, but in some cases, it is unique even if τ is larger than half the minimum distance. This idea is the basis for the Guruswami–Sudan algorithm.

Guruswami–Sudan Algorithm.

```
Input: $r = (r_1, r_2, \ldots r_n)$, $\tau$, $s$.

Solve the $n\binom{s+1}{2}$ equations
  $\sum_{m=u}^{l} \sum_{j=v}^{s(n-\tau)-1-m(k-1)} \binom{m}{u}\binom{j}{v} a_{m,j} x_i^{m-u} r_i^{j-v} = 0$,
  where $i = 1, 2, \ldots, n$, and $0 \leq u + v < s$,
  for the unknown $a_{m,j}$;
for $m$:=0 to $l$ do
  $Q_m(x) := \sum_{j=0}^{s(n-\tau)-1-m(k-1)} a_{m,j} x^j$;
$Q(x,y) := \sum_{m=0}^{l} Q_m(x) y^m$;
for each polynomial $h(x)$ of degree less than $k$ do
  if $y - h(x)$ divides $Q(x,y)$, then output $h(x)$.
```

We remark that the last loop of the algorithm is formulated in this simple form to explain the idea. In actual implementations, this part can be made more efficient. If $\tau < \frac{n(2l-s+1)}{2(l+1)} - \frac{l(k-1)}{2s}$, then the polynomial $f(x)$ of the sent codeword is among the output. The Guruswami–Sudan algorithm is a recent invention. A textbook covering it is the book by Justesen and Høholdt given in Further Reading.

ALGEBRAIC GEOMETRY CODES

Algebraic geometry codes can be considered as generalizations of Reed–Solomon codes, but they offer a wider range of code parameters. The Reed–Solomon codes over F_q have maximum length $n = q - 1$ whereas algebraic geometry codes can be longer. One common method to construct algebraic geometry codes is to select an algebraic curve and a set of functions that are evaluated on the points on the curve. In this way, by selecting different curves and sets of functions, one obtains different algebraic geometry codes. To treat algebraic codes in full generality is outside the scope of this article. We only will give a small flavor of the basic techniques involved by restricting ourselves to considering the class of Hermitian codes, which is the most studied class of algebraic geometry codes. This class of codes can serve as a good illustration of the methods involved.

The codewords in a Hermitian code have symbols from an alphabet F_{q^2}. The Hermitian curve consists of all points $(x,y) \in F_{q^2}^2$ given by the following equation in two variables:

$$x^{q+1} - y^q - y = 0$$

It is a straightforward argument to show that the number of different points on the curve is $n = q^3$. To select the functions to evaluate over the points on the curve, one needs to define an order function ρ. The function ρ is the mapping from the set of polynomials in two variable over F_{q^2} to the set of integers such that

$$\rho(x^i y^j) = iq + j(q+1)$$

and $\rho(f(x,y))$ is the maximum over all nonzero terms in $f(x,y)$.

Let $P_1 = (x_1, y_1), P_2 = (x_2, y_2), \ldots, P_n = (x_n, y_n)$ denote all the points on the Hermitian curve. The Hermitian code C_s is defined by

$$C_s = \{(f(P_1), f(P_2), \ldots, f(P_n)) | \rho(f(x,y)) \leq s \\ \text{and } \deg_x(f(x,y)) \leq q\}$$

where $\deg_x(f(x,y))$ is the maximum degree of x in $f(x,y)$.

Using methods from algebraic geometry, one obtains the following parameters of the Hermitian codes. The length of the code is $n = q^3$, and its dimension is

$$k = \begin{cases} \mu_s & \text{if } 0 \leq s \leq q^2 - q - 2 \\ s + 1 - (q^2 - q)/2 & \text{if } q^2 - q - 2 < s < n - q^2 + q \end{cases}$$

where μ_s is the number of monomials with $\rho(x^i y^j) \leq s$ and $i \leq q$, and the minimum distance is

$$d \geq n - s \text{ if } q^2 - q - 2 < s < n - q^2 + q$$

It is known that the class of algebraic geometry codes contains some very good codes with efficient decoding algorithms. It is possible to modify the Guruswami–Sudan algorithm to decode these codes.

NONLINEAR CODES FROM CODES OVER Z_4

In the previous sections mainly we have considered binary *linear* codes; that is, codes where the sum of two codewords is again a codeword. The main reason has been that the linearity greatly simplified construction and decoding of the codes.

A binary nonlinear (n, M, d) code C is simply a set of M binary n-tuples with pairwise distance at least d, but without any further imposed structure. In general, to find the minimum distance of a nonlinear code, one must compute the distance between all pairs of codewords. This is, of course, more complicated than for linear codes, where it suffices to find the minimum weight among all the nonzero codewords. The lack of structure in a nonlinear code also makes it difficult to decode in an efficient manner.

However, some advantages to nonlinear codes exist. For given values of length n and minimum distance d, sometimes it is possible to construct nonlinear codes with more codewords than is possible for linear codes. For example, for $n = 16$ and $d = 6$, the best linear code has dimension $k = 7$ (i.e., it contains 128 codewords). The code of length 16 obtained by extending the double-error-correcting primitive BCH code has these parameters.

In 1967, Nordstrom and Robinson (3) found a nonlinear code with parameters $n = 16$ and $d = 6$ containing $M = 256$ codewords, which has twice as many codewords as the best linear code for the same values of n and d.

In 1968, Preparata (4) generalized this construction to an infinite family of codes having parameters

$$(2^{m+1}, 2^{2^{m+1}-2m-2}, 6), m \text{ odd}, m \geq 3$$

A few years later, in 1972, Kerdock (5) gave another generalization of the Nordstrom–Robinson code and constructed another infinite class of codes with parameters

$$(2^{m+1}, 2^{2m+2}, 2^m - 2^{\frac{m-1}{2}}), \quad m \text{ odd}, m \geq 3$$

The Preparata code contains twice as many codewords as the extended double-error-correcting BCH code and is optimal in the sense of having the largest possible size for the given length and minimum distance. The Kerdock code has twice as many codewords as the best known linear code. In the case $m = 3$, the Preparata code and the Kerdock codes both coincide with the Nordstrom–Robinson code.

The Preparata and Kerdock codes are *distance invariant*, which means that the distance distribution from a given codeword to all the other codewords is independent of the given codeword. In particular, because they contain the all-zero codeword, their weight distribution equals their distance distribution.

In general, no natural way to define the dual code of a nonlinear code exists, and thus the MacWilliams identities have no meaning for nonlinear codes. However, one can define the weight enumerator polynomial $A(z)$ of a nonlinear code in the same way as for linear codes and compute its *formal dual* $B(z)$ from the MacWilliams identities:

$$B(z) = \frac{1}{M}(1+z)^n A\left(\frac{1-z}{1+z}\right)$$

The polynomial $B(z)$ obtained in this way has no simple interpretation. In particular, it may have coefficients that are nonintegers or even negative. For example, if $C = \{(110), (101), (111)\}$, then $A(z) = 2z^2 + z^3$ and $B(z) = (3 - 5z + z^2 + z^3)/3$.

An observation that puzzled the coding theory community for a long time was that the weight enumerator of the Preparata code $A(z)$ and the weight enumerator of the Kerdock code $B(z)$ satisfied the MacWilliams identities, and in this sense, these *nonlinear* codes behaved like dual linear codes.

Hammons et al. (6) gave a significantly simpler description of the family of Kerdock codes. They constructed a linear code over $Z_4 = \{0, 1, 2, 3\}$, which is an analog of the binary first-order Reed–Muller code. This code is combined with a mapping called the Gray map that maps the elements in Z_4 into binary pairs. The Gray map ϕ is defined by

$$\phi(0) = 00,\ \phi(1) = 01,\ \phi(2) = 11,\ \phi(3) = 10$$

The Lee weight of an element in Z_4 is defined by

$$w_L(0) = 0,\ w_L(1) = 1,\ w_L(2) = 2,\ w_L(3) = 1$$

Extending ϕ in a natural way to a map $\phi : Z_4^n \rightarrow Z_2^{2n}$ one observes that ϕ is a distance preserving map from Z_4^n (under the Lee metric) to Z_2^{2n} (under the Hamming metric).

A linear code over Z_4 is a subset of Z_4^n such that any linear combination of two codewords is again a codeword. From a linear code C of length n over Z_4, one obtains usually a binary nonlinear code $C = \phi(C)$ of length $2n$ by replacing each component in a codeword in C by its image under the Gray map. This code usually is nonlinear.

The minimum Hamming distance of C equals the minimum Lee distance of C and is equal to the minimum Lee weight of C because C is linear over Z_4.

Example. To obtain the Nordstrom–Robinson code, we will construct a code over Z_4 of length 8 and then apply the Gray map. Let $f(x) = x^3 + 2x^2 + x + 3 \in Z_4[x]$. Let β be a zero of $f(x)$; that is, $\beta^3 + 2\beta^2 + \beta + 3 = 0$. Then we can express all powers of β in terms of 1, β, and β^2, as follows:

$$\begin{aligned}
\beta^3 &= 2\beta^2 + 3\beta + 1 \\
\beta^4 &= 3\beta^2 + 3\beta + 2 \\
\beta^5 &= \beta^2 + 3\beta + 3 \\
\beta^6 &= \beta^2 + 2\beta + 1 \\
\beta^7 &= 1
\end{aligned}$$

Consider the code C over Z_4 with generator matrix given by

$$\begin{aligned}
G &= \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & \beta & \beta^2 & \beta^3 & \beta^4 & \beta^5 & \beta^6 \end{bmatrix} \\
&= \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 0 & 0 & 1 & 2 & 3 & 1 \\ 0 & 0 & 1 & 0 & 3 & 3 & 3 & 2 \\ 0 & 0 & 0 & 1 & 2 & 3 & 1 & 1 \end{bmatrix}
\end{aligned}$$

where the column corresponding to β^i is replaced by the coefficients in its expression in terms of 1, β, and β^2. Then the Nordstrom–Robinson code is the Gray map of C.

The dual code $\mathcal{C}^\perp$ of a code $\mathcal{C}$ over Z_4 is defined similarly as for binary linear codes, except that the inner product of the vectors $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ and $\mathbf{y} = (y_1, y_2, \ldots, y_n)$ with components in Z_4 is defined by

$$(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^{n} x_i y_i \pmod 4$$

The dual code $\mathcal{C}^\perp$ of $\mathcal{C}$ is then

$$\mathcal{C}^\perp = \{\mathbf{x} \in Z_4^n | (\mathbf{x}, \mathbf{c}) = 0 \text{ for all } \mathbf{c} \in Z_4^n\}$$

For a linear code C over Z_4, a MacWilliams relation determines the complete weight distribution of the dual code $\mathcal{C}^\perp$ from the complete weight distribution of $\mathcal{C}$. Therefore, one can compute the relation between the Hamming weight distributions of the nonlinear codes $C = \phi(\mathcal{C})$ and $C_\perp = \phi(\mathcal{C}^\perp)$, and it turns out that the MacWilliams identities hold.

Hence, to find nonlinear binary codes related by the MacWilliams identities, one can start with a pair of Z_4-linear dual codes and apply the Gray map. For any odd integer $m \geq 3$, the Gray map of the code K_m over Z_4 with generator matrix

$$G = \begin{bmatrix} 1 & 1 & 1 & 1 & \ldots & 1 \\ 0 & 1 & \beta & \beta^2 & \ldots & \beta^{2^m-2} \end{bmatrix}$$

is the binary, nonlinear $\left(2^{m+1}, 2^{2m+2}, 2^m - 2^{\frac{m-1}{2}}\right)$ Kerdock code. The Gray map of $K_m^{\perp}$ has the same weight distribution as the $(2^{m+1}, 2^{2^{m+1}-2m-2}, 6)$ Preparata code. It is not identical, however, to the Preparata code and is therefore denoted the "Preparata" code. Hence the Kerdock code and the "Preparata" code are the Z_4-analogy of the first-order Reed–Muller code and the extended Hamming code, respectively.

Hammons et al. (6) also showed that the binary code defined by $C = \phi(C)$, where C is the quaternary code with parity-check matrix given by

$$H = \begin{bmatrix} 1 & 1 & 1 & 1 & \dots & 1 \\ 0 & 1 & \beta & \beta^2 & \dots & \beta^{2^m-2} \\ 0 & 2 & 2\beta^3 & 2\beta^6 & \dots & 2\beta^{3(2^m-2)} \end{bmatrix}$$

is a binary nonlinear $(2^{m+1}, 2^{2^{m+1}-3m-2}, 8)$ code whenever $m \geq 3$ is odd. This code has the same weight distribution as the Goethals code, which is a nonlinear code that has four times as many codewords as the comparable linear extended triple-error-correcting primitive BCH code. The code $C_\perp = \phi(C^\perp)$ is identical to a binary nonlinear code, which was constructed in a much more complicated way by Delsarte and Goethals (7–9) more than 30 years ago.

To analyze codes obtained from codes over Z_4 in this manner, one is led to study Galois rings instead of Galois fields. Similar to a Galois field, a Galois ring can be defined as $Z_{p^e}[x]/(f(x))$, where $f(x)$ is a monic polynomial of degree m that is irreducible modulo p. The richness in structure of the Galois rings led to several recently discovered good nonlinear codes that have an efficient and fast decoding algorithm.

BIOINFORMATIC DATABASES

At some time during the course of any bioinformatics project, a researcher must go to a database that houses biological data. Whether it is a local database that records internal data from that laboratory's experiments or a public database accessed through the Internet, such as NCBI's GenBank (1) or EBI's EMBL (2), researchers use biological databases for multiple reasons.

One of the founding reasons for the fields of bioinformatics and computational biology was the need for management of biological data. In the past several decades, biological disciplines, including molecular biology and biochemistry, have generated massive amounts of data that are difficult to organize for efficient search, query, and analysis. If we trace the histories of both database development and the development of biochemical databases, we see that the biochemical community was quick to embrace databases. For example, E. F. Codd's seminal paper, "A Relational Model of Data for Large Shared Data Banks" (3), published in 1970 is heralded as the beginning of the relational database, whereas the first version of the Protein Data Bank (PDB) was established at Brookhaven National Laboratories in 1972 (4).

Since then, especially after the launching of the human genome sequencing project in 1990, biological databases have proliferated, most embracing the World Wide Web technologies that became available in the 1990s. Now there are hundreds of biological databases, with significant research efforts in both the biological as well as the database communities for managing these data. There are conferences and publications solely dedicated to the topic. For example, Oxford University Press dedicates the first issue of its journal *Nucleic Acids Research* (which is freely available) every year specifically to biological databases. The database issue is supplemented by an online collection of databases that listed 858 databases in 14 categories in 2006 (5), including both new and updated ones.

Biological database research now encompasses many topics, such as biological data management, curation, quality, integration, and mining (6). Biological databases can be classified in many different ways, from the topic they cover, to how heavily annotated they are or which annotation method they employ, to how highly integrated the database is with other databases. Popularly, the first two categories of classification are used most frequently. For example, there are archival nucleic acid data repositories [GenBank, the EMBL Data Library, and the DNA Databank of Japan (7)] as well as protein sequence motif/domain databases, like PROSITE (8), that are derived from primary source data.

Modern biological databases comprise not only data, but also sophisticated query facilities and bioinformatic data analysis tools; hence, the term "bioinformatic databases" is often used. This article presents information on some popular bioinformatic databases available online, including sequence, phylogenetic, structure and pathway, and microarray databases. It highlights features of these databases, discussing their unique characteristics, and focusing on types of data stored and query facilities available in the databases. The article concludes by summarizing important research and development challenges for these databases, namely knowledge discovery, large-scale knowledge integration, and data provenance problems. For further information about these databases and access to all hyperlinks presented in this article, please visit http://www.csam.montclair.edu/~herbert/bioDatabases.html.

SEQUENCE DATABASES

Genome and protein sequence databases represent the most widely used and some of the best established biological databases. These databases serve as repositories for wetlab results and the primary source for experimental results. Table 1 summarizes these data repositories and gives their respective URLs.

GenBank, EMBL, and the DNA Databank of Japan

The most widely used biological data bank resource on the World Wide Web is the genomic information stored in the U.S.'s National Institutes of Health's GenBank, the European Bioinformatics Institutes' EMBL, and Japan's National Institute of Genetics DNA Databank of Japan (1, 2, 7). Each of these three databases was developed separately, with GenBank and EMBL launching in 1980 (4). Their collaboration started soon after their development, and DDBJ joined the collaboration shortly after its creation in 1986. The three databases, under the direction of the International Nucleotide Sequence Database Collaboration (INSDC), gather, maintain, and share mainly nucleotide data, each catering to the needs of the region in which it is located (4).

The Ensembl Genome Database

The Ensembl database is a repository of stable, automatically annotated human genome sequences. It is available either as an interactive website or downloadable as flat files. Ensembl annotates and predicts new genes, with annotation from the InterPro (9) protein family databases and with additional annotations from databases of genetic disease [OMIM (10)], expression [SAGE (11,12)] and gene family (13). As Ensembl endeavors to be both portable and freely available, software available at Ensembl is based on relational database models (14).

GeneDB Database

GeneDB (15) is a genome database for prokaryotic and eukaryotic organisms. It currently contains data for 37 genomes generated from the Pathogen Sequencing Unit (PSU) at the Welcome Trust Sanger Institute. The GeneDB

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Table 1. Summary of Genome and Protein Sequence Databases

Database	URL	Feature
GenBank	http://www.ncbi.nlm.nih.gov/	NIH's archival genetic sequence database
EMBL	http://www.ebi.ac.uk/embl/	EBI's archival genetic sequence database
DDBJ	http://www.ddbj.nig.ac.jp/	NIG's archival genetic sequence database
Ensembl	http://www.ensembl.org/	Database that maintains automatic annotation on selected eukaryotic genomes
GeneDB	http://www.cebitec.uni-bielefeld.de/groups/brf/software/gendb_info/	Database that maintains genomic information about specific species related to pathogens
TAIR	http://www.arabidopsis.org/	Database that maintains genomic information about *Arabidopsis thaliana*
SGD	http://www.yeastgenome.org/	A repository for baker's yeast genome and biological data
dbEST	http://www.ncbi.nlm.nih.gov/dbEST/	Division of GenBank that contains expression tag sequence data
Protein Information Resource (PIR)	http://pir.georgetown.edu/	Repository for nonredundant protein sequences and functional information
Swiss-Prot/TrEMBL	http://www.expasy.org/sprot/	Repository for nonredundant protein sequences and functional information
UniProt	http://www.pir.uniprot.org/	Central repository for PIR, Swiss-Prot, and TrEMBL

database has four key functionalities. First, the database stores and frequently updates sequences and annotations. Second, GeneDB provides a user interface, which can be used for access, visualization, searching, and downloading of the data. Third, the database architecture allows integration of different biological datasets with the sequences. Finally, GeneDB facilitates querying and comparisons between species by using structured vocabularies (15).

The Arabidopsis Information Resource (TAIR)

TAIR (16) is a comprehensive genome database that allows for information retrieval and data analysis pertaining to *Arabidopsis thaliana* (a small annual plant belonging to the mustard family). *Arabidopsis thaliana* has been of great interest to the biological community and is one of the few plants whose genome is completely sequenced (16). Due to the complexity of many plant genomes, *Arabidopsis thaliana* serves as a model for plant genome investigations. The database has been designed to be simple, portable, and efficient. One innovate aspect of the TAIR website is MapViewer (http://www.arabidopsis.org/servlets/mapper). MapViewer is an integrated visualization tool for viewing genetic, physical, and sequence maps for each *Arabidopsis* chromosome. Each component of the map contains a hyperlink to an output page from the database that displays all the information related to this component (16).

SGD: Saccharomyces Genome Database

The Saccharomyces Genome Database (SGD) (17) provides information for the complete *Saccharomyces cerevisiae* (baker's and brewer's yeast) genomic sequence, along with its genes, gene products, and related literature. The database contains several types of data, including DNA sequence, gene-encoded proteins, and the structures and biological functions of any known gene products. It also allows full-text searches of articles concerning *Saccharomyces cerevisiae*. The SGD database is not a primary sequence repository (17), but a collection of DNA and protein sequences from existing databases [GenBank (1), EMBL (2), DDBJ (7), PIR (18), and Swiss-Prot (19)]. It organizes the sequences into datasets to make the data more useful and easily accessible.

dbEST Database

dbEST (20) is a division of GenBank that contains sequence data and other information on short, "single-pass" cDNA sequences, or Expressed Sequence Tags (ESTs), generated from randomly selected library clones (http://www.ncbi.nlm.nih.gov/dbEST/). dbEST contains approximately 36,843,572 entries from a broad spectrum of organisms. Access to dbEST can be obtained through the Web, either from NCBI by anonymous ftp or through Entrez (21). The dbEST nucleotide sequences can be searched using the BLAST sequence search program at the NCBI website. In addition, TBLASTN, a program that takes a query amino acid sequence and compares it with six-frame translations of dbEST DNA sequences can also be useful for finding novel coding sequences. EST sequences are available in the FASTA format from the "/repository/dbEST" directory at ftp.ncbi.nih.gov.

The Protein Information Resource

The Protein Information Resource (PIR) is an integrated public bioinformatics resource that supports genomic and proteomic research and scientific studies. PIR has provided many protein databases and analysis tools to the scientific community, including the PIR-International Protein Sequence Database (PSD) of functionally annotated protein sequences. The PIR-PSD, originally created as the Atlas of Protein Sequence and Structure edited by Margaret Dayhoff, contained protein sequences that were highly annotated with functional, structural, bibliographic, and sequence data (5,18). PIR-PSD is now merged with UniProt Consortium databases (22). PIR offers the

PIRSF protein classification system (23) that classifies proteins, based on full-length sequence similarities and their domain architectures, to reflect their evolutionary relationships. PIR also provides the iProClass database that integrates over 90 databases to create value-added views for protein data (24). In addition, PIR supports a literature mining resource, iProLINK (25), which provides multiple annotated literature datasets to facilitate text mining research in the areas of literature-based database curation, named entity recognition, and protein ontology development.

The Swiss-Prot Database

Swiss-Prot (19) is a protein sequence and knowledge database and serves as a hub for biomolecular information archived in 66 databases (2). It is well known for its minimal redundancy, high quality of annotation, use of standardized nomenclature, and links to specialized databases. Its format is very similar to that of the EMBL Nucleotide Sequence Database (2). As Swiss-Prot is a protein sequence database, its repository contains the amino acid sequence, the protein name and description, taxonomic data, and citation information. If additional information is provided with the data, such as protein structures, diseases associated with the protein or splice isoforms, Swiss-Prot provides a table where these data can be stored. Swiss-Prot also combines all information retrieved from the publications reporting new sequence data, review articles, and comments from enlisted external experts.

TrEMBL: A Supplement to Swiss-Prot

Due to the large number of sequences generated by different genome projects, the Swiss-Prot database faces several challenges related to the processing time required for manual annotation. For this reason, the European Bioinformatics Institute, collaborating with Swiss-Prot, introduced another database, TrEMBL (translation of EMBL nucleotide sequence database). This database consists of computer-annotated entries derived from the translation of all coding sequences in the nucleotide databases. This database is divided into two sections: SP-TrEMBL contains sequences that will eventually be transferred to Swiss-Prot and REM-TrEMBL contains those that will not go into Swiss-Prot, including patent application sequences, fragments of less than eight amino acids, and sequences that have proven not to code for a real protein (19, 26, 27).

UniProt

With protein information spread over multiple data repositories, the efforts from PIR, SIB's Swiss-Prot and EBI's TrEMBL were combined to develop the UniProt Consortium Database to centralize protein resources (22). UniProt is organized into three layers. The UniProt Archive (UniParc) stores the stable, nonredundant, corpus of publicly available protein sequence data. The UniProt Knowledgebase (UniProtKB) consists of accurate protein sequences with functional annotation. Finally, the UniProt Reference Cluster (UniRef) datasets provide nonredundant reference clusters based primarily on UniProtKB. UniProt also offers users multiple tools, including searches against the individual contributing databases, BLAST and multiple sequence alignment, proteomic tools, and bibliographic searches (22).

PHYLOGENETIC DATABASES

With all of the knowledge accumulating in the genomic and proteomic databases, there is a great need for understanding how all these types of data relate to each other. As all biological things have come about through the evolutionary process, the patterns, functions, and processes that they possess are best analyzed in terms of their phylogenetic histories. The same gene can evolve a different timing of its expression, a different tissue where it is expressed, or even gain a whole new function along one phylogenetic branch as compared with another. These changes along a branch affect the biology of all descendant species, thereby leaving phylogenetic patterns in everything we see. A detailed mapping between biological data and phylogenetic histories must be accomplished so that the full potential of the data accumulation activities can be realized. Otherwise it will be impossible to understand why certain drugs work in some species but not others, or how we can design therapies against evolving disease agents such as HIV and influenza.

The need to query data using sets of evolutionary related taxa, rather than on single species, has brought up the need to create databases that can serve as repositories of phylogenetic trees, generated by a variety of methods. Phylogeny and phylogenetic trees give a picture of the evolutionary history among species, individuals, or genes. Therefore, there are at least two distinct goals of a phylogenetic database: archival storage and analysis (28). Table 2 summarizes these repositories.

Many of the aforementioned data repositories offer functionalities for browsing phylogenetic and taxonomic information. NCBI offers users the Taxonomy Databases (1, 13), which organize the data maintained in its repositories from the species perspective and allows the user to hierarchically browse data with respect to a Tree of Life organization. NEWT is a taxonomy database (http://www.ebi.ac.uk/newt/) that connects UniProtKB data to the NCBI taxonomy data. For every species, NEWT provides information about the taxon's scientific name, common name and synonym(s), lineage, number of UniProtKB protein entries in the given taxon, and links to each entry.

Tree of Life

The Tree of Life (29) is a phylogenetic repository that aims to provide users with information from a whole-species point of view. The Tree of Life allows users to search for pages about specific species through conventional keyword search mechanisms. Most interestingly, a user can also navigate through the "tree of life" using hierarchical browsing starting at the root organism, popularly referred to as "Life," and traverse the tree until a species of interest is reached. The species web page contains information gathered and edited by recognized experts about the species

Table 2. Summary of Phylogenetic Data Repositories

Database	URL	Feature
NCBI Taxonomy Database	http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=Taxonomy	Whole-species view of genomic and proteomic data stored in GenBank
Tree of Life	http://tolweb.org/tree/	Species-centric hierarchical browsing database modeling the evolutionary relationships between species
TreeFam	http://www.treefam.org/	Repository for phylogenetic trees based on animal genomes
TreeBASE	http://www.treebase.org/treebase/	Archival peer-reviewed phylogenetic tree repository
SYSTERS	http://systers.molgen.mpg.de/	Protein cluster repository with significant phylogenetic functionalities
PANDIT	http://www.ebi.ac.uk/goldman-srv/pandit/	Protein domains repository with inferred phylogenetic trees

as well as peer-reviewed resources accessible through hyperlinks (29).

TreeFam

TreeFam is a database of phylogenetic trees of animal gene families. The goal of TreeFam is to develop a curated database that provides accurate information about ortholog and paralog assignments and evolutionary histories of various gene families (30). To create and curate the trees and families, TreeFam has gathered sequence data from several protein repositories. It contains protein sequences for human (*Homo sapiens*), mouse (*Mus musculus*), rat (*Rattus norvegicus*), chicken (*Gallus gallus*), pufferfish (*Takifugu rubripes*), zebrafish (*Danio rerio*), and fruitfly (*Drosophila melanogaster*), which were retrieved from Ensembl (14), WormBase (31), SGD (17), GeneDB (15), and TIGR (32). The protein sequences in TreeFam are grouped into families of genes that descended from a single gene in the last common ancestor of all animals, or that first appeared in animals. From the above sources, families and trees are automatically generated and then manually curated based on expert review. To manage these data, TreeFam is divided into two parts. TreeFAM-B consists of the automatically generated trees. It obtains clusters from the PhIGs (33) database and uses BLAST (34), MUSCLE (35), and HMMER (36) and neighbor-joining algorithms (37) to generate the trees. TreeFAM-A contains the manually curated trees, which exploit algorithms similar to the DLI algorithm (DLI: H. Li, unpublished data) and the SDI algorithm (38). TreeFAM contains 11,646 families including about 690 families that have curated phylogenetic trees. Therefore, as more trees get curated, the TreeFam-A database increases, whereas TreeFam-B decreases in size.

TreeBASE

TreeBASE (39) was developed to help harness the explosively high growth in the number of published phylogenetic trees. It is a relational database and contains phylogenetic trees and the data underlying those trees. TreeBASE is available at http://www.treebase.org and allows the user to search the database according to different keywords and to see graphical representations of the trees. The user can also access information such as data matrices, bibliographic information, taxonomic names, character states, algorithms used, and analyses performed. Phylogenetic trees are submitted to TreeBASE by the authors of the papers that describe the trees. For data to be accepted by TreeBASE, the corresponding paper must pass the journal's peer review process (39).

SYSTERS Database

SYSTERS is a protein clustering database based on sequence similarity (40). It can be accessed at http://SYSTERS.molgen.mpg.de/. SYSTERS contains 185,000 disjoint protein families gathered from existing sequence repositories: Swiss-Prot (19), TrEMBL (19) and complete genomes: Ensembl (14), The Arabidopsis Information Resource (16), SGD (17), and GeneDB (15). Two innovative features of this repository are the SYSTERS Table and SYSTERS Tree. The SYSTERS Table for a family cluster contains a variety of information, most notably accession numbers as well as accession numbers for a variety of external databases [IMB (41), MSD (42), ENZYME (43), INTERPRO (9), PROSITE (8), GO (44)]. There can be several redundant entries in the table for one protein sequence. As SYSTERS data rely on external protein databases, there is always an entry name (protein name) and an accession number for each entry but there may not be a gene name. For each family cluster that consists of more than two nonredundant entries, a phylogenetic tree is available. The phylogenetic trees are constructed using the UPGMA (45) method. No more than 200 entries are displayed in a tree; the selection process when a cluster contains more than 200 entries is not clear.

PANDIT (Protein and Associated Nucleotide Domains with Inferred Trees)

PANDIT is a nonredundant repository of multiple sequence alignments and phylogenetic trees. It is available at http://www.ebi.ac.uk/goldman-srv/pandit. The database consists of three portions: protein domain sequence alignments from Pfam Database (46), alignments of nucleotide sequences derived from EMBL Nucleotide Sequence Database (2), and phylogenetic trees inferred from each alignment. Currently PANDIT contains 7738 families of homologous protein sequences with corresponding DNA sequences and phylogenetic trees. All alignments are based on Pfam-A (47) seed alignments, which are manually curated and, therefore, make PANDIT data high quality and comparable with alignments used to study evolution. Each family contains three alignments: PANDIT-aa contains the exact Pfam-A seed protein sequence alignment; and PANDIT-dna contains the DNA sequences encoding the protein sequences in PANDIT-aa that could be recovered; and PANDIT-aa-restricted contains only those protein sequences for which a DNA sequence has been recovered. The DNA sequences have been retrieved using cross-references to the EMBL Nucleotide Sequence Database from the Swiss-Prot (19) and TrEMBL (19) databases. To ensure accuracy, PANDIT performs a translation of the cross-referenced DNA sequences back to the corresponding protein sequences.

PANDIT database is intended for studying the molecular evolution of protein families. Therefore, phylogenetic trees have been constructed for families of more than two sequences. For each family, five different methods for tree estimation have been used to produce candidate trees. These methods include neighbor-joining (37), BioNJ (48), Weighbor (49), FastME (50), and PHYML (51). Neighbor-joining, BioNJ and Weighbor are methods used to produce phylogenetic tree estimates from a pairwise distance matrix. FastME uses a minimum evolution criterion with local tree-rearrangements to estimate a tree, and Phyml uses maximum likelihood with local tree searching. At the end, the likelihood of each tree from the candidate set is computed and the tree with the highest likelihood is added to the database.

STRUCTURE AND PATHWAY DATABASES

Knowledge of protein structures and of molecular interactions is key to understanding protein functions and complex regulatory mechanisms underlying many biological processes. However, computationally, these datasets are highly complex. The most popular ways to model these datasets are through text, graphs, or images. Text data tend not to have the descriptive power needed to fully model this type of data. Graphical and the image data require complex algorithms that are computationally expensive and not reliably accurate. Therefore, structural and pathway databases become an interesting niche from both the biological and the computational perspectives. Table 3 lists several prominent databases in this field.

The Protein Data Bank

The Protein Data Bank (PDB) is an archive of structural data of biological macromolecules. PDB is maintained by the Research Collaboratory for Structural Bioinformatics (RCSB). It allows the user to view data both in plain text and through a molecular viewer using Jmol. A key goal of the PDB is to make the data as uniform as possible while improving data accessibility and providing advanced querying options (52, 53).

To have complete information regarding the features of macromolecular structures, PDB allows a wide spectrum of queries through data integration. PDB collects and integrates external data from scientists' deposition, Gene Ontology (GO) (54), Enzyme Commission (55), KEGG Pathways (56), and NCBI resources (57). PDB realizes data integration through data loaders written in Java, which extract information from existing databases based on common identification numbers. PDB also allows data extraction at query run time, which means implemented Web services extract information as the query is executing.

The Nucleic Acid Database

Nucleic Acid Database, also curated by RCSB and similar to the PDB and the Cambridge Structural Database (58), is a repository for nucleic acid structures. It gives users access to tools for extracting information from nucleic acid structures and distributes data and software. The data are stored in a relational database that contains tables of primary and derivative information. The primary information includes atomic coordinates, bibliographic references, crystal data, data collection, and other structural descriptions. The derivative information is calculated from the primary information and includes chemical bond lengths, and angles, virtual bond lengths, and other measures according to various algorithms (59, 60). The experimental data in the NDB database have been collected from published literature, as well as from one of the standard crystallographic archive file types (60, 61) and other sources. Primary information has been encoded in ASCII format file (62). Several programs have been developed to convert between different file formats (60, 63, 64, 65).

The Kyoto Encyclopedia of Genes and Genomes

The Kyoto Encyclopedia of Genes and Genomes (KEGG) (56) is the primary resource for the Japanese GenomeNet service that attempts to define the relationships between

Table 3. Summary of Structural and Pathway Databases

Database	URL	Feature
The Protein Data Bank (PDB)	http://www.rcsb.org/pdb/	Protein structure repository that provides tools for analyzing these structures
The Nucleic Acid Database (NDB)	http://ndbserver.rutgers.edu/	Database housing nucleic acid structural information
The Kyoto Encyclopedia of Genes and Genomes (KEGG)	http://www.genome.jp/kegg/	Collection of databases integrating pathway, genomic, proteomic, and ligand data
The BioCyc Database Collection	http://www.biocyc.org/	Collection of over 200 pathway and genomic databases

the functional meanings and utilities of the cell or the organism and its genome information. KEGG contains three databases: PATHWAY, GENES, and LIGAND. The PATHWAY database stores computerized knowledge on molecular interaction networks. The GENES database contains data concerning sequences of genes and proteins generated by the genome projects. The LIGAND database holds information about the chemical compounds and chemical reactions that are relevant to cellular processes. KEGG computerizes the data and knowledge as graph information. The KEGG/PATHWAY database contains reference diagrams for molecular pathways and complexes involving various cellular processes, which can readily be integrated with genomic information (66). It stores data objects called generalized protein interaction networks (67, 68). The PATHWAY database is composed of four levels that can be accessed through the Web browser. The top two levels contain information about metabolism, genetic information processing, environmental information processing, cellular processes, and human diseases. The others relate to the pathway diagram and the ortholog group table, which is a collection of genes and proteins.

The BioCyc Database Collection

The BioCyc Database Collection (69) is a compilation of pathway and genome information for different organisms. Based on the number of reviews and updates, BioCyc databases are organized into several tiers. Tier 1 consists of three databases, EcoCyc (70), which describes *Escherichia coli* K-12; MetaCyc (71), which describes pathways for more than 300 organisms; and the BioCyc Open Compounds Database (69), which contains a collection of chemical compound data from BioCyc databases. Tier 2 contains 12 databases computationally generated by the Pathologic program. These databases have been updated and manually curated to varying degrees. Tier 3 is composed of 191 databases computationally generated by the Pathologic program with no review and updating (69).

The BioCyc website allows scientists to perform certain operations, e.g., to visualize individual metabolic pathways, to view the complete metabolic map of an organism, and to analyze, metabolomics data using the Omics Viewer. The website also provides a spectrum of browsing capabilities such as moving from a display of an enzyme to a display of a reaction that the enzyme catalyzes or to the gene that encodes the enzyme (69).

MICROARRAY AND BOUTIQUE BIOINFORMATIC DATABASES

Both microarray databases and boutique databases offer interesting perspectives on biological data. The microarray databases allow users to retrieve and interact with data from microarray experiments. Boutique databases offer users specialty services concerning a particular aspect of biological data. This section reviews such databases and synopsizes these reviews in Table 4.

The Stanford Microarray Database

The Stanford Microarray Database (SMD) (72) allows researchers to retrieve, analyze, and visualize gene expression data from microarray experiments. The repository also contains literature data and integrates multiple related resources, including SGD (17), YPD and WormPD (73), UniGene (74), dbEST (20), and Swiss-Prot (19).

Due to the large number of experiments and datasets, SMD uses comprehensive interfaces allowing users to efficiently query the database. For each experiment, the database stores the name of the researcher, the source organism of the microarray probe sequences, along with a category and subcategory that describe the biological view of the experiment. The user can create a query using any of these criteria to narrow down the number of experiments.

The Yale Microarray Database

The Yale Microarray Database (YMD) (75) is another repository for gene expression data. It is Web-accessible and enables users to perform several operations, e.g., tracking DNA samples between source plates and arrays and finding common genes/clones across different microarray platforms. Moreover, it allows the user to access the image file server, to enter data, and to get integrated data through linkage of gene expression data to annotation databases for functional analysis (75). YMD provides several means of querying the database. The website contains a query criteria interface (75), which allows the user to perform common queries. The interface also enables the user to choose the format of the output, e.g., which columns to be included and the type of output display (HTML, EXCEL, TEXT, or CLUSTER). Finally, the query output can also be dynamically linked to external annotation databases such as DRAGON (76).

Table 4. Summary of Microarray and Boutique Databases

Database	URL	Feature
The Stanford Microarray Database	http://genome-www5.stanford.edu/	Repository for raw and normalized microarray data
The Yale Microarray Database	http://www.med.yale.edu/microarray/	Repository for raw and normalized microarray data
The Stem Cell Database	http://stemcell.princeton.edu/	Database for human and mice stem cell data
The BrainML Data Server	http://www.neurodatabase.org,	Databases containing information necessary for understanding brain processes

The Stem Cell Database

The Stem Cell Database (SCDb) (77), supported by Princeton University and the University of Pennsylvania, is a unique repository that contains information about hematopoietic stem cells from mice and humans. It is closely associated with the Stromal Cell Database (http://stromalcell.princeton.edu/), also supported by Princeton University and the University of Pennsylvania. Data for this repository are obtained from various peer-reviewed sources, publications, and libraries. Users can query on various aspects of the data, including gene name and other annotations, as well as sequence data (77).

The BrainML Data Server

The BrainML Data Server is a repository containing data that pertain to the understanding of neural coding, information transmission, and brain processes and provides a venue for sharing neuro-physiological data. It acquires, organizes, annotates, archives, delivers, and displays single- and multi-unit neuronal data from mammalian cerebral cortex (78). Users can obtain the actual datasets, provided by several laboratories, all in common format and annotated compatibly. The Web interface provides a tool called QueryTool that allows the user to search by metadata terms submitted by the researchers. Another Tool, Virtual Scilloscope Java Tool, displays time-series and histogram datasets dynamically. The datasets can also be downloaded for analysis.

RESEARCH CHALLENGES AND ISSUES

Although extensive efforts have been made to catalog and store biological and chemical data, there is still a great amount of work to be done. Scientists are figuratively drowning in data. Therefore, there is a strong need for computational tools that allow scientists to slice through the mounds of data to pinpoint information needed for experiments. Moreover, with research methodologies changing from library-based to Web-based, new methods for maintaining the quality of the data are needed. Maintenance and updates on bioinformatic databases require not only automatic tools but in most cases also in the curation process. This process involves manual checks from biologists to ensure that data are valid and accurate before integrating this data into the database. There are two major research challenges in the area of bioinformatic databases: (1) development of software tools that are reliable, scalable, downloadable, platform-independent, user-friendly, high performance, and open source for discovering, extracting, and delivering knowledge from large amounts of text and biomedical data; and (2) development of large-scale ontology-assisted knowledge integration systems. The two issues also give rise to others, such as how we can maintain the quality (79) and the proper provenance of biological data when it is heavily integrated. Some work has been done toward the first issue, as discussed in Ref. 80.

Knowledge Discovery from Data (KDD)

The KDD process, in its most fundamental form, is to extract interesting, nontrivial, implicit, previously unknown, and potentially useful information from data. When applied to bioinformatic databases, KDD refers to diverse activities, including bioinformatic data cleaning and preprocessing, pattern and motif discovery, classification and clustering, biological network modeling, and bioinformatic data visualization, to name a few. An annual KDD Cup is organized as the Data Mining and Knowledge Discovery competition by the ACM Special Interest Group (81, 82). Various KDD tools have been developed to analyze DNA and protein sequences, whole genomes, phylogeny and evolutionary trees, macromolecule structures, and biological pathways. However, many of these tools suffer from inefficiency, low accuracy, and unsatisfactory performance due to factors, including experimental noise, unknown model complexity, visualization difficulties with very high-dimensional data, and the lack of sufficient samples for computational validation. Another problem is that some KDD tools are platform dependent and their availability is limited.

One emerging trend in KDD is to apply machine learning, natural language processing, and statistical techniques to text and biomedical literature mining. The goal is to establish associations between biological objects and publications from literature databases such as MEDLINE, for example, finding all related literature studying the same proteins from different aspects. It has been shown that incorporating information obtained from biomedical literature mining into sequence alignment tools such as BLAST can increase the accuracy of alignment results. This shows an example of combining KDD methods with traditional sequence analysis tools to improve their performance. However, these KDD methods are not yet fully reliable, scalable, or user-friendly, and many of the methods still need to be improved.

Large-Scale Knowledge Integration (LKI)

LKI of heterogeneous, distributed bioinformatic data is supposed to offer users a seamless view of knowledge. However, with a few exceptions, many current bioinformatic systems use hyperlink navigation techniques to integrate World Wide Web repositories. These techniques result in semantically meaningless integrations. Often, websites are not maintained, datasets are poorly curated, or in some cases, the integration has been done improperly. With these concerns, efforts based on current biological data integration that create advanced tools to help deliver knowledge to the bioinformatics community fail or become dataset dependent.

A major research challenge in bioinformatics is integrating and representing knowledge effectively. The informatics community has effectively integrated and visualized data. However, research must be taken to the next phase where knowledge integration and knowledge management becomes a key interest. The informatics community must work with the biomedical community from the ground up. Effective, structured knowledge bases need to be created that are also relatively easy to use. The computer science community is starting to address this challenge with projects in the areas of the Semantic Web and semantic integration. The bioinformatics community has started to create such knowledge bases with projects like the Gene Ontology (GO) and Stanford's biomedical ontology (http://bioontology.org/) (more are listed under the Open Biological Ontology, http://obo.sourceforge.net/). Ontologies and meta-data are only the beginning. It is well known in the computer science community that meta-data management can be a tricky, complicated process. Attempting this in the biomedical realm is downright difficult. Researchers currently must wield complicated ontologies to classify even more complex data. Extensive research is needed into how to develop better ontologies as well as to manipulate them more effectively.

Ontology also assumes that there is a general consensus within the bioinformatics field as to the format and structure of the data, with mechanisms for minimizing synonyms and homonyms. This is not true for many types of data. For example, many plant species have binomial names identical to animal species. Many genes have been given different names when found in one species or one tissue as compared with another. In almost every area of medicine as well as biology, researchers can identify contentious nomenclature issues. This standardized naming problem has serious consequences.

KDD and LKI are not separate; rather, they interact with each other closely. For example, as mentioned, one area of KDD is extracting knowledge from peer-reviewed journal articles for clinical use. However, due to the variety of ways to specify biological objects such as species, regulatory pathways, and gene names, KDD tools have difficulty extracting knowledge from these articles. These articles often represent a majority of data the scientific community have concerning the various biological objects. Due to the lack of standardized representations, one can only employ information retrieval algorithms and give the user a confidence level to the knowledge extracted. Great amounts of knowledge are lost because we cannot exploit a standardized knowledge base while examining peer-reviewed literature. As another example, the GO contains a graph structure that illustrates the relationship among molecular functions attributed to genes. If this structure can be combined with KDD processes such as clustering and classification algorithms, one can produce more biologically meaningful clusters or classification outcomes. These examples illustrate the importance of combining KDD and LKI, which is a challenging problem in the field.

Data Provenance

As demonstrated by the above databases as well as the previous issues, there are large quantities of data interchanging between tens if not hundreds of databases regularly. Furthermore, scientists are revolutionizing how research is done by relying more and more on the biological databases and less and less on original journal articles. Thus, the issue of preserving how the data are obtained becomes a paramount concern (83). The field of data provenance investigates how to maintain meta-data describing the history of a data item within the database. With databases cross-listing each other's entries, and with data mining and knowledge discovery algorithms generating new information based on data published in these databases, the issue of data provenance becomes more and more significant.

CONTENT-BASED MULTIMEDIA RETRIEVAL

With rapid advances in storage devices, networks, and compression techniques, large-scale multimedia data has become available to average users. How to index and search multimedia data according to its real content is a challenging problem, which has been studied for decades. Since the 1990s, content-based multimedia retrieval (CBMR) had become an increasingly active field, which is defined as searching for desired multimedia data (images or video/audio segments/clips) relevant with issued queries, such as image/audio/video examples, keywords, phrases, sentences, or any combination of them.

Different from text retrieval, CBMR is a more challenging task, as certain understanding of the content of multimedia data is desired. However, the state-of-the-art techniques for multimedia content understanding are still far from satisfactory. It is well-known that a large gap exists between the semantic meaning of multimedia content (what we really want) and the features of multimedia data (what we can actually get). To reduce this gap, CBMR mainly involves two basic problems. One problem is how to represent queries and multimedia content. The other problem is how to match the representations of queries and multimedia content.

Extensive works have been published on CBMR (1), and different paradigms and techniques have been proposed, such as query-by-example (QBE), annotation-based retrieval (ABR), and multimodality retrieval. The target of all these approaches is to address the above two problems. Table 1 illustrates several techniques and their corresponding solutions in terms of these two problems. QBE is the most typical scenario for multimedia retrieval before the year of 2000, whereas ABR and querying by combination of text and examples have become two new mainstream scenarios thereafter. In this article, we will introduce both classical CBMR and the current mainstream. In detail, we will introduce the following topics: feature extraction, query representation, high-dimensional feature indexing, annotation-based retrieval, and interactive multimedia retrieval. Besides that, we will also introduce several specific techniques for web videos search, including categorization, presentation, and recommendation. Before we introduce these concepts in detail, we give an overview of all these techniques.

OVERVIEW

Features for multimedia retrieval can be categorized into two general types: low-level features and high-level features. Low-level features include global features (such as color histogram, color moment, and texture) and local features (such as regional-level features and features extracted from key-points) (2). High-level features are semantic concepts (or keywords) used to describe the content of multimedia data in text (3–5). The approaches to high-level feature extraction are also called video/image annotation or semantic concept detection. Manual annotation of multimedia data is not only labor-intensive but also a time-consuming process. Thus, automatic annotation methods have been widely applied. Typically, it can be accomplished by machine learning methods. For a given concept, its annotation can be formulated as a binary classification task. As a consequence, multimedia annotation has benefited a lot from the advances of machine learning. More sophisticated methods for multimedia annotation include semisupervised learning, multiinstance learning, multilabel learning, and so on (6).

Queries and multimedia content can be described by low-level features, high-level features, or both. QBE adopts low-level features to retrieve desired data, whereas ABR uses high-level features. In QBE, multimedia data are indexed by low-level features, where users provide examples (such as images or video clips) to retrieve similar results. However, in many cases average users would prefer using text to describe what they want. ABR aims to address this issue, where multimedia data is annotated with a lexicon of semantic concepts (i.e., high-level features), and then queries are also mapped to these concepts and multimedia data can thus be retrieved by text-based matching. Another advantage of ABR based approach is that we can leverage existing text-based indexing and searching technologies to index and search multimedia content.

Multimodality retrieval, which has been actively studied recently, is a combination of these two methods (QBE and ABR) (5). For certain types of queries, for example, those about persons and sports, QBE can achieve better performance, whereas for some queries, such as those about scenes, ABR may be better. Thus, multimodal retrieval can outperform each individual method. It can be accomplished by analyzing the type of queries and then fusing the two methods or adopting the most suitable one. Fusing retrieval results from multimodalities also often generates better ones.

For QBE-based multimedia retrieval, typically low-level features of high dimension are required. Computation cost will be increased significantly when feature dimension is high and the size of the multimedia database is large. Therefore, high-dimensional indexing methods for efficient retrieval, such as k-d tree, are proposed to tackle this difficulty. Dimension reduction is also a frequently applied approach to deal with high-dimensional features (7,8).

As mentioned previously, annotation-based retrieval uses semantic concepts to index and search multimedia content. The main research problem in ABR is automatic annotation, which is typically based on a set of predefined semantic concepts, or we can also call it "concept lexicon," or "multimedia semantic ontology." The semantic ontology should satisfy several requirements, such as sufficient broadness and high feasibility. A frequently applied

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Table 1. Several Techniques for CBMR and their Descriptions

Technique	Description
Query-By-Example (QBE)	Represent queries and multimedia content by low-level features.
Annotation-Based Retrieval (ABR)	Represent queries and multimedia content by high-level features (i.e., semantic concepts).
Multimodality Retrieval	Represent queries and multimedia content by multiple modalities, such as visual features, audio and textual features, or low-level features and high-level features.
Relevance Feedback	Interactively bridging the gap between queries and multimedia content.

semantic ontology in academia is large-scale concept ontology for multimedia (LSCOM) (9).

The gap between queries and multimedia content is a central problem in CBMR. Frequently QBE, ABR, and multimodal retrieval cannot bridge this gap. Interaction is a promising approach to deal with this difficulty, which incorporates human factors into the retrieval loops. Relevance feedback is such an approach, which works in an iterative manner. In each round, users manually label some retrieved samples by indicating whether they are relevant, and then retrieval models can be refined based on these labeled samples. In this way, the semantic gap between high-level queries and low-level features can be gradually bridged. In addition, in ABR, users can improve the retrieval performance by manually revising their query representations (for example, changing/adding/removing keywords) or model parameters according to the current retrieved results.

Nowadays, many video-sharing websites are getting popular and attracting more and more attentions. How to access and manage web videos efficiently has got great interests recently. Already several research efforts have focused on web videos, including categorization, retrieval, and recommendation. Note that web videos have richer information than other videos as they typically have surrounding textual information from web pages accompanied with visual and audio content.

FEATURE EXTRACTION

Feature extraction is the basis of content-based image/video/audio retrieval. The features here include low-level visual/audio features and high-level semantic features. Typical low-level visual features include color, texture, shape, color layout, and spatial location. Low-level audio features generally are computed on a window basis. These window-based features can be considered as a short time description of the signal for that particular moment in time. In some cases, the low-level feature is not efficient for content based retrieval (10). If users want to search images or video segments by text query then semantic concepts are required to describe the images and video segments. These concepts may include, for example, human face, car, water, mountain, beach, people walking, indoor, landscape, and so on. In this section, we will have a brief introduction of the widely-applied low-level features and the normally used visual-semantic mapping methods.

Low-Level Visual Features

To perform content-based retrieval, visual features can be either extracted from the entire image/key-frame (global features) or from regions or feature points (local features). Global feature-based retrieval is comparatively simpler, whereas local features-based representation of images is proved to be more consistent to human perception.

Color Feature. Color feature is one of the most widely used features in image and video retrieval. Color features can be defined based on different color spaces, and some typical ones include RGB, LAB, LUV, HSV, and YCrCb (2,10). Generally color features are relatively robust to complex background and nearly invariant to image scale and orientation. Color features can either be extracted from the entire image or regions.

Histogram is the most commonly used color feature for image and video retrieval. It denotes the joint probability of the intensities of one or more of the three color channels. Besides histogram, color moments and color sets are also frequently applied. To overcome the quantization effects in the color histogram, Strieker and Orengo (11) proposed to use the color moments. To facilitate fast search over large-scale image collections, Smith and Chang (12) proposed color sets as an approximation to the color histogram. Correlogram is also a frequently applied feature. It describes image by a table indexed by color pairs, where the kth entry for $<i, j>$ specifies the probability of finding a pixel color j at a distance k from a pixel of color i in the image. Such an image feature turns out to be robust in tolerating large changes in appearance of the same scene caused by changes in viewing positions, changes in the background scene, partial occlusions, camera zoom that causes radical changes in shape, and so on (13).

Texture. Texture provides important structural information of many real-world images, such as fruit skin, trees, clouds, and fabric. Texture features describe the visual patterns that have properties of homogeneity.

Usually applied texture features for describing the visual information include spectral features, such as Gabor texture or wavelet texture, and statistical features (characterizing texture according to local statistical measures), such as the six Tamura texture features and the wold features (2). Among the six Tamura features, that is, *coarseness*, *directionality*, *regularity*, *contrast*, *line-*

likeness, *contrast*, and *roughness*, the first three are more effective, and the other three are related to the first three and have less effectiveness on texture description. Among the various texture features, Gabor texture and wavelet texture are widely used for image retrieval and have been reported to well match the perception of human vision (2). Texture can also be extracted from both the entire image and regions.

Shape. Some content-based visual information retrieval applications require the shape representation of objects that are generally invariant to translation, rotation, and scaling, while others do not. These features include aspect ratio, circularity, Fourier descriptors, moment invariants, consecutive boundary segments, and so on (2,14).

Spatial Location. Besides color and texture, spatial location is also useful for region-based retrieval. For example, "sky" and "sea" could have similar color and texture features, but their spatial locations are typically different in images and videos. "Sky" usually appears at the top of an image, whereas "sea" at the bottom or middle. Spatial location can be defined by two approaches. The first one is absolute spatial location, such as *upper*, *bottom*, *top*, and *centroid*, according to the location of the region in an image, and the other one is relative spatial relationship, such as the directional relationships between objects: *left*, *right*, *above*, and *below*.

Handling Layout Information. Although the global feature (color, texture, edge, etc.) is simple to calculate and can provide reasonable discriminating power in visual information retrieval, it tends to give too many false positives when the image collection is large. Many research results suggested that using layout (both features and spatial relations) is a better solution to image retrieval. To extend the global feature to a local one, a natural approach is to divide the whole image into subblocks and extract features from each subblock. A variation of this approach is the quadtree-based layout approach, in which the entire image was split into a quadtree structure and each tree branch had its own feature to describe its content.

Low-Level Audio Features

Typically, audio analysis algorithms are based on features computed on a window basis. These window-based features can be considered as a short time description of the signal for that particular moment in time. A wide range of audio features exist for audio computing tasks. These features can be divided into two categories: time domain and frequency domain features. The most typical audio features include mel frequency cepstral coefficient (MFCC), zero crossing rates, and short time energy.

Temporal Low-Level Features

Temporal low-level features are calculated from a set of consecutive frames (or a period of time) that have two typical forms: scalar and vector. Scalar temporal features generally are statistical measures along a set of consecutive frames (for visual features) or a period of time (for audio features), say, a shot, a scene, or a 1-second window. Typical scalar temporal feature is the average of general low-level features on a set of frames (for visual features) or a set of time windows (for audio features), for example, average color histogram of the frames in a shot, and average onset rate in a scene. Another exemplary scalar temporal feature is average motion intensity and motion intensity variance within a shot.

Vector temporal feature generally describes the temporal pattern or variance of a given video clip. For example, a trajectory of a moving object, curve of frame-based feature differences, camera motion speed, speaking rate, onset, and so on, are all vector temporal features.

High-Level Semantic Features

Various high-level semantic concepts, such as *Indoor/ Outdoor, People, Car,* and *Water,* occur frequently in the images and video segments. Type of audio, such as music, speech and noise; and type of music, such as rock, classical, and jazz can be regarded as semantic audio features.

Semantic concepts derived from the image or the video segments are very useful for content-based retrieval. However, the low-level features cannot well represent the semantics, which is the well-known semantic gap between low-level feature and high-level semantic. Lots of approaches are proposed to map the low-level feature to high-level semantics. For video data, a great many approaches to high-level semantic extraction have been proposed in the TRECVID competition organized by NIST (15).

The techniques used to derive high-level semantics include (*1*) using ontology to help detect high-level concepts, (*2*) using machine learning methods to map low-level features to high-level semantic concepts, (*3*) generating semantic template to support high-level image retrieval, and (*4*) making use of both the textual information obtained from the Web and the visual content of images for Web multimedia data annotation. Most systems exploit one or more of the above techniques to implement high-level semantic-based retrieval. As some of these topics will be discussed in other sections, we will just have a brief introduction on the concept ontology and machine learning methods.

Concept Ontology. In some cases, semantics can be derived easily from our daily language. For example, sky can be described as *upper, uniform*, and *blue region.* Using such simple semantics, different intermediate-level descriptors are defined to describe the low-level image features, for example, *light green, medium green*, and *dark green.* These descriptors form a simple vocabulary that is the so-called *object-ontology.* Images or video keyframes can be classified into different categories by mapping such descriptors to high-level semantics (keywords) based on our knowledge, for example, *sky* can be defined as *light blue* (color), *uniform* (texture), and *upper* (spatial location).

As automatic annotation techniques attract increasingly more attention in content based retrieval, it becomes ever more important to standardize the defined semantic concepts. Doing so can direct the multimedia research on a well-defined set of semantics. The LSCOM is designed to optimize simultaneously utility to facilitate end-user access, cover a large semantic space, make automated extraction feasible, and increase observability in diverse broadcast news video data sets (15).

In multimedia retrieval, however, ontology typically only consists of a set of terms (concepts/keywords), it actually also contains the relationships of these terms, as well as certain properties of the terms. Ontology with relationship and properties has been introduced to improve the performance of multimedia annotation in recent research.

Machine Learning. In most cases, to derive high-level semantic features requires the use of formal tools such as machine learning. The most commonly used learning techniques in CBMR include supervised learning, semi-supervised learning, and multiple-instance learning. Supervised learning predicts the semantic category label based on a set of input training samples. It is the mostly used learning technique for feature–concept mapping. By leveraging unlabeled data with certain assumptions, semi-supervised learning methods are promising to build more accurate models compared with supervised learning methods. Some have been applied to enhance the performance of multimedia annotation and retrieval. Multiple-instance learning (MIL) is a type of learning algorithms to tackle the problems with coarsely labeled information on bags of instances. This model assumes that instances are contained in bags and the instance labels are hidden. The bag label is related to the hidden labels of the instances as follows: the bag is labeled as positive if any single instance in it is positive, otherwise it is labeled as negative. MIL is widely applied in the content-based image retrieval (CBIR) systems, in which each image is deemed as a labeled bag with multiple instances, and the segmented regions in the images correspond to the instances in the bags. In addition, semantics from video data can be modeled as a multilayer MIL (MLMIL) learning problem, in which both shot and key-frame can be bag when key-frames of the shot and regions in a key-frames are instances, respectively (16).

EVALUATION MEASURES FOR MULTIMEDIA RETREIVAL

Recall and precision are two widely applied ratios to measure the success of a retrieval system. Recall is defined as the number of relevant (or correct) items returned by a query divided by the total number of relevant items in the corresponding data collection. Precision is defined as the number of relevant items returned by a query divided by the total number of items returned by the query. Usually, precision and recall have an inverse relationship: the higher the recall, the lower the precision, and vice versa. The precision-recall (PR) curve gives a more comprehensive illustration of a retrieval system's performance.

Average precision (AP) is also a measure that is often used in CBMR. Different from precision and recall, which actually do not count the rank of the retrieved result, average precision measures the performance of a ranked list (a list of retrieved items in descending order of relevance score). Letx_k be a variable representing the degree of relevance of the kth item in a ranked list that a retrieval system generates for a given query. $x_k = 1$ if the kth item is relevant; otherwise $x_k = 0$. Then the precision of the top-m items is

$$p_m = \frac{1}{m}\sum_{k=1}^{m} x_k \tag{1}$$

Suppose n items are in the ranked list, and R is the number of relevant items in the list, then the average precision of this list is defined as

$$\mathrm{AP} = \frac{1}{R}\sum_{m=1}^{n} x_m p_m \tag{2}$$

Average precision is sensitive to the entire ranking, that is, it will be changed if the order of relevant items and irrelevant ones is changed (order change within relevant items and within irrelevant items will not change average precision). However, this measure is also stable as a small change in ranking only makes a relatively small change in the final score. In addition, average precision has both precision and recall oriented factors, as it is computed over all relevant retrieved items.

Recently researchers proposed a new measure called average typicality precision (ATP) (16), which is more sensitive to order change. As mentioned above, average precision will not change if the order of two relevant (irrelevant) items is changed. That is to say, average precision actually is not sensitive to the "ranks" or the degree of relevant of the retrieved relevant items. ATP takes the degree of relevant (or the typicality score of the retrieved relevant items) into account. Different from counting AP, in which we only care whether a retrieved item is relevant or irrelevant to the query, a score for each retrieved item to indicate the degree of typicality is used to calculate ATP. ATP is defined as

$$\mathrm{ATP} = \frac{1}{n}\sum_{m=1}^{n} tp_m \tag{3}$$

$$tp_m = \begin{cases} \frac{\sum_{r=1}^{m} g_r}{\sum_{r=1}^{m} o_r} & if \quad g_r > 0 \\ 0 & if \quad g_r = 0 \end{cases} \tag{4}$$

where g_r is the ground-truth of the rth sample's typicality score in the ranked list, and o_r is the r-th highest typicality score in the ground-truth. ATP increases when more and more highly relevant items are at the top of the ranked list.

Besides recall, precision, average precision, and average typicality precision, receiver operating characteristic (ROC) curve (which actually is equivalent to PR curve but presented in a different space) and AUC (area under ROC curve) are applied seldom in multimedia retrieval.

QUERY REPRESENTATION

A query is represented in some specific forms by which the user delivers the information of interested multimedia data. Several types of query representation include: QBE, query by text, and multimodality representation.

Query by Text

A text used to specify the query may consist of one or more keywords, phrases, or sentences, which may be matched with the tags, annotations, title, and/or filename of the desired content, to deliver high-level semantic information for the interested multimedia data. Most commercial image and video search engines make use of the associated textual information to perform query by text.

The text can describe an object, a scene, or an action that appears in the media (e.g. video). For example, the keyword, "the great wall," means that the ideal video should contain the object. A query, represented by a phrase "opening a door" may aim to find a video that contains the behavior of opening a door. The text can also reflect the genre of the queried video. For example, a query by word "comedy" means that the user is interested in the comedy videos.

A query represented by a text is an easy way to deliver users' query requirements. Extracting the semantic information from the video content is still a challenging problem, and at present it is far away from practicality. It is very useful in the case that some textual descriptions, including the title, synopsis, tags, and so on, are associated with the videos in the database. And automatic annotation is also another type of text information that can be used to match with textual query. Then the techniques of document retrieval are borrowed for multimedia retrieval.

Query by Example (QBE)

QBE is a method that allows a user to specify a query condition by providing examples that contain the features of interest. Using this representation, the query condition may be directly comparable with the objects. For subsequent comparison, the multimedia data items in the database may be put into a preprocessor to extract the representative features.

Compared with query by text, query by example is an intuitive way of representing the user's interest and also an effective way to deliver the interest information because it can represent subtle difference more easily than representation by words. However, extracting the hidden interest information from the examples is not as straightforward as query by text. To accomplish this goal, video and/or audio analyzing and understanding techniques are required.

QBE for Image Retrieval. In QBE for image retrieval, five popular example representations can be used with different specified features: image, shape, spatial relation, color, and texture (1,2,10,17–20).

The simplest representation of QBE is just a sample image that is much related or similar to the desired images in the database. This representation is easily given by a user, but it is not a good way to pass the manifest interest feature. A subsequent interactive relevance feedback, such as correcting the retrieved results, may help clarify this query. For example, a user may label some retrieved images as relevant, and some retrieved image as irrelevant. Exploring this feedback and the original query specification will make the interest information clearer so that the retrieval will be refined (21,22). More details about relevance feedback will be introduced later in this article.

Query by shape aims to retrieve an image object by evaluating the shapes of object. This query representation is usually applied to the shape-related retrieval task. Two forms of shape specification include: an image with a shape to be retrieved and a shape drawn by a user (or query by sketch).

Query by spatial relation is mainly adopted in geographical image retrieval (e.g., building and river retrieval). This query specifies one or more component objects as an example, in which the important information, the spatial relation among them, is delivered. The possible relations consist of disjoint, meet, overlap, contain, cover, inside, covered-by, equal, and others.

Query by color aims to find images such that they have principal color values and/or spatial distribution similar to the query specification. The query can be specified by just giving colors and/or the spatial distribution. Query by color is often accompanied by the specification of spatial relation of color components specified. In query evaluation, the color difference, its spatial distribution, and the spatial relation of color components may be valued together or separately to the degree of meeting to the query specification.

Query by texture is typically applied to the task that images with specific pattern are queried. This query is specified by a texture image, and then the image database is searched to find images that contain textures similar to the specification.

QBE for Video Retrieval. A video consists of a series of images. The simple way is just viewing it as a collection of images, and then the techniques of query by example for image retrieval may be used directly to specify the query for video retrieval. However, the most important characteristic of videos, which are different from the image, is the temporal relation. A possible query may be a video clip in which the temporal relation is latently encoded. Signal-processing and computer-vision techniques are required to analyze the spatial and temporal relations of video clips to extract the interest information, and sometimes reanalysis is necessary with given relevance feedback. Besides, query specification techniques that use the temporal relations mainly include query by motions and query by spatio-temporal relations.

Query by motions is an approach to retrieve intrinsic features of video data, that is the motion of objects that appear in video. Extracting the motion information directly from a video using the computer vision techniques is still a difficult problem. Motion by sketch is a practical method to realize motion-based retrieval. An example of motion may be specified by moving a mouse, and the trajectory and velocity are sampled. Additionally, size change of the object may also be specified by drawing rectangles along with the timeline. An alternative method is allowing a user to specify trajectory, duration and scaling as well as the basic feature of image such as color, texture, and shape.

Query by spatio-temporal relations aims at specifying the spatio-temporal correlation of multiple objects in the video. A user may define two or more sets of spatial relations sequentially in accordance with the time, which represent spatio-temporal relations of the objects. The temporal relation of each object can be specified by giving the trajectory, velocity, and size. The spatio-temporal relation can also be used for multiple color components, in which the spatial and temporal relations of different color components are specified simultaneously.

QBE for Audio Retrieval. A general approach to content-based audio indexing and retrieval is taken as (23):

(1) Audio is classified into a set of predefined types such as speech, music, and noise. Some types can be divided into small types. For example, music can be classified into classical, rock, jazz, dance, and so on.
(2) Different audio types may be processed and indexed in different ways. For example, if the audio type is speech, then speech recognition is typically applied and the speech is indexed based on recognized text. For other types, a set of low-level and/or perceptual features are often extracted. Low-level features include mel frequency cepstral coefficient (MFCC), zero crossing rates, and short time energy. Exemplary perceptual features include melody, pitch, onset, and mood.
(3) Query audio pieces are then similarly classified, processed, and indexed.
(4) Audio pieces are retrieved based on the similarity between the query index and the audio indices in the database.

QBE for audio retrieval are more applied for retrieving data from music and speech data collections. Query-by-humming (QBH) (24) is a typical setting for music retrieval. QBH system aims at searching a desired piece of music by singing or whistling its tune. It is very useful when you want to find a song from music library but forget its title or artist. In a QBH system, a person humming is entered to the system as an example of a musical phrase. The system retrieves the melody of songs that well match this given example. Humming as the way of representing a query condition for music retrieval is intuitive to a general user. More audio retrieval techniques can be found in Refs. 2,10, and 23.

Query by Multimodality. A query may be specified by multimodality information related with the queried objects, which usually occurs when multiple modalities associated with the queried media are available at hand with a user. Query by multimodality is a more promising specification scheme than any single query specification, and it potentially makes the retrieval easier because it provides more solid interest information. For example, in video retrieval, besides a keyword or phrase, we also can specify a query by giving a video clip or an audio clip at the same time. Multimodality representation also brings a hot topic, that is, how to fuse the formation derived from multimodality.

The most substantial work in this field is presented in the TREC Video Retrieval Evaluation (16). It focuses its efforts to promote progress in content-based retrieval from video via an open, metrics-based evaluation, which is based on the common video datasets and a standard set of queries. The queries include text plus example images and example videos optionally.

A typical multimodal video search system consists of several main components, which include query analysis, uni-modal search, reranking and multimodal fusion. A generic video search framework is illustrated as Fig. 1. By analyzing the query, the multimodal query (i.e., text, key-frames, and shot) are input to individual search models, such as text-based, example-based, and annotation-based model. Then a fusion and reranking model is applied to aggregate the search results.

Usually, video retrieval systems tend to get the most improvement in a multimodal fusion and reranking by leveraging the above three uni-modal search models. In most multimodal fusion systems for video search, different fusion models are constructed for different query classes, with the involvement of human knowledge. However, some query classification methods are designed for a certain video collection, and they may not be appropriate to other collections. How to fuse these uni-model search models remain a challenge and a meaningful research topic. Reranking is a frequently applied technique to tackle this problem. More details about this topic will be presented later in this article.

HIGH-DIMENSIONAL FEATURE INDEXING

The main operations in content-based retrieval, especially for QBE, include similarity evaluation between the features of two objects and feature indexing in the database. The former is time-expensive when the feature is high dimensional, and the latter may suffer from the large-scale database. To make content-based retrieval scalable, especially for QBE, two techniques, dimension reduction and multi-dimensional indexing, are explored for efficient retrieval. Dimension reduction maps high-dimensional features into lower-dimensional space to save computation cost used for feature comparison (similarity calculation). Multidimensional indexing is used to find efficient index structure of a multimedia database to speed up the feature comparison process between the query and the entire database.

Dimension Reduction

Dimension reduction aims to map a higher-dimensional space to a lower-dimensional space (7). Two categories of dimension reduction methods include linear and nonlinear dimension reduction.

Linear Dimension Reduction. Linear dimension reduction consists of two basic steps: linear transformation and dimension discarding. Linear transformation is optimized with various criteria. Principal component analysis (equivalent to Karhunen-Loeve Transformation) finds a linear transformation such that the transformed features are uncorrelated, or equivalently, the covariance matrix of the transformed data is diagonal. The linear transformation is obtained by performing singular value decomposition on the covariance matrix of the original data. The next step discards some dimensions that have smaller variances. By incorporating supervised information, the resulted linear

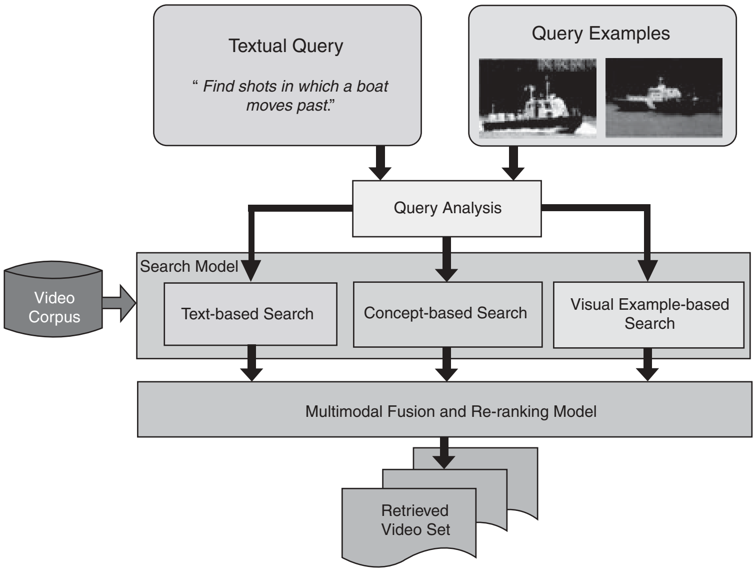

Figure 1. Framework of multimodal video search system.

transformation may be discriminative. Linear discriminant analysis is just such a linear transformation to maximize the between-class variance and minimize the within-class variance in the lower-dimensional space.

Nonlinear Dimension Reduction. Many researchers advocate the use of multidimensional scaling for content-based retrieval applications. MDS comes in different flavors and lacks a general precise definition. A typical approach is to map space R^n into R^m using m transformations, each of which is a linear combination of appropriate radial basis functions. Isometric feature mapping is a special MDS to find a lower-dimensional space such that the Euclidean distance is "close enough" to the "geodesic distance" on the original space. Another popular method, called locally linear embedding, aims to find a lower-dimensional space such that the locally linear reconstructions in the original space are kept. An augmented relation embedding is proposed to map the image space into a semantic manifold that faithfully grasps the user's preferences by combining the similarity relations entailed by the content-based features, and the relevance relations specified in the feedback.

Geometric hashing consists of hashing from a high-dimensional space to a very low-dimensional space. In general, hashing functions are not data dependent, and the metric properties of the hashed space can be significantly different from those of the original space. Ideally, the hash function should spread the database uniformly across the range of the low-dimensionality space, but the design of the hashing function becomes increasingly complex with the dimensionality of the original space. Hence it can be applied to image database only when the dimensionality of the original space is not so high.

The local linear dimension reduction methods, which include clustering and singular value decomposition and vector quantization principal component analysis, are another categorization of nonlinear dimension-reduction method. Those methods consist of two steps. First, the data points are clustered. Second, a linear dimension reduction method is adopted on each local cluster.

Multidimensional Indexing

Given an object database with multidimensional features, an appropriate indexing structure should be constructed to make the retrieval task efficient and effective. Many methods can be used for indexing, which can be roughly divided into two classes: vector-space and metric-space methods (8).

Vector-Space Methods. Vector-space methods represent objects (or feature vectors) as *sets* or *points* in a d-dimensional vector space. For example, gray histograms of images can be viewed as points in high-dimensional (typically 255-dimensional) space, in which each coordinate corresponds to a different bin of the histogram. Algorithmically, vector-space methods can be divided into nonhierarchical methods, hierarchical decomposition methods, and projection-based methods.

The basic nonhierarchical method is a brute-force approach. It scans the whole database table sequentially, and it apparently is very time consuming and not efficient. Besides this naive method, mainly two other classes are suggested: mapping a d-dimensional space onto a real line through a space-filling curve, and partitioning the space into nonoverlapping cells of known size. Most former methods order the database using the positions of the individual items on a space-filling curve, such as the Hibert or Peano-Hilbert curve, or the z-ordering, and obtain a one-dimensional representation. Then, a one-dimensional indexing structure is used to index the mapped records. The space-filling curves tend to map nearby points in the original space into nearby points on a real line, so the one-dimensional indexing techniques, such as range queries, nearest-neighbor queries, and α-cut queries, may be reasonably approximated by executing them in the projected space. The latter partition the search space into a predefined number of nonoverlapping fixed-size regions, which do not dependent on the actual data contained in the database. These two methods are well suited to index low-dimensional spaces (when $d < 10$), but their efficiency decays exponentially when $d > 20$.

Locality sensitive hashing is a recent technique which proposed a locality sensitive hashing function to perform approximate nearest neighbor searching in high-dimensions. The basic idea is to hash the input items so that similar items are mapped to the same buckets with high probability (1).

Hierarchical decomposition methods recursively partition the search space into progressively smaller regions that depend on the dataset. The hierarchical decomposition can be finally represented by a tree. The decomposition techniques vary at the partitioning step with the different tree representation. The typical methods include quadtrees, k-d trees, and R-trees. Those methods were originally developed for low-dimensional search spaces, and unsurprisingly they suffer from the curse of dimensionality and become ineffective in high-dimension cases (when $d > 20$). One of recent researches adopted kd-trees to perform approximate nearest neighbor searching in arbitrarily high dimensions (7,8). The hierarchical clustering methods, such as hierarchical k-means or hierarchical Gaussian mixture models, can also be used for indexing.

Projection-based methods are indexing structures that support approximate nearest-neighbor queries. The techniques vary with different types of approximation performed. Basically two categories exist: fixed-radius queries and $(1 + \varepsilon)$-nearest-neighbor queries. Some former methods project the database onto the coordinate axes, maintain a list for each collection of projections, and use the list to identify a region of the search space quickly that contains a hyper-sphere of radius centered on the query point. Other methods project the database onto appropriate (d + 1)-dimensional hyperplanes, and they find nearest neighbors by tracing an approximate line query point and finding its intersection with the hyperspaces. The latter methods project the high-dimension database into selected or randomly generated lines and index the projections. Both methods are proper for high-dimension queries.

Metric-Space Methods. Metric-space methods index the distances between database items rather than the individual database items. They are useful when the distances are provided with the dataset or where the selected metric is too computationally complex for interactive retrieval (and therefore it is more convenient to compute the pairwise distances while adding items to the database). Most metric-space methods are designed for nearest-neighbor queries, few support alpha-cut, and almost no methods support range queries.

The Voronoi diagram is a method that associates a Voronoi region to each database item if the distance function is given. Different distance functions produce different sets of Voronoi regions. Examples of Voronoi diagrams include cell-and X-tree-based methods.

The ordered list method is proper when all pairwise distances between database items are given. Each database item is associated with an ordered list of all the other items, which are sorted in ascending order of distance. Nearest-neighbor queries are reduced to a point query followed by scanning the list.

Vantage-point methods build a tree structure such that each internal node indexes a disjoint subset of the database, has two children nodes, and is associated with a database item called vantage point. The items indexed by an internal node are well organized according the distance. For example, the median distance is computed, the items closer to the vantage point than the median distance are associated with the left subtree and the remaining ones with the right subtree.

ANNOTATION-BASED RETRIEVAL

Early multimedia search, especially image search, can be traced back to the 1970s. Since the 1990s, it has witnessed strong renaissance in the multimedia search, especially the classic content-based retrieval. Three paradigms exist on the methodological spectrum of the content-based multimedia search. At the earliest extreme, it is the pure manual-labeling paradigm that labels multimedia content, for example, images and video clips, manually with some text labels or concepts and then use text retrieval techniques to search multimedia content indirectly. At the other extreme, it is the automatic content-based search paradigm that can be fully automatic by using the low-level features from multimedia analysis. QBE is the most typical method in this paradigm. However, some difficulties develop in these two paradigms. As for the first manual-based method, a large amount of human labors are required, and the manual labels suffer from the subjectivity of human perception on multimedia content. However, the latter paradigm of the fully automatic method is subject to the well-known "semantic gap" between the low-level features and high-level semantic concepts.

In the past few years, a promising paradigm of the automatic annotation-based multimedia search has been brought into many practical search systems. Compared with the above two extremal paradigms on the methodological spectrum, the third annotation-based paradigm strikes a better balance in the middle and it is an automated method as well (6,9,25). However, this approach is not purely automatic because we need to label some content at the beginning as the training set. It is not purely manual either because once a concept detector is trained based on the labeled training set, the detector can automatically annotate the same concept for other new images and video clips.

Figure 2 illustrates a general framework for automatic annotation (it is also called high-level feature extraction, semantic concept detection, or concept detection in brief). First a set of pre-labeled training samples are used to learn the models of a set of semantic concepts or keywords. These learned models are trained based on some extracted features from training samples, such as color moments, color histograms, color correlogram, wavelet textures and some region features (e.g., SIFT descriptors, shape-based features etc.). These obtained models can then be used to predict the keywords or concepts of any unlabeled images or video clips. Accordingly the trained models here are referred to "classifiers." With these predicted keywords or concepts, the text-based retrieval techniques can be adopted to search the multimedia collections.

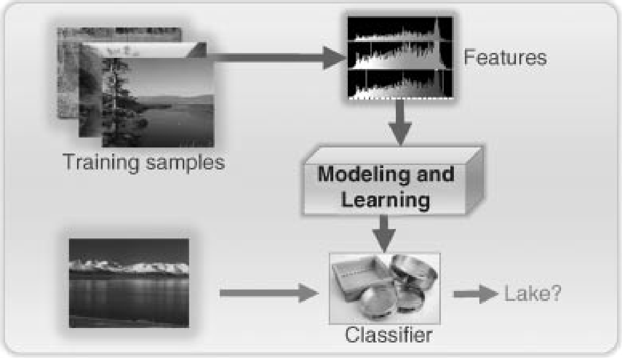

Figure 2. General framework for annotation-based multimedia retrieval.

It is not difficult to recognize that the key factor of the annotation-based paradigm is the classifiers that are used to annotate the keywords to each images and video clips. Some well-defined classifiers have been successfully adopted in content-based retrieval system. These classifiers can be categorized into two main approaches. The first one is the generative models. They explicitly assume the multimedia data is generated by some predefined distributions, such as Hidden Markov Model, Gaussian Mixture Model and so on. These models define a joint probability distribution $P(x, y)$ over the observed low-level features x and their corresponding labels y. In the step of prediction, a conditional distribution $P(y|x)$ is formed to predict the keywords of images or video clips. Opposite to the generative model, the other genre of classifiers is discriminative model. It directly models the dependence of the labels y on the low-level features x, that is, the conditional distribution $P(y|x)$ Some examples of discriminative models used in multimedia retrieval include support vector machine (SVM), boosting, conditional random field, and so on. Both generative and discriminative models are called by "supervised models" for they are all constructed on a prelabeled training set.

In recent years, another type of so-called "semisupervised model" is also applied into annotation-based retrieval. Different from supervised models that only involve training samples in the modeling step, the semisupervised model takes into account the unlabeled samples as well. By leveraging the distribution information revealed by a large amount of unlabeled samples, the semisupervised model can tackle the problem of insufficiency of training samples, and hence the prediction accuracy can be improved. In multimedia retrieval community, existing semisupervised models include manifold models, cotraining models, and so on.

Extracted semantic concepts can be used to index multimedia content directly using text-based technologies, but typically they are integrated with other textual information, such as recognized speech, closed captions, and surrounding text, or even integrated into a multimodality multimedia retrieval system in which QBE techniques are also applied.

The annotation accuracy of the state-of-the-art of concept-detection algorithms is still not satisfactory in the current stage. However, researchers proved that when the number of semantic concepts is relatively large, even it the annotation accuracy is low, annotated semantic concepts (with low accuracy) still can improve the accuracy of the search results significantly (9).

INTERACTIVE MULTIMEDIA RETRIEVAL

As fully automatic content-based retrieval (whether under the typical query-by-example scenario, text-based, or annotation-based scenario) frequently gives unsatisfied results, loop human factor into the retrieval process has been proposed to refine the retrieval accuracy gradually. Typical interactive retrieval method is relevance feedback, whereas interactions can be in other forms, such as manual parameter adjustment and modality selection (3–5,26).

Relevance Feedback

Relevance feedback was originally developed for textual document retrieval and then introduced to CBIR, mainly for QBE scenario. Since then, this topic has attracted tremendous attention in the CBIR community, and a variety of solutions has been proposed within a short period (19,20).

Atypical framework for relevance feedback in CBIR contains the following three main steps, which can be expanded easily to handle video and audio data:

Step 1: For a given query, the machine first provides a list of ranked images according a certain similarity metric.

Step 2: The user marks certain number of ranked images as relevant to the query (positive samples). or irrelevant (negative samples).

Step 3: The machine learns and tries again.

Generally speaking, the earlier CBIR systems without interaction suffer from the two difficulties:

(1) The gap between high-level concepts and low-level features: Low-level visual similarity measures, such as color histogram, do not necessarily match the high-level semantics of images. For example, all three images in Fig. 3 are about cars, but they are of different colors and backgrounds. Their color histograms are very different, although their semantics are close.

(2) Subjectivity of human's perception on media content: Different persons, or the same person under different circumstances, may perceive the same visual content differently. For example, in Fig. 4, one may be interested in the eagle in (a), so (b) is more relevant to (a) compared with (c). But another person may be more interested in the water in (a), and thus (c) is more relevant to what he/she is looking for.

The early relevance feedback schemes for CBIR systems can be classified into two approaches: query point

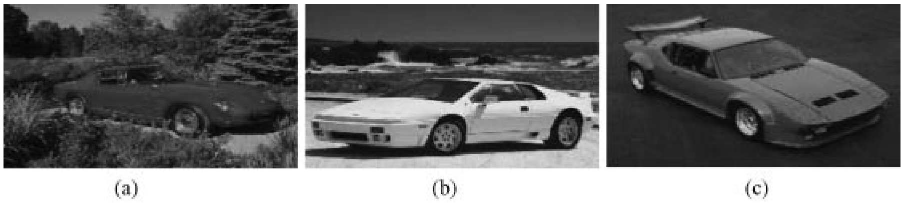

Figure 3. The gap between high-level concepts and low-level features.

movement (query refinement) and reweighting (similarity measure refinement).

The query point movement method tries to improve the estimate of the "ideal query point" by moving it toward positive example points and away from bad example points in the query space. Various ways can be used to update the query. A frequently used technique is Rocchio's formula. That is, for a set of relevant documents D_R and nonrelevant documents D_N given by a user, the optimal query is defined as:

$$Q' = \alpha Q + \beta\left(\frac{1}{N_R}\sum_{i \in D_R} D_i\right) - \gamma\left(\frac{1}{N_N}\sum_{i \in D_N} D_i\right) \qquad (5)$$

where α, β, and γ are suitable constants; N_R and N_N are the number of documents in D_R and D_N, respectively. This technique is also referred to as a learning query vector. It was used in a multimedia retrieval system called "MARS" to replace the document vector with visual feature vectors.

The reweighting method enhances the importance of a feature's dimensions that help retrieve relevant images and reduce the importance of the dimensions that hinder this process. This process is achieved by updating the weights of the feature vectors in the distance metric.

One of the most influential classic researches on relevance feedback has clear roots in the document retrieval field. For example, learning based on "term frequency" and "inverse document frequency" in the text domain was transformed into learning based on ranks of the positive and negative images along each feature axis in the continuous feature space.

The classic query point movement method and reweighting method are both simple learning methods. Relevance feedback can be considered as a learning problem: A user provides feedback about examples retrieved as a result of a query, and the system learns from such examples how to refine the retrieval results.

Three basic issues are generated in relevant feedback for multimedia retrieval, which include small sample size, asymmetry of training samples, and real-time requirement.

The number of training samples is typically less than 20 per round of iteration, which depends on the user's patience and willingness to cooperate. It is very small relative to the dimension of the feature space (from dozens to hundreds, or even more). For such small sample size, some existing learning machines such as SVMS cannot give stable or meaningful results, unless more training samples can be elicited from the user.

In the relevance feedback process, there are usually many more negative feedback samples than positive ones. Learning algorithms tend to be overwhelmed by the major class and ignore the minor one.

Because the user is interacting with the machine in real time, the algorithm should be sufficiently fast and should avoid heavy computations over the whole dataset.

Most published work has focused on the above three issues. However, it should be noted these do not cover all the issues when addressing relevance in CBIR as a learning problem. Other important ones include how to accumulate knowledge learned from the feedback and how to integrate low-level visual and high-level semantic features in query.

Interactive Search

Image/video search is defined as searching for the relevant image/video with issued textual queries (keywords, phrases, or sentences) and/or provided image examples or video clips (or some combination of the two). In the TRECVID video search task hold by NIST, prior work has established that a human searcher in the loop significantly outperforms fully automated video search systems without such a human searcher.

Actually, relevance feedback can also be regarded as a type of interactive search, whereas the interactions in interactive search can be in different forms instead of only indicating whether a certain number of retrieved results are positive or negative. Interactive search is first proposed in TRECVID video search.

In TRECVID video search, interactive search allows users to fuse together multiple searches within each query, which was typically done for answering the query topics. A successful example of interactive search is the IBM Marvel Multimedia Analysis and Retrieval System (IBM, Armonk, NY). It provides search facilities for classic content-based retrieval, model-based (annotation-based) retrieval, and text/speech-based retrieval, and any combination of them. Given the statement of information need and query content, the

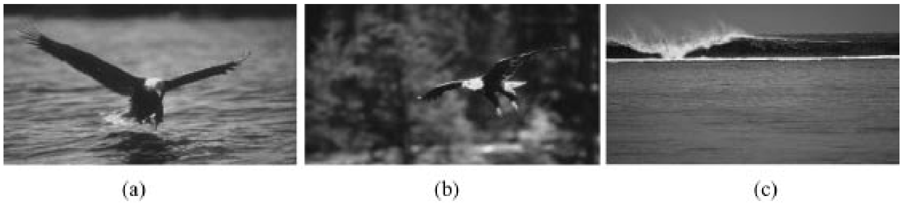

Figure 4. Subjectivity of human perception.

user would typically issue multiple searches based on the example content, models/concepts, and speech terms.

Multiple searches are combined using a set of aggregation functions. Consider scored results list R_k for query k, where $D_k(n)$ gives the score of item with id = n and $Q_d(n)$ the scored result for each item n in the current user-issued search, then the aggregation function rescores the items using function $D_{i+1}(n) = F_a(D_i(n), Q_d(n))$. The following aggregation functions are frequently applied:

Average: Taking the average of the scores of prior result list and current user-search. "Average" deals with "and" semantics, that is, it can be used for queries like "retrieve items that are indoors and contain faces":

$$D_{i+1}(n) = \frac{1}{2}(D_i(n), Q_d(n)) \tag{6}$$

Minimum: Retaining lowest score from prior result list and current user-issued search. "Minimum" provides "or" semantics. This function can be useful in searches such as "retrieve items that are outdoors or have music"

$$D_{i+1}(n) = \min(D_i(n), Q_d(n)) \tag{7}$$

Sum: Taking the sum of scores of prior results list and current user-search. Provides "and" semantics.

$$D_{i+1}(n) = D_i(n) + Q_d(n) \tag{8}$$

Product: Taking the product of scores of prior results list and current user-search. Provides "and" semantics and better favors those matches that have low scores compared to "average."

$$D_{i+1}(n) = D_i(n) \times Q_d(n) \tag{9}$$

Consider user looking for items showing a beach scene. Without interaction, the user can issue a query with the following sequence of searches:

(1) Search for images with color similar to example query images of beach scenes.
(2) Combine results with model = "sky" using "average" aggregation function
(3) Combine with model = "water" using "product" aggregation function
(4) Combine with text = "beach" using "minimum" aggregation function

On the other hand, for interactive search operations the user can issue the following sequence of searches in which the user views the results at each stage, which corresponds to the following query:

(1) Search for text = "beach",
(2) Then, select results that best depict beach scenes and search again based similar color. And then combine with previous results using "product" aggregation function,
(3) Combine with model = "sky" using "average" aggregation function,
(4) Combine with model = "water" using "product" aggregation function

The user interactively builds a query by choosing sequentially among the descriptors and by selecting from various combining and score aggregation functions to fuse results of individual searches. The additional interactivity improves the retrieval performance.

CONTENT-BASED WEB VIDEO RETRIEVAL

Content-based video retrieval, as a challenging yet promising approach to video search, has attracted the attentions of many researchers during the last decades. Many methods are proposed, and some systems are also realized. Currently, with the advent of new video techniques and ever developing network technology, video-sharing websites and video-related Internet-based services are becoming more and more important on the Web. As a result, many videos are generated or uploaded onto the Web every day. This situation brings new challenges and difficulties to content-based video retrieval (27).

Large-Scale Web Video Categorization

Video categorization is used to classify videos into some predefined categories. Traditionally, most methods of video categorization categorize videos into certain typical genres, such as movies, commercials, cartoons, and so on. However, for web videos, the categories include not only genres, but also semantic concepts, such as autos, animals, and so on. Figure 5 shows the category definition excerpted from YouTube (YouTube, LLC, Mountain View, CA).

Using multimodality is a promising approach to categorize web videos. Low-level and semantic features from different information sources, such as visual, audio, and the surrounding text in the web page affiliated with the video can be applied. A classifier can be trained based on one type of features, and then improved results can be obtained by fusing all the output from these classifiers (27).

Content-Based Search Result Re-Ranking

For video retrieval, many information sources can contribute to the final ranking, including visual, audio, concept detection, and text (ASR, OCR, etc.). Combining the evidence from the various modalities often improves the performance of content-based search significantly (28).

One intuitive solution to combine such modalities is to fuse the ranking scores outputted by the search engines using each modality. However, simply fusing them will lead to inaccuracy and maybe propagate the noise. Some researchers propose to train the fusion model separately for different query classes. Some efforts focus on how to

classify the queries automatically, which still remains an open problem.

In the experiments of video retrieval, text information often leads to better performance than other individual modalities. Hence, some methods emerge that first use text information to rank the videos and then use other evidences to adjust the order of videos in the rank list. It is called reranking. Some researchers used the technique called pseudo relevance feedback to rerank the video search results. They assume that the top and bottom fractions of the rank list can be regarded as the positive and negative samples with significant confidences, and then they use these samples to train a model to rerank the search result.

However, such assumption cannot be satisfied in most situations because the state-of-the-art performance of text-based video search is low. One proposed two methods to rerank the video search result from different viewpoints. One is information theory driven reranking, called IB-reranking. It assumes the videos that have many visually similar videos with high text relevance should be ranked top in the search result. The other is context ranking, which formulate the reranking problem into a random work framework.

Content-based search result reranking, although attracted the attentions from the researchers and is applied successfully to TRECVID video search task, many issues need to be solved. The most important is deploying it into real-world video search system to observe whether it can improve the performance.

Content-Based Search Result Presentation

Search result presentation is a critical component for web video retrieval as it is the direct interface to the users. A good search result presentation makes users browse the videos effectively and efficiently.

Typical video presentation forms include static thumbnail, motion thumbnail, and multiple thumbnails.

Static Thumbnail: an image chosen from the video frame sequence, that can represent the video content briefly.

Motion Thumbnail: a video clip composed of the smaller clips selected from the original video sequence based on some criteria to maximize the information preserved in the thumbnail. Motion thumbnail generation uses the same or similar technology for video summarization.

Multiple Thumbnails: selecting multiple representative frames from the video sequence and show them to the user so that the user can quickly recognize the meaning of the video. The number of thumbnails can be determined by the complexity of the video content or can be scalable (that is, can be changed according to users' request). Multiple thumbnails are also generated by video summarization algorithms.

Content-Based Duplicate Detection

As the techniques and tools for copying, recompressing, and transporting videos can be acquired easily, the same videos, although with different formats, frame rates, frame sizes, or even some editing, so-called duplicates, are distributed over the Internet. In some video services, such as video search and video recommendation, duplicated videos that appear in the results will degrade the user experience. Therefore, duplicate detection is becoming an ever important problem, especially when facing web videos. In addition, integrating the textual information of video duplicates also help build a better video index.

Video duplicate detection is similar to QBE-based video search in that they are both to find similar videos, with the difference in similarity measure between videos. For video search, the returned videos should be the videos semantically related to or matching the query video, whereas for duplicate detection, only the duplicates should be returned. Three components for duplicate detection are video signature generation, similarity computation, and search strategy.

Video signature is a compact and effective video representation. Because videos are a temporal image sequence, a sequence of the feature vectors of the frames sampled from the video can be viewed as the video signature. Also, shot detection can be processed first and then the feature vector sequence extracted from the shot key frames can be regarded as video signature. In addition, the statistical information of the frames can be employed as video signature.

The similarity measure depends on the video signature algorithm, which includes L1 norm, L2 norm, and so on. The high-dimensional indexing techniques can be used to speed up the search for duplicate detection, and some heuristic methods that use the characteristics of the specific video signatures can also be employed.

The difficulties of video duplicate detection lie in that: (*1*) It requires low computational cost for video signature generation as well as the duplicate search so as to be applied in large-scale video set and (*2*) the forms of the video duplicates are diverse so that it requires an effective and robust video signature and similarity measure.

A closely related topic to duplicate detection is copy detection, which is a more general algorithm to detect duplicates. Technologies for copy detection often are also called video signatures. Different from duplicate detection, which only cares about videos of the same or close durations, copy detection also needs to detect whether a short clip exists in a longer video, or even whether two videos share one or more segments. Copy detection is generally used against pirating.

Web Video Recommendation

Helping users to find their desired information is a central problem for research and industry. For video information, basically three approaches are dedicated to this problem: video categorization, video search, and video recommendation. Many video-sharing websites, like YouTube, MSN Soapbox, and even most video search websites, like Google (Mountain View, CA) and Microsoft Live Search (Microsoft, Redmond, WA), have provided video recommendation service.

Video recommendation, in some sense, is related to video search in that they both find the videos related to the query (for video search) or a certain video (for video recommendation). However, they are also different in two aspects. First, video search finds the videos mostly matching the query, whereas video recommendation is to find the videos related to the source video. For example, “Apple” video is not a good search result for a query “Orange”, whereas it may be a good recommendation for an “Orange” video. Second, the user profile is an important component for video recommendation.

Most recommendation systems use the user profiles to provide recommended video lists to the specific user. The user’s click and selection of videos and ratings to some items can be parts of user profile, besides the user location and other user information. As well, most video recommendation systems use the text information (such as the name of actors, actresses, directors for the movie, and the surrounding text for the web video) to generate the recommendation list. Content-based video analysis techniques can provide important evidence besides user profile and text to improve the recommendation. With such information, video recommendation can be formulated into a multi-modality analysis framework (29).

CONCLUSION

As aforementioned, CBMR is more challenging than a text search as it requires certain understanding the content of multimedia data, whereas the state-of-the-art of visual and audio content understanding is still far from applicable. Most existing content-based systems are based on low-level feature comparison, and some are based on limited semantic analysis. One of the most significant problems of existing CBMR systems is that they are basically only applicable for relatively smaller data collections. Existing widely-applied large-scale multimedia retrieval systems, such as, video and image search engines provided by Yahoo (Sunnyvale, CA), Microsoft, and Google, are mostly based on textual keyword indexing and search (surrounding text, file metadata, tags and recognized speech). Development has A long way to go for applicable large-scale content-based multimedia retrieval.

High-dimensional feature indexing is still a challenging problem for QBE-based multimedia retrieval, especially for enabling large-scale data indexing and search. Representative content-aware features are also still not satisfactory in the current stage. Multimedia annotation-based retrieval is a promising direction, but current applicable keywords are still limited and large-scale (in term of both semantic concepts and multimedia dataset) and comprehensive annotation is still difficult. Recently, by leveraging resources including existing textual information, tags, and community of users in CBIR attracts more and more interests of researchers. Some researchers believe leveraging these resources is promising to solve difficult problems as multimedia content understanding. Integrating active learning and/or relevance feedback alike technologies are possible solutions to using these information.

COOPERATIVE DATABASE SYSTEMS

Consider posing a query to a human expert. If the posed query has no answer or the complete data for an answer are not available, one does not simply get a null response. The human expert attempts to understand the gist of the query, to suggest or answer related questions, to infer an answer from data that are accessible, or to give an approximate answer. The goal of cooperative database research is to create information systems with these characteristics (1). Thus, the system will provide answers that cooperate with the user. The key component in cooperative query answering is the integration of a knowledge base (represents data semantics) with the database. Research in cooperative answering stems from three areas: natural language interface and dialogue systems, database systems, and logic programming and deductive database systems. In this article, we shall place emphasis on cooperative databases.

We shall first provide an overview of cooperative database systems which covers such topics as presuppositions, misconceptions, intensional query answering, user modeling, query relaxation, and associative query answering. Then, we present the concept of the Type Abstraction Hierarchy (TAH) which provides a structured approach for query relaxation. Methodologies for automatic TAH generation are discussed. Next, we present the cooperative primitives for query relaxation and selected query examples for relational databases. Then, we present the relaxation controls for providing efficient query processing and the filtering of unsuitable answers for the user. The case-based approach for providing relevant information to query answers is then presented. The performance of a set of sample queries generated from an operational cooperative database system (CoBase) on top of a relational database is reported. Finally, we discuss the technology transfer of successful query relaxation to transportation, logistics planning applications, medical image databases, and electronic warfare applications.

OVERVIEW

Presuppositions

Usually when one asks a query, one not only presupposes the existence of all the components of the query, but one also presupposes an answer to the query itself. For example, suppose one asks “Which employees own red cars?” One assumes there is an answer to the query. If the answer is “nobody owns a red car,” the system should provide the user with further explanation (e.g., in the case where no employee owns a red car because no employee owns a car at all). To avoid misleading the user, the answer should be “There are no employees who own a red car because no employee owns a car at all.” Therefore in many queries, “No” as an answer does not provide the user with sufficient information. Further clarification is necessary to resolve the presupposition problem (2). False presuppositions usually occur with respect to the database’s state and schema. Presuppositions assume that the query has an answer. If any presuppositions are false, the query is nonsensical. The following is a method to detect false presuppositions. Let us represent a query as a graph consisting of arcs at the nodes and binary relations between the arcs. The graph is a semantic network, and the query is reexpressed in binary notation. The query answering system checks to see that each connected subgraph is nonempty. If any is empty, this indicates a failed presupposition. A prototype system called COOP (A Cooperative Query System) was constructed and operated with a CODASYL database to demonstrate such cooperative concepts (3).

Misconceptions

A query may be free of any false presuppositions but can still cause misconceptions. False presuppositions concern the schema of the knowledge base. Misconceptions concern the scope of the domain of the knowledge base. Misconceptions arise when the user has a false or unclear understanding of what is necessarily true or false in the database. For example, for the query, “Which teachers take CS10?”, the corresponding answer will be “None” followed by the explanation from the domain knowledge, “Teachers teach courses” and “Students take courses” (4). Whenever the user poses a query that has no answer, the system infers the probable mismatches between the user’s view of the world and the knowledge in the knowledge base. The system then answers with a correction to rectify the mismatch (5).

Intensional Query Answering

Intensional query answering provides additional information about the extensional answer such as information about class hierarchies that define various data classes and relationships, integrity constraints to state the relationships among data, and rules that define new classes in terms of known classes. Intensional query answering can also provide abstraction and summarization of the extensional answer. As a result, the intensional answers can often improve and compliment extensional answers. For example, consider the query “Which cars are equipped with air bags?” The extensional answer will provide a very long list of registration numbers of all the cars that are equipped with air bags. However, an intensional answer will provide a summaried answer and state “All cars built after 1995 are equipped with air bags.” Note that intensional answering gives more meaning to the answer than does the extensional answer. Furthermore, intensional answers take less time to compute than extensional answers. There are different approaches to compute intensional query answers which yield different quality of answers (6–12). The effectiveness of the answer can be measured by completeness, nonredundancy, optimality, relevance, and efficiency (13).

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

User Models

Cooperative query answering depends on the user and context of the query. Thus, a user model will clearly aid in providing more specific query answering and thus improve search efficiency.

User models contain a representation of characteristic information about the user as well as a description of the user's intentions and goals. These models help interpret the content of a user's query and effectively customize results by guiding the query facility in deriving the answer.

Three types of knowledge about a user that are relevant to cooperative query answering are *interests and preferences, needs*, and *goals and intentions*. *Interests and preferences* direct the content and type of answers that should be provided. For example, (14) and (15) rewrite queries to include relevant information that is of interest to the user. *User needs* may vary from user to user. They can be represented by user constraints (16). The notion of user constraints is analogous to the integrity constraints in databases. Unlike integrity constraints, user constraints do not have to be logically consistent with the database. *Goals and intentions* do not vary from user to user. Rather, they vary from session to session and depend on the user who is attempting to achieve the goal. Past dialogue, user models, and other factors can help a system to determine the probable goals and intentions of the user (17–20) and also clarify the user's goals (21). The system can also explain the brief of the system that conflicts with the user's belief to resolve the user's misconceptions (22,23). Hemerly et al. (24) use a predefined user model and maintain a log of previous interactions to avoid misconstruction when providing additional information.

Query Relaxation

In conventional databases, if the required data is missing, if an exact answer is unavailable, or if a query is not well-formed with respect to the schema, the database just returns a null answer or an error. An intelligent system would be much more resourceful and cooperative by relaxing the query conditions and providing an approximate answer. Furthermore, if the user does not know the exact database schema, the user is permitted to pose queries containing concepts that may not be expressed in the database schema.

A user interface for relational databases has been proposed (25) that is tolerant of incorrect user input and allows the user to select directions of relaxation. Chu, et al. (26) proposed to generalize queries by relaxing the query conditions via a knowledge structure called Type Abstraction Hierarchy (TAH). TAHs provide multilevel representation of domain knowledge. Relaxation can be performed via generalization and specialization (traversing up and down the hierarchy). Query conditions are relaxed to their semantic neighbors in the TAHs until the relaxed query conditions can produce approximate answers. Conceptual terms can be defined by labeling the nodes in a type abstraction hierarchy. To process a query with conceptual terms, the conceptual terms are translated into numeric value ranges or a set of nonnumeric information under that node. TAHs can then be generated by clustering algorithms from data sources. There are numerical TAHs that generate by clustering attributes with numerical databases (27,28) and nonnumerical TAHs that generate by rule induction from nonnumerical data sources (29).

Explicit relaxation operators such as approximate, near-to (distance range), and similar-to (based on the values of a set of attributes) can also be introduced in a query to relax the query conditions. Relaxation can be controlled by users with operators such as nonrelaxable, relaxation order, preference list, the number of answers, etc., which can be included in the query. A cooperative languge for relational databases, CoSQL, was developed (30,31) and extended the Structured Query Language (SQL) with these constructs. A cooperative database interface called CoBase was developed to automatically rewrite a CoSQL query with relaxation and relaxation control into SQL statements. As a result, CoBase can run on top of conventional relational databases such as Oracle, Sybase, etc., to provide query relaxation as well as conceptual query answering (answering to a query with conceptual terms) (27,31).

Gaasterland, et al. (32) have used a similar type of abstraction knowledge representation for providing query relaxation in deductive databases by expanding the scope of query constraints. They also used a meta-interpreter to provide users with choices of relaxed queries.

Associative Query Answering

Associative Query Answering provides the user with additional useful relevant information about a query even if the user does not ask for or does not know how to ask for such information. Such relevant information can often expedite the query answering process or provide the user with additional topics for dialogue to accomplish a query goal. It can also provide valuable past experiences that may be helpful to the user in problem solving and decision making. For example, consider the query “Find an airport that can land a C5.” In addition to the query answer regarding the location of the airport, additional relevant information for a pilot may be the *weather* and *runway conditions* of the airport. The additional relevant information for a transportation planner may be the existence of *railway facilities* and *storage facilities* nearby the airport. Thus associative information is both user- and context-sensitive. Cuppens and Demolombe (14) use a rule-based approach to rewrite queries by adding additional attributes to the query vector to provide additional relevant information. They defined a meta-level definition of a query, which specifies the query in three parts: entity, condition, and retrieved attributes. Answers to queries provide values to the variables designated by the retrieved attributes. They have defined methods to extend the retrieved attributes according to heuristics about topics of interest to the user.

CoBase uses a case-based reasoning approach to match past queries with the posed query (33). Query features consist of the query topic, the output attribute list, and the query conditions (15). The similarity of the query features can be evaluated from a user-specific semantic model based on the database schema, user type, and context. Cases with the same topic are searched first. If insufficient cases were found, then cases with related topics are searched. The attributes in the matched cases are then extended to the original query. The extended query is then processed to derive additional relevant information for the user.

STRUCTURED APPROACH FOR QUERY RELAXATION

Query relaxation relaxes a query scope to enlarge the search range or relaxes an answer scope to include additional information. Enlarging and shrinking a query scope can be accomplished by viewing the queried objects at different conceptual levels because an object representation has wider coverage at a higher level and, inversely, more narrow coverage at a lower level. We propose the notion of a type abstraction hierarchy (27–29) for providing an efficient and organized framework for cooperative query processing. A TAH represents objects at different levels of abstraction. For example, in Fig. 1, the Medium-Range (i.e., from 4000 to 8000 ft) in the TAH for runway length is a more abstract representation than a specific runway length in the same TAH (e.g., 6000 ft). Likewise, SW Tunisia is a more abstract representation than individual airports (e.g., Gafsa). A higher-level and more abstract object representation corresponds to multiple lower levels and more specialized object representations. Querying an abstractly represented object is equivalent to querying multiple specialized objects.

A query can be modified by relaxing the query conditions via such operations as generalization (moving up the TAH) and specialization (moving down the TAH, moving, for example, from 6000 ft to Medium-Range to (4000 ft, 8000 ft). In addition, queries may have conceptual conditions such as runway-length = Medium-Range. This condition can be transformed into specific query conditions by specialization. Query modification may also be specified explicitly by the user through a set of cooperative operators such as similar-to, approximate, and near-to.

The notion of multilevel object representation is not captured by the conventional semantic network and object-oriented database approaches for the following reasons. Grouping objects into a class and grouping several classes into a superclass provide only a common *title* (type) for the involved objects without concern for the object instance values and without introducing abstract object representations. Grouping several objects together and identifying their aggregation as a single (complex) object does not provide abstract instance representations for its component objects. Therefore, an object-oriented database deals with information only at two general layers: the metalayer and the instance layer. Because forming an object-oriented type hierarchy does not introduce new instance values, it is impossible to introduce an additional instance layer. In the TAH, instances of a supertype and a subtype may have different representations and can be viewed at different instance layers. Such multiple-layer knowledge representation is essential for cooperative query answering.

Knowledge for query relaxation can be expressed as a set of logical rules, but such a rule-based approach (14) lacks a systematic organization to guide the query transformation process. TAHs provide a much simpler and more intuitive representation for query relaxation and do not have the complexity of the inference that exists in the rule-based system. As a result, the TAH structure can easily support flexible relaxation control, which is important to improve relaxation accuracy and efficiency. Furthermore, knowledge represented in a TAH is customized; thus changes in one TAH represent only a localized update and do not affect other TAHs, simplifying TAH maintenance (see subsection entitled "Maintenance of TAHs"). We have developed tools to generate TAHs automatically from data sources (see the next section), which enable our system to scale up and extend to large data sources.

AUTOMATIC KNOWLEDGE ACQUISITION

The automatic generation of a knowledge base (TAHs) from databases is essential for CoBase to be scalable to large systems. We have developed algorithms to generate automatically TAHs based on database instances. A brief discussion about the algorithms and their complexity follow.

Numerical TAHs

COBWEB (34), a conceptual clustering system, uses category utility (35) as a quality measure to classify the objects described by a set of attributes into a classification tree. COBWEB deals only with categorical data. Thus, it cannot be used for abstracting numerical data. For providing

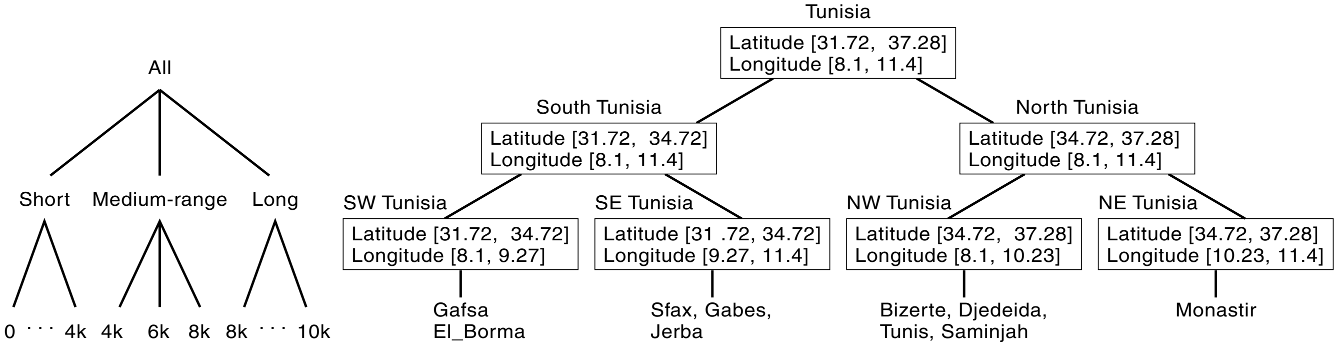

Figure 1. Type abstraction hierarchies: (a) runway length and (b) airport location in Tunisia.

approximate answers, we want to build a classification tree that minimizes the difference between the desired answer and the derived answer. Specifically, we use relaxation error as a measure for clustering. The relaxation error (RE) is defined as the average difference between the requested values and the returned values. $\mathrm{RE}_1(C)$ can also be interpreted from the standpoint of query relaxation. Let us define the relaxation error of x_i, $\mathrm{RE}_1(x_i)$, as the average difference from x_i to x_j, $j = 1, \ldots, n$. That is,

$$\mathrm{RE}_1(x_i) = \sum_{j=1}^{n} P(x_j)|x_i - x_j| \tag{1}$$

where $P(x_j)$ is the occurrence probability of x_j in C. $\mathrm{RE}_1(x_i)$ can be used to measure the quality of an approximate answer where x_i in a query is relaxed to x_j, $j = 1, \ldots, n$. Summing $\mathrm{RE}_1(x_i)$ over all values x_i in C, we have

$$\mathrm{RE}_1(C) = \sum_{i=1}^{n} P(x_i)\mathrm{RE}_1(x_i) \tag{2}$$

Thus, $\mathrm{RE}_1(C)$ is the expected error of relaxing any value in C.

If $\mathrm{RE}_1(C)$ is large, query relaxation based on C may produce very poor approximate answers. To overcome this problem, we can partition C into subclusters to reduce relaxation error. Given a partition $P = \{C_1, C_2, \ldots, C_N\}$ of C, the relaxation error of the partition P is defined as

$$\mathrm{RE}_1(P) = \sum_{k=1}^{N} P(C_k)\mathrm{RE}_1(C_k) \tag{3}$$

where $P(C_k)$ equals the number of tuples in C_k divided by the number of tuples in C. In general, $\mathrm{RE}_1(P) < \mathrm{RE}_1(C)$.

Relaxation error is the expected pairwise difference between values in a cluster. The notion of relaxation error for multiple attributes can be extended from single attributes.

Distribution Sensitive Clustering (DISC) (27,28) partitions sets of numerical values into clusters that minimize the relaxation error. We shall now present a class of DISC algorithms for clustering numerical values. We shall present the algorithm for a single attribute and then extend it for multiple attributes.

The Clustering Algorithm for a Single Attribute. Given a cluster with n distinct values, the number of partitions is exponential with respect to n, so the best partition takes exponential time to find. To reduce computation complexity, we shall consider only binary partitions. Later we shall show that a simple hill-climbing strategy can be used for obtaining N-ary partitions from binary partitions.

Our method is top down: we start from one cluster consisting of all the values of an attribute, and then we find *cuts* to partition recursively the cluster into smaller clusters. (A *cut* c is a value that separates a cluster of numbers $\{x | a \leq x \leq b\}$ into two subclusters $\{x | a \leq x \leq c\}$ and $\{x | c < x \leq b\}$.) The partition result is a concept hierarchy called type abstraction hierarchy. The clustering algorithm is called the DISC method and is given in Table 1.

In Ref. 30, an implementation of the algorithm BinaryCut is presented whose time complexity is $O(n)$. Because DISC needs to execute BinaryCut $n - 1$ times at most to generate a TAH, the worst case time complexity of DISC is $O(n^2)$. [The average case time complexity of DISC is $O(n \log n)$.]

***N*-ary Partitioning.** N-ary partitions can be obtained from binary partitions by a hill-climbing method. Starting from a binary partition, the subcluster with greater relaxation error is selected for further cutting. We shall use RE as a measure to determine if the newly formed partition is better than the previous one. If the RE of the binary partition is less than that of the trinary partition, then the trinary partition is dropped, and the cutting is terminated. Otherwise, the trinary partition is selected, and the cutting process continues until it reaches the point where a cut increases RE.

The Clustering Algorithm for Multiple Attributes. Query relaxation for multiple attributes using multiple single-attribute TAHs relaxes each attribute independently disregarding the relationships that might exist among attributes. This may not be adequate for the applications where

Table 1. The Algorithms DISC and BinaryCut

```
Algorithm DISC(C)
  if the number of distinct values $\in C < T$, return /* $T$ is a threshold */
  let $cut$ = the best cut returned by BinaryCut(C)
  partition values in $C$ based on $cut$
  let the resultant subclusters be $C_1$ and $C_2$
    call DISC($C_1$) and DISC($C_2$)

Algorithm BinaryCut(C)
/* input cluster $C = \{x_1, \ldots, x_n\}$ */
  for $h = 1$ to $n - 1$/* evaluate each cut*/
    Let $P$ be the partition with clusters $C_1 = \{x_1, \ldots, x_h\}$ and $C_2 = \{x_{h+1}, \ldots, x_n\}$
    compute $\mathrm{RE}_1(P)$
    if $\mathrm{RE}_1(P) <$ MinRE then
      MinRE $= \mathrm{RE}_1(P)$, $cut = h$/* the best cut */
  Return $cut$ as the best cut
```

attributes are dependent. (Dependency here means that all the attributes as a whole define a coherent concept. For example, the length and width of a rectangle are said to be "semantically" dependent. This kind of dependency should be distinguished from the functional dependency in database theory.) In addition, using multiple single-attribute TAHs is inefficient because it may need many iterations of query modification and database access before approximate answers are found. Furthermore, relaxation control for multiple TAHs is more complex because there is a large number of possible orders for relaxing attributes. In general, we can rely only on simple heuristics such as best first or minimal coverage first to guide the relaxation (see subsection entitled "Relaxation Control"). These heuristics cannot guarantee best approximate answers because they are rules of thumb and not necessarily accurate.

Most of these difficulties can be overcome by using Multiattribute TAH (MTAH) for the relaxation of multiple attributes. Because MTAHs are generated from semantically dependent attributes, these attributes are relaxed together in a single relaxation step, thus greatly reducing the number of query modifications and database accesses. Approximate answers derived by using MTAH have better quality than those derived by using multiple single-attribute TAHs. MTAHs are context- and user-sensitive because a user may generate several MTAHs with different attribute sets from a table. Should a user need to create an MTAH containing semantically dependent attributes from different tables, these tables can be joined into a single view for MTAH generation.

To cluster objects with multiple attributes, DISC can be extended to Multiple attributes–DISC or M-DISC (28). MTAHs are generated. The algorithm DISC is a special case of M-DISC, and TAH is a special case of MTAH. Let us now consider the time complexity of M-DISC. Let m be the number of attributes and n be the number of distinct attribute values. The computation of relaxation error for a single attribute takes $O(n \log n)$ to complete (27). Because the computation of RE involves computation of relaxation error for m attributes, its complexity is $O(mn \log n)$. The nested loop in M-DISC is executed mn times so that the time complexity of M-DISC is $O(m^2n^2 \log n)$. To generate an MTAH, it takes no more than n calls of M-DISC; therefore, the worst case time complexity of generating an MTAH is $O(m^2n^3 \log n)$. The average case time complexity is $O[m^2n^2(\log n)^2]$ because M-DISC needs only to be called $\log n$ times on the average.

Nonnumerical TAHs

Previous knowledge discovery techniques are inadequate for clustering nonnumerical attribute values for generating TAHs for Cooperative Query Answering. For example, Attribute Oriented Induction (36) provides summary information and characterizes tuples in the database, but is inappropriate since attribute values are focused too closely on a specific target. Conceptual Clustering (37,38) is a top-down method to provide approximate query answers, iteratively subdividing the tuple-space into smaller sets. The top-down approach does not yield clusters that provide the best correlation near the bottom of the hierarchy. Cooperative query answering operates from the bottom of the hierarchy, so better clustering near the bottom is desirable. To remedy these shortcomings, a bottom-up approach for constructing attribute abstraction hierarchies called Pattern-Based Knowledge Induction (PKI) was developed to include a nearness measure for the clusters (29).

PKI determines clusters by deriving rules from the instance of the current database. The rules are not 100% certain; instead, they are rules-of-thumb about the database, such as

If the car is a sports car, then the color is red

Each rule has a *coverage* that measures how often the rule applies, and *confidence* measures the validity of the rule in the database. In certain cases, combining simpler rules can derive a more sophisticated rule with high confidence.

The PKI approach generates a set of useful rules that can then be used to construct the TAH by clustering the premises of rules sharing a similar consequence. For example, if the following two rules:

If the car is a sports car, then the color is red
If the car is a sports car, then the color is black

have high confidence, then this indicates that for sports cars, the colors *red* and *black* should be clustered together. Supporting and contradicting evidence from rules for other attributes is gathered and PKI builds an initial set of clusters. Each invocation of the clustering algorithm adds a layer of abstraction to the hierarchy. Thus, attribute values are clustered if they are used as the premise for rules with the same consequence. By iteratively applying the algorithm, a hierarchy of clusters (TAH) can be found. PKI can cluster attribute values with or without expert direction. The algorithm can be improved by allowing domain expert supervision during the clustering process. PKI also works well when there are NULL values in the data. Our experimental results confirm that the method is scalable to large systems. For a more detailed discussion, see (29).

Maintenance of TAHs

Because the quality of TAH affects the quality of derived approximate answers, TAHs should be kept up to date. One simple way to maintain TAHs is to regenerate them whenever an update occurs. This approach is not desirable because it causes overhead for the database system. Although each update changes the distribution of data (thus changing the quality of the corresponding TAHs), this may not be significant enough to warrant a TAH regeneration. TAH regeneration is necessary only when the cumulative effect of updates has greatly degraded the TAHs. The quality of a TAH can be monitored by comparing the derived approximate answers to the expected relaxation error (e.g., see Fig. 7), which is computed at TAH generation time and recorded at each node of the TAH. When the derived approximate answers significantly deviate from the expected quality, then the quality of the TAH is deemed to be inadequate and a regeneration is necessary. The following incremental TAH regeneration procedure can be used. First, identify the node within the TAH that has the worst query relaxations. Apply partial TAH regeneration for all the database instances covered by the node. After several such partial regenerations, we then initiate a complete TAH regeneration.

The generated TAHs are stored in UNIX files, and a TAH Manager (described in subsection entitled "TAH Facility") is responsible to parse the files, create internal representation of TAHs, and provide operations such as generalization and specialization to traverse TAHs. The TAH Manager also provides a directory that describes the characteristics of TAHs (e.g., attributes, names, user type, context, TAH size, location) for the users/systems to select the appropriate TAH to be used for relaxation.

Our experience in using DISC/M-DISC and PKI for ARPA Rome Labs Planning Initiative (ARPI) transportation databases (94 relations, the biggest one of which has 12 attributes and 195,598 tuples) shows that the clustering techniques for both numerical and nonnumerical attributes can be generated from a few seconds to a few minutes depending on the table size on a SunSPARC 20 Workstation.

COOPERATIVE OPERATIONS

The cooperative operations consist of the following four types: context-free, context-sensitive, control, and interactive.

Context-Free Operators

- *Approximate operator* $\wedge v$ relaxes the specified value v within the approximate range predefined by the user. For example, `∧9am` transforms into the interval (8am, 10am).
- *Between* (v_1, v_2) specifies the interval for an attribute. For example, time `between (7am, ∧9am)` transforms into (7am, 10am). The transformed interval is prespecified by either the user or the system.

Context-Sensitive Operators

- *Near-to X* is used for specification of spatial nearness of object X. The near-to measure is context- and user-sensitive. "Nearness" can be specified by the user. For example, `near-to 'BIZERTE'` requests the list of cities located within a certain Euclidean distance (depending on the context) from the city Bizerte.
- *Similar-to X based-on* [(a_1 w_1)(a_2 w_2) $\cdots$ (a_n w_n)] is used to specify a set of objects semantically similar to the target object *X* based on a set of attributes (a_1, a_2, ..., a_n) specified by the user. Weights (w_1, w_2, ..., w_n) may be assigned to each of the attributes to reflect the relative importance in considering the similarity measure. The set of similar objects can be ranked by the similarity. The similarity measures that computed from the nearness (e.g., weighted mean square error) of the prespecified attributes to that of the target object. The set size is bound by a prespecified nearness threshold.

Control Operators

- *Relaxation-order* (a_1, a_2, ..., a_n) specifies the order of the relaxation among the attributes (a_1, a_2, ..., a_n) (i.e., a_i precedes a_{i+1}). For example, `relaxation-order (runway_length, runway_width)` indicates that if no exact answer is found, then runway_length should be relaxed first. If still no answer is found, then relax the runway_width. If no relaxation-order control is specified, the system relaxes according to its default relaxation strategy.
- *Not-relaxable* (a_1, a_2, ..., a_n) specifies the attributes (a_1, a_2, ..., a_n) that should not be relaxed. For example, `not-relaxable location_name` indicates that the condition clause containing location_name must not be relaxed.
- *Preference-list* (v_1, v_2, ..., v_n) specifies the preferred values (v_1, v_2, ..., v_n) of a given attribute, where v_i is preferred over v_{i+1}. As a result, the given attribute is relaxed according to the order of preference that the user specifies in the preference list. Consider the attribute "food style"; a user may prefer Italian food to Mexican food. If there are no such restaurants within the specified area, the query can be relaxed to include the foods similar to Italian food first and then similar to Mexican food.
- *Unacceptable-list* (v_1, v_2, ..., v_n) allows users to inform the system not to provide certain answers. This control can be accomplished by trimming parts of the TAH from searching. For example, `avoid airlines X and Y` tells the system that airlines X and Y should not be considered during relaxation. It not only provides more satisfactory answers to users but also reduces search time.
- *Alternative-TAH (TAH-name)* allows users to use the TAHs of their choices. For example, a vacation traveler may want to find an airline based on its fare, whereas a business traveler is more concerned with his schedule. To satisfy the different needs of the users, several TAHs of airlines can be generated, emphasizing different attributes (e.g., price and nonstop flight).
- *Relaxation-level* (v) specifies the maximum allowable range of the relaxation on an attribute, i.e., [0, v].
- *Answer-set* (s) specifies the minimum number of answers required by the user. CoBase relaxes query conditions until enough number of approximate answers (i.e., $\geq s$) are obtained.
- *Rank-by* ((a_1, w_1), (a_2, w_2), ..., (a_n, w_n)) *METHOD* (*method* $-$ *name*) specifies a method to rank the answers returned by CoBase.

User/System Interaction Operators

- *Nearer, Further* provide users with the ability to control the near-to relaxation scope interactively. Nearer reduces the distance by a prespecified percentage, whereas further increases the distance by a prespecified percentage.

Editing Relaxation Control Parameters

Users can browse and edit relaxation control parameters to better suit their applications (see Fig. 2). The parameters include the relaxation range for the approximately-equal operator, the default distance for the near-to operator, and the number of returned tuples for the similar-to operator.

Cooperative SQL (CoSQL)

The cooperative operations can be extended to the relational database query language, SQL, as follows: The context-free and context-sensitive cooperative operators can be used in conjunction with attribute values specified in the WHERE clause. The relaxation control operators can be used only on attributes specified in the WHERE clause, and the control operators must be specified in the WITH clause after the WHERE clause. The interactive operators can be used alone as command inputs.

Examples. In this section, we present a few selected examples that illustrate the capabilities of the cooperative operators. The corresponding TAHs used for query modification are shown in Fig. 1, and the relaxable ranges are shown in Fig. 2.

Query 1. List all the airports with the runway length greater than 7500 ft and runway width greater than 100 ft. If there is no answer, relax the runway length condition first. The following is the corresponding CoSQL query:

```
SELECT aport_name, runway_length_ft,
  runway_width_ft
FROM aports
WHERE runway_length_ft > 7500 AND
  runway_width_ft > 100
WITH RELAXATION-ORDER (runway_length_ft,
  runway_width_ft)
```

Approximate operator relaxation range

Relation name	Attribute name	∧Range
Aports	Runway_length_ft	500
Aports	Runway_width_ft	10
Aports	Parking_sq_ft	100000
GEOLOC	Latitude	0.001
GEOLOC	Longitude	0.001

Near-to operator relaxation range

Relation name	Attribute name	Near-to range	Nearer/further
Aports	Aport_name	100 miles	50%
GEOLOC	Location_name	200 miles	50%

Figure 2. Relaxation range for the approximate and near-to operators.

Based on the TAH on runway length and the relaxation order, the query is relaxed to

```
SELECT aport_name, runway_length_ft,
  runway_width_ft
FROM aports
WHERE runway_length_ft >= 7000 AND
  runway_width_ft > 100
```

If this query yields no answer, then we proceed to relax the range runway width.

Query 2. Find all the cities with their geographical coordinates near the city Bizerte in the country Tunisia. If there is no answer, the restriction on the country should not be relaxed. The near-to range in this case is prespecified at 100 miles. The corresponding CoSQL query is as follows:

```
SELECT location_name, latitude, longitude
FROM GEOLOC
WHERE location_name NEAR-TO ‘Bizerte’
  AND country_state_name = ‘Tunisia’
WITH NOT-RELAXABLE country_state_name
```

Based on the TAH on location Tunisia, the relaxed version of the query is

```
SELECT location_name, latitude, longitude
FROM GEOLOC
WHERE location_name IN {‘Bizerte’ , ‘Djedeida’ ,
  ‘Gafsa’ ,
      ‘Gabes’ , ‘Sfax’ , ‘Sousse’ , ‘Tabarqa’ ,
        ‘Tunis’}
    AND country_state_name_= ‘Tunisia’
```

Query 3. Find all airports in Tunisia similar to the Bizerte airport. Use the attributes runway_length_ft and runway_width_ft as criteria for similarity. Place more similarity emphasis on runway length than runway width; their corresponding weight assignments are 2 and 1, respectively. The following is the CoSQL version of the query:

```
SELECT aport_name
FROM aports, GEOLOC
WHERE aport_name SIMILAR-TO ‘Bizerte’
      BASED-ON ((runway_length_ft 2.0)
        (runway_width_ft 1.0))
  AND country_state_name = ‘TUNISIA’
  AND GEOLOC.geo_code = aports.geo_code
```

To select the set of the airport names that have the runway length and runway width similar to the ones for the airport in Bizerte, we shall first find all the airports in Tunisia and, therefore, transform the query to

```
SELECT aport_name
FROM aports, GEOLOC
WHERE country_state_name_ = ‘TUNISIA’
  AND GEOLOC.geo_code = aports.geo_code
```

After retrieving all the airports in Tunisia, based on the runway length, runway width, and their corresponding weights, the similarity of these airports to Bizerte can be computed by the prespecified nearness formula (e.g.,

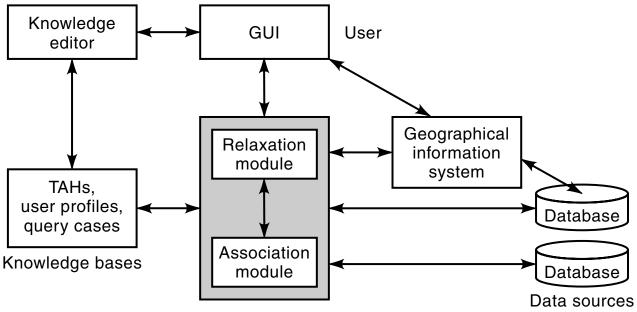

Figure 3. CoBase functional architecture.

weighted mean square error). The order in the similarity set is ranked according to the nearness measure, and the size of the similarity set is determined by the prespecified nearness threshold.

A SCALABLE AND EXTENSIBLE ARCHITECTURE

Figure 3 shows an overview of the CoBase System. Type abstraction hierarchies and relaxation ranges for the explicit operators are stored in a knowledge base (KB). There is a TAH directory storing the characteristics of all the TAHs in the system. When CoBase queries, it asks the underlying database systems (DBMS). When an approximate answer is returned, context-based semantic nearness will be provided to rank the approximate answers (in order of nearness) against the specified query. A graphical user interface (GUI) displays the query, results, TAHs, and relaxation processes. Based on user type and query context, associative information is derived from past query cases. A user can construct TAHs from one or more attributes and modify the existing TAH in the KB.

Figure 4 displays the various cooperative modules: Relaxation, Association, and Directory. These agents are connected selectively to meet applications' needs. An application that requires relaxation and association capabilities, for example, will entail a linking of Relaxation and Association agents. Our architecture allows incremental growth with application. When the demand for certain modules increases, additional copies of the modules can be added to reduce the loading; thus, the system is scalable. For example, there are multiple copies of relaxation agent and association agent in Fig. 4. Furthermore, different types of agents can be interconnected and communicate with each other via a common communication protocol [e.g., FIPA (http.//www.fipa.org), or Knowledge Query Manipulation Language (KQML) (39)] to perform a joint task. Thus, the architecture is extensible.

Relaxation Module

Query relaxation is the process of understanding the semantic context, intent of a user query and modifying the query constraints with the guidance of the customized knowledge structure (TAH) into near values that provide best-fit answers. The flow of the relaxation process is depicted in Fig. 5. When a CoSQL query is presented to the Relaxation Agent, the system first go through a preprocessing phase. During the preprocessing, the system first relaxes any context-free and/or context-sensitive cooperative operators in the query. All relaxation control operations specified in the query will be processed. The information will be stored in the relaxation manager and be ready to be used if the query requires relaxation. The modified SQL query is then presented to the underlying database system for execution. If no answers are returned, then the cooperative query system, under the direction of the Relaxation Manager, relaxes the queries by query modification. This is accomplished by traversing along the TAH node for performing generalization and specialization and rewriting the query to include a larger search scope. The relaxed query is then executed, and if there is no answer, we repeat the relaxation process until we obtain one or more approximate answers. If the system fails to produce an answer due to overtrimmed TAHs, the relaxation manager will deactivate certain relaxation rules to restore part of a trimmed TAH to broaden the search scope until answers are found. Finally, the answers are postprocessed (e.g., ranking and filtering).

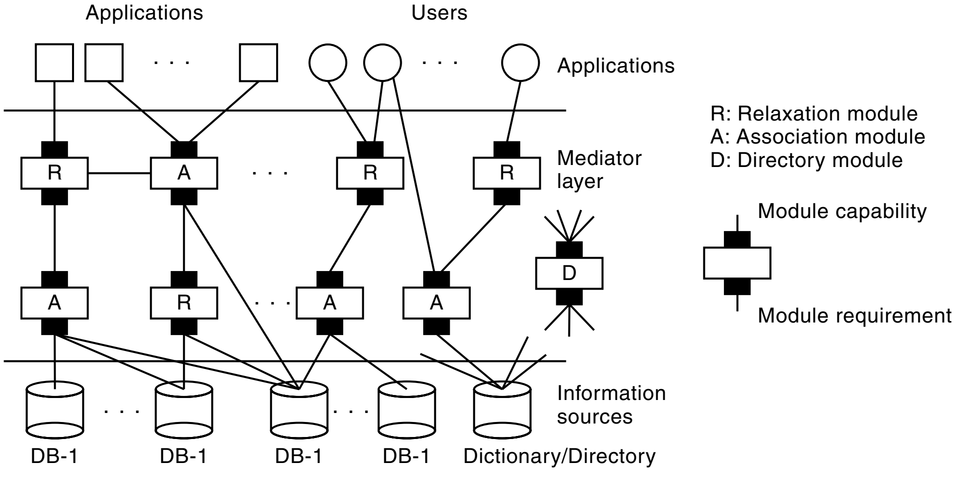

Figure 4. A scalable and extensible cooperative information system.

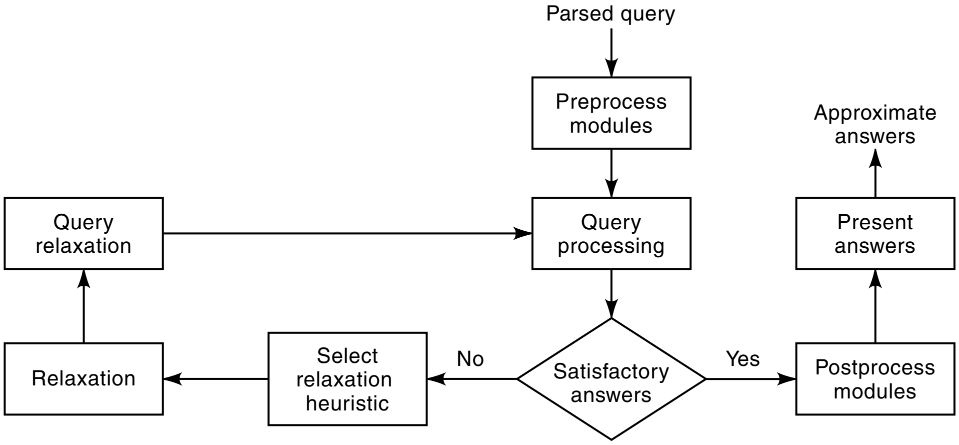

Figure 5. Flow chart for processing CoBase queries.

Relaxation Control. Relaxation without control may generate more approximations than the user can handle. The policy for relaxation control depends on many factors, including user profile, query context, and relaxation control operators as defined previously. The Relaxation Manager combines those factors via certain policies (e.g., minimizing search time or nearness) to restrict the search for approximate answers. We allow the input query to be annotated with control operators to help guide the agent in query relaxation operations.

If control operators are used, the Relaxation Manager selects the condition to relax in accordance with the requirements specified by the operators. For example, a relaxation-order operator will dictate "relax location first, then runway length." Without such user-specified requirements, the Relaxation Manager uses a default relaxation strategy by selecting the relaxation order based on the minimum coverage rule. Coverage is defined as the ratio of the cardinality of the set of instances covered by the entire TAH. Thus, coverage of a TAH node is the percentage of all tuples in the TAH covered by the current TAH node. The minimum coverage rule always relaxes the condition that causes the minimum increase in the scope of the query, which is measured by the coverage of its TAH node. This default relaxation strategy attempts to add the smallest number of tuples possible at each step, based on the rationale that the smallest increase in scope is likely to generate the close approximate answers. The strategy for choosing which condition to be relaxed first is only one of many possible relaxation strategies; the Relaxation Manager can support other different relaxation strategies as well.

Let us consider the following example of using control operators to improve the relaxation process. Suppose a pilot is searching for an airport with an 8000 ft runway in Bizerte but there is no airport in Bizerte that meets the specifications. There are many ways to relax the query in terms of location and runway length. If the pilot specifies the relaxation order to relax the location attribute first, then the query modification generalizes the location Bizerte to NW Tunisia (as shown in Fig. 1) and specifies the locations Bizerte, Djedeida, Tunis, and Saminjah, thus broadening the search scope of the original query. If, in addition, we know that the user is interested only in the airports in West Tunisia and does not wish to shorten the required runway length, the system can eliminate the search in East Tunisia and also avoid airports with short and medium runways, as shown in Fig. 6. As a result, we can limit the query relaxation to a narrower scope by trimming the TAHs, thus improving both the system performance and the answer relevance.

Spatial Relaxation and Approximation. In geographical queries, spatial operators such as located, within, contain, intersect, union, and difference are used. When there are no exact answers for a geographical query, both its spatial and nonspatial conditions can be relaxed to obtain the approximate answers. CoBase operators also can be used for describing approximate spatial relationships. For example, "an aircraft-carrier is *near* seaport Sfax." Approximate spatial operators, such as near-to and between are developed for the approximate spatial relationships. Spatial approximation depends on contexts and domains (40,41). For example, a hospital near to LAX is different from an airport near to LAX. Likewise, the nearness of a hospital in a metropolitan area is different from the one in a rural area. Thus, spatial conditions should be relaxed differently in different circumstances. A common approach to this problem is the use of prespecified ranges. This approach requires experts to provide such information for all possible situations, which is difficult to scale up to larger applications or to extend to different domains. Because TAHs are user- and context-sensitive, they can be used to provide context-sensitive approximation. More specifically, we can generate TAHs based on multidimensional spatial attributes (MTAHs).

Furthermore, MTAH (based on latitude and longitude) is generated based on the distribution of the object locations. The distance between nearby objects is context-sensitive: the denser the location distribution, the smaller the distance among the objects. In Fig. 7, for example, the default neighborhood distance in Area 3 is smaller than the one in Area 1. Thus, when a set of airports is clustered based on the locations of the airports, the ones in the same cluster of the MTAH are much closer to each other than to those outside the cluster. Thus, they can be considered near-to each other. We can apply the same approach to other approximate spatial operators, such as between (i.e., a cluster near-to the center of two objects). MTAHs also can

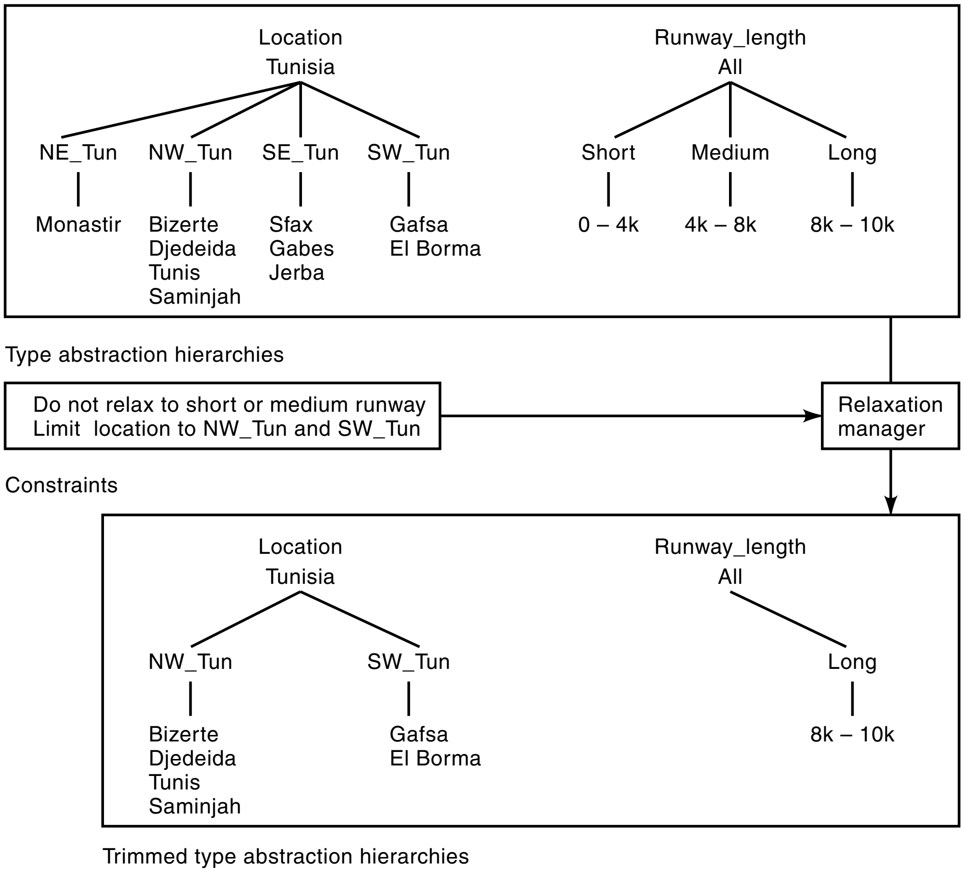

Figure 6. TAH trimming based on relaxation control operators.

be used to provide context-sensitive query relaxation. For example, consider the query: "Find an airfield at the city Sousse." Because there is no airfield located exactly at Sousse, this query can be relaxed to obtain approximate answers. First, we locate the city Sousse with latitude 35.83 and longitude 10.63. Using the MTAH in Fig. 7, we find that Sousse is covered by Area 4. Thus, the airport Monastir is returned. Unfortunately, it is not an airfield. So the query is further relaxed to the neighboring cluster—the four airports in Area 3 are returned: Bizerte, Djedeida, Tunis, and Saminjah. Because only Djedeida and Saminjah are airfields, these two will be returned as the approximate answers.

MTAHs are automatically generated from databases by using our clustering method that minimizes relaxation error (27). They can be constructed for different contexts and user type. For example, it is critical to distinguish a friendly airport from an enemy airport. Using an MTAH for friendly airports restricts the relaxation only within the set of friendly airports, even though some enemy airports are

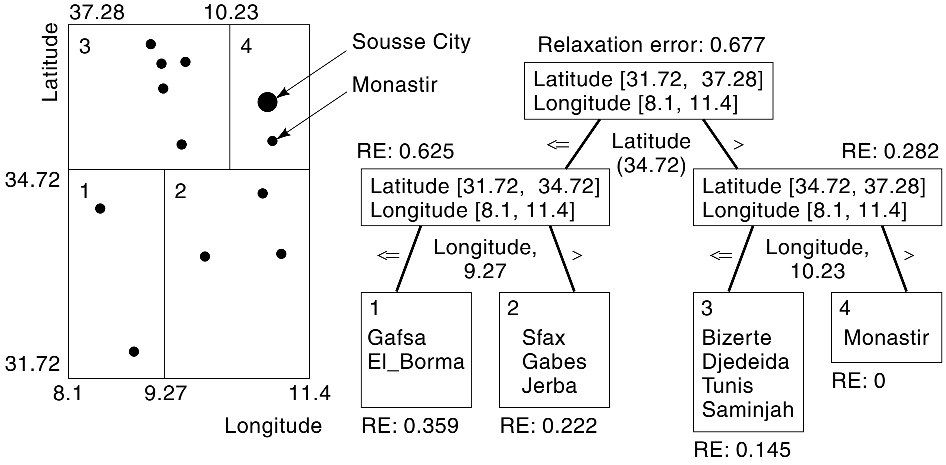

Figure 7. An MTAH for the airports in Tunisia and its corresponding two-dimensional space.

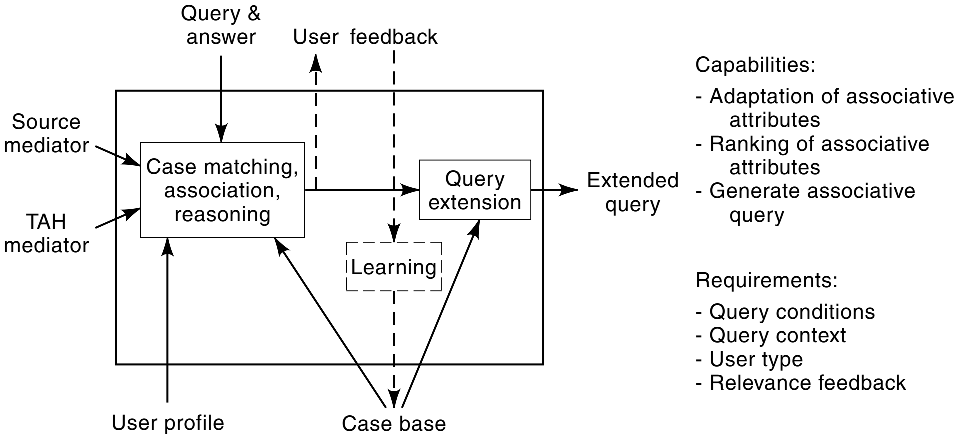

Figure 8. Associative query answering facility.

geographically nearby. This restriction significantly improves the accuracy and flexibility of spatial query answering. The integration of spatial and cooperative operators provides more expressiveness and context-sensitive answers. For example, the user is able to pose such queries as, "find the airports similar-to LAX and near-to City *X*." When no answers are available, both near-to and similar-to can be relaxed based on the user's preference (i.e., a set of attributes). To relax near-to, airports from neighboring clusters in the MTAH are returned. To relax similar-to, the multiple-attribute criteria are relaxed by their respective TAHs.

Cooperativeness in geographic databases was studied in Ref. 42. A rule-based approach is used in their system for approximate spatial operators as well as query relaxation. For example, they define that "P is near-to Q iff the distance from P to Q is less than $n^{*}length\_unit$, where *length_unit* is a context dependent scalar parameter, and n is a scalar parameter that can be either unique for the application and thus defined in domain model, or specific for each class of users and therefore defined in the user models." This approach requires n and *length_unit* be set by domain experts. Thus, it is difficult to scale up. Our system uses MTAHs as a representation of the domain knowledge. The MTAHs can be generated automatically from databases based on contexts and provide a structured and context-sensitive way to relax queries. As a result, it is scalable to large applications. Further, the relaxation error at each node is computed during the construction of TAHs and MTAHs. It can be used to evaluate the quality of relaxations and to rank the nearness of the approximate answers to the exact answer.

Associative Query Answering via Case-Based Reasoning

Often it is desirable to provide additional information relevant to, though not explicitly stated in, a user's query. For example, in finding the location of an airport satisfying the runway length and width specifications, the association module (Fig. 8) can provide additional information about the runway quality and weather condition so that this additional information may help the pilot select a suitable airport to land his aircraft. On the other hand, the useful relevant information for the same query if posed by a transportation planner may be information regarding railway facilities and storage facilities nearby the airport. Therefore, associative information is user- and context-sensitive.

Association in CoBase is executed as a multistep post-process. After the query is executed, the answer set is gathered with the query conditions, user profile, and application constraints. This combined information is matched against query cases from the case base to identify relevant associative information (15,33). The query cases can take the form of a CoBase query, which can include any CoBase construct, such as conceptual conditions (e.g., runway_length_ft = short) or explicitly cooperative operations (city near-to 'BIZERTE').

For example, consider the query

```
SELECT name, runway_length_ft
FROM airports
WHERE runway_length_ft > 6000
```

Based on the combined information, associative attributes such as runway conditions and weather are derived. The associated information for the corresponding airports is retrieved from the database and then appended to the query answer, as shown in Fig. 9.

Our current case base, consisting of about 1500 past queries, serves as the knowledge server for the association module. The size of the case base is around 2 Mb. For association purposes, we use the 300-case set, which is composed of past queries used in the transportation domain. For testing performance and scalability of the

Query answer		Associative information	
Name	Runway_length	Runway_condition	Weather
Jerba	9500	Damaged	Sunny
Monastir	6500	Good	Foggy
Tunis	8500	Good	Good

Figure 9. Query answer and associative information for the selected airports.

system, we use a 1500-case set, which consists of randomly generated queries based on user profile and query template over the transportation domain. Users can also browse and edit association control parameters such as the number of association subjects, the associated links and weights of a given case, and the threshold for association relevance.

PERFORMANCE EVALUATION

In this section, we present the CoBase performance based on measuring the execution of a set of queries on the CoBase testbed developed at UCLA for the ARPI transportation domain. The performance measure includes response time for query relaxation, association, and the quality of answers. The response time depends on the type of queries (e.g., size of joins, number of joins) as well as the amount of relaxation, and association, required to produce an answer. The quality of the answer depends on the amount of relaxation and association involved. The user is able to specify the relaxation and association control to reduce the response time and also to specify the requirement of answer accuracy. In the following, we shall show four example queries and their performances. The first query illustrates the relaxation cost. The second query shows the additional translation cost for the “similar-to” cooperative operator, whereas the third query shows the additional association cost. The fourth query shows the processing cost for returned query answers as well as the quality of answers by using TAH versus MTAH for a very large database table (about 200,000 tuples).

Query 4. Find nearby airports can land C-5.

Based on the airplane location, the relaxation module translates *nearby* to a prespecified or user-specified latitude and longitude range. Based on the domain knowledge of C-5, the mediator also translates *land* into required runway length and width for landing the aircraft. The system executes the translated query. If no airport is found, the system relaxes the distance (by a predefined amount) until an answer is returned. In this query, an airport is found after one relaxation. Thus, two database retrievals (i.e., one for the original query and one for the relaxed query) are performed. Three tables are involved: Table GEOLOC (50,000 tuples), table RUNWAYS (10 tuples), and table AIRCRAFT_AIRFIELD_CHARS (29 tuples). The query answers provide airport locations and their characteristics.

```
Elapsed time: 5 seconds processing time for
                relaxation
              40 seconds database retrieval time
```

Query 5. Find at least three airports similar-to Bizerte based on runway length and runway width.

The relaxation module retrieves runway characteristics of Bizerte airport and translates the similar-to condition into the corresponding query conditions (runway length and runway width). The system executes the translated query and relaxes the runway length and runway width according to the TAHs until at least three answers are returned. Note that the TAH used for this query is a Runway-TAH based on runway length and runway width, which is different from the Location-TAH based on latitude and longitude (shown in Fig. 7). The nearness measure is calculated based on weighted mean square error. The system computes similarity measure for each answer obtained, ranks the list of answers, and presents it to the user. The system obtains five answers after two relaxations. The best three are selected and presented to the user. Two tables are involved: table GEOLOC (50000 tuples) and table RUNWAYS (10 tuples).

```
Elapsed time: 2 seconds processing time for
                relaxation
              10 seconds database retrieval time
```

Query 6. Find seaports in Tunisia with a refrigerated storage capacity of over 50 tons.

The relaxation module executes the query. The query is not relaxed, so one database retrieval is performed. Two tables are used: table SEAPORTS (11 tuples) and table GEOLOC (about 50,000 tuples).

```
Elapsed time: 2 seconds processing time for
                relaxation
              5 seconds database retrieval time
```

The association module returns relevant information about the seaports. It compares the user query to previous similar cases and selects a set of attributes relevant to the query. Two top-associated attributes are selected and appended to the query. CoBase executes the appended query and returns the answers to the user, together with the additional information. The two additional attributes associated are location name and availability of railroad facility near the seaports.

```
Elapsed time: 10 seconds for association
                computation time
```

Query 7. Find at least 100 cargos of code ‘3FKAK’ with the given volume (length, width, height), code is nonrelaxable.

The relaxation module executes the query and relaxes the height, width, and length according to MTAH, until at least 100 answers are returned. The query is relaxed four times. Thus, five database retrievals are performed. Among the tables accessed is table CARGO_DETAILS (200,000 tuples), a very large table.

```
Elapsed time: 3 seconds processing time for
                relaxation using MTAH
              2 minutes database retrieval time
                for 5 retrievals
```

By using single TAHs (i.e., single TAHs for height, width, and length, respectively), the query is relaxed 12 times. Thus, 13 database retrievals are performed.

```
Elapsed time: 4 seconds for relaxation by
                single TAHs
              5 minutes database retrieval time
                for 13 retrievals
```

For queries involving multiple attributes in the same relation, using an MTAH that covers multiple attributes would provide better relaxation control than using a combination of single-attribute TAHs. The MTAH compares favorably with multiple single-attribute TAHs in both quality and efficiency. We have shown that an MTAH yields a better relaxation strategy than multiple single-attribute TAHs. The primary reason is that MTAHs capture attribute-dependent relationships that cannot be captured when using multiple single-attribute TAHs.

Using MTAHs to control relaxation is more efficient than using multiple single-attribute TAHs. For this example, relaxation using MTAHs require an average of 2.5 relaxation steps, whereas single-attribute TAHs require 8.4 steps. Because a database query is posed after each relaxation step, using MTAHs saves around six database accesses on average. Depending on the size of tables and joins involved, each database access may take from 1 s to about 30 s. As a result, using MTAHs to control relaxation saves a significant amount of user time.

With the aid of domain experts, these queries can be answered by conventional databases. Such an approach takes a few minutes to a few hours. However, without the aid of the domain experts, it may take hours to days to answer these queries. CoBase incorporates domain knowledge as well as relaxation techniques to enlarge the search scope to generate the query answers. Relaxation control plays an important role in enabling the user to control the relaxation process via relaxation control operators such as relaxation order, nonrelaxable attributes, preference list, etc., to restrict the search scope. As a result, CoBase is able to derive the desired answers for the user in significantly less time.

TECHNOLOGY TRANSFER OF COBASE

CoBase stemmed from the transportation planning application for relaxing query conditions. CoBase was linked with SIMS (43) and LIM (44) as a knowledge server for the planning system. SIMS performs query optimizations for distributed databases, and LIM provides high-level language query input to the database. A Technical Integration Experiment was performed to demonstrate the feasibility of this integrated approach. CoBase technology was implemented for the ARPI transportation application (45). Recently, CoBase has also been integrated into a logistical planning tool called Geographical Logistics Anchor Desk (GLAD) developed by GTE/BBN. GLAD is used in locating desired assets for logistical planning which has a very large database (some of the tables exceed one million rows). CoBase has been successfully inserted into GLAD (called CoGLAD), generating the TAHs from the databases, providing similarity search when exact match of the desired assets are not available, and also locating the required amount of these assets with spatial relaxation techniques. The spatial relaxation avoids searching and filtering the entire available assets, which greatly reduces the computation time.

In addition, CoBase has also been successfully applied to the following domains. In electronic warfare, one of the key problems is to identify and locate the emitter for radiated electromagnetic energy based on the operating parameters of observed signals. The signal parameters are radio frequency, pulse repetition frequency, pulse duration, scan period, and the like. In a noisy environment, these parameters often cannot be matched exactly within the emitter specifications. CoBase can be used to provide approximate matching of these emitter signals. A knowledge base (TAH) can be constructed from the parameter values of previously identified signals and also from the peak (typical, unique) parameter values. The TAH provides guidance on the parameter relaxation. The matched emitters from relaxation can be ranked according to relaxation errors. Our preliminary results have shown that CoBase can significantly improve emitter identification as compared to conventional database techniques, particularly in a noisy environment. From the line of bearing of the emitter signal, CoBase can locate the platform that generates the emitter signal by using the near-to relaxation operator.

In medical databases that store x rays and magnetic resonance images, the images are evolution and temporal-based. Furthermore, these images need to be retrieved by object features or contents rather than patient identification (46). The queries asked are often conceptual and not precisely defined. We need to use knowledge about the application (e.g., age class, ethnic class, disease class, bone age), user profile and query context to derive such queries (47). Further, to match the feature exactly is very difficult if not impossible. For example, if the query "Find the treatment methods used for tumors *similar to* X_i ($location_{x_i}$, $size_{x_i}$) on 12-year-old Korean males" cannot be answered, then, based on the TAH shown in Fig. 10, we can relax tumor X_i to tumor Class X, and 12-year-old Korean male to pre-teen Asian, which results in the following relaxed query: "Find the treatment methods used for tumor Class X on pre-teen Asians." Further, we can obtain such relevant information as the success rate, side effects, and cost of the treatment from the association operations. As a result, query relaxation and modification are essential

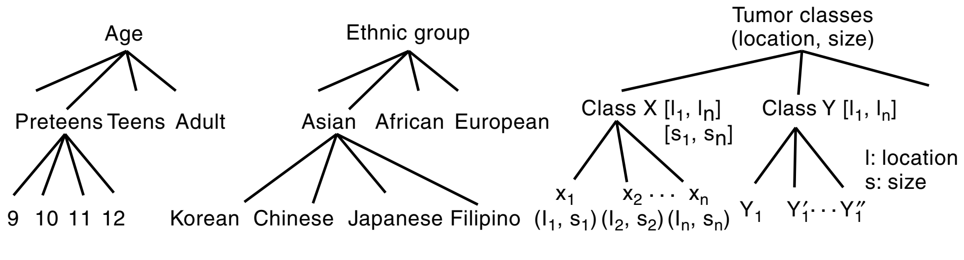

Figure 10. Type abstraction hierarchies for the medical query example.

to process these queries. We have applied CoBase technology to medical imaging databases (48). TAHs are generated automatically based on context-specific (e.g., brain tumor) image features (e.g., location, size, shape). After the TAHs for the medical image features have been constructed, query relaxation and modification can be carried out on the medical features (49).

The use of CoSQL constructs such as *similar-to*, *near-to*, and *within* can be used in combination, thus greatly increasing the expressibility for relaxation. For example, we can express "Find tumors *similar-to* the tumor x *based-on* (shape, size, location) and *near-to* object O *within* a specific range (e.g., angle of coverage)." The relaxation control operators, such as matching tumor features in accordance to their importance, can be specified by the operator *relaxation-order* (location, size, shape), to improve the relaxation quality.

CONCLUSIONS

After discussing an overview of cooperative database systems, which includes such topics as presuppositions, misconceptions, intensional query answering, user modeling, query relaxation, and associative query answering, we presented a structured approach to query relaxation via Type Abstraction Hierarchy (TAH) and a case-based reasoning approach to provide associative query answering. TAHs are user- and context-sensitive and can be generated automatically from data sources for both numerical and nonnumerical attributes. Therefore, such an approach for query relaxation can scale to large database systems. A set of cooperative operators for relaxation and relaxation control was presented in which these operators were extended to SQL to form a cooperative SQL (CoSQL). A cooperative database (CoBase) has been developed to automatically translate CoSQL queries into SQL queries and can thus run on top of conventional relational databases to provide query relaxation and relaxation control.

The performance measurements on sample queries from CoBase reveal that the cost for relaxation and association is fairly small. The major cost is due to database retrieval which depends on the amount of relaxation required before obtaining a satisfactory answer. The CoBase query relaxation technology has been successfully transferred to the logistics planning application to provide relaxation of asset characteristics as well as spatial relaxation to locate the desired amount of assets. It has also been applied in a medical imaging database (x ray, MRI) for approximate matching of image features and contents, and in electronic warfare for approximate matching of emitter signals (based on a set of parameter values) and also for locating the platforms that generate the signals via spatial relaxation.

With the recent advances in voice recognition systems, more and more systems will be providing voice input features. However, there are many ambiguities in the natural language. Further research in cooperative query answering techniques will be useful in assisting systems to understand users' dialogue with the system.

ACKNOWLEDGMENTS

The research and development of CoBase has been a team effort. I would like to acknowledge the past and present CoBase members—Hua Yang, Gladys Kong, X. Yang, Frank Meng, Guogen Zhang, Wesley Chuang, Meng-feng Tsai, Henrick Yau, and Gilles Fouques—for their contributions toward its design and implementation. The author also wishes to thank the reviewers for their valuable comments.

CoXML: COOPERATIVE XML QUERY ANSWERING

INTRODUCTION

As the World Wide Web becomes a major means in disseminating and sharing information, there has been an exponential increase in the amount of data in web-compliant format such as HyperText Markup Language (HTML) and Extensible Markup Language (XML). XML is essentially a textual representation of the hierarchical (tree-like) data where a meaningful piece of data is bounded by matching starting and ending tags, such as `<name>` and `</name>`. As a result of the simplicity of XML as compared with SGML and the expressiveness of XML as compared with HTML, XML has become the most popular format for information representation and data exchange.

To cope with the tree-like structure in the XML model, many XML-specific query languages have been proposed (e.g., XPath[1] and XQuery (1)). All these query languages aim at the exact matching of query conditions. Answers are found when those XML documents match the given query condition *exactly*, which however, may not always be the case in the XML model. To remedy this condition, we propose a cooperative query answering framework that derives *approximate* answers by relaxing query conditions to *less* restricted forms. Query relaxation has been successfully used in relational databases (e.g., Refs. 2–6) and is important for the XML model because:

1. Unlike the relational model where users are given a relatively small-sized schema to ask queries, the schema in the XML model is substantially bigger and more complex. As a result, it is unrealistic for users to understand the full schema and to compose complex queries. Thus, it is desirable to relax the user's query when the original query yields null or not sufficient answers.
2. As the number of data sources available on the Web increases, it becomes more common to build systems where data are gathered from heterogeneous data sources. The structures of the participating data source may be different even though they use the same ontologies about the same contents. Therefore, the need to be able to query differently structured data sources becomes more important (e.g., (7,8)). Query relaxation allows a query to be structurally relaxed and routed to diverse data sources with different structures.

Query relaxation in the relational model focuses on value aspects. For example, for a relational query "*find a person with a salary range 50K–55K*," if there are no answers or insufficient results available, the query can be relaxed to "*find a person with a salary range 45K–60K*." In the XML model, in addition to the value relaxation, a new type of relaxation called *structure relaxation* is introduced, which relaxes the structure conditions in a query. Structure relaxation introduces new challenges to the query relaxation in the XML model.

FOUNDATION OF XML RELAXATION

XML Data Model

We model an XML document as an ordered, labeled tree in which each element is represented as a node and each element-to-subelement relationship is represented as an edge between the corresponding nodes. We represent each data node u as a triple (*id, label*, <*text*>), where *id* uniquely identifies the node, *label* is the name of the corresponding element or attribute, and *text* is the corresponding element's text content or attribute's value. *Text* is optional because not every element has a text content.

Figure 1 presents a sample XML data tree describing an article's information. Each circle represents a node with the node *id* inside the circle and *label* beside the circle. The text of each node is represented in italic at the leaf level.

Due to the hierarchical nature of the XML data model, we consider the text of a data node u as part of the text of any of u's ancestor nodes in the data tree. For example, in the sample XML data tree (Fig. 1), the node 8 is an ancestor of the node 9. Thus, the text of the node 9 (i.e., "*Algorithms for mining frequent itemsets*...") is considered part of the text of the node 8.

XML Query Model

A fundamental construct in most existing XML query languages is the tree-pattern query or *twig*, which selects elements or attributes with a tree-like structure. In this article, we use the twig as our basic query model. Similar to the tree representation of XML data, we model a query twig as a rooted tree. More specifically, a query twig T is a tuple (*root, V, E*), where

- *root* is the root node of the twig;
- V is the set of nodes in the twig, where each node is a tripe (*id, label*, <*cont*>), where *id* uniquely identifies the node, *label* is the name of the corresponding element or attribute, and *cont* is the content condition on the corresponding node. *cont* is optional because not every query node may have a content condition;
- The content condition for a query node is either a database-style value constraint (e.g., a Boolean condition such as equality, inequality, or range constraint) or an IR-style keyword search. An IR-style content condition consists of a set of terms, where

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

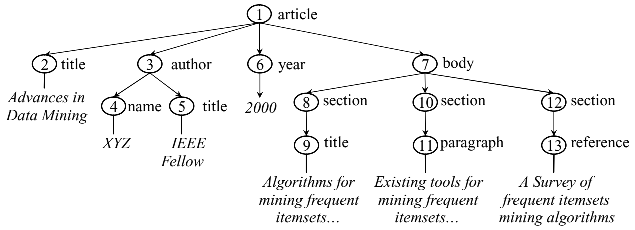

Figure 1. A sample XML data tree.

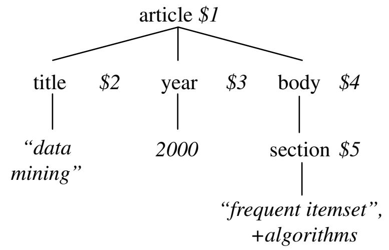

Figure 2. As sample XML twig.

each term is either a single word or a phrase. Each term may be prefixed with modifiers such as "+" or "−" for specifying preferences or rejections over the term. An IR-style content condition is to be processed in a nonBoolean style; and

- E is the set of edges in the twig. An edge from nodes $\$u$[2] to $\$v$, denoted as $e_{\$u,\$v}$, represents either a parent-to-child (i.e., "/") or an ancestor-to-descendant (i.e., "//") relationship between the nodes $\$u$ and $\$v$.

Given a twig T, we use $T.root$, $T.V$, and $T.E$ to represent its root, nodes, and edges, respectively. Given a node $\$v$ in the twig T (i.e., $v \in T.V$), we use $\$v.id$, $\$v.label$, and $\$v.cont$ to denote the unique ID, the name, and the content condition (if any) of the node respectively. The IDs of the nodes in a twig can be skipped when the labels of all the nodes are distinct.

For example, Fig. 2 illustrates a sample twig, which searches for articles with a title on "*data mining*," a year in 2000, and a body section about "*frequent itemset algorithms*." In this query, the user has a preference over the term *algorithm*. The twig consists of five nodes, where each node is associated with an unique *id* next to the node. The text under a twig node, shown in italic, is the content or value condition on the node.

The terms "twig" and "query tree" will be used interchangeably throughout this article.

XML Query Answer

With the introduction of XML data and query models, we shall now introduce the definition of an XML query answer. An answer for a query twig is a set of data nodes that satisfy the structure and content conditions in the twig. We formally define a query answer as follows:

Definition 1. ***Query Answer*** *Given an XML data tree D and a query twig T, an answer for the twig T, denoted as*$\mathcal{A}_D^T$, *is a set of nodes in the data D such that*:

- $\forall \$u \in T.V$, *there exists an unique data node u in* $\mathcal{A}_D^T$ *s.t* $\$u.label = u.label$. *Also, if* $\$u.cont \neq null$ *and* $\$u.cont$ *is a database-style value constraint, then the text of the data node* $u.text$ *satisfies the value constraint. If* $\$u:cont \neq null$ *and* $\$u.cont$ *is an IR-style content condition, then the text of* $u.text$ *should contain all the terms that are prefixed with "+" in* $\$u.cont$ *and must not contain any terms that are prefixed with "−" in* $\$u.cont$;
- $\forall e_{\$u,\$v} \in T.E$, *let u and v be the data nodes in* $\mathcal{A}_D^T$ *that correspond to the query node* $\$u$ *and* $\$v$, *respectively, then the structural relationship between u and v should satisfy the edge constraint* $e_{\$u,\$v}$.

For example, given the twig in Fig. 2, the set of nodes {1, 2, 6, 7, 8} in the sample XML data tree (Fig. 1) is an answer for the query, which matches the query nodes {\$1, \$2, \$3, \$4, \$5}, respectively. Similarly, the set of nodes {1, 2, 6, 7, 12} is also an answer to the sample query. Although the text of the data node 10 contain the phrase "*frequent itemset*," it does not contain the term *algorithm*, which is prefixed with "+." Thus, the set of data nodes {1, 2, 6, 7, 10} is not an answer for the twig.

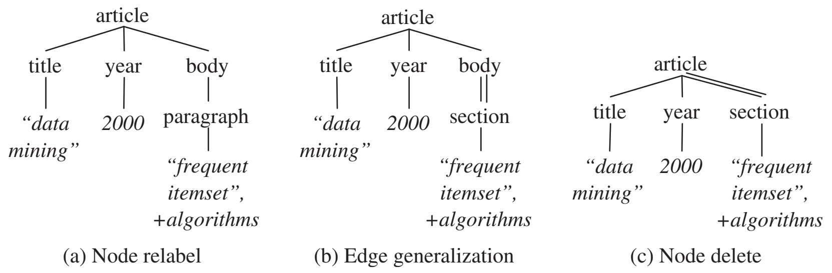
XML Query Relaxation Types

In the XML model, there are two types of query relaxations: *value relaxation* and *structure relaxation*. A value relaxation expands a value scope to allow the matching of additional answers. A structure relaxation, on the other hand, derives approximate answers by relaxing the constraint on a node or an edge in a twig. Value relaxation is orthogonal to structure relaxation. In this article, we focus on structure relaxation.

Many structure relaxation types have been proposed (8–10). We use the following three types, similar to the ones proposed in Ref. 10, which capture most of the relaxation types used in previous work.

- **Node Relabel.** With this relaxation type, a node can be relabeled to similar or equivalent labels according to domain knowledge. We use $rel(\$u, l)$ to represent a relaxation operation that renames a node $\$u$ to label l. For example, the twig in Fig. 2 can be relaxed to that in Fig. 3(a) by relabeling the node *section* to *paragraph*.
- **Edge Generalization.** With an edge relaxation, a parent-to-child edge ('/') in a twig can be generalized to an ancestor-to-descendant edge ('//'). We use $gen(e_{\$u,\$v})$ to represent a generalization of the edge between nodes $\$u$ and $\$v$. For example, the twig in Fig. 2 can be relaxed to that in Fig. 3(b) by relaxing the edge between nodes *body* and *section*.

[2] To distinguish a data node from a query node, we prefix the notation of a query node with a \$.



(a) Node relabel (b) Edge generalization (c) Node delete

Figure 3. Examples of structure relaxations for Fig.2.

- **Node Deletion.** With this relaxation type, a node may be deleted to derive approximate answers. We use *del*($*v*) to denote the deletion of a node $*v*. When $*v* is a leaf node, it can simply be removed. When $*v* is an internal node, the children of node $*v* will be connected to the parent of $*v* with ancestor-descendant edges ("//"). For instance, the twig in Fig. 2 can be relaxed to that in Fig. 3(c) by deleting the internal node *body*. As the root node in a twig is a special node representing the search context, we assume that any twig root cannot be deleted.

Given a twig T, a *relaxed twig* can be generated by applying one or more relaxation operations to T. Let m be the number of relaxation operations applicable to T, then there are at most $\binom{m}{1} + \ldots + \binom{m}{m} = 2^m$ relaxation operation combinations. Thus, there are at most 2^m relaxed twigs.

XML QUERY RELAXATION BASED ON SCHEMA CONVERSION

One approach to XML query relaxation is to convert XML schema, transform XML documents into relational tables with the converted schema, and then apply relational query relaxation techniques. A schema conversion tool, called XPRESS (*X*ml *P*rocessing and *R*elaxation in r*E*lational *S*torage *S*ystem) has been developed for these purposes: XML documents are mapped into relational formats so that queries can be processed and relaxed using existing relational technologies. Figure 4 illustrates the query relaxation flow via the schema conversion approach. This process first begins by extracting the schema information, such as DTD, from XML documents via tools such as XML Spy(see http://www.xmlspy.com.) Second, XML schema is transformed to relational schema via schema conversion ([e.g., XPRESS). Third, XML documents are parsed, mapped into tuples, and inserted into the relational databases. Then, relational query relaxation techniques [e.g., CoBase (3,6)] can be used to relax query conditions. Further, semi-structured queries over XML documents are translated into SQL queries. These SQL queries are processed and relaxed if there is no answer or there are insufficient answers available. Finally, results in the relational format are converted back into XML (e.g., the Nesting-based Translation Algorithm (NeT) and Constraints-based Translation Algorithm (CoT) (11) in XPRESS). The entire process can be done automatically and is transparent to users. In the following sections, we shall briefly describe the mapping between XML and relational schema.

Mapping XML Schema to Relational Schema

Transforming a hierarchical XML model to a flat relational model is a nontrivial task because of the following

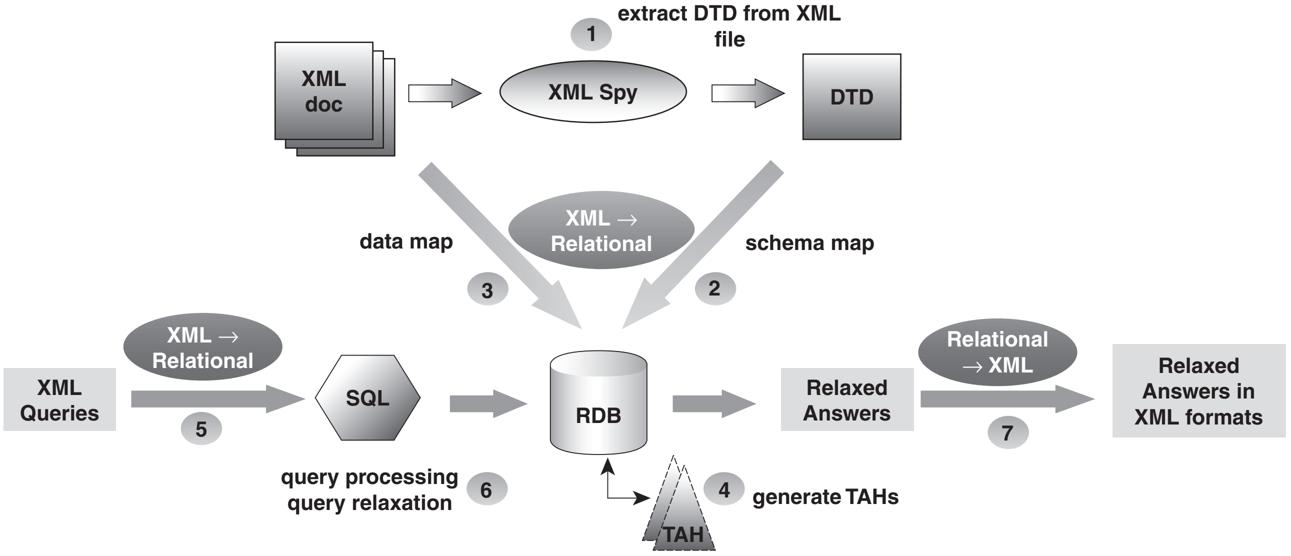


Figure 4. The processing flow of XML query relaxation via schema conversion.

inherent difficulties: the nontrivial 1-to-1 mapping, existence of set values, complicated recursion, and/or fragmentation issues. Several research works have been reported in these areas. Shanmugasundaram et al. (12) mainly focuses on the issues of structural conversion. The Constraints Preserving Inline (CPI) algorithm (13) considers the semantics existing in the original XML schema during the transformation. CPI inclines as many descendants of an element as possible into a single relation. It maps an XML element to a table when there is 1-to-$\{0,\ldots\}$ or 1-to-$\{1,\ldots\}$ cardinality between its parent and itself. The first cardinality has the semantics of "any," denoted by * in XML. The second means "at least," denoted by +. For example, consider the following DTD fragment:

```
<!ELEMENT author (name, address)>
<!ELEMENT name (firstname?, lastname)>
```

A naive algorithm will map every element into a separate table, leading to excessive fragmentation of the document, as follows:

```
author (address, name_id)
name (id, firstname, lastname)
```

The CPI algorithm converts the DTD fragment above into a single relational table as **author** (firstname, lastname, address).

In addition, semantics such as #REQUIRED in XML can be enforced in SQL with NOT NULL. Parent-to-child relationships are captured with KEYS in SQL to allow join operations. Figure 5 overviews the CPI algorithm, which uses a structure-based conversion algorithm (i.e., a hybrid algorithm) (13), as a basis and identifies various semantic constraints in the XML model. The CPI algorithm has been implemented in XPRESS, which reduces the number of tables generated while preserving most constraints.

Mapping Relational Schema to XML Schema

After obtaining the results in the relational format, we may need to represent them in the XML format before returning them back to users. XPRESS developed a Flat Translation (FT) algorithm (13), which translates tables in a relational schema to elements in an XML schema and columns in a relational schema to attributes in an XML schema. As FT translates the "flat" relational model to a "flat" XML model in a one-to-one manner, it does not use basic "non-flat" features provided by the XML model such as representing subelements though regular expression operator (e.g., "*" and "+"). As a result, the NeT algorithm (11) is proposed to decrease data redundancy and obtains a more intuitive schema by: (1) removing redundancies caused by multivalued dependencies; and (2) performing grouping on attributes. The NeT algorithm, however, considering tables one at a time, cannot obtain an overall picture of the relational schema where many tables are interconnected with each other through various other dependencies. The CoT algorithm (11) uses inclusion dependencies (INDs) of relational schema, such as foreign key constraints, to capture the interconnections between relational tables and represent them via parent-to-child hierarchical relationships in the XML model.

Query relaxation via schema transformation (e.g., XPRESS) has the advantage of leveraging on the well-developed relational databases and relational query relaxation techniques. Information, however, may be lost during the decomposition of hierarchical XML data into "flat" relational tables. For example, by transforming the following XML schema into the relational schema author (firstname, lastname, address), we lose the hierarchical relationship between element *author* and element *name*, as well as the information that element *firstname* is optional.

```
<!ELEMENT author (name, address)>
<!ELEMENT name (firstname?,lastname)>
```

Further, this approach does not support structure relaxations in the XML data model. To remedy these shortcomings, we shall perform query relaxation on the XML model directly, which will provide both value relaxation and structure relaxation.

A COOPERATIVE APPROACH FOR XML QUERY RELAXATION

Query relaxation is often user-specific. For a given query, different users may have different specifications about which conditions to relax and how to relax them. Most existing approaches on XML query relaxation (e.g., (10)) do not provide control during relaxation, which may yield undesired approximate answers. To provide user-specific approximate query answering, it is essential for an XML system to have a relaxation language that allows users to specify their relaxation control requirements and to have the capability to control the query relaxation process.

Furthermore, query relaxation usually returns a set of approximate answers. These answers should be ranked based on their relevancy to both the structure and the content conditions of the posed query. Most existing ranking models (e.g., (14,15)) only measure the content similarities between queries and answers, and thus are

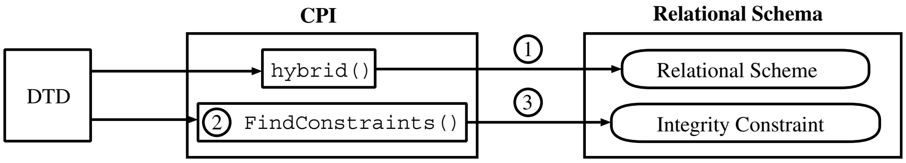

Figure 5. Overview of the CPI algorithm.

inadequate for ranking approximate answers that use structure relaxations. Recently, in Ref. (16), the authors proposed a family of structure scoring functions based on the occurrence frequencies of query structures among data without considering data semantics. Clearly, using the rich semantics provided in XML data in design scoring functions can improve ranking accuracy.

To remedy these shortcomings, we propose a new paradigm for XML approximate query answering that places users and their demands in the center of the design approach. Based on this paradigm, we develop a cooperative XML system that provides userspecific approximate query answering. More specifically, we first, develop a relaxation language that allows users to specify approximate conditions and control requirements in queries (e.g., preferred or unacceptable relaxations, nonrelaxable conditions, and relaxation orders).

Second, we introduce a relaxation index structure that clusters twigs into multilevel groups based on relaxation types and their distances. Thus, it enables the system to control the relaxation process based on users' specifications in queries.

Third, we propose a semantic-based tree editing distance to evaluate XML structure similarities, which is based on not only the number of operations but also the operation semantics. Furthermore, we combine structure and content similarities in evaluating the overall relevancy.

In Fig. 6, we present the architecture of our CoXML query answering system. The system contains two major parts: offline components for building relaxation indexes and online components for processing and relaxing queries and ranking results.

- *Building relaxation indexes.* The *Relaxation Index Builder* constructs relaxation indexes, XML Type Abstraction Hierarchy (XTAH), for a set of document collections.
- *Processing, relaxing queries, and ranking results.* When a user posts a query, the *Relaxation Engine* first sends the query to an *XML Database Engine* to search for answers that exactly match the structure conditions and approximately satisfy the content conditions in the query. If enough answers are found, the *Ranking Module* ranks the results based on their relevancy to the content conditions and returns the ranked results to the user. If there are no answers or insufficient results, then the *Relaxation Engine*, based on the user-specified relaxation constructs and controls, consults the relaxation indexes for the best relaxed query. The relaxed query is then resubmitted to the *XML Database Engine* to search for approximate answers. The *Ranking Module* ranks the returned approximate answers based on their relevancies to both structure and content conditions in the query. This process will be repeated until either there are enough approximate answers returned or the query is no longer relaxable.

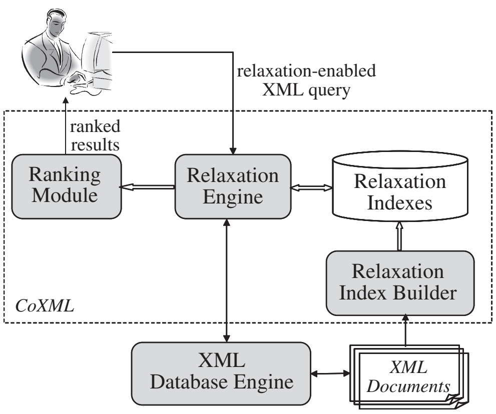

Figure 6. The CoXML system architecture.

The CoXML system can run on top of any existing XML database engine (e.g., BerkeleyDB[3], Tamino[4], DB2XML[5]) that retrieves exactly matched answers.

XML QUERY RELAXATION LANGUAGE

A number of XML approximate search languages have been proposed. Most extend standard query languages with constructs for approximate text search (e.g., XIRQL (15), TeXQuery (17), NEXI (18)). For example, TeXQuery extends XQuery with a rich set of full-text search primitives, such as proximity distances, stemming, and thesauri. NEXI introduces *about* functions for users to specify approximate content conditions. XXL (19) is a flexible XML search language with constructs for users to specify both approximate structure and content conditions. It, however, does not allow users to control the relaxation process. Users may often want to specify their preferred or rejected relaxations, nonrelaxable query conditions, or to control the relaxation orders among multiple relaxable conditions.

To remedy these shortcomings, we propose an XML relaxation language that allows users both to specify approximate conditions and to control the relaxation process. A relaxation-enabled query $\mathcal{Q}$ is a tuple ($\mathcal{T}$, $\mathcal{R}$, $\mathcal{C}$, $\mathcal{S}$), where:

- $\mathcal{T}$ is a twig as described earlier;
- $\mathcal{R}$ is a set of relaxation constructs specifying which conditions in $\mathcal{T}$ may be approximated when needed;
- $\mathcal{C}$ is a boolean combination of relaxation control stating how the query shall be relaxed; and
- $\mathcal{S}$ is a stop condition indicating when to terminate the relaxation process.

The execution semantics for a relaxation-enabled query are as follows: We first search for answers that exactly match the query; we then test the stop condition to check whether relaxation is needed. If not, we repeatedly relax

</inex_topic>
```

Figure 8. Topic 267 in INEX 05.

the twig based on the relaxation constructs and control until either the stop condition is met or the twig cannot be further relaxed.

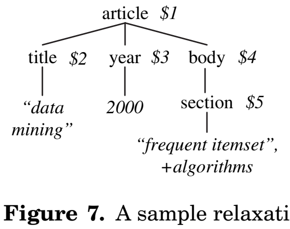
Given a relaxation-enabled query $\mathcal{Q}$, we use $\mathcal{Q}.\mathcal{T}$, $\mathcal{Q}.\mathcal{R}$, $\mathcal{Q}.\mathcal{C}$, and $\mathcal{Q}.\mathcal{S}$ to represent its twig, relaxation constructs, control, and stop condition, respectively. Note that a twig is required to specify a query, whereas relaxation constructs, control, and stop condition are optional. When only a twig is present, we iteratively relax the query based on similarity metrics until the query cannot be further relaxed.

A relaxation construct for a query $\mathcal{Q}$ is either a specific or a generic relaxation operation in any of the following forms:

- *rel*$(u,-)$, where $u \in \mathcal{Q}.\mathcal{T}.V$, specifies that node u may be relabeled when needed;
- *del*(u), where $u \in \mathcal{Q}.\mathcal{T}.V$, specifies that node u may be deleted if necessary; and
- *gen*$(e_{u,v})$, where $e_{u,v} \in \mathcal{Q}.\mathcal{T}.E$, specifies that edge $e_{u,v}$ may be generalized when needed.

The relaxation control for a query $\mathcal{Q}$ is a conjunction of any of the following forms:

- Nonrelaxable condition $!r$, where $r \in \{rel(u,-), del(u), gen\ (e_{u,v}) | u, v \in \mathcal{Q}.\mathcal{T}.V, e_{u,v} \in \mathcal{Q}, \mathcal{T}.E\}$, specifies that node u cannot be relabeled or deleted or edge $e_{u,v}$ cannot be generalized;
- $Pre\,fer(u, l_1, \ldots, ln)$, where $u \in \mathcal{Q}.\mathcal{T}.V$ and l_i is a label $(1 \leq \mathrm{i} \leq \mathrm{n})$, specifies that node u is preferred to be relabeled to the labels in the order of $(l_1, \ldots, l_n)$;
- $Reject(u, l_1, \ldots, l_n)$, where $u \in \mathcal{Q}.\mathcal{T}.V$, specifies a set of unacceptable labels for node u;
- $RelaxOrder(r_1, \ldots, r_n)$, where $r_i \in \mathcal{Q}.\mathcal{R}.\,(1 \leq \mathrm{i} \leq \mathrm{n})$, specifies the relaxation orders for the constructs in R to be $(r_1, \ldots, r_n)$; and
- $UseRType(rt_1, \ldots, rt_k)$, where $rt_i \in \{node\_relabel, node\_delete, edge\_generalize\} (1 \leq i \leq \mathrm{k} \leq 3)$, specifies the set of relaxation types allowed to be used. By default, all three relaxation types may be used.



$R = \{gen(e_{\$4,\$5}), del(\$3)\}$

$C = !del(\$4) \wedge !gen(e_{\$1,\$2}) \wedge !gen(e_{\$1,\$4}) \wedge$ UseRType(node_delete, edge_generalize)

$S = AtLeast(20)$

Figure 7. A sample relaxation-enabled query.

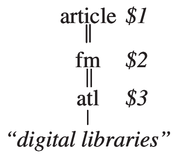
A stop condition $\mathcal{S}$ is either:

- $AtLeast(n)$, where n is a positive integer, specifies the minimum number of answers to be returned; or
- $\mathrm{d}(\mathcal{Q}.\mathcal{T}.T') \leq \tau$, where T' stands for a relaxed twig and τ a distance threshold, specifies that the relaxation should be terminated when the distance between the original twig and a relaxed twig exceeds the threshold.

Figure 7 presents a sample relaxation-enabled query. The minimum number of answers to be returned is 20. When relaxation is needed, the edge between *body* and *section* may be generalized and node *year* may be deleted. The relaxation control specifies that node *body* cannot be deleted during relaxation. For instance, a *section* about "*frequent itemset*" in an article's appendix part is irrelevant. Also, the edge between nodes *article* and *title* and the edge between nodes *article* and *body* cannot be generalized. For instance, an article with a reference to another article that possesses a title on "*data mining*" is irrelevant. Finally, only *edge generalization* and *node deletion* can be used.

We now present an example of using the relaxation language to represent query topics in INEX 05[6]. Figure 8 presents Topic 267 with three parts: *castitle* (i.e., the query formulated in an XPath-like syntax), *description*, and *narrative*. The *narrative* part describes a user's detailed information needs and is used for judging result relevancy.

The user considers an article's title (*atl*) non-relaxable and regards titles about "digital libraries" under the bibliography part (*bb*) irrelevant. Based on this narrative, we formulate this topic using the relaxation language as shown in Fig. 9. The query specifies that node *atl* cannot be relaxed (either deleted or relabeled) and node *fm* cannot be relabeled to *bb*.



$C = !rel(\$3, -) \wedge !del(\$3) \wedge Reject(\$2, bb)$

Figure 9. Relaxation specifications for Topic 267.

XML RELAXATION INDEX

Several approaches for relaxing XML or graph queries have been proposed (8,10,16,20,21). Most focus on efficient algorithms for deriving top-k approximate answers without relaxation control. For example, Amer-yahia et al. (16) proposed a DAG structure that organizes relaxed twigs based on their "consumption" relationships. Each node in a DAG represents a twig. There is an edge from twig T_A to twig T_B if the answers for T_B is a superset of those for T_A. Thus, the twig represented by an ancestor DAG node is always less relaxed and thus closer to the original twig than the twig represented by a descendant node. Therefore, the DAG structure enables efficient top-k searching when there are no relaxation specifications. When there are relaxation specifications, the approach in Ref. 16 can also be adapted to top-k searching by adding a postprocessing part that checks whether a relaxed query satisfies the specifications. Such an approach, however, may not be efficient when relaxed queries do not satisfy the relaxation specifications.

To remedy this condition, we propose an XML relaxation index structure, XTAH, that clusters relaxed twigs into multilevel groups based on relaxation types used by the twigs and distances between them. Each group consists of twigs using similar types of relaxations. Thus, XTAH enables a systematic relaxation control based on users' specifications in queries. For example, *Reject* can be implemented by pruning groups of twigs using unacceptable relaxations. *RelaxOrder* can be implemented by scheduling relaxed twigs from groups based on the specified order.

In the following, we first introduce XTAH and then present the algorithm for building an XTAH.

XML Type Abstraction Hierarchy—XTAH

Query relaxation is a process that enlarges the search scope for finding more answers. Enlarging a query scope can be accomplished by viewing the queried object at different conceptual levels.

In the relational database, a tree-like knowledge representation called Type Abstraction Hierarchy (TAH) (3) is introduced to provide systematic query relaxation guidance. A TAH is a hierarchical cluster that represents data objects at multiple levels of abstractions, where objects at higher levels are more general than objects at lower levels. For example, Fig. 10 presents a TAH for brain tumor sizes, in which a medium tumor size (i.e., 3–10 mm) is a more abstract representation than a specific tumor size (e.g., 10 mm). By such multilevel abstractions, a query can be relaxed by modifying its conditions via *generalization* (moving up the TAH) and *specialization* (moving down the TAH). In addition, relaxation can be easily controlled via TAH. For example, *REJECT* of a relaxation can be implemented by pruning the corresponding node from a TAH.

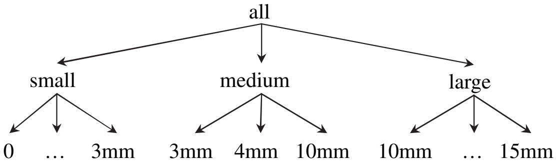

Figure 10. A TAH for brain tumor size.

To support query relaxation in the XML model, we propose a relaxation index structure similar to TAH, called XML Type Abstraction Hierarchy (XTAH). An XTAH for a twig structure T, denoted as XT_T , is a hierarchical cluster that represents relaxed twigs of T at different levels of relaxations based on the types of operations used by the twigs and the distances between them. More specifically, an XTAH is a multilevel labeled cluster with two types of nodes: internal and leaf nodes. A leaf node is a relaxed twig of T. An internal node represents a cluster of relaxed twigs that use similar operations and are closer to each other by distance. The label of an internal node is the common relaxation operations (or types) used by the twigs in the cluster. The higher level an internal node in the XTAH, the more general the label of the node, the less relaxed the twigs in the internal node.

XTAH provides several significant advantages: (1) We can efficiently relax a query based on relaxation constructs by fetching relaxed twigs from internal nodes whose labels satisfy the constructs; (2) we can relax a query at different granularities by traversing up and down an XTAH; and (3) we can control and schedule query relaxation based on users' relaxation control requirements. For example, relaxation control such as nonrelaxable conditions, Reject or UseRType, can be implemented by pruning XTAH internal nodes corresponding to unacceptable operations or types.

Figure 11 shows an XTAH for the sample twig in Fig. 3(a).[7] For ease of reference, we associate each node in the XTAH with a unique ID, where the IDs of internal nodes are prefixed with *I* and the IDs of leaf nodes are prefixed with *T*'.

Given a relaxation operation r, let I_r be an internal node with a label $\{r\}$. That is, I_r represents a cluster of relaxed twigs whose common relaxation operation is r. As a result of the tree-like organization of clusters, each relaxed twig belongs to only one cluster, whereas the twig may use multiple relaxation operations. Thus, it may be the case that not all the relaxed twigs that use the relaxation operation r are within the group I_r. For example, the relaxed twig T'_2, which uses two operations $gen(e_{\$1,\$2})$ and $gen(e_{\$4,\$5})$, is not included in the internal node that represents $\{gen(e_{\$4,\$5})\}$, I_7, because T'_2 may belong to either group I_4 or group I_7 but is closer to the twigs in group I_4.

To support efficient searching or pruning of relaxed twigs in an XTAH that uses an operation r, we add a virtual link from internal node I_r to internal node I_k, where I_k is not a descendant of I_r, but all the twigs within I_k use operation r. By doing so, relaxed twigs that use operation r are either within group I_r or within the groups connected to I_r by virtual links. For example, internal node I_7 is connected to internal nodes I_{16} and I_{35} via virtual links.

[7] Due to space limitations, we only show part of the XTAH here.

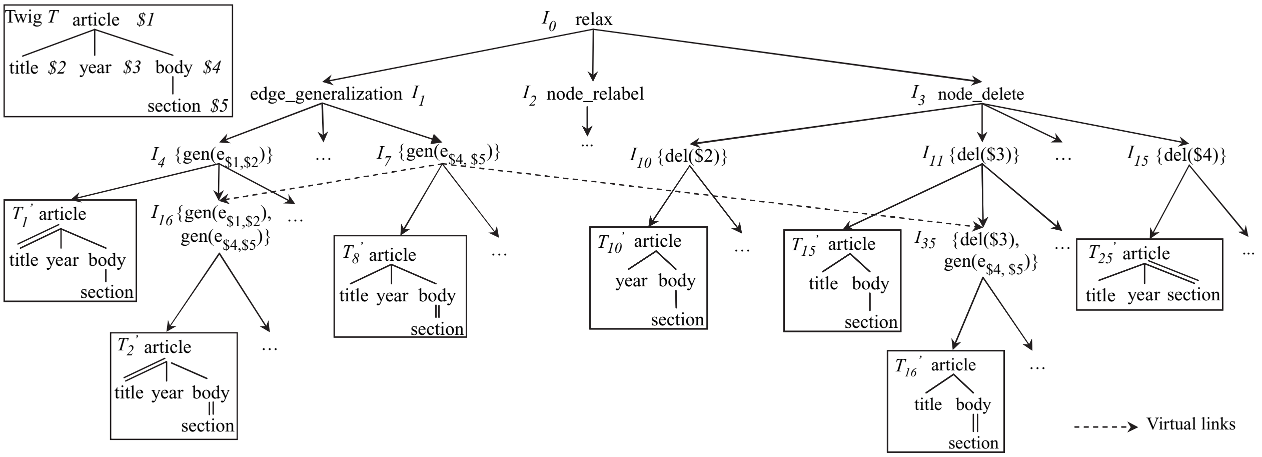

Figure 11. An example of XML relaxation index structure for the twig T.

Thus, all the relaxed twigs using the operation $gen(e_{\$4,\$5})$ are within the groups I_7, I_{16}, and I_{35}.

Building an XTAH

With the introduction of XTAH, we now present the algorithm for building the XTAH for a given twig T.

Algorithm 1 Building the XTAH for a given twig T

```
Input: T: a twig
    K: domain knowledge about similar node labels
Output: $XT_T$ : an XTAH for T
 1: $RO_T \leftarrow$ GerRelaxOperations(T, K) {GerRelaxOperations
    (T, K) returns a set of relaxation operations applicable to the
    twig T based on the domain knowledge K}
 2: let $XT_T$ be a rooted tree with four nodes: a root node relax
    with three child nodes node_relabel, node_delete and
    edge_generalization
 3: for each relaxation operation $r \in RO_T$ do
 4:     rtype ← the relaxation type of r
 5:     InsertXTNode(/relax/rtype, {r}) {InsertXTNode(p, n)
        inserts node n into $XT_T$ under path p}
 6:     $T' \leftarrow$ the relaxed twig using operation r
 7:     InsertXTNode (/relax/rtype, /{r}, T')
 8: end for
 9: for $k = 2$ to$|RO_T|$ do
10:     $S_k \leftarrow$ all possible combinations of k relaxation operations
        in $RO_T$
11:     for each combination $s \in S_k$ do
12:         let $s = \{r_1, \ldots, r_k\}$
13:         if the set of operations in s is applicable to T then
14:             $T' \leftarrow$ the relaxed twig using the operations in s
15:             $I_i \leftarrow$ the node representing $s - \{r_i\}(1 \le i \le k)$
16:             $I_j \leftarrow$ the node s.t. $\forall i, d(T', I_j) \le d(T', I_i)(1 \le \text{i,j} \le \text{k})$
17:             InsertXTNode(//$I_j$, $\{r_1, \ldots, r_k\}$)
18:             InsertXTNode(//$I_j$/$\{r_1, \ldots, r_k\}$, T')
19:             AddVLink(//$\{r_j\}$, //$I_j$) {AddV Link($p_1$,$p_2$) adds a
                virtual link from the node under path $p_1$ to the node
                under path $p_2$}
20:         end if
21:     end for
22: end for
```

In this subsection, we assume that a distance function is available that measures the structure similarity between twigs. Given any two twigs T_1 and T_2, we use $d(T_1, T_2)$ to represent the distance between the two twigs. Given a twig T and an XTAH internal node I, we measure the distance between the twig and the internal node, $d(T, I)$, as the average distance between T and any twig T′ covered by I.

Algorithm 1 presents the procedure of building the XTAH for twig T in a top-down fashion. The algorithm first generates all possible relaxations applicable to T (Line 1). Next, it initializes the XTAH with the top two level nodes (Line 2). In Lines 3–8, the algorithm generates relaxed twigs using one relaxation operation and builds indexes on these twigs based on the type of the relaxation used: For each relaxation operation r, it first adds a node to represent r, then inserts the node into the XTAH based on r's type, and places the relaxed twig using r under the node. In Lines 9–22, the algorithm generates relaxed twigs using two or more relaxations and builds indexes on these twigs. Let s be a set of k relaxation operations ($\text{k} \ge 2$), T′ a relaxed twig using the operations in s, and I an internal node representing s. Adding node I into the XTAH is a three-step process: (1) it first determines I's parent in the XTAH (Line 16). In principle, any internal node that uses a subset of the operations in s can be I's parent. The algorithm selects an internal node I_j to be I's parent if the distance between T' and I_j is less than the distance between T' and other parent node candidates; (2) It then connects node I to its parent I_j and adds a leaf node representing T' to node I (Lines 17 and 18). (3) Finally, it adds a virtual link from the internal node representing the relaxation operation r_j to node I (Line 19), where r_j is the operation that occurs in the label of I but not in label of its parent node I_j .

QUERY RELAXATION PROCESS

Query Relaxation Algorithm

Algorithm 2 Query Relaxation Process

```
Input: $XT_T$: an XTAH
       $\mathcal{Q} = \{\mathcal{T}, \mathcal{R}, \mathcal{C}, \mathcal{S}\}$: a relaxation-enabled query
Output: $\mathcal{A}$: a list of answers for the query $\mathcal{Q}$
 1: $\mathcal{A} \leftarrow$ SearchAnswer($\mathcal{Q}.T$); {Searching for exactly matched
    answers for $\mathcal{Q}.T$}
 2: if (the stop condition $\mathcal{Q}.\mathcal{S}$ is met) then
 3:     return $\mathcal{A}$
 4: end if
 5: if (the relaxation controls $\mathcal{Q}.\mathcal{C}$ are non-empty) then
 6:     PruneXTAH($XT_T$, $\mathcal{Q}.\mathcal{C}$) {Pruning nodes in $XT_T$ that
        contain relaxed twigs using unacceptable relaxation
        operations based on $\mathcal{Q}.\mathcal{C}$}
 7: end if
 8: if the relaxation constructs $\mathcal{Q}.\mathcal{R}$ are non-empty then
 9:     while ($\mathcal{Q}.\mathcal{S}$ is not met)&&(not all the constructs in $\mathcal{Q}.\mathcal{R}$ have
        been processed) do
10:         $T' \leftarrow$ the relaxed twig from $XT_T$ that best satisfies the
            relaxation specifications $\mathcal{Q}.\mathcal{R}$ & $\mathcal{Q}.\mathcal{C}$
11:         Insert SearchAnswer($T'$) into $\mathcal{A}$
12:     end while
13: end if
14: while ($\mathcal{Q}.\mathcal{T}$ is relaxable)&&($\mathcal{Q}.\mathcal{S}$ is not met) do
15:     $T' \leftarrow$ the relaxed twig from $XT_T$ that is closest to $\mathcal{Q}.\mathcal{T}$ based
        on distance
16:     Insert SearchAnswer($T'$) into $\mathcal{A}$
17: end while
18: return $\mathcal{A}$
```

Figure 12 presents the control flow of a relaxation process based on XTAH and relaxation specifications in a query. The *Relaxation Control* module prunes irrelevant XTAH groups corresponding to unacceptable relaxation operations or types and schedules relaxation operations based on *Prefer* and *RelaxOrder* as specified in the query. Algorithm 2 presents the detailed steps of the relaxation process:

1. Given a relaxation-enabled query $\mathcal{Q} = \{\mathcal{T}, \mathcal{R}, \mathcal{C}, \mathcal{S}\}$ and an XTAH for $\mathcal{Q}.\mathcal{T}$, the algorithm first searches for exactly matched answers. If there are enough number of answers available, there is no need for relaxation and the answers are returned (Lines 1–4).
2. If relaxation is needed, based on the relaxation control $\mathcal{Q}.\mathcal{C}$ (Lines 5–7), the algorithm prunes XTAH internal nodes that correspond to unacceptable operations such as nonrelaxable twig nodes (or edges), unacceptable node relabels, and rejected relaxation types. This step can be efficiently carried out by using internal node labels and virtual links. For example, the relaxation control in the sample query (Figure 7) specifies that only *node_delete* and *edge_generalization* may be used. Thus, any XTAH node that uses *node_relabel*, either within group I_2 or connected to I_2 by virtual links, is disqualified from searching. Similarly, the internal nodes I_{15} and I_4, representing the operations $del(\$4)$ and $gen(e_{\$1,\ \$2})$, respectively, are pruned from the XTAH by the *Relaxation Control* module.
3. After pruning disqualified internal groups, based on relaxation constructs and control, such as *RelaxOrder* and *Prefer*, the *Relaxation Control* module schedules and searches for the relaxed query that best satisfies users' specifications from the XTAH. This step terminates when either the stop condition is met or all the constructs have been processed. For example, the sample query contains two relaxation constructs: $gen(e_{\$4,\$5})$ and $del(\$3)$. Thus, this step selects the best relaxed query from internal groups, I_7 and I_{11}, representing the two constructs, respectively.
4. If further relaxation is needed, the algorithm then iteratively searches for the relaxed query that is closest to the original query by distance, which may use relaxation operations in addition to those specified in the query. This process terminates when either the stop condition holds or the query cannot be further relaxed.
5. Finally, the algorithm outputs approximate answers.

Searching for Relaxed Queries in an XTAH

We shall now discuss how to efficiently search for the best relaxed twig that has the least distance to the query twig from its XTAH in Algorithm 2.

A brute-force approach is to select the best twig by checking all the relaxed twigs at the leaf level. For a twig T with m relaxation operations, the number of relaxed twigs can be up to 2^m. Thus, the worst case time complexity for this approach is $O(2^m)$, which is expensive.

To remedy this condition, we propose to assign representatives to internal nodes, where a representative summarizes the distance characteristics of all the relaxed twigs covered by a node. The representatives facilitate the searching for the best relaxed twig by traversing an

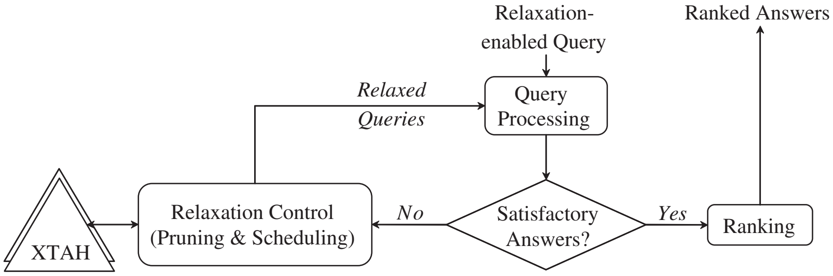

Figure 12. Query relaxation control flow.

XTAH in a top-down fashion, where the path is determined by the distance properties of the representatives. By doing so, the worst case time complexity of finding the best relaxed query is $O(d * h)$, where d is the maximal degree of an XTAH node and h is the height of the XTAH. Given an XTAH for a twig T with m relaxation operations, the maximal degree of any XTAH node and the depth of the XTAH are both $O(m)$. Thus, the time complexity of the approach is $O(m^2)$, which is far more efficient than the brute-force approach ($O(2^m)$).

In this article, we use M-tree (22) for assigning representatives to XTAH internal nodes. M-tree provides an efficient access method for similarity search in the "metric space," where object similarities are defined by a distance function. Given a tree organization of data objects where all the data objects are at the leaf level, M-tree assigns a data object covered by an internal node I to be the representative object of I. Each representative object stores the covering radius of the internal node (i.e., the maximal distance between the representative object and any data object covered by the internal node). These covering radii are then used in determining the path to a data object at the leaf level that is closest to a query object during similarity searches.

XML RANKING

Query relaxation usually generates a set of approximate answers, which need to be ranked before being returned to users. A query contains both structure and content conditions. Thus, we shall rank an approximate answer based on its relevancy to both the structure and content conditions of the posed query. In this section, we first present how to compute XML content similarity, then describe how to measure XML structure relevancy, and finally discuss how to combine structure relevancy with content similarity to produce the overall XML ranking.

XML Content Similarity

Given an answer $\mathcal{A}$ and a query $\mathcal{Q}$, the content similarity between the answer and the query, denoted as cont_sim(A and $\mathcal{Q}$), is the sum of the content similarities between the data nodes and their corresponding matched query nodes. That is,

$$cont\_sim(\mathcal{A}, \mathcal{Q}) = \sum_{v \in \mathcal{A}, \$u \in \mathcal{Q}.\mathcal{T}.v, u \; matches \; \$u} cont\_sim(v, \$u) \tag{1}$$

For example, given the sample twig in Fig. 2, the set of nodes {1, 2, 6, 7, 8} in the sample data tree is an answer. The content similarity between the answer and the twig equals to $cont\_sim(2, \$2) + cont\_sim(6, \$3) + cont\_sim(8, \$5)$.

We now present how to evaluate the content similarity between a data node and a query node. Ranking models in traditional IR evaluate the content similarity between a document to a query and thus need to be extended to evaluating the content similarity between an XML data node and a query node. Therefore, we proposed an extended vector space model (14) for measuring XML content similarity, which is based on two concepts: *weighted term frequency* and *inverse element frequency*.

Weighted Term Frequency. Due to the hierarchical structure of the XML data model, the text of a node is also considered as a part of the ancestor nodes' text, which introduces the challenge of how to calculate the content relevancy of an XML data node v to a query term t, where t could occur in the text of any node nested within the node v. For example, all three *section* nodes (i.e., nodes 8, 10, and 12) in the XML data tree (Fig. 1) contain the phrase "frequent itemsets" in their text parts. The phrase "frequent itemsets" occurs at the *title* part of the node 8, the *paragraph* part in the node 10, and the *reference* part in the node 12. The same term occurring at the different text parts of a node may be of different weights. For example, a "frequent itemset" in the *title* part of a *section* node has a higher weight than a "frequent itemset" in the *paragraph* part of a *section* node, which, in turn, is more important than a "frequent itemset" in the *reference* part of a *section* node. As a result, it may be inaccurate to measure the weight of a term t in the text of a data node v by simply counting the occurrence frequency of the term t in the text of the node v without distinguishing the term's occurrence paths within the node v.

To remedy this condition, we introduce the concept of "weighted term frequency," which assigns the weight of a term t in a data node v based on the term's occurrence frequency and the weight of the *occurrence path*. Given a data node v and a term t, let $p = v_1.v_2 \ldots .v_k$ be an *occurrence path* for the term t in the node v, where v_k is a descendant node of v, v_k directly contains the term t, and $v \rightarrow v_1 \rightarrow \ldots \rightarrow v_k$ represents the path from the node v to the node v_k. Let $w(p)$ and $w(v_i)$ denote the weight for the path p and the node v_i, respectively. Intuitively, the weight of the path $p = v_1.v_2 \ldots .v_k$ is a function of the weights of the nodes on the path (i.e., $w(p) = \mathrm{f}(w(v_1), \ldots w(v_k))$), with the following two properties:

1. $\mathrm{f}(w(v_1), w(v_2), \ldots, w(v_\mathrm{k}))$ is a monotonically increasing function with respect to $w(v_i)$ ($1 \leq \mathrm{i} \leq \mathrm{k}$); and
2. $\mathrm{f}(w(v_1), w(v_2), \ldots, w(v_\mathrm{k}))) = 0$ if any $w(v_i) = 0$ ($1 \leq \mathrm{i} \leq \mathrm{k}$).

The first property states that the path weight function is a monotonically increasing function. That is, the weight of a path is increasing if the weight of any node on the path is increasing. The second property states that if the weight of any node on the path is zero, then the weight of the path is zero. For any node v_i ($1 \leq \mathrm{i} \leq \mathrm{k}$) on the path p, if the weight of the node v_i is zero, then it implies that users are not interested in the terms occurring under the node v_i. Therefore, any term in the text of either the node v_i or a descendant node of v_i is irrelevant.

A simple implementation of the path weight function $\mathrm{f}(w(v_1), w(v_2), \ldots, w(v_k))$ that satisfies the properties stated above is to let the weight of a path equal to the

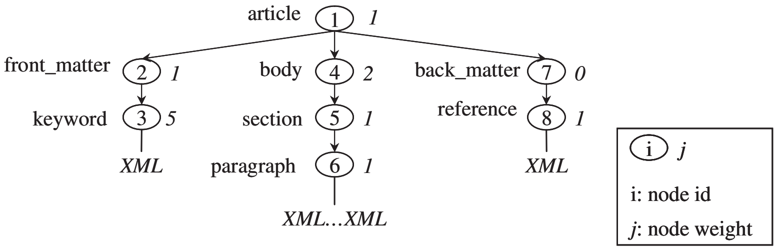

Figure 13. An example of weighted term frequency.

product of the weights of all nodes on the path:

$$w(p) = \prod_{i=1}^{k} w(v_i) \tag{2}$$

With the introduction of the weight of a path, we shall now define the weighted term frequency for a term t in a data node v, denoted as $tf_w(v,\, t)$, as follows:

$$tf_w(v,t) = \sum_{j=1}^{m} w(p_j) \times tf(v,p_j,t) \tag{3}$$

where m is the number of paths in the data node v containing the term t and $tf\ (v,\, p_j,\, t)$ is the frequency of the term t occurred in the node v via the path p_j.

For example, Fig. 13 illustrates an example of an XML data tree with the weight for each node shown in italic beside the node. The weight for the *keyword* node is 5 (i.e., $w(keyword) = 5$). From Equation (2), we have $w(front\_matter.keyword)$ = 5*1 = 5, $w(body.section.paragraph)$ = 2*1*1 = 2, and $w(back\_matter.reference)$ = 0*1 = 0, respectively. The frequencies of the term "XML" in the paths *front_matter.keyword*, *body.section.paragraph*, and *back_ matter.reference* are 1, 2, and 1, respectively. Therefore, from Equation (3), the weighted term frequency for the term "XML" in the data node *article* is 5*1 + 2*2 + 0*1 = 9.

Inverse Element Frequency. Terms with different popularity in XML data have different degrees of discriminative power. It is well known that a term frequency (*tf*) needs to be adjusted by the inverse document frequency (*idf*) (23). A very popular term (with a small *idf*) is less discriminative than a rare term (with a large *idf*). Therefore, the second component in our content ranking model is the concept of "inverse element frequencys" (*ief*), which distinguishes terms with different discriminative powers in XML data. Given a query Q and a term t, let \$$u$ be the node in the twig $Q.\mathcal{T}$ whose content condition contains the term t (i.e., $t \in \$u.cont$). Let DN be the set of data nodes such that each node in DN matches the structure condition related with the query node \$$u$. Intuitively, the more frequent the term t occurs in the text of the data nodes in DN, the less discriminative power the term t has. Thus, the inverse element frequency for the query term t can be measured as follows:

$$ief(\$u,\, t) = log\left(\frac{N_1}{N_2} + 1\right) \tag{4}$$

where N_1 denotes the number of nodes in the set DN and N_2 represents the number of the nodes in the set DN that contain the term t in their text parts.

For example, given the sample XML data tree (Fig. 1) and the query twig (Fig. 2), the inverse element frequency for the term "frequent itemset" can be calculated as follows: First, the content condition of the query node \$5 contains the term "frequent itemset"; second, there are three data nodes (i.e., nodes 8, 10, and 12) that match the query node \$5; and third, all the three nodes contain the term in their text. Therefore, the inverse element frequency for the term "frequent itemset" is log(3/3 + 1) = log2. Similarly, as only two nodes (i.e., nodes 8 and 12) contain the term "algorithms," the inverse element frequency for the term "algorithms" is log(3/2 + 1) = log(5/2).

Extended Vector Space Model. With the introduction "weighted term frequency" and "inverse element frequency," we now first present how we compute the content similarity between a data node and a query node and then present how we calculate the content similarity between an answer and a query.

Given a query node \$$u$ and a data node v, where the node v matches the structure condition related with the query node \$$u$, the content similarity between the nodes v and \$$u$ can be measured as follows:

$$cont_sim(v,\$u) = \sum_{t \in \$u.cont} w(m(t)) \times tf_w(v,t) \times ief(\$u,t) \tag{5}$$

where t is a term in the content condition of the node \$$u$, $m(t)$ stands for the modifier prefixed with the term t (e.g., "+", " ", "−"), and $w(m(t))$ is the weight for the term modifier as specified by users.

For example, given the *section* node, \$5, in the sample twig (Fig. 2), the data node 8 in Fig. 1 is a match for the twig node \$5. Suppose that the weight for a "+" term modifier is 2 and the weight for the *title* node is 5, respectively. The content similarity between the data node 8 and the twig node \$5 equals to tf_w(8, *"frequent itemset"*)× ief(\$5, *"frequent itemset"*) + w('+') × tf_w(8, *"algorithms"*) × *ief*(\$5, *"algorithms"*), which is 5 × log2 + 2 × 5 × log(5/2) = 18.22. Similarly, the data node 2 is a match for the twig node *title* (i.e., \$2) and the content similarity between them is tf_w(2, *"data mining"*) × ief(\$2, "data mining") = 1.

Discussions. The extended vector space model has shown to be very effective in ranking content similarities of SCAS retrieval results[8](14). SCAS retrieval results are usually of relatively similar sizes. For example, for the twig in Fig. 2, suppose that the node *section* is the target node (i.e., whose matches are to be returned as answers). All the SCAS retrieval results for the twig will be sections inside article bodies. Results that approximately match the twig, however, could be nodes other than *section* nodes, such as *paragraph*, *body*, or *article* nodes, which are of varying sizes. Thus, to apply the extended vector space model for evaluating content similarities of approximate answers under this condition, we introduce the factor of "weighted sizes" into the model for normalizing the biased effects caused by the varying sizes in the approximate answers (24):

$$cont\_sim(\mathcal{A}, \mathcal{Q}) = \sum_{v \in \mathcal{A}, \$u \in \mathcal{Q}.\mathcal{T}.\mathcal{V}, v\, matches\, \$u} \frac{cont\_sim(v, \$u)}{log_2\, wsize(v)} \tag{6}$$

where *wsize*(v) denotes the weighted size of a data node v.

Given an XML data node v, *wsize*(v) is the sum of the number of terms directly contained in node v's text, *size*-($v.text$), and the weighted size of all its child nodes adjusted by their corresponding weights, as shown in the following equation.

$$wsize(v) = size(v.text) + \sum_{v_i\ s.t.\ v|v_i} wsize(v_i) * w(v_i) \tag{7}$$

For example, the weighted size of the *paragraph* node equals the number of terms in its text part, because the *paragraph* node does not have any child node.

Our normalization approach is similar to the scoring formula proposed in Ref. 25, which uses the log of a document size to adjust the product of tf and *idf*.

Semantic-based Structure Distance

The structure similarity between two twigs can be measured using tree editing distance (e.g., (26)), which is frequently used for evaluating tree-to-tree similarities. Thus, we measure the structure distance between an answer $\mathcal{A}$ and a query $\mathcal{Q}$, *struct_dist*($\mathcal{A}$, $\mathcal{Q}$), as the editing distance between the twig $\mathcal{Q}\cdot\mathcal{T}$ and the least relaxed twig T', $d(\mathcal{Q}.\mathcal{T}, T')$, which is the total costs of operations that relax $\mathcal{Q}.\mathcal{T}$ to T':

$$struct\_dist(\mathcal{A}, \mathcal{Q}) = d(\mathcal{Q}.\mathcal{T}, T') = \sum_{i=1}^{k} cost(r_i) \tag{8}$$

where $\{r_1, \ldots, r_k\}$ is the set of operations that relaxes $\mathcal{Q}.\mathcal{T}$ to T' and $cost(r_i)$ $(0 \leq cost(r_i) \leq 1)$ is equal to the cost of the relaxation operation $r_i(1 \leq \mathrm{i} \leq \mathrm{k})$.

Existing edit distance algorithms do not consider operation cost. Assigning equal cost to each operation is simple, but does not distinguish the semantics of different operations. To remedy this condition, we propose a semantic-based relaxation operation cost model.

We shall first present how we model the semantics of XML nodes. Given an XML dataset D, we represent each data node v_i as a vector $\{w_{i1}, w_{i2}, \ldots, w_{iN}\}$, where N is the total number of distinct terms in D and w_{ij} is the weight of the *jth* term in the text of v_i. The weight of a term may be computed using *tf***idf* (23) by considering each node as a "document." With this representation, the similarity between two nodes can be computed by the cosine of their corresponding vectors. The greater the cosine of the two vectors, the semantically closer the two nodes.

We now present how to model the cost of an operation based on the semantics of the nodes affected by the operation with regard to a twig T as follows:

- Node Relabel – *rel*(u, l)
  A node relabel operation, *rel*(u, l), changes the label of a node u from $u.label$ to a new label l. The more semantically similar the two labels are, the less the relabel operation will cost. The similarity between two labels, $u.label$ and l, denoted as *sim*($u.label$, l), can be measured as the cosine of their corresponding vector representations in XML data. Thus, the cost of a relabel operation is:

$$cost(rel(u, l)) = 1 - sim(u.lable,\ l) \tag{9}$$

  For example, using the INEX 05 data, the cosine of the vector representing *section* nodes and the vector representing *paragraph* nodes is 0.99, whereas the cosine of the vector for *section* nodes and the vector for *figure* nodes is 0.38. Thus, it is more expensive to relabel node *section* to *paragraph* than to *figure*.

- Node Deletion – *del*(u)
  Deleting a node u from the twig approximates u to its parent node in the twig, say v. The more semantically similar node u is to its parent node v, the less the deletion will cost. Let $\mathrm{V}_{v/u}$ and V_v be the two vectors representing the data nodes satisfying v/u and v, respectively. The similarity between $v\,/\,u$ and v, denoted as *sim*($v\,/\,u$, v), can be measured as the cosine of the two vectors $V_{v\,/\,u}$ and V_v. Thus, a node deletion cost is:

$$cost(del(u)) = 1 - sim(v/u,\ u) \tag{10}$$

  For example, using the INEX 05 data, the cosine of the vector for *section* nodes inside *body* nodes and the vector for *body* nodes is 0.99, whereas the cosine of the vector for *keyword* nodes inside *article* nodes and the vector for *article* nodes is 0.2714. Thus, deleting the *keyword* node in Fig. 3(a) costs more than deleting the *section* node.

- Edge Generalization – *gen*($e_{v,u}$)
  Generalizing the edge between nodes $\$v$ and $\$u$ approximates a child node $v\,/\,u$ to a descendant node $v\,/\,/\,u$. The closer $v\,/\,u$ is to $v\,/\,/\,u$ in semantics, the less the edge generalization will cost. Let $V_{v\,/\,u}$ and $V_{v\,/\,/\,u}$ be two vectors representing the data nodes satisfying

[8] In a SCAS retrieval task, structure conditions must be matched exactly whereas content conditions are to be approximately matched.

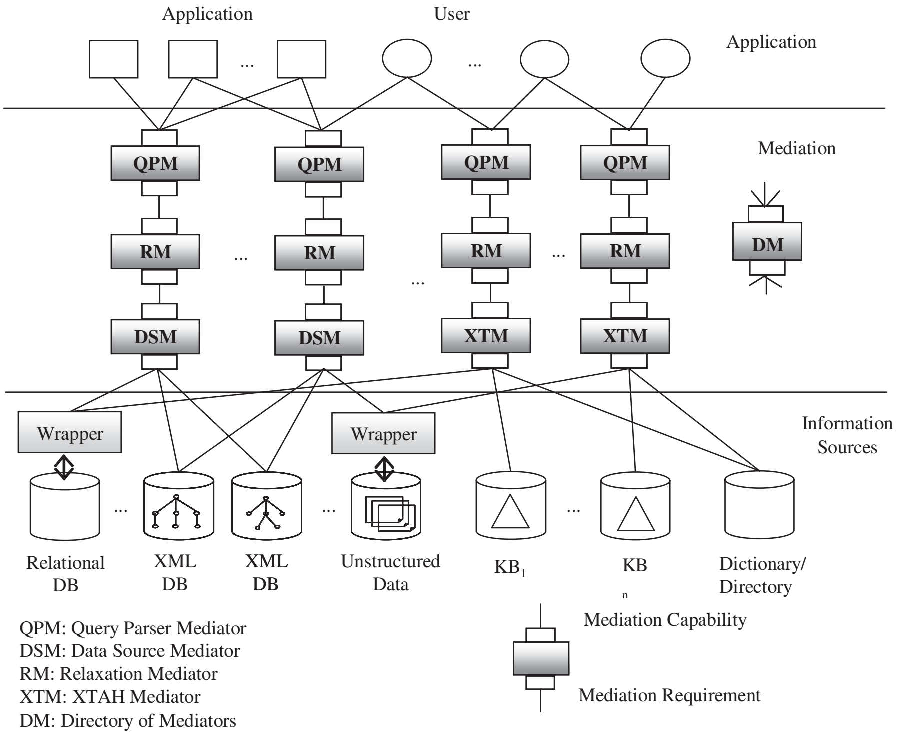

Figure 14. A scalable and extensible cooperative XML query answering system.

v/u and $v//u$, respectively. The similarity between v/u and $v//u$, denoted as $sim(v/u, v//u)$, can be measured as the cosine of the two vectors $V_{v/u}$ and $V_{v//u}$. Thus, the cost for an edge generalization can be measured as:

$$cost(gen(e_{v,u})) = 1 - sim(v/u, v//u) \qquad (11)$$

For example, relaxing *article/title* in Fig. 3(a) to *article//title* makes the title of an article's author (i.e., */article/author/title*) an approximate match. As the similarity between an article's title and an author's title is low, the cost of generalizing *article/title* to *article//title* may be high.

Note that our cost model differs from Amer-Yahia et al. (16) in that Amer-Yahia et al. (16) applies *idf* to twig structures without considering node semantics, whereas we applied *tf*idf* to nodes with regard to their corresponding data content.

The Overall Relevancy Ranking Model

We now discuss how to combine structure distance and content similarity for evaluating the overall relevancy.

Given a query $\mathcal{Q}$, the relevancy of an answer $\mathcal{A}$ to the query $\mathcal{Q}$, denoted as $sim(\mathcal{A}, \mathcal{Q})$, is a function of two factors: the structure distance between $\mathcal{A}$ and $\mathcal{Q}$ (i.e., $struct\_dist(\mathcal{A}, \mathcal{Q})$), and the content similarity between $\mathcal{A}$ and $\mathcal{Q}$, denoted as $cont\_sim(\mathcal{A}, \mathcal{Q})$. We use our extended vector space model for measuring content similarity (14). Intuitively, the larger the structure distance, the less the relevancy; the larger the content similarity, the greater the relevancy. When the structure distance is zero (i.e., exact structure match), the relevancy of the answer to the query should be determined by their content similarity only. Thus, we combine the two factors in a way similar to the one used in XRank (27) for combining element rank with distance:

$$sim(\mathcal{A}, \mathcal{Q}) = \alpha^{struct\_dist(\mathcal{A},\mathcal{Q})} * cost\_sim(\mathcal{A}, \mathcal{Q}) \qquad (12)$$

where α is a constant between 0 and 1.

A SCALABLE AND EXTENSIBLE ARCHITECTURE

Figure 14 illustrates a mediator architecture framework for a cooperative XML system. The architecture consists of an application layer, a mediation layer, and an information source layer. The information source layer includes a set of heterogeneous data sources (e.g., relational databases, XML databases, and unstructured data), knowledge bases, and knowledge base dictionaries or directories. The knowledge base dictionary (or directory) stores the characteristics of all the knowledge bases, including XTAH and domain knowledge in the system. Non-XML data can be converted into the XML format by wrappers. The mediation layer consists of data source mediators, query parser mediators, relaxation mediators, XTAH mediators, and directory mediators. These mediators are selectively interconnected to meet the specific application requirements. When the demand for certain mediators increases, additional copies of the mediators can be added to reduce the loading. The mediator architecture allows incremental growth with application, and thus the system is *scalable*. Further,

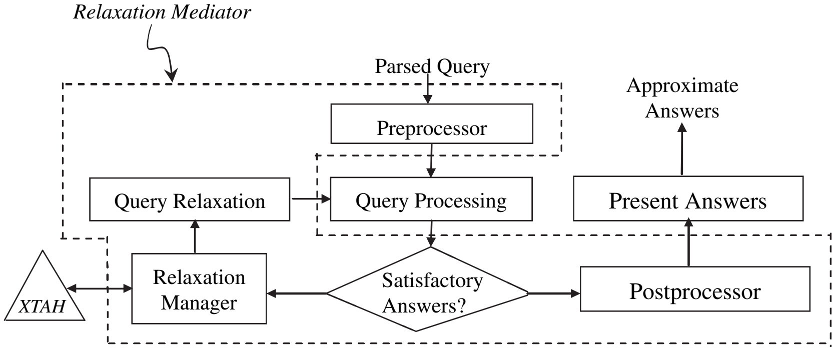

Figure 16. The flow chart of XML query relaxation processing.

different types of mediators can be interconnected and can communicate with each other via a common communication protocol (e.g., KQML (28), FIPA[9]) to perform a joint task. Thus, the architecture is *extensible*.

For query relaxation, based on the set of frequently used query tree structures, the XTAHs for each query tree structure can be generated accordingly. During the query relaxation process, the XTAH manager selects the appropriate XTAH for relaxation. If there is no XTAH available, the system generates the corresponding XTAH on-the-fly.

We shall now describe the functionalities of various mediators as follows:

- **Data Source Mediator (DSM)**
  The data source mediator provides a virtual database interface to query different data sources that usually have different schema. The data source mediator maintains the characteristics of the underlying data sources and provides a unified description of these data sources. As a result, XML data can be accessed from data sources without knowing the differences of the underlying data sources.
- **Query Parser Mediator (PM)**
  The query parser mediator parses the queries from the application layer and transforms the queries into query representation objects.
- **Relaxation Mediator (RM)**
  Figure 15 illustrates the functional components of the relaxation mediator, which consists of a pre-processor, a relaxation manager, and a post-processor. The flow of the relaxation process is depicted in Fig. 16. When a relaxation-enabled query is presented to the relaxation mediator, the system first goes through a pre-processing phase. During pre-processing, the system transforms the relaxation constructs into standard XML query constructs. All relaxation control operations specified in the query are processed and forwarded to the relaxation manager and are ready for use if the query requires relaxation. The modified query is then presented to the underlying databases for execution. If no answers are returned, then the relaxation manager relaxes the query conditions guided by the relaxation index (XTAH). We repeat the relaxation process until either the stop condition is met or the query is no longer relaxable. Finally, the returned answers are forwarded to the post-processing module for ranking.
- **XTAH Mediator (XTM)**
  The XTAH mediator provides three conceptually separate, yet interlinked functions to peer mediators: XTAH Directory, the XTAH Management, and the XTAH Editing facilities, as illustrated in Fig. 17.

  Usually, a system contains a large number of XTAHs. To allow other mediators to determine which XTAHs exist within the system and their characteristics, the XTAH mediator contains a directory. This directory is searchable by the XML query tree structures.

  The XTAH management facility provides client mediators with traversal functions and data extraction functions (for reading the information out of XTAH nodes). These capabilities present a common interface so that peer mediators can traverse and extract data from an XTAH. Further, the XTAH

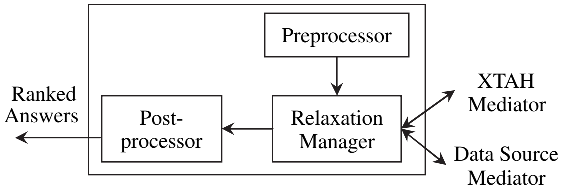

Figure 15. The relaxation mediator.

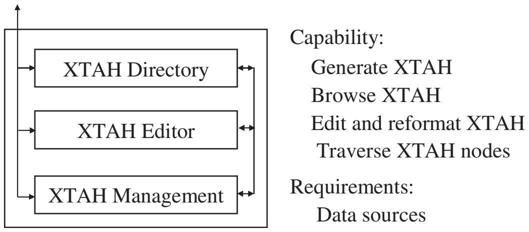

Figure 17. The XTAH mediator.

[9] See http://www.fipa.org.

mediator has an editor that allows users to edit XTAHs to suit their specific needs. The editor handles recalculation of all information contained within XTAH nodes during the editing process and supports exportation and importation of entire XTAHs if a peer mediator wishes to modify it.

- **Directory Mediator (DM)**
  The directory mediator provides the locations, characteristics, and functionalities of all the mediators in the system and is used by peer mediators for locating a mediator to perform a specific function.

A COOPERATIVE XML (CoXML) QUERY ANSWERING TESTBED

A CoXML query answering testbed has been developed at UCLA to evaluate the effectiveness of XML query relaxation through XTAH. Figure 18 illustrates the architecture of CoXML testbed, which consists of a query parser, a preprocessor, a relaxation manager, a database manager, an XTAH manager, an XTAH builder, and a post-processor. We describe the functionality provided by each module as follows:

- *XTAH Builder*. Given a set of XML documents and the domain knowledge, the *XTAH builder* constructs a set of XTAHs that summarizes the structure characteristics of the data.
- *Query Parser*. The *query parser* checks the syntax of the query. If the syntax is correct, then it extracts information from the parsed query and creates a query representation object.
- *Preprocessor*. The pre-processor transforms relaxation constructs (if any) in the query into the standard XML query constructs.
- *Relaxation Manager*. The relaxation manager performs the following services: (1) building a relaxation structure based on the specified relaxation constructs and controls; (2) obtaining the relaxed query conditions from the XTAH Manager; (3) modifying the query accordingly; and (4) retrieving the exactly matched answers.
- *Database Manager*. The database manager interacts with an XML database engine and returns exactly matched answers for a standard XML query.
- *XTAH Manager*. Based on the structure of the query tree, the XTAH manager selects an appropriate XTAH to guide the query relaxation process.
- *Post-processor*. The post-processor takes unsorted answers as input, ranks them based on both structure and content similarities, and outputs a ranked list of results.

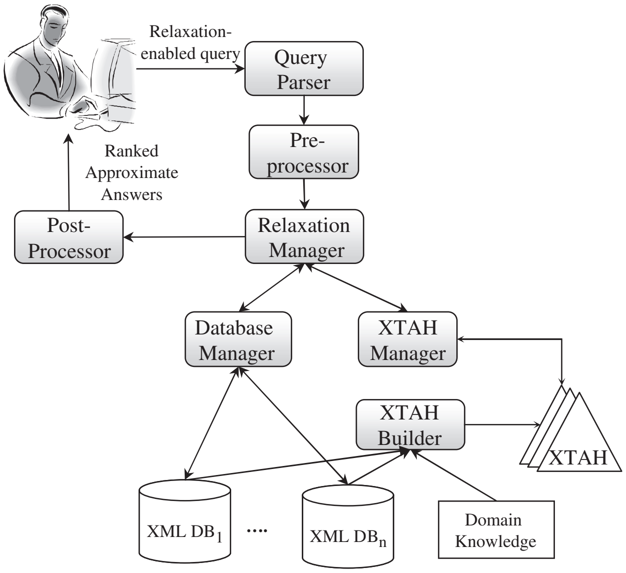

Figure 18. The architecture of the CoXML testbed.

EVALUATION OF XML QUERY RELAXATION

INEX is a DELOS working group[10] that aims to provide a means for evaluating XML retrieval systems in the form of a large heterogeneous XML test collection and appropriate scoring methods. The INEX test collection is a large set of scientific articles, represented in XML format, from publications of the IEEE Computer Society covering a range of computer science topics. The collection, approximately 500 megabytes, contains over 12,000 articles from 18 magazines/transactions from the period of 1995 to 2004, where an article (on average) consists of 1500 XML nodes. Different magazines/transactions have different data organizations, although they use the same ontology for representing similar content.

There are three types of queries in the INEX query sets: content-only (CO), strict content and structure (SCAS), and vague content and structure (VCAS). CO queries are traditional information retrieval (IR) queries that are written in natural language and constrain the content of the desired results. Content and structure queries not only restrict content of interest but also contain either explicit or implicit references to the XML structure. The difference between a SCAS and a VCAS query is that the structure conditions in a SCAS query must be interpreted exactly whereas the structure conditions in a VCAS query may be interpreted loosely.

To evaluate the relaxation quality of the CoXML system, we perform the VCAS retrieval runs on the CoXML testbed and compare the results against the INEX's relevance assessments for the VCAS task, which can be viewed as the "gold standard." The evaluaion studies reveal the expressiveness of the relaxation language and the effectiveness of using XTAH in providing user-desired relaxation control. The evaluation results demonstrate that our content similarity model has significantly high precision at low recall regions. The model achieves the highest average precision as compared with all the 38 official submissions in

[10] See http://www.iei.pi.cnr.it/DELOS

INEX 03 (14). Furthermore, the evaluation results also demonstrate that using the semantic-based distance function yields results with greater relevancy than using the uniform-cost distance function. Comparing with other systems in INEX 05, our user-centeric relaxation approach retrieves approximate answers with greater relevancy (29).

SUMMARY

Approximate matching of query conditions plays an important role in XML query answering. There are two approaches to XML query relaxation: either through schema conversion or directly through the XML model. Converting the XML model to the relational model by schema conversion can leverage on the mature relational model techniques, but information may be lost during such conversions. Furthermore, this approach does not support XML structure relaxation. Relaxation via the XML model approach remedies these shortcomings. In this article, a new paradigm for XML approximate query answering is proposed that places users and their demands at the center of the design approach. Based on this paradigm, we develop an XML system that cooperates with users to provide user-specific approximate query answering. More specifically, a relaxation language is introduced that allows users to specify approximate conditions and relaxation control requirements in a posed query. We also develop a relaxation index structure, XTAH, that clusters relaxed twigs into multilevel groups based on relaxation types and their interdistances. XTAH enables the system to provide user-desired relaxation control as specified in the query. Furthermore, a ranking model is introduced that combines both content and structure similarities in evaluating the overall relevancy of approximate answers returned from query relaxation. Finally, a mediatorbased CoXML architecture is presented. The evaluation results using the INEX test collection reveal the effectiveness of our proposed user-centric XML relaxation methodology for providing user-specific relaxation.

ACKNOWLEDGMENTS

The research and development of CoXML has been a team effort. We would like to acknowledge our CoXML members, Tony Lee, Eric Sung, Anna Putnam, Christian Cardenas, Joseph Chen, and Ruzan Shahinian, for their contributions in implementation, testing, and performance evaluation.

DATA ANALYSIS

What is data analysis? Nolan (1) gives a definition, which is a way of making sense of the patterns that are in, or can be imposed on, sets of figures. In concrete terms, data analysis consists of an observation and an investigation of the given data, and the derivation of characteristics from the data. Such characteristics, or features as they are sometimes called, contribute to the insight of the nature of data. Mathematically, the features can be regarded as some variables, and the data are modeled as a realization of these variables with some appropriate sets of values. In traditional data analysis (2), the values of the variables are usually numerical and may be transformed into symbolic representation. There are two general types of variables, discrete and continuous. Discrete variables vary in units, such as the number of words in a document or the population in a region. In contrast, continuous variables can vary in less than a unit to a certain degree. The stock price and the height of people are examples of this type. The suitable method for collecting values of discrete variables is counting, and for continuous ones, it is measurement.

The task of data analysis is required among various application fields, such as agriculture, biology, economics, government, industry, medicine, military, psychology, and science. The source data provided for different purposes may be in various forms, such as text, image, or waveform. There are several basic types of purposes for data analysis:

1. Obtain the implicit structure of data.
2. Derive the classification or clustering of data.
3. Search particular objects in data.

For example, the stockbroker would like to get the future trend of the stock price, the biologist needs to divide the animals into taxonomies, and the physician tries to find the related symptoms of a given disease. The techniques to accomplish these purposes are generally drawn from statistics that provide well-defined mathematical models and probability laws. In addition, some theories, such as fuzzy-set theory, are also useful for data analysis in particular applications. This article is an attempt to give a brief introduction of these techniques and concepts of data analysis. In the following section, a variety of fundamental data analysis methods are introduced and illustrated by examples. In the second section, the methods for data analysis on two types of Internet data are presented. Advanced methods for Internet data analysis are discussed in the third section. At last, we give a summary of this article and highlight the research trends.

FUNDAMENTAL DATA ANALYSIS METHODS

In data analysis, the goals are to find significant patterns in the data and apply this knowledge to some applications. Data analysis is generally performed in the following stages:

1. Feature selection.
2. Data classification or clustering.
3. Conclusion evaluation.

The first stage consists of the selection of the features in the data according to some criteria. For instance, features of people may include their height, skin color, and fingerprints. Considering the effectiveness of human recognition, the fingerprint, which is the least ambiguous, may get the highest priority in the feature selection. In the second stage, the data are classified according to the selected features. If the data consist of at least two features, e.g., the height and the weight of people, which can be plotted in a suitable coordinate system, we can inspect so-called scatter plots and detect clusters or contours for data grouping. Furthermore, we can investigate ways to express data similarity. In the final stage, the conclusions drawn from the data would be compared with the actual demands. A set of mathematical models has been developed for this evaluation. In the following, we first divide the methods of data analysis into two categories according to different initial conditions and resultant uses. Then, we introduce two famous models for data analysis. Each method will be discussed first, followed by examples. Because the feature selection depends on the actual representations of data, we postpone the discussion about this stage until the next section. In this section, we focus on the classification/clustering procedure based on the given features.

A Categorization of Data Analysis Methods

There are a variety of ways to categorize the methods of data analysis. According to the initial conditions and the resultant uses, there can be two categories, supervised data analysis and unsupervised data analysis. The term *supervised* means that the human knowledge has to be provided for the process. In supervised data analysis, we specify a set of classes called a *classification template* and select some samples from the data for each class. These samples are then labeled by the names of the associated classes. Based on this initial condition, we can automatically classify the other data termed as *to-be-classified data*. In *unsupervised* data analysis, there is no classification template, and the resultant classes depend on the samples. The following are descriptions of supervised and unsupervised data analysis with an emphasis on their differences.

Supervised Data Analysis. The classification template and the well-chosen samples are given as an initial state and contribute to the high accuracy of data classification. Consider the K nearest-neighbor (K *NNs*) classifier, which is a typical example of supervised data analysis. The input

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

to the classifier includes a set of labeled samples S, a constant value K, and a to-be-classified datum X. The output after the classification is a label denoting a class to which X belongs. The classification procedure is as follows:

1. Find the K NNs of X from S.
2. Choose the dominant classes by K NNs.
3. If only one dominant class exists, label X by this class; otherwise, label X by any dominant class.
4. Add X to S and the process terminates.

The first step selects K samples from S such that the values of the selected features (also called patterns) of these K samples are closest to those of X. Such a similarity may be expressed in a variety of ways. The measurement of distances among the patterns is one of the suitable instruments, for example, the Euclidean distance as shown in Equation (1). Suppose the K samples belong to a set of classes; the second step is to find the set of dominant classes C’. A dominant class is a class that contains the majority of the K samples. If there is only one element in C’, say class C_i, we assign X to C_i. On the other hand, if C’ contains more than one element, X is assigned to an arbitrary class in C’. After deciding the class of X, we label it and add it into the set S.

$$\delta(X, Y) = \sqrt{\sum_{k=1}^{m} (X_k - Y_k)^2} \tag{1}$$

where each datum is represented by m features.

Example. Suppose there is a dataset about the salaries and ages of people. Table 1 gives such a set of samples S and the corresponding labels. There are three labels that denote three classes: Rich, Fair, and Poor. These classes are determined based on the assumption that the Richness depends on the values of the salary and age. In Table 1, we also append the rules of assigning labels for each age value. From the above, we can get the set membership of each class:

$$C_{\text{Rich}} = \{Y_1, Y_4, Y_8\}, \; C_{\text{Fair}} = \{Y_{2,} Y_5, Y_6, Y_{10}\}, \\ C_{\text{Poor}} = \{Y_3, Y_7, Y_9\}$$

Table 1. A Set of Samples with the Salary and Age Data

Sample	Age	Salary	Label	Assumed Rules to Assign Labels
Y_1	20	25k	Rich	Rich, >20k; Poor, <10k
Y_2	22	15k	Fair	Rich, >26k; Poor, <13k
Y_3	24	15k	Poor	Rich, >35k; Poor, <16k
Y_4	24	40k	Rich	
Y_5	28	25k	Fair	Rich, >44k; Poor, <22k
Y_6	30	40k	Fair	Rich, > 50k; Poor, <25k
Y_7	30	20k	Poor	
Y_8	32	60k	Rich	Rich, >56k; Poor, <28k
Y_9	36	30k	Poor	Rich, >68k; Poor, <34k
Y_{10}	40	70k	Fair	Rich, >80k; Poor, <40k
X	26	35k	Fair	Rich, >38k; Poor, <19k

If there is a to-be-classified datum X with age 26 and salary \$35,000 (35k), we apply the classification procedure to classify it. Here we let the value of K be 4 and use the Euclidean distance as the similarity measure:

1. The set of 4 NNs is $\{Y_4, Y_5, Y_6, Y_9\}$.
2. The dominant class is the class C_{Fair} because Y_6, $Y_5 \in C_{\text{Fair}}$, $Y_4 \in C_{\text{Rich}}$, and $Y_9 \in C_{\text{Poor}}$.
3. Label X by C_{Fair}.
4. New S contains an updated class $C_{\text{Fair}} = \{Y_2, Y_5, Y_6, Y_{10}, X\}$.

We can also give an assumed rule to decide the corresponding label for the age of X as shown in Table 1. Obviously, the conclusion drawn from the above classification coincides with such an assumption from human knowledge.

Unsupervised Data Analysis. Under some circumstances, data analysis consists of a partition of the whole data set into many subsets. Moreover, the data within each subset have to be similar to a high degree, whereas the data between different subsets have to be similar to a very low degree. Such subsets are called clusters, and the way to find a good partition is sometimes also called cluster analysis. A variety of methods have been developed to handle this problem. A common characteristic among them is the iterative nature of the algorithms.

The c-mean clustering algorithm is representative in this field. The input contains the sample set S and a given value c, which denotes the number of clusters in the final partition. Notice that no labels are assigned to the samples in S in advance. Before clustering, we must give an initial partition W_0 with c clusters. The algorithm terminates when it converges to a stable situation in which the current partition remains the same as the previous one. Different initial partitions can lead to different final results. One way to get the best partition is to apply this algorithm with all different W_0’s. To simplify the illustration, we only consider a given W_0 and a fixed c. The clustering procedure is as follows:

1. Let W be W_0 on S.
2. Compute the mean of each cluster in W.
3. Evaluate the nearest mean of each sample and move a sample if its current cluster is not the one corresponding to its nearest mean.
4. If any movement occurs, go to step 2; otherwise, the process terminates.

The first step sets the current partition W to be W_0. Then we compute a set of means M in W. In general, a mean is a virtual sample representing the whole cluster. It is straightforward to use averaging as the way to find M.

Next, we measure the similarity between each sample in S and every mean in M. Suppose a sample Y_j belongs to a cluster C_i in the previous partition W, whereas another cluster C_k has a mean nearest to Y_j. Then we move Y_j from C_i to C_k. Finally, if such a sample movement exists, the partition W would become a new one and requires more iteration. On the other hand, if no such movement occurs during iteration, the partition would become stable and the final clustering is produced.

Example. Consider the data in Table 1 again. Suppose there is no label on each sample and only the salary and the age data are used as the features for analysis. For clarity, we use a pair of values on the two features to represent a sample; for instance, the pair (20, 25k) refers to the sample Y_1. Suppose there is an initial partition containing two clusters C_1 and C_2. Let the means of these clusters be M_1 and M_2, respectively. The following shows the iterations for the clustering:

1. For the initial partition $W : C_1 = \{Y_1, Y_2, Y_3, Y_4, Y_5\}$, $C_2 = \{Y_6, Y_7, Y_8, Y_9, Y_{10}\}$.
   a. The first iteration: $M_1 = (23.6,\ 26\text{k})$, $M_2 = (33.6,\ 44\text{k})$.
   b. Move Y_4 from C_1 to C_2, move Y_7 and Y_9 from C_2 to C_1.
2. For the new partition $W : C_1 = \{Y_1, Y_2, Y_3, Y_5, Y_7, Y_9\}$, $C_2 = \{Y_4, Y_6, Y_8, Y_{10}\}$.
   a. The second iteration: $M_1 = (26.6,\ 21.6\text{k})$, $M_2 = (31.5,\ 52.5\text{k})$.
   b. There is no sample movement; the process terminates.

We can easily find a simple discriminant rule behind this final partition. All the samples with salaries lower than 40k belong to C_1, and the others belong to C_2. Hence we may conclude with a discriminant rule that divides S into two clusters by checking the salary data. If we use another initial partition, say W', where C_1 is $\{Y_1, Y_3, Y_5, Y_7, Y_9\}$ and C_2 is $\{Y_2, Y_4, Y_6, Y_8, Y_{10}\}$, the conclusion is the same. The following process yields another partition with three clusters.

1. For the initial partition $W : C_1 = \{Y_1, Y_4, Y_7\}$, $C_2 = \{Y_2, Y_5, Y_8\}$, $C_3 = \{Y_3, Y_6, Y_9, Y_{10}\}$.
   a. The first iteration: $M_1 = (24.6,\ 28.3\text{k})$, $M_2 = (27.3,\ 33.3\text{k})$, $M_3 = (32.5,\ 38.7\text{k})$.
   b. Move Y_4 from C_1 to C_2, move Y_2 and Y_5 from C_2 to C_1, move Y_8 from C_2 to C_3, move Y_3 from C_3 to C_1, move Y_9 from C_3 to C_2.
2. For the new partition $W : C_1 = \{Y_1, Y_2, Y_3, Y_5, Y_7\}$, $C_2 = \{Y_4, Y_9\}$, $C_3 = \{Y_6, Y_8, Y_{10}\}$.
   a. The second iteration: 2 $M_1 = (24.8,\ 20\text{k})$, $M_2 = (30,\ 35\text{k})$, $\mathrm{M}_3 = (34,\ 56.6\text{k})$.
   b. Move Y_6 from C_3 to C_2.
3. For the new partition $W : C_1 = \{Y_1, Y_2, Y_3, Y_5, Y_7\}$, $C_2 = \{Y_4, Y_6, Y_9\}$, $C_3 = \{Y_8, Y_{10}\}$.
   a. The third iteration: $M_1 = (24.8,\ 20\text{k})$, $M_2 = (30,\ 36.6\text{k})$, $M_3 = (36,\ 65\text{k})$.
   b. There is no sample movement; the process terminates.

After three iterations, we have a stable partition and conclude with a discriminant rule that all samples with salaries lower than 30k belong to C_1, the other samples with salaries lower than 60k belong to C_2 and the remainder belongs to C_3. The total number of iterations depends on the initial partition, the number of clusters, the given features, and the similarity measure.

Methods for Data Analysis

In the following, we introduce two famous methods for data analysis. One is Bayesian data analysis based on probability theory, and the other is fuzzy data analysis based on fuzzy-set theory.

Bayesian Data Analysis. Bayesian inference, as defined in Ref. 3, is the process of fitting a probability model to a set of samples, which results in a probability distribution to make predictions for to-be-classified data. In this environment, a set of samples is given in advance and labeled by their associated classes. Observing the patterns contained in these samples, we can obtain not only the distributions of samples for the classes but also the distributions of samples for the patterns. Therefore, we can compute a distribution of classes for these patterns and use this distribution to predict the classes of the to-be-classified data based on their patterns. A typical process of Bayesian data analysis contains the following stages:

1. Compute the distributions from the set of labeled samples.
2. Derive the distribution of classes for the patterns.
3. Evaluate the effectiveness of these distributions.

Suppose a sample containing the pattern a on some features is labeled class C_i. First, we compute a set of probabilities $P(C_i)$ that denotes a distribution of samples for different classes and let each $P(a|C_i)$ denote the conditional probability of a sample containing the pattern a, given that the sample belongs to the class C_i. In the second stage, the conditional probability of a sample belonging to the class C_i, given that the sample contains the pattern a, can be formulated as follows:

$$P(C_i|a) = \frac{P(a|C_i) \times P(C_i)}{P(a)}, \text{ where}$$
$$P(a) = \sum_j P(a|C_j) \times P(C_j) \qquad (2)$$

From Equation (2), we can derive the probabilities of a sample belonging to classes according to the patterns contained in the sample. Finally, we can find a way to determine the class by using these probabilities. The following is a simple illustration of data analysis based on this technique.

Example. Consider the data in Table 1. We first gather the statistics and transform the continuous values into discrete ones as in Table 2. Here we have two discrete

Table 2. A Summary of Probability Distribution for the Data in Table 1

Sample	Rich	Fair	Poor	Expressions of New Condensed Features
Young	2	2	1	Age is lower than 30
Old	1	2	2	The others
Low	1	2	3	Salary is lower than 36k
Median	1	1	0	The others
High	1	1	0	Salary is higher than 50k

levels, young and old, representing the age data, and three levels, low, median, and high, referring to the salary data. We collect all the probabilities and derive the ones for prediction based on Equation (2):

$P(\text{young, low} \mid C_{\text{Rich}}) = 1/3$, $P(\text{young, low} \mid C_{\text{Fair}}) = 1/2$, $P(\text{young, low} \mid C_{\text{Poor}}) = 1/3$,

$P(\text{young, median} \mid C_{\text{Rich}}) = 1/3$, $P(\text{young, median} \mid C_{\text{Fair}}) = 0$, $P(\text{young, median} \mid C_{\text{Poor}}) = 0, \ldots$

$P(\text{young, low}) = 4/10$, $P(\text{young, median}) = 1/10$, $P(\text{young, high}) = 0, \ldots$

$P(C_{\text{Rich}}) = 3/10$, $P(C_{\text{Fair}}) = 2/5$, $P(C_{\text{Poor}}) = 3/10$

$P(C_{\text{Rich}} \mid \text{young, low}) = 1/4$, $P(C_{\text{Fair}} \mid \text{young, low}) = 1/2$, $P(C_{\text{Poor}} \mid \text{young, low}) = 1/4$,

$P(C_{\text{Rich}} \mid \text{young, median}) = 1$, $P(C_{\text{Fair}} \mid \text{young, median}) = 0$, $P(C_{\text{Poor}} \mid \text{young, median}) = 0, \ldots$

Because there are two features representing the data, we compute the joint probabilities instead of individual probabilities. Here we assume that the two features have the same degree of significance. At this point, we have constructed a model to express the data with their two features. The derived probabilities can be regarded as a set of rules to decide the classes of to-be-classified data.

If there is a to-be-classified datum X whose age is 26 and salary is 35k, we apply the derived rules to label X. We transform the pattern of X to indicate that the age is young and the salary is low. To find the suitable rules, we can define a penalty function $\lambda(C_i|C_j)$, which denotes the payment when a datum belonging to C_j is classified into C_i. Let the value of this function be 1 if C_j is not equal to C_i and 0 if two classes are the same. Furthermore, we can define a distance measure $\iota(X, C_i)$ as in Equation (3), which represents the total amount of payments when we classify X into C_i. We conclude that the lower the value of $\iota(X, C_i)$, the higher the probability that X belongs to C_i. In this example, we label X by C_{Fair} because $\iota(X, C_{\text{Fair}})$ is the lowest.

$$\iota(X, C_i) = \sum_j \lambda(C_i|C_j) \times P(C_j|X)$$
$$\therefore\ \iota(X, C_{\text{Rich}}) = 3/4,\ \iota(X, C_{\text{Fair}}) = 1/2,\ \iota(X, C_{\text{Poor}}) = 3/4 \quad (3)$$

Fuzzy Data Analysis. Fuzzy-set theory, established by Zadeh (4) allows a gradual membership $MF_A(X)$ for any datum X on a specified set A. Such an approach more adequately models the data uncertainty than using the common notion of set membership. Take cluster analysis as an example. Each datum belongs to exactly one cluster after the classification procedure. Often, however, the data cannot be assigned exactly to one cluster in the real world, such as the jobs of a busy person, the interests of a researcher, or the conditions of the weather. In the following, we replace the previous example for supervised data analysis with the fuzzy-set notion to show its characteristic.

Consider a universe of data U and a subset A of U. Set theory allows us to express the membership of A on U by the characteristic function $F_A(X) : U \to \{0, 1\}$.

$$F_A(X) = \begin{cases} 1, X \in A \\ 0, X \notin A \end{cases} \quad (4)$$

From the above, it can be clearly determined whether X is an element of A. However, many real-world phenomena make such a unique decision impossible. In this case, expressing in a degree of membership is more suitable. A fuzzy set A on U can be represented by the set of pairs that describe the membership function $MF_A(X) : U \to [0, 1]$ as defined in Ref. 5.

$$A = \{(X, MF_A(X)) | X \in U, MF_A(X) \in [0, 1]\} \quad (5)$$

Example. Table 3 contains a fuzzy-set representation of the dataset in Table 1. The membership function of each sample is expressed in a form of possibility that stands for the degree of the acceptance that a sample belongs to a class. Under the case of supervised data analysis, the to-be-classified datum X needs to be labeled using an appropriate classification procedure. The distance between each sample and X is calculated using the two features and Euclidean distance:

1. Find the K NNs of X from S.
2. Compute the membership function of X for each class.
3. Label X by the class with a maximal membership.
4. Add X to S and stop the process.

The first stage in finding K samples with minimal distances is the same, so we have the same set of 4 NNs

Table 3. Fuzzy-Set Membership Functions for the Data in Table 1

Sample	Rich	Fair	Poor	Estimated Distance Between Each Sample and X
Y_1	0.5	0.2	0.3	11.66
Y_2	0.1	0.5	0.4	20.39
Y_3	0	0.2	0.8	20.09
Y_4	0.6	0.3	0.1	5.38
Y_5	0.2	0.5	0.3	10.19
Y_6	0.2	0.5	0.2	6.4
Y_7	0	0	1	15.52
Y_8	0.9	0.1	0	25.7
Y_9	0	0.3	0.7	11.18
Y_{10}	0.4	0.6	0	37.69
X	0.2	0.42	0.38	

$\{Y_4, Y_5, Y_6, Y_9\}$ when the value of $K = 4$. Let $\delta(X, Y_j)$ denote the distance between X and the sample Y_j. In the next stage, we calculate the membership function $MF_{C_i}(X)$ of X for each class C_i as follows:

$$MF_{C_i}(X) = \frac{\sum_j MF_{C_i}(Y_j) \times \delta(X, Y_j)}{\sum_j \delta(X, Y_j)}, \forall Y_j \in K \text{ NNs of } X \quad (6)$$

$$MF_{C_{\text{rich}}}(X) = \frac{0.6 \times 5.38 + 0.2 \times 10.19 + 0.2 \times 6.4 + 0 \times 11.18}{5.38 + 10.19 + 6.4 + 11.18} \approx 0.2$$

$$MF_{C_{\text{fair}}}(X) = \frac{0.3 \times 5.38 + 0.5 \times 10.19 + 0.6 \times 6.4 + 0.3 \times 11.18}{5.38 + 10.19 + 6.4 + 11.18} \approx 0.42$$

$$MF_{C_{\text{poor}}}(X) = \frac{0.1 \times 5.38 + 0.3 \times 10.19 + 0.2 \times 6.4 + 0.7 \times 11.18}{5.38 + 10.19 + 6.4 + 11.18} \approx 0.38$$

Because the membership of X for class C_{Fair} is higher than all others, we label X by C_{Fair}. The resultant membership directly gives a confidence measure of this classification.

INTERNET DATA ANALYSIS METHODS

The dramatic growth of information systems over the past years has brought about the rapid accumulation of data and an increasing need for information sharing. The World Wide Web (WWW) combines the technologies of the uniform resource locator (URL) and hypertext to organize the resources in the Internet into a distributed hypertext system (6). As more and more users and servers register on the WWW, data analysis on its rich content is expected to produce useful results for various applications. Many research communities such as network management (7), information retrieval (8), and database management (9) have been working in this field.

The goal of Internet data analysis is to derive a classification or clustering of Internet data, which can provide a valuable guide for the WWW users. Here the Internet data can be two kinds of materials, web page and web log. Each site within the WWW environment contains one or more web pages. Under this environment, any WWW user can make a request to any site for any web page in it, and the request is then recorded in its log. Moreover, the user can also roam through different sites by means of the anchors provided in each web page. Such an approach leads to the essential difficulties for data analysis:

1. Huge amount of data.
2. Frequent changes.
3. Heterogeneous presentations.

Basically the Internet data originate from all over the world; the amount of data is huge. As any WWW user can create, delete, and update the data, and change the locations of the data at any time, it is difficult to get a precise view of the data. Furthermore, the various forms of expressing the same data also reveal the status of the chaos on the WWW. As a whole, Internet data analysis should be able to handle the large amount of data and to control the uncertainty factors in a practical way. In this section, we first introduce the method for data analysis on web pages and then describe the method for data analysis on web logs.

Web Page Analysis

Many tools for Internet resource discovery (10) use the results of data analysis on the WWW to help users find the correct positions of the desired resources. However, many of these tools essentially keep a keyword-based index of the available web pages. Owing to the imprecise relationship between the semantics of keywords and the web pages (11), this approach clearly does not fit the user requests well. From the experiments in Ref. 12, the text-based classifier that is 87% accurate for Reuters (news documents) yields only 32% precision for Yahoo (web pages). Therefore, a new method for data analysis on web pages is required. Our approach is to use the anchor information in each web page, which contains much stronger semantics for connecting the user interests and those truly relevant web pages.

A typical data analysis procedure consists of the following stages:

1. Observe the data.
2. Collect the samples.
3. Select the features.
4. Classify the data.
5. Evaluate the results.

In the first stage, we observe the data and conclude with a set of features that may be effective for classifying the data. Next, we collect a set of samples based on a given scope. In the third stage, we estimate the fitness of each feature for the collected samples to determine a set of effective features. Then, we classify the to-be-classified data according to the similarity measure on the selected features. At last, we evaluate the classified results and find a way for the further improvement. In the following, we first give some results of the study on the nature of web pages. Then we show the feature selection stage and a procedure to classify the web pages.

Data Observation. In the following, we provide two directions for observing the web pages.

Semantic Analysis. We may consider the semantics of a web page as potential features. Keywords contained in a web page can be analyzed to determine the semantics such as which fields it belongs to or what concepts it provides. There are many ongoing efforts on developing techniques to derive the semantics of a web page. The research results of information retrieval (13,14) can also be applied for this purpose.

Observing the data formats of web pages, we can find several parts expressing the semantics of the web pages to some extent. For example, the title of a web page usually refers to a general concept of the web page. An anchor, which is constructed by the web page designer, provides a URL of another web page and makes a connection between the two web pages. As far as the web page designer is concerned, the anchor texts must sufficiently express the semantics of the whole web page to which the anchor points. As to the viewpoint of a WWW user, the motivation to follow an anchor is based on the fact that this anchor expresses desired semantics for the user. Therefore, we can make a proper connection between the user's interests and those truly relevant web pages. We can group the anchor texts to generate a corresponding classification of the web pages pointed to by these anchor texts. Through this classification, we can relieve the WWW users of the difficulties on Internet resource discovery through a query facility.

Syntactic Analysis. Because the data formats of web pages follow the standards provided on the WWW, for example, hypertext markup language (HTML), we can find potential features among the web pages. Consider the features shown in Table 4. The white pages, which mean the web pages with a list of URLs, can be distinguished from the ordinary web pages by a large number of anchors and the short distances between two adjacent anchors within a web page. Note that here the distance between two anchors means the number of characters between them. For the publication, the set of headings has to contain some specified keywords, such as "bibliography" or "reference." The average distance between two adjacent anchors has to be lower than a given threshold, and the placement of anchors has to center to the bottom of the web page.

According to these features, some conclusions may be drawn in the form of classification rules. For instance, the web page is designed for publication if it satisfies the requirements of the corresponding features. Obviously, this approach is effective only when the degree of support for such rules is high enough. Selection of effective features is a way to improve the precision of syntactic analysis.

Sample Collection. It is impossible to collect all web pages and thus, choosing a set of representative samples becomes a very important task. On the Internet, we have two approaches to gather these samples, as follows:

1. Supervised sampling.
2. Unsupervised sampling.

Supervised sampling means that the sampling process is based on the human knowledge specifying the scope of the samples. In supervised data analysis, a classification template that consists of a set of classes exists. The sampling scope can be set based on the template. The sampling is more effective when all classes in the template contain at least one sample. On the other hand, we consider unsupervised sampling if there is not enough knowledge about the scope, as in the case of unsupervised data analysis. The most trivial way to get samples is to choose any subset of web pages. However, this arbitrary sampling may not fit the requirement of random sampling well. We recommend the use of search engines that provide different kinds of web pages in the form of a directory.

Table 4. Potential Features for Some Kinds of Home Pages

Type of Web Page	Potential Feature
White page	Number of anchors, average distance between two adjacent anchors
Publication	Headings, average distance between two adjacent anchors, anchor position
Person	Title, URL directory
Resource	Title, URL filename

Feature Selection. In addition to collecting enough samples, we have to select suitable features for the subsequent classification. No matter how good the classification scheme is, the accuracy of the results would not be satisfactory without effective features. A measure for the effectiveness of a feature is to estimate the degree of class separability. A better feature implies higher class separability. This measure can be formulated as a criterion to select effective features.

Example. Consider the samples shown in Table 5. From Table 4, there are two potential features for white pages, the number of anchors (F_0) and the average distance between two adjacent anchors (F_1). We assume that $F_0 \geq 30$ and $F_1 \leq 3$ when the sample is a white page. However, a sample may actually belong to the class of white pages although it does not satisfy the assumed conditions. For example, Y_6 is a white page although its $F_0 < 30$. Therefore, we need to find a way to select effective features.

From the labels, the set membership of the two classes is as follows, where the class C_1 refers to the class of white pages:

$$C_0 = \{Y_1, Y_2, Y_3, Y_4, Y_5\}, C_1 = \{Y_6, Y_7, Y_8, Y_9, Y_{10}\}$$

We can begin to formulate the class separability. In the following formula, we assume that the number of classes is c, the number of samples within class C_j is n_j,

Table 5. A Set of Samples with Two Features

Sample	F_0	F_1	White Page
Y_1	8	5	No
Y_2	15	3.5	No
Y_3	25	2.5	No
Y_4	35	4	No
Y_5	50	10	No
Y_6	20	2	Yes
Y_7	25	1	Yes
Y_8	40	2	Yes
Y_9	50	2	Yes
Y_{10}	80	8	Yes

Note: F_0 denotes the number of anchors.
F_1 denotes the average distance for two adjacent anchors.
The labels are determined by human knowledge.

and Y_k^i denotes the kth sample in the class C_i. First, we define interclass separability D_b, which represents the ability of a feature to distinguish the data between two classes. Next, we define the intraclass separability D_w, which expresses the power of a feature to separate the data within the same class. The two measures are formulated in Equations (7) and (8) based on the Euclidean distance defined in Equation (1). As a feature with larger D_b and smaller D_w can get a better class separability, we define a simple criterion function D_{F_j} [Equation (9)] as a composition of D_b and D_w to evaluate the effectiveness of a feature F_j. Based on this criterion function, we get $D_{F_0} = 1.98$ and $D_{F_1} = 8.78$. Therefore, F_1 is more effective than F_0 because of its higher class separability.

$$D_b = \frac{1}{2}\sum_{i=1}^{c} P_i \sum_{j \neq i} P_j \frac{1}{n_i \times n_j} \sum_{k=1}^{n_i}\sum_{m=1}^{n_j} \delta(Y_k^i,\, Y_m^j), \text{ where}$$
$$P_i = \frac{n_i}{\sum_{j=1}^{c} n_j} \tag{7}$$

$$D_w = \frac{1}{2}\sum_{i=1}^{c} P_i \sum_{j = i} P_j \frac{1}{n_i \times n_j} \sum_{k=1}^{n_i}\sum_{m=1}^{n_j} \delta(Y_k^i, Y_m^i), \text{ where}$$
$$P_i = \frac{n_i}{\sum_{j=1}^{c} n_j} \tag{8}$$

$$D_{F_j} = D_b - D_w \tag{9}$$

We have several ways to choose the most effective set of features, as follows:

1. Ranking approach.
2. Top-down approach.
3. Bottom-up approach.
4. Mixture approach.

The ranking approach selects the features one by one according to the rank of their effectiveness. Each time we include a new feature from the rank, we compute the joint effectiveness of the features selected so far by Equations (7)–(9). When the effectiveness degenerates, the process terminates. Using a top-down approach, we consider all features as the initial selection and drop the features one by one until the effectiveness degenerates. On the contrary, the bottom-up approach adds a feature at each iteration. The worse case of the above two approaches occurs if we choose the bad features earlier in the bottom-up approach or the good features earlier in the top-down approach. The last approach allows us to add and drop the features at each iteration by combining the above two approaches. After determining the set of effective features, we can start the classification process.

Data Classification. In the following, we only consider the anchor semantics as the feature, which is based on the dependency between an anchor and the web page to which the anchor points. As mentioned, the semantics expressed by the anchor implies the semantics of the web page to which the anchor points, and describes the desired web pages for the users. Therefore, grouping the semantics of the anchors is equivalent to classifying the web pages into different classes. The classification procedure consists of the following stages:

1. Label all sample pages.
2. For each labeled page, group the texts of the anchors pointing to it.
3. Record the texts of the anchors pointing to the to-be-classified page.
4. Classify the to-be-classified page based on the anchor information.
5. Refine the classification process.

In the beginning, we label all samples and record all anchors pointing to them. Then we group together the anchor texts contained in the anchors pointing to the same page. In the third stage, we group the anchor texts contained in the anchors pointing to the to-be-classified page. After the grouping, we decide the class of the to-be-classified page according to the corresponding anchor texts. At last, we can further improve the effectiveness of the classification process. There are two important measures during the classification process. One is the similarity measure of two data, and the other is the criterion for relevance feedback.

Similarity Measure. After the grouping of samples, we have to measure the degree of membership between the to-be-classified page and each class. Considering the Euclidean distance again, there are three kinds of approaches for such measurement:

1. Nearest-neighbor approach.
2. Farthest-neighbor approach.
3. Mean approach.

The first approach finds the sample in each class nearest to the to-be-classified page. Among these representative samples, we can choose the class containing the one with a minimal distance and assign the page to it. On the other hand, we can also find the farthest sample in each class from the page. Then we assign the page to the class that contains the representative sample with a minimal distance. The last approach is to take the mean of each class into consideration. As in the previous approaches, the mean of each class represents a whole class, and the one with a minimal distance from the page would be chosen. An example follows by using the mean approach.

Example. Inspect the data shown in Table 6. There are several web pages and anchor texts contained in some anchors pointing to the web pages. Here we consider six types of anchor texts, T_1, T_2, ..., and T_6. The value of an anchor text for a web page stands for the number of the anchors pointing to the web page, which contain the anchor text. The labeling is the same as in the previous example.

Table 6. A Set of Home Pages with Corresponding Anchor Texts and Labels

Sample	T_1	T_2	T_3	T_4	T_5	T_6	White Page
Y_1	0	0	0	1	1	2	No
Y_2	0	1	2	0	0	2	No
Y_3	0	2	0	4	0	0	No
Y_4	0	0	3	0	0	1	No
Y_5	2	2	0	0	0	0	No
Y_6	1	3	0	0	2	3	Yes
Y_7	3	3	1	6	3	0	Yes
Y_8	4	2	5	0	1	0	Yes
Y_9	5	5	3	0	0	2	Yes
Y_{10}	8	4	4	1	4	2	Yes
X	5	2	0	0	5	0	Yes

Note: T_1 = “list”, T_2 = “directory”, T_3 = “classification”, T_4 = “bookmark”, T_5 = “hot”, and T_6 = “resource”.
The labels are determined by human knowledge.

We calculate the means of the two classes as follows:

$$M_0 = (0.4,\ 1,\ 1,\ 1,\ 0.2,\ 1),\ M_1 = (4.2,\ 3.4,\ 2.6,\ 1.4,\ 2,\ 1.4)$$

Suppose there is a web page X to be classified as shown in Table 6. We can compute the distances between X and the two means. They are $\delta(X, M_0) = 6.94$ and $\delta(X, M_1) = 4.72$. Thus, we assign X to class C_1.

Relevance Feedback. The set of samples may be enlarged after a successful classification by including the classified pages. However, the distance between a to-be-classified page and the nearest mean may be very large, which means that the current classification process does not work well on this web page. In this case, we reject to classify such a web page and wait until more anchor texts for this web page are accumulated. This kind of rejection not only expresses the extent of the current ability to classify web pages, but also it promotes the precision of the classified results. Furthermore, by the concept of class separability formulated in Equations (7)–(9), we can define a similar criterion function D_S to evaluate the performance of the current set of samples:

$$D_S = D_F(S) \tag{10}$$

where F is the set of all effective features and S is the current set of samples.

Example. Reconsider the data shown in Table 6. Before we assign X to C_1, the initial D_S equals to 0.75. When C_1 contains X, $D_{S\cup\{X\}}$ yields a smaller value 0.16. On the other hand, $D_{S\cup\{X\}}$ becomes 1.26 if we assign X to C_0. Hence, although X is labeled by C_1, it is not suitable to become a new sample for the subsequent classification. The set of samples can be enlarged only when such an addition of new samples gains a larger D_S value, which means the class separability is improved.

Web Log Analysis

The browsing behavior of the WWW users is also interesting to data analyzers. Johnson and Fotouhi (15) propose a technique to aid users in roaming through the hypertext environment. They gather and analyze the browsing paths of some users to generate a summary as a guide for other users. Within the WWW environment, the browsing behavior can be found in three positions, the history log of the browser, the access log of the proxy server, and the request log of the web server. Data analysis on the web logs at different positions will lead to different applications. Many efforts have been made to apply the results of web log analysis, for example, the discovery of marketing knowledge (16) the dynamic generation of anchors (17) and the quality evaluation of website design (18).

For web log analysis, we can also follow the typical data analysis procedure as described previously. Here we illustrate with an example of unsupervised data analysis. In the first stage, we observe the content of the web log to identify a set of features that can represent the desired user behavior. Next, we may collect a set of samples from the entire log to reduce the processing cost. In the third stage, we choose a proper subset of feature values according to some criteria such as arrival time and number of occurrences. Then, we divide the users into clusters according to the similarity measure on the features representing their behaviors. At last, we evaluate the clustered results and find a way for further improvement. In the following, we first introduce two kinds of representations of user behavior, or user profiles as they are sometimes called (19). Then we show a procedure to derive user clusters from the web log.

Data Observation and Feature Selection. The web log usually keeps the details of each request. The following is an example record:

```
890984441.324 0 140.117.11.12 UDP_MISS/000 76 ICP_QUERY http://www.yam.org.tw/b5/yam/...
```

According to application needs, only parts of the fields are retrieved, for instance, arrival time (890984441.324), IP address (140.117.11.12), and URL (http://www.yam.org.tw/b5/yam/). The records with the same IP address can be concatenated as a long sequence by the order of their arrival times. Such a long sequence often spans a long time and implies the user behavior composed of more than one browses, where a browse means a series of navigations for a specific goal. We can examine the arrival times of every two consecutive requests to cut the sequence into shorter segments, which exactly correspond to the individual browses. In this way, a browse is represented as a sequence of requests (URLs) within a time limit.

We may also represent the browsing behavior without temporal information. For a sequence of URLs, we can count the number of occurrences for each URL in it and represent this sequence as a vector. For example, we can represent a sequence $<a, b, a, b, c, d, b, c>$ as a vector [2 3 2 1], where each value stands for the number of occurrences of a, b, c, and d, respectively. Compared with the previous one, this representation emphasizes the frequency of each URL instead of their order in a browse.

User Clustering. In the following, we consider the vector representation as the browsing behavior and assume that similar vectors imply two browses with similar information needs. Therefore, clustering the vectors is equivalent to clustering the users' information needs. We use the leader algorithm (20) and Euclidean distance as defined in Equation (1) for clustering. The input is a set of vectors S and the output is a set of clusters C. Two thresholds *min* and *max* are also given to limit, respectively, the sum of values in a vector and the distance between two vectors in the same cluster. The algorithm processes the vectors one by one and terminates after all of them are processed. Different orderings of vectors can lead to different final partitions. One way to get the best partition is to try this algorithm on all different orderings. Without loss of generality, we consider that a fixed ordering of vectors and the clustering procedure is as follows:

For each vector v in S, do the following steps:

1. If the sum of values in v is smaller than *min*, discard v.
2. Compute the distance between v and the mean of each cluster in C; let the cluster with the minimum distance be c, and let d denote the minimum distance.
3. If d is larger than *max*, create a new cluster $\{v\}$ and add it to C; otherwise, assign v to c.
4. Compute the mean of each cluster in C.

The first step filters out the vector with a small number of requests because it is not very useful in applications. Then the distance between the vector v and the mean of each cluster is computed. The cluster c with the minimum distance d is then identified. If d is large, we treat v as the mean of a new cluster; otherwise, v is assigned to c.

Example. Consider the data in Table 7. There is a set of vectors on four URLs. Let *min* and *max* be set to 2 and 6, respectively. The following shows the iterations for the clustering:

For $Y_1 = [0\ 0\ 0\ 1]$,
  1 The sum of value $< min \Rightarrow \text{discard}\ Y_1$.

For $Y_2 = [1\ 3\ 0\ 0]$,
  1–3 Create $C_1 = \{Y_2\}$.
  4 Set the median $M_1 = [1\,3\,0\,0]$.

For $Y_3 = [3\ 3\ 1\ 6]$,
  1,2 Compute the distance between Y_3 and M_1: $d_1 = 6.4$.
  3 $d_1 > max \Rightarrow \text{Create}\ C_2 = \{Y_3\}$.
  4 Set the median $M_2 = [3\,3\,1\,6]$.

Table 7. A Set of Vectors on Six URLs

Vector	URL$_1$	URL$_2$	URL$_3$	URL$_4$
Y_1	0	0	0	1
Y_2	1	3	0	0
Y_3	3	3	1	6
Y_4	4	2	5	0
Y_5	5	5	3	0

For $Y_4 = [4\ 2\ 5\ 0]$,
  1,2 Compute the distance between Y_4 and M_1: $d_1 = 5.9$; the distance between Y_4 and M_2: $d_2 = 7.3$.
  3 $d_1 < max \Rightarrow \text{assign}\ Y_4\ \text{to}\ C_1 = \{Y_2,\ Y_4\}$.
  4 Compute the new median $M_1 = [2.5\ 2.5\ 2.5\ 0]$.

For $Y_5 = [5\ 5\ 3\ 0]$,
  1,2 Compute the distance between Y_5 and M_1: $d_1 = 3.6$; the distance between Y_5 and $M_2 : d_2 = 6.9$.
  3 $d_1 < max \Rightarrow \text{assign}\ Y_5\ \text{to}\ C_1 = \{Y_2,\ Y_4,\ Y_5\}$.
  4 Compute the new median $M_1 = [3.3\ 3.3\ 2.7\ 0]$.

ADVANCED INTERNET DATA ANALYSIS METHODS

Although the previous procedures fit the goal of data analysis well, there are still problems, such as speed or memory requirements and the complex nature of real-world data. We have to use some advanced techniques to improve the performance. For example, the number of clusters given in unsupervised data analysis has a significant impact on the time spent in each iteration and the quality of final partition. Notice that the initial partition may contribute to a specific sequence of adjustments and then to a particular solution. Therefore, we have to find an ideal number of clusters during the analysis according to the given initial partition. The bottom-up approach with decreasing the number of clusters in iterations is a way to adjust the final partition. Given a threshold of similarity among the clusters, we can merge two clusters that are similar enough to become a new single cluster. The number of clusters is determined when there are no more similar clusters to be merged. In the following subsections, we introduce two advanced techniques for Internet data analysis.

Techniques for Web Page Analysis

The approach to classifying Web pages by anchor semantics requires a large amount of anchor texts. These anchor texts may be contained in the anchors pointing to the Web pages in different classes. An anchor text is said to be indiscernible when it cannot be used to distinguish the Web pages in different classes. We use the rough-set theory (21, 22) to find the indiscernible anchor texts, which will then be removed. The remaining anchor texts will contribute to a higher degree of accuracy for the subsequent classification. In addition, the cost of distance computation can also be reduced. In the following, we introduce the basic idea of the rough-set theory and an example for the reduction of anchor texts (23).

Rough-Set Theory. By the rough-set theory, an information system is modeled in the form of a 4-tuple (U, A, V, F), where U represents a finite set of objects, A refers to a finite set of attributes, V is the union of all domains of the attributes in A, and F is a binary function $(F :\ U \times A \rightarrow V)$. The attribute set A often consists of two subsets, one refers to condition attribute C and the other stands for decision attribute D. In the classification on web pages, U stands for all web pages, A is the union of the anchor texts

(C) and the class of web pages (D), V is the union of all the domains of the attributes in A, and F handles the mappings. Let B be a subset of A. A binary relation called the indiscernibility relation is defined as

$$\mathrm{IND}_B = \{(X_i, X_j) \in U \times U | \forall\, p \in B,\ p(X_i) = p(X_j)\} \quad (11)$$

That is, X_i and X_j are indiscernible by the set of attributes B if $p(X_i)$ is equal to $p(X_j)$ for every attribute p in B. IND_B is an equivalence relation that produces an equivalence class denoted as $[X_i]_B$ for each sample X_i. Two web pages X_i and X_j, which have the same statistics for each anchor text in C, belong to the same equivalence class $[X_i]_C$ (or $[X_j]_C$). Let U' be a subset of U. A lower approximation $\mathrm{LOW}_{B,U'}$, which contains all samples in each equivalence class $[X_i]_B$ contained in U', is defined as

$$\mathrm{LOW}_{B,U}' = \{X_i \in U | [X_i]_B \subset U'\} \quad (12)$$

Based on Equation (12), $\mathrm{LOW}_{C,[X_i]_D}$ contains the web pages in the equivalence classes produced by IND_C, and these equivalence classes are contained in $[X_i]_D$ for a given X_i. A positive region $\mathrm{POS}_{C,D}$ is defined as the union of $\mathrm{LOW}_{C,[X_i]_D}$ for each equivalence class produced by IND_D·$\mathrm{POS}_{C,D}$ refers to the samples that belong to the same class when they have the same anchor texts. As defined in Ref. 24, C is independent on D if each subset C_i in C satisfies the criterion that $\mathrm{POS}_{C,D} \neq \mathrm{POS}_{C_i,D}$; otherwise, C is said to be dependent on D. The degree of dependency $\gamma_{C,D}$ is defined as

$$\gamma_{C,D} = \frac{\mathrm{card}(\mathrm{POS}_{C,D})}{\mathrm{card}(U)} \quad (13)$$

where card denotes set cardinality.

$$\mathrm{CON}_{p,\gamma_{C,D}} = \gamma_{C,D} - \gamma_{C-\{p\},D} \quad (14)$$

From these equations, we define the contribution $\mathrm{CON}_{p,\gamma_{C,D}}$ of an anchor text p in C to the degree of dependency $\gamma_{C,D}$ by using Equation (14). According to Equation (13), we say an anchor text p is dispensable if $\gamma_{C-\{p\},D} = \gamma_{C,D}$. That is, the anchor text p makes no contribution to $\gamma_{C,D}$ and the value of $\mathrm{CON}_{p,\gamma_{C,D}}$ equals 0. The set of indispensable anchor texts is the core of the reduced set of anchor texts. The remaining task is to find a minimal subset of C called a reduct of C, which satisfies Equation (15) and the condition that the minimal subset is independent on D.

$$\mathrm{POS}_{C,D} = \mathrm{POS}_{\text{minimal subset of } C,D} \quad (15)$$

Reduction of Anchor Texts. To employ the concepts of the rough-set theory for the reduction of anchor texts, we transform the data shown in Table 6 into those in Table 8. The numeric value of each anchor text is transformed into a symbol according to the range in which the value falls. For instance, a value in the range between 0 and 2 is transformed into the symbol L. This process is a generalization technique usually used for a large database.

Table 8. A Set of Data in Symbolic Values Transformed from Table 6

Sample	T_1	T_2	T_3	T_4	T_5	T_6	White Page
Y_1	L	L	L	L	L	L	No
Y_2	L	L	L	L	L	L	No
Y_3	L	L	L	M	L	L	No
Y_4	L	L	M	L	L	L	No
Y_5	L	L	L	L	L	L	No
Y_6	L	M	L	L	L	M	Yes
Y_7	M	M	L	H	M	L	Yes
Y_8	M	L	M	L	L	L	Yes
Y_9	M	M	M	L	L	L	Yes
Y_{10}	H	M	M	L	M	L	Yes
X	M	L	L	L	M	L	Yes

Note: L = [0, 2], M = [3, 5], H = [6, 8].

By Equation (14), we can compute $\mathrm{CON}_{p,\gamma_{C,D}}$ for each anchor text p and sort them in ascending order. In this case, all $\mathrm{CON}_{p,\gamma_{C,D}}$ are 0 except $\mathrm{CON}_{T_1,\gamma_{C,D}}$. That is, only the anchor text T_1 is indispensable, which becomes the unique core of C. Next, we use a heuristic method to find a reduct of C because such a task has been proved to be NP-complete in Ref. 25. Based on an arbitrary ordering of the dispensable anchor texts, we check the first anchor text to see whether it is dispensable. If it is, then remove it and continue to check the second anchor text. This process continues until no more anchor texts can be removed.

Example. Suppose we sort the dispensable anchor texts as the sequence <T_2, T_3, T_4, T_5, T_6>, we then check one at a time to see whether it is dispensable. At last, we obtain the reduct $\{T_1, T_6\}$. During the classification process, we only consider these two anchor texts for a similarity measure. Let the symbols used in each anchor text be transformed into three discrete values, 0, 1, and 2. The means of the two classes are $M_0 = (0, 0)$ and $M_1 = (1, 0.8)$. Finally, we classify X into the class C_1 due to its minimum distance. When we use the reduct $\{T_1, T_6\}$ to classify data, the class separability $D_{\{T_1, T_6\}}$ is 0.22. Different reducts may result in different values of class separability. For instance, the class separability becomes 0.27 if we choose the reduct $\{T_1, T_2\}$.

Techniques for Web Log Analysis

The approach to clustering the user behaviors must adapt itself to the rich content, large amount, and dynamic nature of log data. As mentioned, the web log can provide a variety of descriptions of a request. Consider the web log of an online bookstore. As the user browses an article in it, the web log may record several fields about that article, such as URL, title, authors, keywords, and categories. Notice that the last three fields represent a request as a set of items, and thus, a browse is represented as a sequence of itemsets. In addition, the dynamic nature of log data implies that the users may change their interests or behaviors as time passes. Therefore, extracting the most significant information from a long history of user browsing is important. We apply the association mining concepts (26) to extract the most representative information (use profile) from a sequence of itemsets. In the following, we introduce the basic concepts used in the data mining field and illustrate by an example how to derive the user profile with data mining techniques (27).

Association Mining Concepts. According to the definition in Ref. 26, a transaction has two fields, transaction-time and the items purchased. An itemset is a nonempty set of items, and thus, each transaction is also an itemset. The length of an itemset is the total number of items in it. A k-itemset stands for an itemset with length k. Furthermore, if a transaction contains an itemset I, we call that the transaction supports I. The support of an itemset is the percentage of transactions that support it in the entire database. If the support of an itemset is larger than a minimum support threshold, we call it a frequent itemset. Given a transaction database, the goal of association mining is to efficiently find all the frequent itemsets.

Consider the web log analysis for an online bookstore. We can regard a transaction as the set of categories (or authors or keywords) logged during a time period that the user enters the online bookstore. The categories in a transaction are equally treated. Thus, for each user, there will be a series of transactions recorded in the web log. Moreover, we can identify a set of categories, for instance, {"data mining", "database", "multimedia"}, which has frequently appeared in these transactions, to represent the user's interests.

Profile Derivation. We employ the association mining concepts to derive the user profile from the transactions in the web log. Due to the accumulation of transactions, the profile derivation may incur high overheads if we use the traditional mining method (28). Therefore, we adopt an incremental method to derive the user profile. The core of our method is the *interest table*, which is built for each user to keep the categories in the transactions. An interest table consists of four columns, while each row of the table refers to a category. An example with four transactions is shown in Table 9. The Category column lists the categories that appear in the transactions. The First and Last columns record the first and the last transactions in which each category appears, respectively. Finally, the Count column keeps the number of occurrences for each category since its first transaction. From the interest table, we can compute the support of each category as follows (where c is a category and T is the current transaction):

$$\text{Support}(c) = \text{Count}(c)/(T - \text{First}(c) + 1) \tag{16}$$

This formula indicates that only the transactions after the first transaction of this category are considered in the support measure. In other words, we ignore the effects of the transactions before the first transaction of this category. Consider the scenario that a category first appears in $T91$ and then continually shows up from $T92$ to $T100$. By the traditional method, its support is small (10%). In contrast, our formula computes the support at 100%, indicating that this category appears frequently in the recent transactions. Given a threshold α, the user profile is $\{c|Support(c) \geq \alpha\}$.

By Equation (16), when a category first appears, its support will be always 100%, which is not reasonable. Therefore, we define a threshold, called minimal count (denoted by β), to filter out the categories with very small counts. On the other hand, we observe that the support of a category can be very low if its first transaction is very far from the current transaction. Consider the scenario that a category first appears in $T1$, disappears from $T2$ to $T91$, and continually shows up from $T92$ to $T100$. By Equation (16), its support is just 10%. However, the fact that this category appears frequently in the recent transactions implies that the user is getting interested in it recently. Therefore, we define another threshold, called expired time (denoted by γ), to restrict the interval between the last and the current transactions. When this interval exceeds γ, both the First and the Last columns of the category are changed to the current transaction.

Example. Take the four transactions in Table 9 as an example. As category c appears in $T1$, $T2$, and $T4$, its count has a value 3. Moreover, the first and the last transactions of category c are $T1$ and $T4$, respectively. The rightmost column of Table 9 lists the support of each category. In this example, the thresholds α, β, and γ are set to 75%, 2, and 4, respectively. We do not compute the support of category a because its count is less than β. As a result, $\{c, d, e\}$ is derived as the user profile.

When a new transaction $T5$ arrives, we recalculate the supports of the categories that appear in $T5$ or the user profile to update the interest table. As Table 10 shows, the supports of all categories except a are recalculated. By α, we derive the new user profile $\{b, c, e, f\}$. Note that category d is removed from the user profile because its new support is lower than α.

Table 9. Four Transactions and the Interest Table

Transactions	Category	First	Last	Count	Support
T1 {*a*, *c*, *e*}	*a*	*T1*	*T1*	1	N/A
T2 {*b*, *c*, *e*, *f*}	*b*	*T2*	*T4*	2	67%
T3 {*d*, *e*, *f*}	*c*	*T1*	*T4*	3	75%
T4 {*b*, *c*, *d*}	*d*	*T3*	*T4*	2	100%
	e	*T1*	*T3*	3	75%
	f	*T2*	*T3*	2	67%

Table 10. The Interest Table After T5 Arrives

Transactions	Category	First	Last	Count	Support
T1 {*a*, *c*, *e*}	*a*	*T1*	*T1*	1	N/A
T2 {*b*, *c*, *e*, *f*}	*b*	*T2*	*T5*	3	75%
T3 {*d*, *e*, *f*}	*c*	*T1*	*T5*	4	80%
T4 {*b*, *c*, *d*}	*d*	*T3*	*T4*	2	67%
T5 {*b*, *c*, *e*, *f*, *g*}	*e*	*T1*	*T5*	4	80%
	f	*T2*	*T5*	3	75%
	g	*T5*	*T5*	1	N/A

SUMMARY

In this article, we describe the techniques and concepts of data analysis. A variety of data analysis methods are introduced and illustrated by examples. Two categories, supervised data analysis and unsupervised data analysis, are presented according to their different initial conditions and resultant uses. Two methods for data analysis are also described, which are based on probability theory and fuzzy-set theory, respectively. The methods for data analysis on two types of Internet data are presented. Advanced techniques for Internet data analysis are also discussed.

Research Trends

The research trend of data analysis can be seen from two viewpoints. From the viewpoint of data, new data types such as transactions, sequences, trees, graphs, and relational tables, bring new challenges to data analysis. From the viewpoint of knowledge, or the result of data analysis, new interestingness measures of patterns, such as support, confidence, lift, chi-square value, and entropy gain, also bring new challenges to data analysis. It is not easy to come up with a single method that can meet all combinations of these challenges. Several ideas and solutions have been proposed, but many challenges remain. In the following, we introduce two research directions that have recently attracted great attention from the data analyzers.

In many of the new applications, several continuous data streams rapidly flow through computers to be either read or discarded by people. Examples are the data flows on computer, traffic, and telecommunication networks. Recently, data analysis on continuous data streams has become widely recognized (29). Its applications include intrusion detection, trend analysis, and grid computing. The characteristics of data analysis on continuous data streams are as follows:

1. Continuity—Data are continuous and arrive at a variable rate.
2. Infinity—The total amount of data is unbounded.
3. Uncertainty—The order of data cannot be predetermined.
4. Expiration—Data can be read only once.
5. Multiplicity—More than one data stream may arrive at a single site for data analysis.

Data analysis on graphs has become popular due to a variety of new applications emerging in the fields like biology, chemistry, and networking (30). The prevalent use of HTML and XML formats also pushes the data analyzers toward this research direction. The characteristics of data analysis on graphs are as follows:

1. Variety—Graph has various substructures such as a connected subgraph, an ordered tree, and a path.
2. Isomorphism—It is NP-complete to decide whether one graph is a subgraph of another one.
3. Interestingness—The measure of pattern interestingness depends on application needs.
4. Complexity—A very efficient mechanism is required to keep the complex structure of graph data.

DATABASE LANGUAGES

BACKGROUND

The DBMS has a DDL complier that processes DDL statements to generate the schema descriptions and store them into the DBMS catalog. The catalog contains metadata that are consulted before the actual data are accessed.

There are two types of DMLs: *low-level* or *procedural* DMLs and *high-level* or *nonprocedural* DMLs. A low-level DML requires the user to specify *how* the data are manipulated. This type of DML typically retrieves and processes individual records from a database. Therefore, a low-level DML is also called a *record-at-a-time* DML. A high-level DML allows users to specify *what* the result is, leaving the decision about how to get the result to the DBMS. Therefore, a high-level DML is also called a *declarative* DML. A high-level DML can specify and retrieve many records in a single statement and is hence called a *set-at-a-time* or *set-oriented* DML. A declarative DML is usually easier to learn and use than a procedural DML. In addition, a declarative DML is sometimes faster in overall processing than its procedural counterpart by reducing the number of communications between a client and a server. A low-level DML may be embedded in a general-purpose programming language such as COBOL, C/C++, or Java. A general-purpose language in this case is called the *host language*, and the DML is called the *data sublanguage*. On the other hand, a high-level DML called a *query language* can be used in a standard-alone and interactive manner.

The main criterion used to classify a database language is the data model based on which the language is defined. The existing data models fall into three different groups: *high-level* or *conceptual data models, implementation data models*, and *physical data models* (1). Conceptual models provide concepts that are close to the way users perceive data, whereas physical data models provide concepts for describing the details about how data are stored. Implementation data models specify the overall logical structure of a database and yet provide a high-level description of the implementation.

High-level data models are sometimes called *object-based* models because they mainly describe the objects involved and their relationships. The *entity-relationship* (E–R) model and the *object-oriented* model are the most popular high-level data models. The E–R model (2) is usually used as a high-level conceptual model that can be mapped to the relational data model. The object-oriented data model adapts the object-oriented paradigm for a database by adding concepts in object-oriented programming such as persistence and collection.

Implementation data models are used most frequently in a commercial DBMS. There are three widely used implementation data models: *relational*, *network*, and *hierarchical*. They organize the data in record structures and hence are sometimes called *record-based* data models. Many database systems in early days were built based on either the network model or the hierarchical model. However, because these two models only support low-level queries and record-at-a-time retrievals, their importance has decreased over the years. The relational model has been successfully used in most commercial database management systems today. This is because the relational model and relational database languages provide high-level query specifications and set-at-a-time retrievals.

The *object-relational* data model is a hybrid of the object-oriented and the relational models. It extends the relational data model by providing an extended type system and object-oriented concepts such as object identity, inheritance, encapsulation, and complex objects.

With the popularity of Extensible Markup Language (XML), XML is becoming a standard tool for data representation and exchange between multiple applications and database systems. Later, we will discuss some advanced database languages developed based on temporal, spatial, and active models.

RELATIONAL DATA MODEL, RELATIONAL ALGEBRA, RELATIONAL CALCULUS, AND RELATIONAL QUERY LANGUAGES

Relational Data Model

The relational data model was introduced by Codd (3). It was developed based on the mathematical notion of a *relation*. Its root in mathematics allows it to provide the simplest and the most uniform and formal representation. The relational data model represents the data in a database as a collection of relations. Using the terms of the E–R model, both entity sets and relationship sets are relations. A relation is viewed as a two-dimensional table in which the rows of the table correspond to a collection of related data values and the values in a column all come from the same domain. In database terminology, a row is called a *tuple* and a column name is called an *attribute*. A *relation schema* R, denoted by $R(A_1, A_2, \ldots, A_n)$, is a set of attributes $R = \{A_1, A_2, \ldots, A_n\}$. Each attribute A_i is a descriptive property in a domain D. The domain of A_i is denoted by dom(A_i). A relation schema is used to describe a relation, and R is called the name of the relation. The degree of a relation is the number of the attributes of its relation schema. A relation instance r of the relation schema $R(A_1, A_2, \ldots, A_n)$, also denoted by $r(R)$, is a set of m-tuples $r = \{t_1, t_2, \ldots, t_m\}$. Each tuple t is an ordered list of n values $t = <v_1, v_2, \ldots, v_n>$, where each value v_i is an element of dom(A_i).

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Relational Algebra

A query language is a language in which users can request data from a database. Relational algebra is a procedural language. The fundamental operations in the relational algebra are usually divided into two groups. The first group includes *select*, *project*, and *join* operations that are developed specifically for relational databases. The second group includes set operations from mathematical set theory such as *union, interaction, difference*, and *Cartesian product*. These operations allow us to perform most data retrieval operations.

The Select Operation. The select operation selects a subset of the tuples from a relation. These tuples must satisfy a given predicate. The lowercase Greek letter sigma (σ) is used to denote the select operation and followed by a predicate as a subscript to σ. The argument relation R is given in the parentheses following σ. Suppose we have a sample *University* database that consists of three relations: *Faculty*, *Department*, and *Membership* as shown in Fig. 1. If we wish to find information of all faculty members whose salary is greater than $50,000, we would write

$$\sigma_{\text{salary} > 50000}(\text{Faculty})$$

In general, the select operation is denoted by

$$\sigma_{\Sigma\text{condition}i}(R)$$

Note that the select operation is commutative; that is,

$$\sigma_{\text{condition1}}(\sigma_{\text{condition2}}(R)) = \sigma_{\text{condition2}}(\sigma_{\text{condition1}}(R))$$

In addition, we can combine a cascade of select operations into a single select operation with logical "AND" connectives; that is,

$$\sigma_{\text{condition1}}(\sigma_{\text{condition2}}(\ldots\sigma_{\text{conditionn}}R)))$$
$$= \sigma_{\text{condition1 AND}}\sigma_{\text{condition2 AND ... AND}}\ \sigma_{\text{conditionn}}(R)$$

The Project Operation. The project operation produces a vertical subset of the table by extracting the values from a set of specified columns, eliminating duplicates and placing the values in a new table. The lowercase Greek letter pi (π) is used to denote the project operation and followed by a list of attribute names that we wish to extract in the result as a subscript to π. For example, the following operation produces the names and birthdates of all faculty members:

$$\pi_{\text{name, birthdate}}(\text{Faculty})$$

Relational Expressions. As each relational algebra operation produces a set, we can combine several relational algebra operations into a relational expression. For example, suppose that we want the names of all faculty members whose salary is greater than 50,000 (Fig. 1). We can write a relational expression as follows:

$$\pi_{\text{name}}(\sigma_{\text{salary} > 50000}(\text{Faculty}))$$

The Cartesian Product Operation. The Cartesian product operation, denoted by a cross (X), allows us to combine tuples from two relations so that the result of $R1(A_1, A_2, \ldots, A_n)$ X $R2(B_1, B_2, \ldots, B_m)$ is a relation Q with $n + m$ attributes $Q(A_1, A_2, \ldots, A_n, B_1, B_2, \ldots, B_m)$ in

that order. The tuples of the relation Q are all combinations of the rows from $R1$ and $R2$. Specifically, it combines the first row of $R1$ with the first row of $R2$, then with the second row of $R2$, and so on, until all combinations of the first row of $R1$ with all the rows of $R2$ have been formed. The procedure is repeated for the second row of $R1$, then the third row of $R1$, and so on. Assume that we have p tuples in $R1$ and q tuples in $R2$. Then, there are $p \times q$ tuples in Q.

The Join Operation. In fact, the Cartesian product is rarely used by itself. We can define several useful operations based on the Cartesian product operation. The join operation, denoted by $\bowtie$, is used to combine *related tuples* from two relations. The general form of the join operation on two relations $R1(A_1, A_2, \ldots, A_n)$ and $R2\ (B_1, B_2, \ldots, B_m)$ is

$$R1 \bowtie_{<\text{join condition}>} R2$$

The result of the join operation is a relation $Q(A_1, A_2, \ldots, A_n, B_1, B_2, \ldots, B_m)$ that satisfies the join condition. The join condition is specified on the attributes of $R1$ and $R2$ and is evaluated for each tuple from the Cartesian product $R1 \times R2$. The join condition is of the form:

$$<\text{condition}> \text{ AND } <\text{condition}> \text{ AND } \ldots \text{ AND } <\text{condition}>$$

where each condition is of the form $A_i \Theta B_j$, A_i is an attribute of $R1, B_j$ is an attribute of $R2$, both A_i and B_j belong to the same domain, and Θ is one of the following comparison operators: $=, \leq, <, >, \geq, \neq$. A join operation with such a general join condition is called a *theta join*.

The most common join operation involves only equality comparisons. When a join only involves join conditions with equality operators, such a join is called an *equijoin*. As an illustration of an equijoin join, the following query retrieves the names of all faculty members of each department in the *University* database:

$$\pi_{\text{name}}(\text{Faculty} \bowtie_{\text{Faculty.dcode}=\text{Department.dcode}} \text{Department})$$

The result of the equijoin is shown in Fig. 2. You may notice that we always have at least two attributes that have identical values in every tuple as shown in Fig. 2. As it is unnecessary to include repeated columns, we can define a *natural join* by including an equality comparison between every pair of common attributes and eliminating the repeated columns in the result of an equijoin. A natural join for the above example can be expressed as follows in Fig. 3.

Relational Calculus

Relational calculus is a declarative query language in which users specify what data should be retrieved, but not how to retrieve them. It is a formal language, based on *predicate calculus*, a branch of mathematical logic. There are two types of relational calculus: *tuple-related calculus* and *domain-related calculus*. Both are subsets of predicate calculus, which deals with quantified variables and values.

A query in the tuple-related calculus is expressed as

$$\{t|P(t)\}$$

which designates the set of all tuples t such that the predicate *P(t)* is true.

We may connect a set of predicates by the logical connectives AND ($\wedge$), OR ($\vee$), and NOT ($\sim$) to form compound predicates such as *P(t)* AND *Q(t)*, *P(t)* OR NOT *Q(t)*, and NOT *P(t)* OR *Q(t)*, which can be written as $P(t) \wedge Q(t)$, $P(t) \vee \sim Q(t)$, and $\sim P(t) \vee Q(t)$, respectively. A *conjunction* consists of predicates connected by a set of logical ANDs,

fid	*Faculty.name*	*birthdate*	*salary (dollar)*	*Faculty. dcode*	*Department.name*
91239876	John Smith	01/09/67	40000	2	Computer Science
33489783	Perry Lee	12/08/55	68000	2	Computer Science
78738498	Tom Bush	06/20/41	79000	4	Mechanical Engineering
12323567	Jane Rivera	09/15/72	35000	3	Electrical Engineering
87822384	Joyce Adams	11/10/59	54000	1	Chemical Engineering
78898999	Frank Wong	07/31/79	30000	3	Electrical Engineering
22322123	Alicia Johnson	08/18/80	28000	1	Chemical Engineering

Figure 3. Result of the natural join of *Faculty* and *Department*.

a *disjunction* consists of predicates connected by a set of logical ORs, and a *negation* is a predicate preceded by a NOT. For example, to retrieve all faculty members whose salary is above \$50,000, we can write the following tuple-related calculus expression:

$$\{t|Faculty(t) \wedge t.Salary > 50000\}$$

where the condition *Faculty(t)* specifies that the range of the tuple variable t is *Faculty* and each *Faculty* tuple t satisfies the condition $t.Salary > 50000$.

There are two quantifiers, the *existential quantifier* ($\exists$) and the *universal quantifier* ($\forall$), used with predicates to qualify tuple variables. An existential quantifier can be applied to a variable of predicate to demand that the predicate must be true for at least one tuple of the variable. A universal quantifier can be applied to a variable of a predicate to demand that the predicate must be true for all possible tuples that may instantiate the variable. Tuple variables without any quantifiers applied are called *free variables*. A tuple variable that is quantified by a $\exists$ or $\forall$ is called a *bound variable*.

In domain-related calculus, we use variables that take their values directly from individual domains to form a tuple variable. An expression in domain-related calculus is of the form

$$\{<x_1, x_2, \ldots, x_n>|P(x_1, x_2, \ldots, x_n)\}$$

where $<x_1, x_2, \ldots, x_n>$ represents domain variables and $P(x_1, x_2, \ldots, x_n)$ stands for a predicate with these variables. For example, to retrieve the names of all faculty members whose salary is above \$50,000, we can write the following domain-related calculus expression:

$$\{<n>|(\exists\, n)Faculty(f, n, b, s, d) \wedge s > 50000\}$$

where *f, n, b, s,* and *d* are variables created from the domain of each attribute in the relation *Faculty*, i.e., *fid, name, birthdate, salary*, and *dcode*, respectively.

Structured Query Language (SQL)

A formal language such as relational algebra or relational calculus provides a concise notation for representing queries. However, only a few commercial database languages have been proposed based directly on a formal database language. A Structured Query Language (SQL) is a high-level relational database language developed based on a combination of the relational algebra and relational calculus. SQL is a comprehensive database language that includes features for data definition, data manipulation, and view definition.

Originally, SQL was designed and implemented in a relational DBMS called SYSTEM R developed by IBM. In 1986, the America National Standards Institute (ANSI) published an SQL standard, called SQL86, and the International Standards Organization (ISO) adopted SQL86 in 1987. The U. S. Government's Federal Information Processing Standard (FIPS) adopted the ANSI/ISO standard. In 1989, a revised standard known commonly as SQL89 was published.

The SQL92 was published to strength the standard in 1992. This standard addressed several weaknesses in SQL89 as well as extended SQL with some additional features. The main updated features include session management statements; connection management, including CONNECT, SET CONNECTION, and DISCONNECT; self-referencing DELETE, INSERT, and UPDATE statements; subqueries in a CHECK constraint; and deferrable constraints.

More recently, in 1999, the ANSI/ISO SQL99 standard was released. The SQL99 (4,5) is the newest SQL standard. It contains many additional features beyond SQL92. This standard addresses some of the more advanced and previously nonaddressed areas of modern SQL systems, such as object-oriented, call-level interfaces, and integrity management.

Data Definition. The basic commands in SQL for data definition include CREATE, ALTER, and DROP. They are used to define the attributes of a table, to add an attribute to a table, and to delete a table, respectively. The basic format of the CREATE command is

CREATE TABLE table-name < attribute-name >: < attribute-type >: [< constraints >]

where each attribute is given its name, a data type defines its domain, and possibly some constraints exist.

The data types available are basic types including numeric values and strings. Numeric data types include integer number, real number, and formatted number. A String data type may have a fixed length or a variable length. There are also special data types, such as date and currency.

As SQL allows NULL (which means "unknown") to be an attribute value, a constraint NOT NULL may be specified on an attribute if NULL is not permitted for that attribute. In general, the *primary key* attributes of a table are restricted to be NOT NULL. The value of the primary key can identify a tuple uniquely. The same constraint can also be specified on any other attributes whose values are required to be NOT NULL. The *check clause* specifies a predicate P that must be satisfied by every tuple in the table. The table defined by the CREATE TABLE statement is called a *base table*, which is physically stored in the database. Base tables are different from *virtual tables* (*views*), which are not physically stored in the database. The following example shows how a *Faculty* table can be created using the above CREATE TABLE command:

```
CREATE TABLE Faculty
(fid: char (10) NOT NULL,
name: char(20) NOT NULL,
"birthdate": date,
salary: integer,
dcode: integer
PRIMARY KEY (fid),
CHECK (salary >= 0))
```

If we want to add an attribute to the table, we can use the ALTER command. In this case, the new attributes may have NULL as the value of the new attribute. For example, we can add an attribute SSN (Social Security Number) to the *Faculty* table with the following command:

```
ALTER TABLE Faculty
ADD SSN char(9)
```

If the *Faculty* table is no longer needed, we can delete the table with the following command:

```
DROP TABLE Faculty
```

Data Manipulation—Querying. SQL has one basic statement for retrieving information from a database: the SELECT statement. The basic form of the SELECT statement consists of three clauses: SELECT, FROM, and WHERE and has the following form:

```
SELECT <attribute list>
FROM <table list>
WHERE <condition>
```

where the SELECT clause specifies a set of attributes to be retrieved by the query, the FROM clause specifies a list of tables to be used in executing the query, and the WHERE clause consists of a set of predicates that qualifies the tuples of the tables involved in forming the final result.

The followings are three example queries, assuming that the tables *Faculty*, *Department*, and *Membership* are defined as follows:

Faculty (fid, name, birthdate, salary, dcode)
Department (dcode, name)
Membership (fid, society)

Query 1. Retrieve the faculty IDs and names of all faculty members who were born on August 18, 1980.

```
SELECT fid, name
FROM Faculty
WHERE birthdate = '08/18/80'
```

Query 2. Retrieve the names of all faculty members associated with the Computer Science department.

```
SELECT Faculty.name
FROM Faculty, Department
WHERE Department.name = 'Computer Science' AND
  Faculty.dcode = Department.dcode
```

Query 3. Retrieve the faculty IDs and names of all faculty members who are members of any society of which Frank Wong is a member.

```
SELECT Faculty.fid, Faculty.name
FROM Faculty, Membership
WHERE Faculty.fid = Membership.fid AND
  society IN (SELECT society
    FROM Membership, Faculty
    WHERE Faculty.fid = Membership.fid AND
        Faculty.name = 'Frank Wong')
```

Note that Query 3 is a *nested query*, where the *inner query* returns a set of values, and it is used as an operand in the *outer query*.

Aggregate functions are functions that take a set of values as the input and return a single value. SQL offers five built-in aggregate functions: COUNT, SUM, AVG, MAX, and MIN. The COUNT function returns the number of values in the input set. The functions SUM, AVG, MAX, and MIN are applied to a set of numeric values and return the sum, average, maximum, and minimum, respectively. In many cases, we can apply the aggregate functions to subgroups of tuples based on some attribute values. SQL has a GROUP BY clause for this purpose. Some example queries are as follows:

Query 4. Find the average salary of all faculty members associated with the Computer Science department.

```
SELECT AVG (salary)
FROM Faculty, Department
WHERE Faculty.dcode = Department.code AND
  Department.name = 'Computer Science'
```

Query 5. For each department, retrieve the department name and the average salary.

```
SELECT Department.name, AVG(salary)
FROM Faculty, Department
WHERE Faculty.dcode = Department.dcode
GROUP BY Department.name
```

Sometimes it is useful to state a condition that applies to groups rather than to tuples. For example, we might be interested in only those departments where the average salary is more than $60,000, This condition does not apply to a single tuple but applies to each group of tuples constructed by the GROUP BY clause. To express such a query, the HAVING clause is provided, which is illustrated in Query 6.

Query 6. Find the departments whose the average salary is more than $60,000.

```
SELECT Department.name, AVG(salary)
FROM Faculty, Department
WHERE Faculty.dcode = Department.dcode
GROUP BY Department.name
HAVING AVG(salary) > 60000
```

Data Manipulation—Updates. In SQL, there are three commands to modify a database: INSERT, DELETE, and UPDATE. The INSERT command is used to add one or more tuples into a table. The values must be listed in the same order as the corresponding attributes are defined in the schema of the table if the insert column list is not specified explicitly. The following example shows a query to insert a new faculty member into the *Faculty* table:

```
INSERT Faculty
VALUES ('78965456', 'Gloria Smith', '12/12/81',
  25000, 1)
```

The DELETE command removes tuples from a table. It includes a WHERE clause to select the tuples to be deleted. Depending on the number of tuples selected by the condition in the WHERE clause, the tuples can be deleted by a single DELETE command. A missing WHERE clause indicates that all tuples in the table are to be deleted. We must use the DROP command to remove a table completely. The following example shows a query to delete those faculty members with the highest salary:

```
DELETE FROM Faculty
WHERE salary IN (SELECT MAX (salary) FROM Faculty)
```

Note that the subquery is evaluated only once before executing the command.

The UPDATE command modifies certain attribute values of some selected tuples. As in the DETELTE command, a WHERE clause in the UPDATE command selects the tuples to be updated from a single table. A SET clause specifies the attributes to be modified and their new values. The following example shows a query to increase by 10% the salary of each faculty member in the Computer Science department:

```
UPDATE Faculty
SET salary = salary * 1.1
WHERE dcode IN (SELECT code
    FROM Department
    WHERE name='Computer Science')
```

View Definition. A view in SQL is a table that is derived from other tables. These other tables can be base tables or previously defined views. A view does not exist in the physical form, so it is considered a virtual table in contrast to the base tables that physically exist in a database. A view can be used as a table in any query as if it existed physically. The command to define a view is as follows:

```
CREATE VIEW <view name>
AS <query statement>
```

The following example shows the definition of a view called *Young-Faculty-Members* who were born after 01/01/1970:

```
CREATE VIEW Young-Faculty-Members
AS SELECT name, birth-date
    FROM Faculty
    WHERE birth-date > '01/01/1970'
```

Object-Oriented Database Model and Languages

The object-oriented data model was developed based on the fundamental object-oriented concepts from a database perspective. The basic concepts in the object-oriented model include encapsulation, object identity, inheritance, and complex objects.

The object-oriented concepts had been first applied to programming. The object-oriented approach to programming was first introduced by the language, Simular67. More recently, C++ and Java have become the most widely known object-oriented programming languages. The object-oriented database model extends the features of object-oriented programming languages. The extensions include object identity and pointer, persistence of data (which allows transient data to be distinguished from persistent data), and support for collections.

A main difference between a programming language and a database programming language is that the latter directly accesses and manipulates a database (called *persistent data*), whereas the objects in the former only last during program execution. In the past, two major approaches have been taken to implement database programming languages. The first is to embed a database language such as SQL in conventional programming languages; these languages are called embedded languages. The other approach is to extend an existing programming language to support persistent data and the functionality of a database. These languages are called *persistent programming languages*.

However, the use of embedded languages leads to a major problem, namely *impedance mismatch*. In other words, conventional languages and database languages differ in their ways of describing data structures. The data type systems in most programming languages do not support relations in a database directly, thus requiring complex mappings from the programmer. In addition, because conventional programming languages do not understand database structures, it is not possible to check for type correctness.

In a persistent programming language, the above mismatch can be avoided. The query language is fully integrated with the host language, and both share the same type system. Objects can be created and stored in a database without any explicit type change. Also, the code for data manipulation does not depend on whether the data it manipulated are short-lived or persistent. Despite these advantages, however, persistent programming languages have some drawbacks. As a programming language accesses a database directly, it is relatively easy to make programming errors that damage the database. The complexity of such languages also makes high-level optimization (e.g., disk I/O reduction) difficult. Finally, declarative querying is, in general, not supported.

Object Database Management Group (ODMG). The Object Database Management Group (ODMG), which is a consortium of object-oriented DBMS vendors, has been working on standard language extensions including class libraries to C++ and Smalltalk to support persistency. The standard includes a common architecture and a definition for object-oriented DBMS, a common object model with an object definition language, and an object query language for C++, Smalltalk, and Java. Since ODMG published ODMG1.0 for their products in 1993, ODMG 2.0 and ODMG 3.0 were released in 1997 and 2000, respectively (6).

The components of the ODMG specification include an Object Model, an Object Definition Language (ODL), an Object Query Language (OQL), and language bindings to Java, C++, and Smalltalk:

ODMG Object Model is a superset of the Object Management Group (OMG) Object Model that gives it database capabilities, including relationships, extents, collection classes, and concurrency control. It is the unifying concept for the ODMG standard and is completely language-independent.

Object Definition Language (ODL) is used to define a database schema in terms of object types, attributes, relationships, and operations. The resulting schema can be moved from one database to another and is programming language-independent. ODL is a superset of OMG's Interface Definition Language (IDL).

Object Query Language (OQL) is an ODMG's query language. It closely resembles SQL99, and it includes support for object sets and structures. It also has object extensions to support object identity, complex objects, path expressions, operation invocation, and inheritance.

The *language bindings* to Java, C++, and Smalltalk are extensions of their respective language standards to allow the storage of persistent objects. Each binding includes support for OQL, navigation, and transactions. The advantage of such an approach is that users can build an entire database application from within a single programming language environment.

The following example shows the schema of two object types, *Faculty* and *Course*, in ODMG ODL:

```
interface Faculty (extent Faculties, key fid) {
    attribute integer fid;
    attribute string name;
    attribute birthdate date;
    attribute salary integer;
    relationship Set<Course> teachCourses
    inverse Course::faculties;
};
interface Course (extent Courses, key CID) {
    attribute string CID;
    attribute string title;
    relationship Set<Faculty>Faculties
    inverse Faculty::teachCourses;
};
```

where *interface* names an ODL description, *extent* names the set of objects declared, *key* declares the key, *attribute* declares an attribute, *set* declares a collection type, *relationship* declares a relationship, and *inverse* declares an inverse relationship to specify a referential integrity constraint.

The following example shows an example query in ODMG OQL to retrieve the course IDs and course titles of the courses instructed by John Smith:

```
SELECT f.teachCourse.CID, f. teachCourse.title
FROM Faculties f
WHERE f.name = 'John Smith';
```

Note that the FROM clause *f* refers to the extent *Faculties*, not the class *Faculty*. The variable *f* is used to range over the objects in *Faculties*. Path expressions using a dot (.) to separate attributes at different levels are used to access any property (either an attribute or a relationship) of an object.

Object-Relational Database Model and Languages

The object-relational data model extends the relational data model by providing extended data types and object-oriented features such as inheritance and references to objects. Extended data types include nested relations that support nonatomic data types such as collection types and structured types. Inheritance provides reusability for attributes and methods of exiting types. A reference is conceptually a pointer to tuples of a table. An object-relational database language extends a relational language such as SQL by adding object-oriented features. The following discussion is primarily based on the SQL99 standard (4,5):

Object Type. Objects are typed in an object-relational database. A value of an object type is an instance of that type. An object instance is also called an object. An object type consists of two parts: attributes and methods. Attributes are properties of an object and hold values at a given moment. The values of attributes describe an object's state. An attribute may be an instance of a declared object type, which can, in turn, be of another object type. Methods are invoked and executed in response to a message. An object type may have any number of methods or no method at all. For instance, we can define an object type *Address* as follows:

```
CREATE TYPE Address AS
    (street varchar(20),
    city varchar(20),
    state varchar(2))
METHOD change-address()
```

In the above, the object type *Address* contains the attributes *street*, *city*, and *state*, and a method *change-address()*.

Collection Type. Collection types such as sets, arrays, and multisets are used to permit mulivalued attributes. Arrays are supported by SQL99. The following attribute definition illustrates the declaration of a *Course-array* that contains up to 10 course names taught by a faculty member:

```
Course-array varchar(20) ARRAY [10]
```

Large Object Type. To deal with multimedia data types such as texts, audios, images, and video streams, SQL99 supports large object types. Two types of large objects (LOBs) can be defined depending on their locations: *internal* LOB and *external* LOB. Internal LOBs are stored in the database space, whereas external LOBs, or BFILEs (Binary FILEs), are stored in the file system that is outside of the database space. The following example shows the declaration of some LOB types:

```
Course-review CLOB (10KB)
Course-images BLOB (10MB)
Course-video BLOB (2GB)
```

Structured Type. In the relational model, the value of an attribute must be primitive as required by the first normal form. However, the object relational model extends the relational model so that the value of an attribute can be an object or a set of objects. For example, we may define an object type *Faculty* as follows:

```
create type Address AS
    (street varchar(20),
    city varchar(20),
    state varchar(2))
create type Name as
    (firstname varchar(20),
    middlename varchar(20),
    lastname varchar(20))
create type Faculty as
    (fid integer,
    name Name,
    address Address,
    Course-array varchar(20) array[10])
```

Type Inheritance. Inheritance allows an existing type's attributes and methods to be reused. Thus, it enables users to construct a type hierarchy to support *specialization* and *globalization*. The original type that is used to derive a new one is called a *supertype* and the derived type is called a *subtype*. For example, we can define two types *Graduate-student* and *University-staff* as two subtypes of *University-personnel* as follows:

```
CREATE TYPE University-personnel AS
    (name Name,
    address Address)

CREATE TYPE Graduate-student
UNDER University-personnel
    (student-id char(10),
    department varchar(20))

CREATE TYPE University-staff
UNDER University-personnel
    (years-of-experience: integer
    salary: integer)
METHOD compute-salary()
```

Both *Graduate-student* and *University-staff* types inherit the attributes from the type *University-personnel* (i.e., *name* and *address*). Methods of a supertype are inherited by its subtypes, just as attributes are. However, a subtype can redefine the method it inherits from its supertype. Redefining an inherited method allows the subtype to execute its own method. Executing its own method results in *overriding* an inherited method. For example, the type *Research-assistant* has its own method *compute-salary()*, which overrides *computer-salary()* defined in *Graduate-student*:

```
CREATE TYPE Research-assistant
UNDER University-staff, Graduate-student
METHOD compute-salary()
```

In the above example, the subtype *Research-assistant* inherits the attributes and methods defined in *University-staff* and *Graduate-student*. This is called *multiple inheritance*.

Reference Type. A reference can refer to any object created from a specific object type. A reference enables users to navigate between objects. The keyword REF is used to declare an attribute to be of the reference type. The restriction that the scope of a reference is the objects in a table is mandatory in SQL99. For example, we can include a reference to the *Faculty* object type in the *Graduate-student* object type as follows:

```
CREATE TYPE Graduate-student
UNDER University-personnel
    (student-id char(10),
    department varchar(20)
    advisor REF(Faculty) scope Faculty)
```

Here, the reference is restricted to the objects of the *Faculty* table.

Extensible Markup Language (XML)

Extensible Markup Language, abbreviated XML, describes a class of data objects called XML documents, which are well formed (7). XML is a subset of Standard Generalized Markup Language (SGML) and was originally developed for document management in the World Wide Web (WWW) environment as was the Hyper-Text Markup Language (HTML). However, unlike SGML and HTML, XML is also playing an important role in representing and exchanging data.

XML can be used for *data-centric documents* as well as *document-centric documents*. In general, document-centric documents are used by humans and characterized by less regular structures and larger grained data. On the other hand, data-centric document are designed to facilitate the communication between applications. When XML is used for data-centric documents, many database issues develop, including mapping from the logical model to the XML data model, organizing, manipulating, querying, and storing XML data.

As other markup languages, XML takes the form of tags enclosed in a pair of angle brackets. Tags are used in pairs with <tag-name> and </tag-name> delimiting the beginning and the end of the *elements*, which are the fundamental constructs in an XML document. An XML document consists of a set of elements that can be nested and may have attributes to describe each element. The nested elements are called *subelements*. For example, we may have a nested XML representation of a university information document as follows:

```
<university>
    <faculty>
        <fid> 91239876 </fid>
        <name> John Smith </name>
        <birthdate> 01/09/67 </birthdate>
        <salary> 40000 </salary>
        <dcode> 2 </dcode>
    </faculty>
    <faculty>
        <fid> 33489783 </fid>
        <name> Perry Lee </name>
        <birthdate> 12/08/55 </birthdate>
        <salary> 68000 </salary>
        <dcode> 2 </dcode>
    </faculty>
</university>
```

XML Data Modeling. The mapping from the entity-relationship model to the XML data model is fairly straightforward. An entity becomes an *element*, and the attributes of an entity often become *subelements*. These subelements are sometimes consolidated into a complex type. Moreover, XML supports the concepts of collections including one-to-many and many-to-many relationships and references.

Like the mapping from the E–R model to the XML data model, mapping an XML schema to a relational schema is straightforward. An XML element becomes a table and it's attributes become columns. However, for an XML element that contains complex elements, key attributes must be considered depending on whether the element represents a one-to-many or many-to-many relationship.

XML Document Schema. The document type definition (DTD) language allows users to define the structure of a type of XML documents. A DTD specification defines a set of tags, the order of tags, and the attributes associated with each tag. A DTD is declared in the XML document using the !DOCTYPE tag. A DTD can be included within an XML document, or it can be contained in a separate file. If a DTD is in a separate file, say document.dtd, the corresponding XML document may reference it using:

```
<!DOCTYPE Document SYSTEM "document.dtd">
```

The following shows a part of an example DTD for a university information document:

```
<!DOCTYPE university [
        <!ELEMENT university (faculty)>
        <!ELEMENT faculty (fid name birthdate
            salary dcode)>
        <!ELEMENT fid (#PCDATA)>
        <!ELEMENT name (#PCDATA)>
        <!ELEMENT birth-date (#PCDATA)>
        <!ELEMENT salary (#PCDATA)>
        <!ELEMENT dcode (#PCDATA)>
]>
```

where the keyword # PCDATA refers to text data and its name was derived from "parsed character data."

XML Schema (8) offers facilities for describing the structures and constraining the contents of XML documents by exploiting the XML *namespace* facility. The XML Schema, which is itself represented in XML and employs namespaces, substantially reconstructs and considerably extends the capabilities supported by DTDs. XML Schema provides several benefits: It provides user-define types, it allows richer and more useful data types, it is written in the XML syntax, and it supports namespaces. The following shows an XML Schema for a university information document:

```
<xsd:schema xmlns:xsd="http://www.w3.org/
  2001/XMLschema.xsd">
<xsd:element name="university" type=
  "UniveristyType">
<xsd:elemant name="faculty">
  <xsd:complexType>
    <xsd:sequence>
      <xsd:element name="fid" type="xsd:string"/>
      <xsd:element name="name" type="xsd:string"/>
      <xsd:element name="birthdate" type="xsd:string"/>
      <xsd:element name="salary" type="xsd:decimal"/>
    </xsd:sequence>
  </xsd:complexType>
</xsd:element>
<xsd:complexType name="UniversityType">
  <xsd:sequence>
      <xsd:element ref="faculty" minOccurs="0"
maxOccurs="unbounded"/>
    </xsd:sequence>
</xsd:complexType>
</xsd:schema>
```

XML Query Language. The World Wide Web Consortium (W3C) has been developing XQuery (9), a query language of XML. XQuery uses the structure of XML and expresses queries across diverse data sources including structured and semi-structured documents, relational databases, and object repositories. XQuery is designed to be broadly applicable across many types of XML data sources.

XQuery provides a feature called a *FLWOR* expression that supports iteration and binding of variables to intermediate results. This kind of expression is often useful for computing joins between two or more documents and for restructuring data. The name *FLWOR*, pronounced "flower," came from the keywords *for*, *let*, *where*, *order by*, and *return*.

The *for* clause in a *FLWOR* expression generates a sequence of variables. The *let* clause allows complicated expressions to be assigned to variable names for simplicity. The *where* clause serves to filter the variables, retaining some result and discarding the others. The *order by* clause imposes an ordering on the result. The *return* clause constructs the result of the *FLWOR* expression.

A simple *FLWOR* expression that returns all faculty members whose salary is over $50,000 by checking the salaries based on an XML document is as follows:

```
for $x in /university/faculty/name
where $x/salary > 50000
return <fid>$x </fid>
```

where /university/faculty is a *path expression* (10) that shows a sequence of locations separated by "/". The initial "/" indicated the root of the document. The path expression /university/faculty/name would return <name>John Smith</name> <name>Perry Lee</name>. With a condition, $x/salary > 50000, the tuple <name>Perry Lee</name> is returned as the result for the above XQuery.

ADVANCED DATABASE MODELS AND LANGUAGES

Although relation, object-oriented, and object-relational databases have been used successfully in various areas, specialized databases are required for many applications. For example, in order to deal with temporal data, spatial data, and rules, we may need a temporal database, spatial database, and active database, respectively.

Temporal Database Models and Languages

Time is an important aspect of real-world applications. However, most nontemporal database models do not capture the *time-varying* nature of the problems they model. Nontemporal databases represent the current state of a database and their languages provide inadequate support for time-varying applications.

In general, a temporal database must support time points, time intervals, and relationships involving time such as *before*, *after*, and *during*. Temporal data models also need to represent time-varying information and time-invariant information separately. The temporal relational model (11) extends the relational model based on the above consideration. In this model, a database is classified as two sets of relations *Rs* and *Rt*, where *Rs* is the set of time-invariant relations and *Rt* is the set of time-varying relations. Every time-variant relation must have two time stamps (stored as attributes): time start (*Ts*) and time end (*Te*). An attribute value is associated with *Ts* and *Te* if it is valid in [*Ts, Te*].

TSQL2 is an extension of SQL92 with temporal constructs. TSQL2 allows both time-varying relations and time-invariant relations. Thus, SQL92 is directly applicable to time-invariant relations. TSQL2 has been proposed to be included as a part of SQL99. TSQL2 has a number of major temporal constructs as illustrated by the following example relation:

Faculty (fid, name, birthdate, rank, salary, Ts, Te)

where a tuple (f, n, b, *r*, s, Ts, Te) states the salary history of a faculty member whose name is n and birth-date is b.

For example, suppose that the following table stores Perry Lee's salary history:

fid	name	birth-date	rank	salary	Ts	Te
33489783	Perry Lee	12/08/55	Assistant	40000	01/01/91	12/31/97
33489783	Perry Lee	12/08/55	Associate	52000	01/01/98	12/31/02
33489783	Perry Lee	12/08/55	Full	68000	01/01/03	12/31/03

The following query retrieves Perry Lee's history in TSQL2;

Query: Retrieve Perry Lee's salary history.

```
SELECT salary
FROM Faculty
WHERE Name = 'Perry Lee'
```

Spatial Data Models and Languages

Spatial databases deal with spatial objects. For modeling spatial objects, the fundamental abstractions are *point*, *line*, and *region*. A point can be represented by a set of numbers. In a two-dimensional space, a point can be modeled as (x, y). A *line segment* can be represented by two endpoints. A *polyline* consists of a connected sequence of line segments. An arbitrary curve can be modeled as a set of polylines. We can represent a polygon by a set of vertices in order. An alternative representation of polygon is to divide a polygon into a set of triangles. The process of dividing a more complex polygon into simple triangles is called *triangulation*. Geographic databases are a subset of spatial databases created for geographic information management such as maps. In a geographic database, a city may be modeled as a point. Roads, rivers, and phone cables can be modeled as polylines. A country, a lake, or a national park can be modeled as polygons.

In nonspatial databases, the most common queries are exact match queries, in which all values of attributes must match. In a spatial database, approximations such as *nearness* queries and *region* queries are supported. Nearness queries search for objects that lie near a specified location. A query to find all gas stations that lie within a given distance of a car is an example of a nearness query. A *nearest-neighbor* query searches for the objects that are the nearest to a specified location. Region queries (range queries) search for objects that lie inside or partially inside a specified region. For example, a query to locate all the restaurants in a given square-mile area is a region query. Queries may also request intersections and unions of regions. Extensions of SQL have been proposed to permit relational databases to store and retrieve spatial information to support spatial queries as illustrated below (12):

Query: Find all gas stations within 5 miles from the current location of the car '1001'

```
SELECT g.name
FROM Gas AS g, Car AS c
WHERE c.id = '1001' and
distance (c.location , g.location) < 5
```

Table 1. Comparison of database languages

	Relational	Object-Relational	Object-Oriented	XML	Temporal	Spatial	Active
Structure	Flat table	Nested table	Class	XML document	Table with time	Table	Table with trigger
Query type	Declarative	Declarative	Procedural, Declarative	Declarative	Declarative	Declarative	Declarative
Language	SQL	SQL99	Persistent C++	XQuery	TSQL, SQL99	SQL99	SQL99
Optimization	System	System	User	System	System	System	System

ACTIVE DATABASE MODELS AND LANGUAGES

Conventional database systems are passive. In other words, data are created, retrieved, and deleted only in response to operations posed by the user or from application programs. Sometimes, it is more convenient that a database system itself performs certain operations automatically in response to certain events or conditions that must be satisfied. Such systems are called *active*. Typically, an active database supports (1) specification and monitoring of general integrity constraints, (2) flexible timing of constraint verification, and (3) automatic execution of actions.

A major construct in active database systems is the notion of *event-condition-action* (EAC) rules. An active database rule is triggered when its associated event occurs; in the meantime, the rule's condition is checked and, if the condition is true, it's action is executed. Typical triggering events include data modifications (i.e., insertion, deletion, and update), data retrieval, and user-defined events. The condition part of an ECA rule is a WHERE clause and an action could be a data modification, data retrieval, or call to a procedure in an application program. The following SQL-like statement illustrates the use of an ECA rule:

```
<EVENT>:       UPDATE Faculty
               Set salary = salary * 1.1
<CONDITION>:   salary > 100000
<ACTION>:      INSERT INTO High-paid-faculty-member
```

Several commercial relational database systems support some forms of active database rules, which are usually referred to as triggers. In SQL99, each trigger reacts to a specific data modification on a table. The general form of a trigger definition is as follows (13):

```
<SQL99 trigger>::= CREATE TRIGGER <trigger name>
                   {BEFORE|AFTER}<trigger event>
                   ON <table name>
                   [FOR EACH{ROW|STATEMENT}]
                   WHEN <condition>
                   <SQL procedure statements>
<trigger-event>::= INSERT|DELETE|UPDATE
```

where <trigger-event> is a monitored database operation, <condition> is an arbitrary SQL predicate, and <action> is a sequence of SQL procedural statements that are serially executed. A trigger may be executed BEFORE or AFTER the associated event, where the unit of data that can be processed by a trigger may be a tuple or a transaction. A trigger can execute FOR EACH ROW (i.e., each modified tuple) or FOR EACH STATEMENT (i.e., an entire SQL statement).

CONCLUSION

We have considered several modern database languages based on their underlying data models. The main criterion used to classify database languages is the data model on which they are defined. A comparison of the database languages discussed in this article is summarized in Table 1.

DATA CLASSIFICATION

INTRODUCTION

To succeed in data classification, we have to begin to survey data and usually to preprocess it to have suitable forms of data to be input to a classification program. In the following discussion, a cavalcade of focal classification methods are briefly described and shown how they can be used for an actual classification problem stemmed from medical informatics. First, a dataset and its features are introduced because these naturally have influence on the preprocessing needed and on the opportunities to apply classification methods.

An ample variety of classification methods are available that use different approaches to group objects into different classes. Discriminant analysis, cluster analysis, nearest-neighbor searching, Bayesian rule, and decision trees have been applied (1). Later, new methods have been developed such as neural networks and support vector machines (1, 2).

In the following discussion, classification algorithms are not presented thoroughly to delimit the text, but a practical view is introduced for how they can be applied to a nontrivial dataset. Numerous literary sources are available for classification methods (1–4). Instead, fewer presentations are given to explain how to exploit them for real-world data.

VARIABLES AND DATA

Variables are also called attributes or features. Although a dataset can comprise one or more variable types, most datasets consist of one variable type, usually binary, integer, or real values. The statistical convention to categorize them is very suitable: binary, nominal, ordinal, interval, or ratio scales. Actually, binary variables are a special case of nominal variables, but here a variable is called nominal if it has more than two discrete categories. The difference in interval and ratio scales is that the latter has a genuinely fixed zero point, where the quantity represented by the variable disappears. Temperature can have different scales, but length and weight have exactly one constant zero value. For classification purpose, these two are recognized as one common type.

Data can include symbolic variables, but such variable values have to be coded with numeric values in some suitable way. If only two variable values or categories are used, then the binary type is selected. For example, for the replies of a question, two alternatives “no” and “yes”, are typically encoded with 0 and 1. For more alternatives, a nominal variable is used. For instance, for “black”, “brown”, and “white”, the categories would be 0, 1, and 2. Because these values are nominal, it is important to remember which statistics can be calculated for them. For example, the mode can be determined, but not the mean. If there is an order between them, like “no symptom”, “mild”, “strong”, and “severe”, the data are encoded as an ordinal variable of categories 0, 1, 2, and 3. If we measure some phenomenon with a device understood—it could even be a mere ruler—very widely, we obtain a recording of a sample or several samples. These values form a sample sequence, which is always discrete even if it describes some continuous phenomenon recorded typically in the course of time. Such samples are of interval or ratio scale types encoded with integer or real values. We can also name the variable types as qualitative, which are binary and nominal, and quantitative, which are the others.

It is straightforward to assume a dataset to include only integers or real values and then to apply different distance measures in their computation. However, what would a difference or distance be for “black”, “brown”, or “white”? When these values are encoded with 0, 1, and 2, a difference can “technically” be computed, but it would be meaningless. The consequences of this error may be difficult to observe. Therefore, it is important to employ proper distance measures. We call a difference to be distance, but dissimilarity is used, and it is the opposite of similarity. The latter naturally requires slightly modified equations, for instance,

$$s(x,y) = 1 - ds(x,\ y)$$

in which similarity s of instances x and y is defined to be equal to 1 if they are entirely similar (i.e., identical), and 0 if they are entirely different. Dissimilarity ds is defined in the opposite way. The minimum and maximum of a distance can likewise be other than 0 and 1 (e.g., 0 and 100).

Obviously, the best-known distance measure is Euclidean distance

$$D(x,y) = \sqrt{\sum_{i=1}^{n} d(x_i,y_i)^2}, d(x_i,y_i) = \frac{|x_i - y_i|}{R_i}$$

where the differences of n variables are computed for instances x and y and where R_i is the range (the minimum subtracted from the maximum) of variable i used to normalize the absolute difference. Normalization or scaling with R_i is often, but not always, important to set all variables to the same scale. Some classification methods can be sensitive to different scales and could give more influence on variables, (e.g., with the scale of [0,100] than for those of [0,1]). It is important to remember that this distance is inappropriate for nominal variables (except binary).

For a nominal variable, an appropriate method is to calculate differences between variables with the following formula:

$$d(x_i,y_i) = \begin{cases} 1, x_i \neq y_i \\ 0, x_i = y_i \end{cases}$$

This formula determines the minimum of 0 for identical values and the maximum of 1 for different values.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Several distance measures have been designed especially for binary data (2). Perhaps the Hamming distance is the simplest measure. Let element $n_{1,1}$ be equal to the number of binary variables that have value pair $i = 1$ and $j = 1$ (i.e., both are 1), $n_{0,0}$ equal to the number of $i = 0$ and $j = 0$, and $n_{1,0}$ and $n_{0,1}$ be the opposite cases. Hamming distance is defined as the number of variables with opposite values.

$$H(i, j) = n_{1,0} + n_{0,1}$$

Several distance measures of binary data are known. The following equations are given as exemplar similarity measures: Jaccard coefficient J and Dice coefficient Di.

$$J(i, j) = \frac{n_{1,1}}{n_{1,1} + n_{1,0} + n_{0,1}}$$

$$Di(i, j) = \frac{2n_{1,1}}{2n_{1,1} + n_{1,0} + n_{0,1}}$$

We often expect no missing value, which is not always self-evident. If a person is interviewed according to a list of questions, then it is possible that some questions receive no reply. The alternatives to treat such a situation in classification are either (1) to leave out such an instance or even the whole variable or (2) to estimate the missing value somehow (5). This preprocessing step is often necessary before classification. However, some classification methods like decision trees can be programmed to cope with data with missing values, but it can mean that the program does not use the variable with a missing value at all for some decision steps, which may partly lose decision information slightly. Several missing values is a problem. If a considerable quantity of the values of individual variables is missing, then these variables can be useless, and it can be best to abandon them. The significance or usefulness of variables for classification can be important, and it is reasonable to investigate with statistical methods like correlation and statistical tests. Algorithms are used to evaluate the usefulness of variables based on their values and distributions (4, 6). “Dead” variables rarely exist, which are constant for all instances. All dead variables can be discarded self-evidently, which also decreases dimensionality.

A possible way to handle missing values is to modify a distance measure that defines a maximum difference when one or both values are unknown or missing. This “pessimistic” method assumes the worst case (i.e., the farthest distance). For binary and nominal variables, it can be as follows:

$$d(x_i, y_i) = \begin{cases} 1, x_i \neq y_i \\ 1, x_i \text{ or } y_i \text{ unknown} \\ 0, x_i = y_i \end{cases}$$

For quantitative variables we could use the following definition:

$$d(x_i, y_i) = \begin{cases} \dfrac{|x_i - y_i|}{R_i} \\ 1, x_i \text{ or} y_i \text{ unknown} \end{cases}$$

where range R_i (the minimum subtracted from the maximum) of variable i is used as above.

A dataset may contain several types of variables. Distance measures are used for these variables. For instance, a heterogeneous Euclidean-overlap metric (7) uses the preceding $d(x_i,y_i)$ values and the above formula $D(x,y)$. In fact, this measure is not metric but pseudometric, because distance $D(a,a) = 0$ for the case of instance a is not true if it includes missing values. The other conditions required that a measure be a metric for instances a, b, and c are $D(a,b) > 0$, if $a \neq b$, $D(a,b) = D(b,a)$, and $D(a,c) \leq D(a,b) + D(b,c)$ (triangular inequality). The metric property is very useful for the purpose of distance computation; but even without it, we can come through, even with a more limited selection of computational methods.

A DATASET

In the following discussion, we consider a medical dataset of vertiginous patients to show how it is prepared for classification and how the methods selected classify its instances. Medical data are interesting, because their classification is often a complicated and elaborate task. Often, several different types of data are present in such a dataset. Vertigo or dizziness and other balance disorders are a common nuisance and can be symptoms of a serious disease. These problems are investigated in otoneurology (8) to find their causes, to devise new treatments, and to prevent possible accidents originated from such harms. For this purpose, computational classification methods can be used to identify a patient’s disease and to separate disease instances from each other.

The dataset consisted of 815 patient cases, whose diagnoses were made by two specialists in otoneurology. Six diseases appeared with frequencies as follows: 130 vestibular schwannoma cases (16%), 146 benign positional cases (18%), 313 Menière’s disease cases (38%), 41 sudden deafness cases (5%), 65 traumatic vertigo cases (8%), and 120 vestibular neuritis cases (15%). In all, 38 variables were discovered among patients’ symptoms, medical history, and clinical findings (Table 1). These variables were found to be the most important of a larger variable set in our research (8) and fairly infrequently contained missing values. Overall, 11% of values were missing in the whole dataset. They were imputed or substituted using modes for 11 binary variables and 1 nominal variable and using medians for 10 ordinal and 16 quantitative variables. The mean could have been applied to the quantitative variables, but as known from statistics, in principle, it is a poorer central tendency estimate under the circumstances of scarce data or biased-value distributions. The only genuine nominal (four-valued) variable [14] in Table 1 was still substituted by three binary variables to enable the use of a Euclidean measure in its strictest way. As mentioned, the Euclidean measure cannot be applied to nominal attributes. When its four values were “no hearing loss”, “sudden”, “progressive”, and “both disorders”, the last three corresponded to new three binary variables with value 1. If all of them were equal to 0, then it was the same as “no hearing loss” of the original variable. Thus, we had 40 variables altogether.

Table 1. Variables and their Types: B = Binary, N = Nominal, O = Ordinal, and Q = Quantitative; Category Numbers After the Nominal and Ordinal

Variable	Type	Variable	Type	Variable	Type
[1] patient's age	Q	[14] hearing loss type	N 4	[27] caloric asymmetry %	Q
[2] time from symptoms	O 7	[15] severity of tinnitus	O 4	[28] nystagmus to right	Q
[3] frequency of spells	O 6	[16] time of first tinnitus	O 7	[29] nystagmus to left	Q
[4] duration of attack	O 6	[17] ear infection	B	[30] pursuit eye movement amplitude gain %	Q
[5] severity of attack	O 5	[18] ear operation	B	[31] and its latency (ms)	Q
[6] rotational vertigo	Q	[19] head or ear trauma with noise injury	B	[32] audiometry 500 Hz right ear (dB)	Q
[7] swinging or floating vertigo or unsteadiness	Q	[20] chronic noise exposure	B	[33] audiometry 500 Hz left ear (dB)	Q
[8] Tumarkin-type drop attacks	O 4	[21] head trauma	B	[34] audiometry 2 kHz right (dB)	Q
[9] positional vertigo	Q	[22] ear trauma	B	[35] and left ear (dB)	Q
[10] unsteadiness outside attacks	O 4	[23] spontaneous nystagmus	B	[36] nausea or vomiting	O 4
[11] duration of hearing symptoms	O 7	[24] swaying velocity of posturography eyes open (cm/s)	Q	[37] fluctuation of hearing	B
[12] hearing loss of right ear between attacks	B	[25] swaying velocity of posturography eyes closed (cm/s)	Q	[38] lightheadedness	B
[13] hearing loss of left ear between attacks	B	[26] spontaneous nystagmus (eye movement) velocity (°/s)	Q		

Imputation was carried out class by class, it was important to follow class-wise variable distributions because it is essential that differences exist between classes, which is actually the ground of any classification. Using modes and medians in imputation is straightforward but sufficient in this case, because the number of the missing values was pretty small. We observed (10) that the more sophisticated techniques of linear regression and the Expectation-Maximization algorithm (11) gave no better results while using discriminant analysis for the classification of otoneurological data. Of course, such a property of missing values is not common. Each dataset has its own peculiarities that must be analyzed before classification (12).

Often, numbers that describe the central tendency, for example, modes for binary and nominal variables and medians or means for other variable types, are used to impute data. It is realistic to assume that the data are missing at random (11) (i.e., the missing values of a variable may depend on the values of other variables, but not on the values of the variable itself). Then likelihood-based methods, such as the Expectation-Maximization method, are appropriate. Linear regression and nearest-neighbor estimator (11) are also used for imputation.

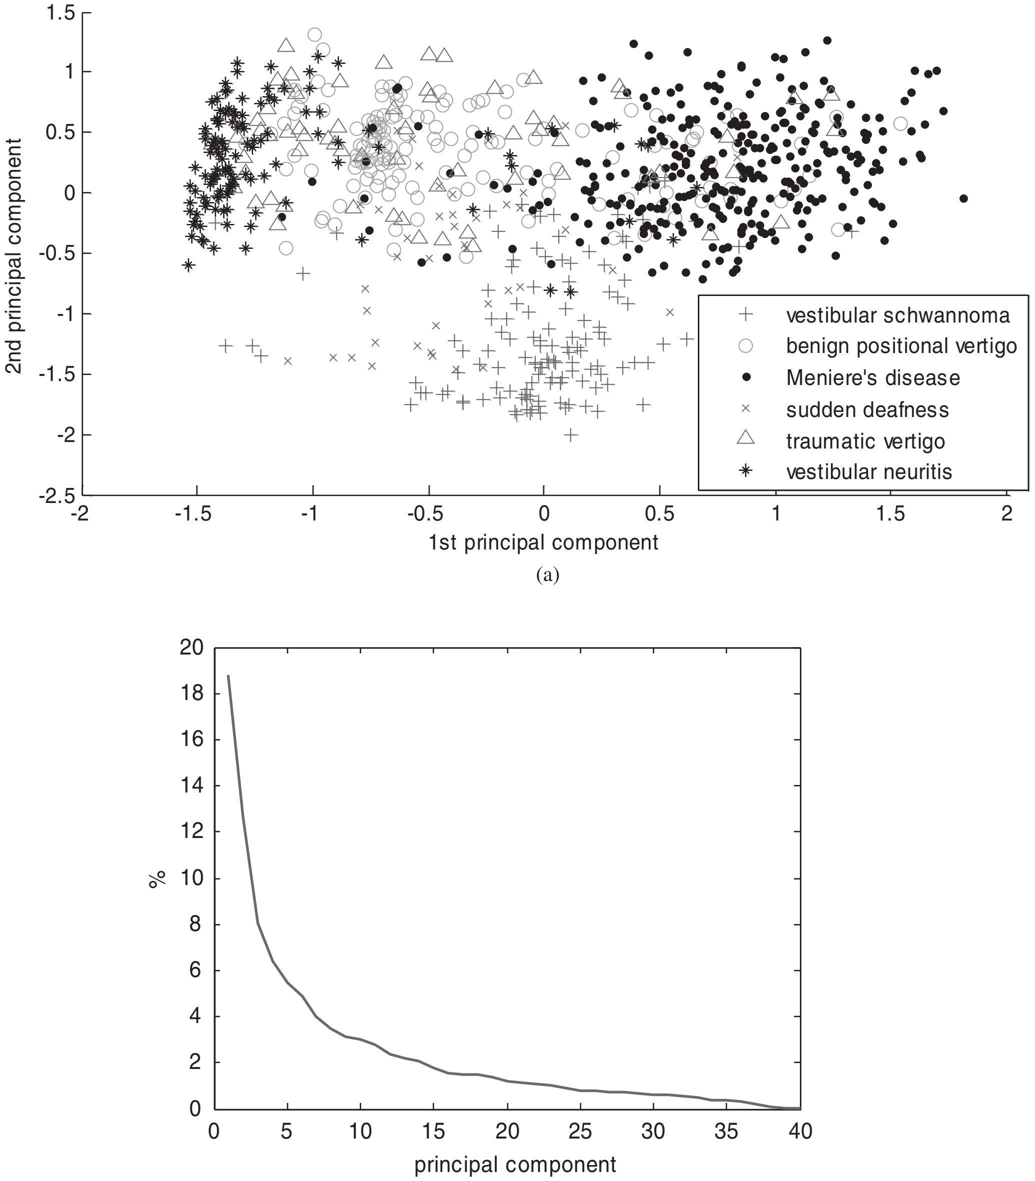
Outliers (1, 13) are data that are exceptional or inconsistent with other values of one or more variables. They are often some measurement or input errors. They can usually be revealed considering variable distributions. In the current dataset of vertiginous patients, 14 subjects were originally used, whose data included zero ages. This was observed on the basis of the distribution of age variable (1) (Table 1). Because it was surely known for the sake of medical reasons that the data could not contain ages below six years, these values were erroneous. If such values had not been corrected. then these patient cases should have been eliminated from the dataset.

The subset of Menière's disease was essentially larger than two small subsets of sudden deafness and traumatic vertigo. This imbalanced class distribution is an ordinary nuisance in actual datasets. It is a difficulty for some classification methods, at least for multilayer perceptron neural networks. Because neural networks are learning methods, they may learn majority classes and lose minority classes.

Principal component analysis (1, 2, 13, 14) is often used to reduce a high dimensionality. It can be also applied to visualize data distribution crudely between different classes. It can be understood as a rotation of the axes of the original coordinate system to a new system of orthogonal axes ordered in terms of the magnitude of variation that they account for in the original data. Forty principal components were computed from the original data. The most important two components are shown in Fig. 1(a), which indicates that the six disease classes are more or less divided into separate areas, which is essential for classification. Their importance was calculated on the basis of their eigenvalues [Fig. 1(b)], which explained 31.5% of data variance with the two first principal components. The principal components slowly decreased down to almost zero while advancing to the fortieth component. Including no clear abrupt decrease between the successive eigenvalues, this indicated that it was not sensible to reduce the dimensionality of the data, but almost all 40 components included useful information.

CLASSIFICATION METHODS AND THEIR TESTING

The following methods are examined and compared with the given dataset: Bayesian decision rule, k–nearest-neighbor searching, discriminant analysis, k-means clustering, decision trees, multilayer perceptron neural networks, Kohonen networks (self-organizing maps), and support-vector machines. All implementations were programmed with Matlab using various values of control parameters like numbers of clusters or network hidden nodes.



(a)

(b)

Figure 1. (a) The data distribution of the vertiginous patient cases into six classes according to the two first principal components. (b) Eigenvalue spectrum (in percents) of 40 principal components as the ratio between each eigenvalue and the sum of all eigenvalues.

Maybe the simplest classification method is based on conditional probabilities determined by Bayesian rule

$$p(c_{k|}\,\mathbf{x}) = \frac{p(\mathbf{x}|c_k)p(c_k)}{\sum\limits_{i=1}^{k} p(\mathbf{x}|c_i)p(c_i)}$$

in which the formula estimates the probability of class c_k given instance (vector of variables) $\mathbf{x}$. Altogether, there are K classes whose a priori probabilities $p(c_i)$ are known or estimated from data. Actually, the formula is based on finding all identical instances in each class and counting the numbers of such identical instances. Unfortunately, there were several variables (40), and it was then very improbable that there would be any identical instances. An additional difficulty was that there were some real (continuous) variables that make it virtually impossible to find any identical instances. Thus, there were none in our dataset.

We can sometimes attempt to bypass the preceding problem by means of discretization of quantitative variables. Although it is not important in the current context, it can be useful for such classification or other data-analysis methods that provide discrete integer values. Several algorithms for this purpose can divide the range of a variable into uniform intervals (e.g., 10 intervals). More sophisticated techniques function on the basis of the value distribution of a variable (6). We could apply another way, which is often a good and reliable choice: the use of expert knowledge. Two experienced otoneurologists defined 2–5 suitable values for the quantitative variables in Table 1: [1], [6], [7], [9], [24]–[35]. For instance, they discretised the audiometric variables of [32]–[35] with 5 values: 0 for hearing decrease of 0–15 dB (normal hearing), 1 for 16–30 dB (slight hearing loss), 2 for 31–60 dB (moderate hearing loss), 3 for 61–90 dB (severe hearing loss), and 4 for 91–120 dB (deaf). The specialists' discretization is not possible if hundreds or more variables are used.

Notwithstanding discretization, no identical instances were encountered in the current dataset. This result is understandable because there were 40 variables. If all the variables were binary (i.e., including the minimum of categories per variable), then there would be $2^{40} = 1024^4$ different permutations of variable values. Consequently, identical instances would be very improbable; thus, we gave up the current discretization and returned to the original data of 40 variables and applied the Bayesian rule (13, 14) in a more sophisticated manner as follows. Let us assume that a normal distribution underlies every variable. We computed the Bayesian decision rule for the q-dimensional ($q = 40$) Gaussian (normal) distribution (3), which gives the probability for instance vector $\mathbf{x}$ provided class $c_j, j = 1, \ldots, 6,$ when mean $\mathbf{s}_j$ and covariance matrix $\sum_j$ were computed from the instances of class j of a training set.

$$p(\mathbf{x}|c_j) = 2\pi^{-\frac{q}{2}} \left|\sum_j\right|^{-\frac{1}{2}} \exp\left(-\frac{1}{2}(\mathbf{x}-\mathbf{s}_j)^T \sum_j^{-1}(\mathbf{x}-\mathbf{s}_j)\right)$$

Let $p(c_j)$ be the probability of class j. The Bayesian decision rule then predicted class j for test case $\mathbf{x}$ if

$$p(\mathbf{x}|c_j) > \frac{p(c_k)}{p(c_j)}\, p(\mathbf{x}|c_k)$$

for all $k \neq j, k$ in $\{1, \ldots, 6\}$.

Nonetheless, data matrices required by Bayesian rule were singular for the current dataset because they incorporated such variables that included purely zeroes for some classes (not for the whole data). These crucial variables were impossible to eliminate. Singular matrices would rule out their inversions required. If no singular matrices occur that highly depend on data, the naïve Bayesian method can give good results.

A crude way is to ignore dependence between variables, which is not made above. If we assume them to be independent, then we obtain the following joint probability.

$$p(\mathbf{x}|c_j) = p(x_1, \ldots, x_n|c_j) = p(c_j)\prod_{i=1}^{n} p(x_i|c_j)$$

Independent conditional probabilities $p(x_i|c_j)$ can be estimated from data. Because this computation includes no iterative training algorithm, its execution is normally far faster than those of machine learning methods that will be dealt with subsequently. By allowing one or more dependences between variables, frequently efficient Bayesian networks (1) can be formed. However, these networks are skipped here.

To test classification methods, we need training and testing sets that are independent of each other but extracted from the same data source. If such a data source encompassed virtually almost unlimited number of data, we would extract many separate training and test sets. A training set is used to train a classification algorithm programmed, and the corresponding test set is used to test its capability to classify correctly. Several training and test-set pairs are necessary to justify statistically a final conclusion about the capability of the method. Inasmuch as we survey actual datasets, the preceding ideal circumstances are infrequently met. Therefore, we have to use more complicated techniques to infer statistical evidence about tests. One common way is to employ cross-validation.

We divided our dataset of N instances into 10 pairs of a learning subset (90% of instances) and a test subset (10%) in accordance with 10-fold cross-validation, so that every instance was incorporated in exactly one test set. The selection into the subsets was performed randomly, but in accordance with the class distribution. In other words, when the frequency of Menière's disease was 38% in our dataset, the same approximate proportion was preserved in all training and test sets. Most classification methods involve random initializations. Therefore, 10 runs for each crossvalidation pair and 100 runs altogether were repeated with an exception. Two test and training set pairs were discarded for discriminant analysis, because they consisted of matrices, which were not positive definitive (i.e., their processing could not be continued). Accordingly, 80 runs were executed for it. The same pairs of training and test sets were applied to all classification methods to be presented.

Other ways to test with a restricted dataset are leave-one-out and bootstrapping (4). In the former, each instance is used alternately as a single test set, and the other instances are used as the corresponding training set. In a way, this method is the extreme N-fold cross-validation situation, where the size of every training set is maximal in accordance with the principle that such a training set is statistically as representative as possible. The latter efficiently exploits random sampling, in which extracted instances are returned to the dataset for the later process, (i.e., they are replaced, which is not done in cross-validation).

Means and standard deviations can be calculated for sensitivity, specificity, positive predictive value, and accuracy. Let us define *tp* as the number of true positive classifications, *fn* the number of false-negative classifications, *fp* as the number of false-positive classifications, and *tn* as the number of true negative classifications. Their sum is naturally equal to the whole number N of instances. The term "positive" now means that some certain disease class is predicted to an instance. It is either true or false, depending on the matter whether this instance really belongs to the predicted class. The term "negative" means that an instance is classified into some other than the certain class, either correctly or incorrectly.

Table 2. Means and Standard Deviations of Nearest-Neighbor Searching (%) for 100 Test Runs

Number of Neighbors	Static	Vestibular Schwannoma	Benign Positional Vertigo	Menière's Disease	Sudden Deafness	Traumatic Vertigo	Vestibular neuritis
1-nearest	Sensitivity	88.5 ± 9.8	80.7 ± 19.7	87.6 ± 6.5	92.5 ± 12.1	82.6 ± 19.7	86.7 ± 13.1
	Accuracy	96.4 ± 1.6	91.8 ± 3.6	90.4 ± 4.8	99.4 ± 1.0	97.8 ± 2.2	96.6 ± 2.1
3-nearest	Sensitivity	89.2 ± 10.4	77.3 ± 23.6	87.9 ± 5.6	92.5 ± 12.1	78.8 ± 16.5	84.2 ± 13.9
	Accuracy	96.0 ± 2.5	91.2 ± 4.3	89.6 ± 5.2	99.4 ± 1.0	97.6 ± 2.4	96.5 ± 2.5
5-nearest	Sensitivity	79.2 ± 16.2	83.3 ± 18.9	89.5 ± 5.8	90.5 ± 12.3	80.2 ± 16.4	90.0 ± 11.7
	Accuracy	96.4 ± 2.7	92.2 ± 3.4	89.1 ± 6.0	99.4 ± 0.9	97.9 ± 1.7	97.1 ± 2.2
weighted	Sensitivity	88.5 ± 10.4	77.3 ± 23.6	87.9 ± 5.6	92.5 ± 12.1	84.5 ± 15.2	84.2 ± 13.9
3-nearest	Accuracy	95.8 ± 2.7	91.6 ± 4.3	89.5 ± 5.2	99.4 ± 1.0	98.0 ± 2.3	96.5 ± 2.5
weighted	Sensitivity	79.2 ± 16.2	82.7 ± 19.4	90.1 ± 6.1	92.5 ± 12.1	83.1 ± 15.8	90.8 ± 11.4
5-nearest	Accuracy	96.5 ± 2.6	92.5 ± 3.3	89.6 ± 5.3	99.5 ± 0.9	98.0 ± 1.7	97.1 ± 2.2

Sensitivity is given as the ratio:

$$sens = \frac{tp}{tp + fn} 100\%$$

Specificity is defined as the formula:

$$spec = \frac{tn}{tn + fp} 100\%$$

Positive predictive value is equal to:

$$ppv = \frac{tp}{tp + fp} 100\%$$

Accuracy is as follows:

$$a = \frac{tp + tn}{tp + tn + fp + fn} 100\% = \frac{tp + tn}{N} 100\%$$

In the following discussion, sensitivity and accuracy are given to delimit the number of results presented. Other validation quantities are applied to testing, but many of them, [e.g., negative predictive value, receiver operating characteristic (ROC) curves, and area under ROC curves (AUC)], are related to the aforementioned basic quantities. In addition, some quantities are unsuitable for multiclass circumstances; instead, they are meant for two-class classification. These terms are used commonly in medical informatics. Elsewhere various terms can be used, often for the same concepts. For instance, recall and precision are used. The former is equivalent to sensitivity, and the latter is equal to positive predictive value.

Nearest-neighbor searching techniques (1, 2, 13, 14) are straightforward. They are heuristic, which means that nothing guarantees that a correct solution is found. Despite this theoretical concept, they can function efficiently in practice. They search for the nearest instance from the training set and label a test instance according to the class of the nearest neighbor. Neighbors can be weighted, for example, using the inverse of the distance between the test instance and the near instance next to be processed. The nearer the training case is to the test case, the greater weight is given it. We computed tests of nearest-neighbor searching for one, three, and five nearest neighbors using Euclidean metric. Their average results are presented in Table 2. An increase of nearest neighbors k did not improve otherwise satisfactory results, which is possible depending on the data. The results of vestibular schwannoma and benign positional vertigo varied depending on k, which represents that their instances were mixed erroneously between the two classes. The weighted nearest-neighbor searching produced similar results. When the accuracy value of each class was weighted with its number of the instances, mean weighted accuracies were as follows: 93.5 ± 2.3, 93.0 ± 2.9 and 93.2 ± 2.8% for k equal to 1, 3, and 5, and 93.1 ± 2.9 and 93.5 ± 2.8% for the weighted versions of k equal to 3 and 5. When all means are considerably high and standard deviations are small, these examples show how this simple method classified this complicated data.

In discriminant analysis (13, 14), the aim is to split the variable space including all instances so that its parts represent the different classes. Bounds between such parts discriminate the classes to separate regions. The simplest choice is linear discriminant analysis, which is also run for the current dataset by applying the Euclidean metric. Its results are characterized in Table 3. This analysis was exceptionally successful for the class of sudden deafness, which can be hard to distinguish medically because it is the smallest class. The other classes were also detected successfully. A mean weighted accuracy of 95.5 ± 1.8% was obtained.

Table 3. Means and Standard Deviations of Linear Discriminant Analysis (%) for 80 Test Runs

Static	Vestibular Schwannoma	Benign Positional Vertigo	Menière's Disease	Sudden Deafness	Traumatic Vertigo	Vestibular Neuritis
Sensitivity	87.5 ± 8.6	87.5 ± 15.5	89.6 ± 4.8	100.0 ± 0.0	90.5 ± 13.3	95.8 ± 8.4
Accuracy	97.5 ± 1.5	93.2 ± 2.4	93.4 ± 3.1	99.5 ± 0.6	98.8 ± 1.2	98.2 ± 1.7

Table 4. Means and Standard Deviations of k-means Clustering (%) for 100 Test Runs

Number k of Clusters	Static	Vestibular Schwannoma	Benign Positional Vertigo	Menière's Disease	Sudden Deafness	Traumatic Vertigo	Vestibular Neuritis
6	Sensitivity	81.2 ± 14.2	66.2 ± 33.4	92.8 ± 7.3	12.0 ± 32.7	53.8 ± 44.4	84.8 ± 20.2
	Accuracy	93.7 ± 3.2	88.1 ± 6.0	88.0 ± 6.7	95.5 ± 1.6	95.3 ± 3.4	94.9 ± 5.1
8	Sensitivity	80.5 ± 15.0	70.1 ± 29.9	93.1 ± 6.5	41.5 ± 48.4	78.1 ± 30.2	86.9 ± 14.6
	Accuracy	94.6 ± 3.2	91.4 ± 5.0	88.3 ± 6.2	97.0 ± 2.3	97.0 ± 3.1	96.2 ± 4.0
12	Sensitivity	80.8 ± 13.1	71.7 ± 28.5	93.3 ± 6.2	68.3 ± 40.0	87.2 ± 16.3	86.3 ± 14.4
	Accuracy	95.7 ± 2.7	92.5 ± 4.9	88.7 ± 6.2	98.2 ± 2.1	97.8 ± 2.6	96.4 ± 3.2
20	Sensitivity	81.2 ± 13.3	74.9 ± 26.0	91.2 ± 8.1	88.8 ± 17.5	85.7 ± 18.4	87.2 ± 13.6
	Accuracy	96.0 ± 2.4	92.3 ± 5.4	88.6 ± 6.4	99.3 ± 1.0	97.9 ± 2.2	96.8 ± 2.2
30	Sensitivity	83.0 ± 13.9	74.8 ± 25.4	90.3 ± 9.0	87.5 ± 17.9	83.9 ± 17.9	85.8 ± 13.5
	Accuracy	96.4 ± 2.5	91.4 ± 5.8	88.7 ± 6.5	99.2 ± 1.0	97.6 ± 2.6	96.7 ± 2.5

By attempting to apply Mahalanobis (generalized Euclidean metric) or quadratic discriminant function, discriminant analysis suffered from the similar complication of unsatisfying the requirement of positive-definite matrices as the naïve Bayesian rule.

Clustering (1, 2, 13, 14) is an old technique to group instances by computing distances between instances and assigning them to separate groups or clusters on the basis of the mutual distances between clusters and between instances. Many ways can be used to compute distances between clusters and between instances (1, 3). Table 4 introduces results yielded by k-means clustering with Euclidean metric; from the results, several values of k five alternatives are given. Here, as with most other methods, more variations were computed to find proper limits of classifier structures, for instance, for k in clustering. We present conditions with small system-parameter values of k here and then increase it to reasonably large values related to the methods and to the numbers of instances and variables. The minimum of the clusters was six, which is the same number of the classes. Apart from sudden deafness, the number k of clusters between 12 and 40 produced equally high average results. For sudden deafness, 20 clusters sufficed to evolve sensitivities up to 89%. Benign positional vertigo remained the poorest recognized class here. Mean weighted accuracies of 90.9 ± 3.8, 92.8 ± 3.5, 92.9 ± 3.6, and 92.8 ± 3.7% were achieved for k equal to 6, 12, 20, and 30.

A decision tree (2, 12) selects a variable, which, at the current stage of process, best divides instances between classes and sets the variable to the next node built in the tree. Such an evaluation of variables is based on various principles of information theory. We exploited the pruning leaves of decision trees to estimate the best tree size according to residual variance. The best size gained was 36.2 leaves on average. As to the current data, decision trees were not effective for benign positional vertigo and especially sudden deafness (Table 5), although their variances were large (i.e., some trees were good but others were poor). This evaluation stemmed from a special situation that variable [14] named 'hearing loss type' in Table 2; is this variable crucial for sudden deafness. Thus, decision trees often "raised" it high in their process, in which variables are chosen according to criteria based on their information theoretic values. Unfortunately, in this specific data, lots of values were missing for this variable, in which for the six diseases 88%, 54%, 59%, 15%, 34%, and 62% of the values were absent. Altogether, 53% of all values of variable (14) were missing. Although sudden deafness was the best of all with only 15% of data missing, the others suffered from too many missing values. Note that the missing values were imputed, but because of their high numbers, most instances received the same mode within each class. In this method, the variable did not aid separate instances successfully. Therefore, decision trees occasionally misclassified data, whereas other methods were not so dependent on single variables, because their computation approaches were different. A mean weighted accuracy of 89.4 ± 2.5% was gained for the decision trees.

Multilayer percepton networks (12–17) could not classify the dataset tending to put most cases to the largest Menière's disease class and to lose the two smallest classes entirely. Hence, principal component analysis (1) was first computed as described at the end of the third section, using transformed values according to all 40 principal components as input data. Its main role is to reduce the dimensions of highly variable numbers. In a way, via its coordinate system, transform data are rearranged to a more appropriate form. Here, the idea was not to decrease the number of variables, but to use its rearrangement. Every perceptron network comprised 40 input nodes for principal components and 6 output nodes after the diseases. The only free parameter in the network topology was the number of hidden nodes. Adaptive learning and momentum coefficient were used with the backpropagation training algorithm, which was to run no more than 200 epochs to

Table 5. Means and Standard Deviations of Decision Trees (%) for 100 Test Runs

prevent overlearning. Overlearning means learning continued too long so that the weights of the network start to adapt to random noises present in the data. Tests were conducted using 4–16 hidden nodes. A recommendation states that the number of connections (weights) in a perceptron neural network should not be greater than one tenth of a training set, so that efficient learning would succeed (1, 17). Nevertheless, the networks with 6–16 hidden nodes produced valid results (Table 6). Benign positional vertigo was the most difficult to detect. Mean weighted accuracies of 92.9 ± 3.5%, 94.9 ± 2.9%, 95.0 ± 3.0%, and 95.0 ± 2.9% were achieved for 4, 6, 10, and 16 hidden nodes.

Kohonen neural networks (13–17) were run varying their sizes from 3 × 3 to 10 × 10 nodes. A hexagonal neighborhood pattern was employed as the topological structure with link distance. For every network, 400 learning epochs were completed. According to the results, 7 × 7 nodes were sufficient for the current data, and data as small as 5 × 5 nodes were available for the other than sudden deafness. Table 7 includes a breakdown for four network sizes. Benign positional vertigo and sudden deafness obtained slightly poorer results compared with the remaining four classes. Mean weighted accuracies of 90.3 ± 3.7%, 92.1 ± 3.5%, 92.7 ± 3.3%, and 92.7 ± 3.3% were attained for these networks.

Support vector machines (1, 13) map data nonlinearly to a multidimensional space where it can be linearly classified. Kernel functions are used to decrease the number of computation needed in optimization. We employed two-degree radial basis and polynomial functions as kernels (Table 8). Their mean weighted accuracies were 93.8 ± 2.3% and 93.7 ± 2.3%. Linear and Gaussian kernels did not facilitate reasonable outcomes.

The running time (100 tests with a 2.6-GHz processor) of discriminant analysis was approximately 10 seconds. They were 23–104 seconds for clusterings, 68–90 seconds for nearest-neighbor searchings, 5 minutes 30 seconds for decision trees and multilayer perceptron networks, 23–29 hours for Kohonen networks and 2–3 minutes for support vector machines. Because these were slow Matlab programs and not optimized at all, running times could naturally be decreased. Although Kohonen networks were very slow, it is worth noting that the training phase took most of the time. In classification, however, training is seldom necessary in actual applications, because a trained classifier is run mostly to classify, not to test its effectiveness.

Table 8. Means and Standard Deviations of Support Vector Machines (%) for 100 Test Runs

Type	Static	Vestibular Schwannoma	Benign Positional Vertigo	Menière's Disease	Sudden Deafness	Traumatic Vertigo	Vestibular Neuritis
Radial basis	Sensitivity	86.9 ± 8.5	80.7 ± 17.8	92.7 ± 3.8	92.5 ± 11.5	80.2 ± 18.1	83.3 ± 14.0
	Accuracy	96.9 ± 1.3	94.3 ± 2.6	89.9 ± 4.0	99.4 ± 0.6	97.3 ± 2.5	96.6 ± 2.2
Polynomial	Sensitivity	83.8 ± 11.2	79.3 ± 19.8	94.2 ± 3.8	92.5 ± 11.5	83.6 ± 17.9	82.5 ± 14.7
	Accuracy	96.6 ± 1.7	94.5 ± 3.1	89.4 ± 3.9	99.4 ± 0.6	97.9 ± 2.3	96.6 ± 2.2

CONCLUSION AND SUMMARY

By adopting the best results from Tables 2–8, simple linear discriminant analysis was the best method by correctly classifying with the mean weighted accuracy of 95.5%, and decision trees yielded the poorest results of 89.4%. Statistically significant differences between the most of the methods were found according to t test (0.001 significance level). The results of individual disease classes varied between the methods and between the classifier structures (table rows). The results typically become more reliable when a structure was extended. Such an increase cannot be continued further, since the size of training sets was limited. Naturally, results always depend on data. Another dataset could result in different outcomes. No general conclusion between the methods could be drawn according to the computations of merely one dataset. Their motivation was to demonstrate actual applications.

Methods other than multilayer perceptron networks did not benefit from using principal components as input because the results were very reliable. For linear discriminant analysis, the results were identical independent of this preprocessing for the sake of its linear character as is also in principal component analysis.

This article focused on a practical approach to how classification methods can be applied to a complicated dataset. Data preprocessing was emphasised because this sector is often neglected or ignored, which, nevertheless, is crucial for successful classification.

To observe the classification algorithms in detail, the attached book references are a good start.

DATA COMMUNICATION

INTRODUCTION

This chapter considers data communication as the data exchange process between devices linked directly by a transmission medium with or without multiaccess, and without intermediate switching nodes. The scope of discussion is confined to the physical and data link layers in the Open Systems Interconnection (OSI) reference model.

The physical layer focuses on the exchange of an unstructured data bit stream via modulated electromagnetic signals (i.e., electrical and optical) transmission over a physical link channel. Modulation determines the spectral efficiency or the ratio of transmitted data bit rate to the signal bandwidth. Data bits may be received in error when signal waveforms are impaired by channel noises. Long-distance transmission involves signal propagation and regeneration by repeaters. Unlike analog transmission, digital transmission must recover the binary data content first before regenerating the signals. The physical layer specifies the mechanical and the electromagnetic characteristics of the transmission medium, and the access interface between the device and the transmission medium. Transmission between two devices can be simplex (unidirectional), full-duplex (simultaneous bidirectional), or half-duplex (bidirectional but one direction at a time).

The data link layer is concerned with the exchange of structured data bit stream via frames over a logical link channel with error recovery control to optimize link reliability. Channel coding adds structured redundancy to the data bit stream to enable error detection or error correction. Each frame consists of data payload and control overhead bits, which convey control procedures between sending and receiving devices. Link control procedures include flow control, error recovery, and device addressing in multiaccess medium.

Elements of Data Communication System

Figure 1 illustrates the elements of a data communication system. The elements include digital source, digital sink, transmitter interface, receiver interface, and physical medium of a communication channel.

The digital source consists of data source and source encoder. The *data source* generates either an analog signal (e.g., audio, video), or a digital data stream (sequence of discrete symbols or binary bits stored in computing memory) to the source encoder. The analog-to-digital converter (ADC) converts an analog signal to a digital data stream of bits through discrete sampling and quantization of the analog signal. Common ADC schemes include pulse code modulation (PCM) that maps each sampled signal-amplitude to a digital data, and delta modulation (DM) that maps the change from the previous sampled value to a digital data.

The *source encoder* employs data compression coding to reduce data redundancy and communication capacity requirements for more efficient data transmission over the communication channel. Lossless compression algorithms (e.g., Huffman) result in decompressed data that is identical to the original data. Lossy compression algorithms (e.g., discrete cosine transform, wavelet compression) result in decompressed data that is a qualified approximation to the original data. Information theory defines the compression ratio limit without data information loss for a given data stream (1).

The transmitter interface consists of the channel encoder and the signal waveform generator in the form of a digital modulator. The *channel encoder* employs error-detection or error-correction coding to introduce structured redundancy in digital data to combat signal degradation (noise, interference, etc.) in channel. The *digital modulator* enables baseband or passband signaling for digital data. The digital baseband modulator maps the digital data stream to the modulated pulse train of discrete-level digital signals. The digital passband modulator maps the digital data stream to the modulated sinusoidal waveform of continuous-level analog signals.

The transmitted digital or analog signals propagate through the physical medium (wire or wireless) of a communication channel. Signal transmission impairments can be caused by the attenuation of signal energy along propagation path, delay distortions because of the propagation velocity variation with frequency, and noises because of the unwanted energy from sources other than transmitter. Thermal noise is caused by the random motion of electrons. Cross talk noise is caused by the unwanted coupling between signal paths. Impulse noise is a spike caused by external electromagnetic disturbances such as lightning and power line disturbances.

The receiver interface consists of the channel decoder and the signal waveform detector or digital demodulator. The *digital demodulator* converts the incoming modulated pulse train or sinusoidal waveform to a digital data stream with potential bit errors incurred by signal transmission impairments. The *channel decoder* detects or corrects bit errors in received data.

The digital sink consists of a source decoder and a data sink. The *source decoder* maps incoming compressed digital data into original digital data transmitted by the data source. The digital-to-analog converter (DAC) converts a digital data stream to an analog signal. The *data sink* receives either an analog signal or a digital data from the source decoder.

PHYSICAL LAYER

Communication Channel

The physical medium of a communication channel is used to transmit electromagnetic signals from the transmitter to the receiver. The physical media can be either guided media for wired transmission, or unguided media for wireless transmission. A signal that propagates along a guided medium is directed and is contained within a physical conductor. An unguided medium transports signal without using a physical conductor.

Guided media include twisted-pair cable, coaxial cable, and optical fiber. Figure 2 shows the electromagnetic spectrum used by wired transmission in these guided media. Consisting of two insulated copper conductors twisted together; twisted-pair cables commonly are used in subscriber loops to telephone networks. Coaxial cable consists of an inner solid wire conductor surrounded by an outer conductor of metal braid, with an insulting ring between the two conductors. Coaxial cables are used widely in cable TV networks, local area networks, and long-distance telephone networks. Coaxial cable offers a larger bandwidth and less interference or crosstalk than that of twisted-pair cable.

Consisting of a thin glass or plastics central core surrounded by a cladding layer, optical fiber transports light signal through the core by means of reflection. Optical fiber offers a wider bandwidth, lower attenuation, and lighter weight than that of coaxial or twisted-pair cables. The wider bandwith is achieved at a relatively higher cost. Optical fiber cables commonly are used in backbone networks and in long-haul undersea links because its wide bandwidth is cost effective.

Unguided media include the air atmosphere, outer space, and water. Wireless transmission and the reception of electromagnetic signals in unguided media are accomplished through an antenna. For unidirectional wireless transmission, the transmitted signal is a focused electromagnetic beam and the receiving antenna must be aligned properly for signal reception. For omni-directional wireless transmission, the transmitted signal spreads out in all directions to enable reception by many antennas. Antenna size depends on the operating frequency of electromagnetic wave (2).

Wireless transmission in the air medium commonly is classified according to the operational frequency ranges or bands of the electromagnetic signals. These signals include radio waves that range from 3 KHz to 1 GHz, microwaves that range from 1 GHz to 300 GHz, and infrared waves that range from 300 GHz to 400 THz. Radio waves mostly are omni-directional; these waves are appropriate for multicasting or broadcasting communication. Their applications include AM and FM radio, television, and cordless phones. Microwaves are unidirectional and are appropriate for unicast communication. Their applications include cellular, satellite, and wireless local area networks. Infrared waves are unidirectional and cannot penetrate physical barriers, thus they can be used for short-range unicast communication. Their applications include communications between computers and peripheral devices such as keyboards, mice, and printers. Figure 2 shows the electromagnetic spectrum used by wireless transmission in the air medium.

Channel capacity is the maximum rate at which data can be transmitted over a medium, using whatever means, with negligible errors. For binary digital data, the transmission rate is measured in bits-per-seconds (bps). Channel capacity increases with transmission bandwidth (W in Hz) and increases with the ratio of received signal power (S in Watts) to noise power (R in Watts); also it is limited by the Shannon theorem: Channel Capacity $= \mathrm{W} \cdot \log_2 (1 + S/R)$.

Channel Transmission Impairments. Communication channels impair transmitted signals, and the exact form of signal degradation depends primarily on the type of transmission medium. Affecting all channels, *additive*

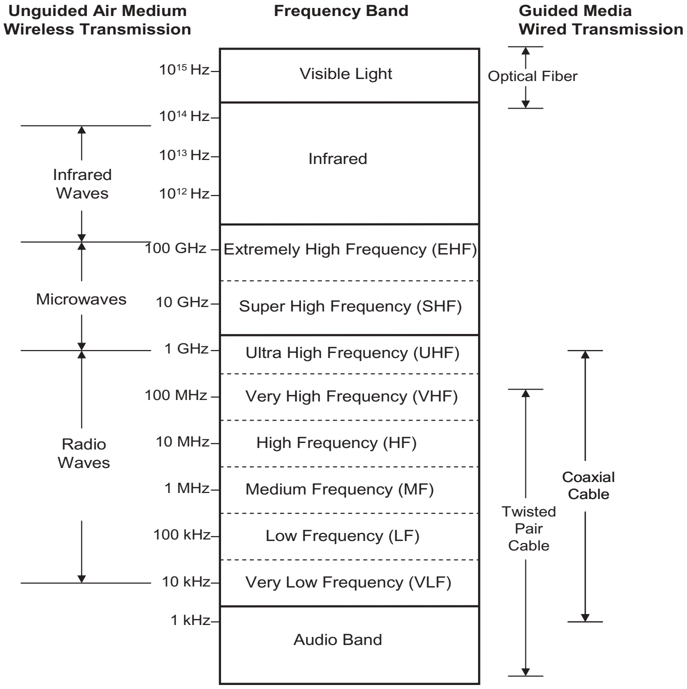

Figure 2. Electromagnetic spectrum used for wired and wireless transmission.

noise is an unwanted electromagnetic signal that is superimposed on the transmitted waveform. Noise is the single most important factor that limits the performance of a digital communication system. Other channel impairments include *attenuation, dispersion*, and *fading.* Attenuation is the decrease of transmitted signal strength as observed over distance. Dispersion is caused by delay distortions. Dispersion in wireless medium is caused by multipath propagation, which occurs when a transmitted signal is received via multiple propagation paths of different delays. It leads to inter-symbol interference (ISI), or the smearing of transmission pulses that represent transmitted symbols causing mutual interference between adjacent symbols. Fading is another problem that is associated with multipath propagation over a wireless medium. It occurs when signal components that arrive via different paths add destructively at the receiver.

In wireline medium, the dispersion and the ISI is caused by amplitude and phase distortion properties of the particular medium. The ISI could be minimized by several techniques, including limiting data rate R to less than twice the channel bandwidth W (i.e., $R < 2{\cdot}W$), pulse shaping (e.g., raised cosine spectrum), adaptive equalization, and correlative coding.

The objective of the data communication system design is to implement a system that minimizes channel impairments. The performance of the digital channel is measured in terms of bit-error-probability or bit-error-rate (BER), block-error probability, and error-free seconds. The communication problem can be stated as follows: given the communication medium, data rate, design transmitter/receiver so as to minimize BER subject to given power and bandwidth constraints; or to minimize power and/or bandwidth subject to given BER objective.

Communication Channel Models. The simplest and most used model for both wireline and wireless communication channels is the additive noise channel. The cumulative noises are caused by thermal noise in the channel and electronic noise in devices. Under this model, the communication channel is assumed to add a random noise process on the transmitted signal. When the statistics of the noise process is assumed to be uncorrelated (white) Gaussian, the model is known as *additive white Gaussian noise (AWGN) channel*. Channel attenuation can be incorporated into this model by introducing a multiplicative term. The *linear filter channel* model is similar to the additive noise channel, which differs only in the linear filtering operation that precedes noise addition. For wireline channels, the filtering effect usually is assumed to be time-invariant.

Digital transmission over wireless mobile channels must account for signal fading because of multipath propagation and Doppler shift. Multipath propagation occurs when a direct line-of-sight (LOS) path and multiple indirect paths exist between a transmitter and a receiver. Signal components that arrive at a receiver with different delay shifts and combine in a distorted version of the transmitted signal. Frequency-selective fading occurs when the amplitudes and the phases of the signal's frequency components are distorted or faded independently.

Doppler shift occurs when a transmitter and a receiver are in a relative motion, which causes the multipath received signal components to undergo different frequency shifts and to combine in a distorted version of the transmitted signal. Time-selective fading occurs when the signal's time components are faded independently.

A wireless mobile channel is modeled as a *Rayleigh fading channel* when a dominant path does not exist among direct and indirect paths between the transmitter and the receiver. The rayleigh model can be applied in complex outdoor environments with several obstructions, such as urban downtown. A wireless mobile channel is modeled as a *Rican fading channel* when a dominant direct or LOS path exists. The rican model can be applied in an open-space, outdoor environment or an indoor environment.

Digital Modulation: Signal Waveform Generation

Digital modulation enables a digital data stream to encode its information contents onto a pulse train signal via *baseband modulation,* or onto a sinusoidal carrier signal via *passband modulation*. Each signal element of the resulting waveform can carry one or more data elements or bits of the data stream. The data rate and the signal rate measures respectively the number of bits and signal elements transmitted in one second. The signal rate is also referred as the baud rate or modulation rate. The signal rate is proportional directly to the date rate, and proportional inversely to the number of data elements carried per signal element.

Besides single-carrier modulation (baseband and passband), this section will also present *spreading code modulation* (i.e., spread spectrum) that hides the signal behind the noise to minimize signal jamming and interception. *Multicarrier modulation* maximizes the spectral efficiency of a frequency-selective fading channel.

Digital Baseband Modulation. Digital baseband modulation or line coding is the process of converting a digital data stream to an amplitude modulated pulse train of discrete-level for transmission in low-pass communication channel. The pulse amplitude modulation formats or line codes include unipolar, polar, bipolar, and biphase. For unipolar codes, the signal has single polarity pulses, which results in a direct current (DC) component. Unipolar codes include unipolar return-to-zero (RZ) that specifies "on" pulses for half bit duration followed by a return to the zero level; and unipolar non-return-to-zero (NRZ) that specifies "on" pulses for full bit duration.

For polar and bipolar codes, the signal has opposite polarity pulses, which reduce the DC component. Polar codes include polar NRZ with signal levels that include positive and negative, and polar RZ with signal levels that include positive, negative, and zero. Bipolar codes specify that data bits with one binary level are represented by zero, whereas successive data bits with the other binary level are represented by pulses with alternative polarity. Bipolar codes include bipolar alternate mark inversion or pseudo-ternary with signal levels that include positive, negative, and zero.

For biphase codes, a transition at the middle of each data bit period always exists to provide clocking synchronization. Biphase codes include Manchester that specifies low-to-high and high-to-low transitions to represent "1" and "0" bits, respectively, and differential Manchester that combines transitions at the beginning and the middle of data bit periods.

The selection of signaling type depends on design considerations such as bandwidth, timing recovery, error detection, and implementation complexity. Bipolar and biphase signaling have no DC spectral component. Also, the main lobe of biphase spectrum is twice as wide as NRZ and bipolar (tradeoff between synchronization or timing recovery and bandwidth).

Signal waveform detection or demodulation recovers the original data sequence from the incoming signal at the receiver end. The original data sequence is subjected to channel impairments. Consider the simplest case of NRZ signaling. The simplest detection is to sample the received pulses at the mid-points of bit periods. This detection method suffers from the poor noise immunity. Optimum detection employs a correlator or a matched filter (integrate and dump for NRZ). This achieves better noise immunity because the noise perturbation is averaged over bit period.

Digital Passband Modulation. Digital passband modulation is the process of converting a digital data stream to a modulated sinusoidal waveform of continuous-level for transmission in band-pass communication channel, which passes frequencies in some frequency bands (3). The conversion process imbeds a digital data stream onto a sinusoidal carrier by changing (keying) one or more of its key parameters such as amplitude, phase, or frequency. Digital passband modulation schemes include amplitude shift keying (ASK), phase shift keying (PSK), and frequency shift keying (FSK).

In binary ASK, the binary data values are mapped to two distinct amplitude variations; one of them is zero and the other one is specified by the presence of the carrier signal. In binary FSK, the binary data values are mapped to two distinct frequencies usually that are of equal but opposite offset from the carrier frequency. In binary PSK, the binary data values are mapped to two distinct phases of the carrier signal; one of them with a phase of 0 degrees, and the other one with a phase of 180 degrees.

In M-ary or multilevel ASK, FSK, and PSK modulation, each signal element of M-levels carries $\log_2 M$ bits. Quadrature amplitude modulation (QAM) combines ASK and PSK. In QAM, two carriers (one shifted by 90 degrees in phase from the other) are used with each carrier that is ASK modulated.

Spreading Code Modulation: Spread Spectrum. Spreading spectrum (4) enables a narrow-band signal to spread across a wider bandwidth of a wireless channel by imparting its information contents onto a spreading code (generated by a pseudo-noise or pseudo-number generator), with the combined bit stream that attains the data rate of the original spreading code bit stream. Spread spectrum technique hides the signal behind the noise to minimize signal jamming and interception. Two common techniques to spread signal bandwidth are frequency hopping spreading spectrum (FHSS) and direct sequence spread spectrum (DSSS).

On the transmitter side, FHSS enables the original signal to modulate or to hop between a set of carrier frequencies at fixed intervals. A pseudo-random number generator or pseudo-noise (PN) source generates a spreading sequence of numbers, with each one serving as an index into the set of carrier frequencies. The resulting bandwidth of the modulated carrier signal is significantly greater than that of the original signal. On the receiver side, the same spreading sequence is used to demodulate the spread spectrum signal.

On the transmitter side, DSSS spreads the original signal by replacing each data bit with multiple bits or chips using a spreading code. A PN source generates a pseudo-random bit stream, which combines with the original signal through multiplication or an exclusive-OR operation to produce the spread spectrum signal. On the receiver side, the same spreading code is used to despread the spread spectrum signal. Multiple DSSS signals can share the same air link if appropriate spreading codes are used such that the spread signals are mutually orthogonal (zero cross-correlation), or they do not interfere with the dispreading operation of a particular signal.

Multi-carrier Modulation: Orthogonal Frequency Division Multiplexing (OFDM). OFDM coverts a data signal into multiple parallel data signals, which modulate multiple closely spaced orthogonal subcarriers onto separate subchannels. Each subcarrier modulation employs conventional single-carrier passband signaling scheme, such as quadrature phase shift keying (QPSK). When a rectangular subcarrier pulse is employed, OFDM modulation can be performed by a simple inverse discrete fourier transform (IDFT) to minimize equipment complexity. OFDM increases the spectral efficiency (ratio of transmitted data rate to signal bandwidth) of a transmission channel by minimizing subcarrier frequency channel separation while maintaining orthogonality of their corresponding time domain waveforms; and by minimizing intersymbol interference (e.g., in mulitpath fading channel) with lower bit-rate subchannels.

Multiplexing

Multiplexing is a methodology to divide the resource of a link into accessible components, to enable multiple data devices to share the capacity of the link simultaneously or sequentially. Data devices access a link synchronously through a single multiplexer. In a later section on general multiple access methodology, data devices can access a link synchronously or asynchronously through distributed access controllers.

Frequency Division Multiplexing (FDM). FDM divides a link into a number of frequency channels assigned to different data sources; each has full-time access to a portion of the link bandwidth via centralized access control. In FDM, signals are modulated onto different carrier frequencies. Each modulated signal is allocated with a frequency channel of specified bandwidth range or a band centered on its carrier frequency. Guard bands are allocated between adjacent frequency channels to counteract inter-channel interference. Guard bands reduce the overall capacity of a link.

Wavelength division multiplexing is similar to FDM, but it operates in the optical domain. It divides an optical link or a fiber into multiple optical wavelength channels assigned to different data signals, which modulate onto optical carriers or light beams at different optical wavelengths. Optical multiplexers and demultiplexers can be realized via various mechanical devices such as prisms and diffraction gratings.

Time Division Multiplexing (TDM). TDM divides a link into a number of time-slot channels assigned to different signals; each accesses the full bandwidth of the channel alternately at different times via centralized transmission access control. The time domain is organized into periodic TDM frames, with each frame containing a cycle of time slots. Each signal is assigned with one or more time-slots in each frame. Therefore, the time-slot channel is the sequence of slots assigned from frame to frame. TDM requires a guard-time for each time slot to counteract inter-channel interference in the time domain.

Instead of preassigning time slots to different signals, *statistical time division multiplexing* (asynchronous TDM with on-demand sharing of time slots) improves bandwidth efficiency by allocating time slots dynamically only when data sources have data to transmit. In statistical TDM, the number of time slots in each frame is less than the number of data sources or input lines to the multiplexer. Data from each source is accompanied by the line address such that the demultiplexer can output the data to the intended output line. Short-term demand exceeding link capacity is handled by buffering within the multiplexer.

Code Division Multiplexing (CDM). CDM divides a wireless channel into code channels assigned to different data signals, each of which modulates an associated unique spreading code to span the whole spectrum of the wireless channel (see previous section on spread spectrum modulation). A receiver retrieves the intended data signal by demodulating the input with the associated spreading code. CDM employs orthogonal spreading codes (e.g., Walsh codes) in which all pair-wise cross correlations are zero.

OFDM. OFDM divides a link into multiple frequency channels with orthogonal subcarriers. Unlike FDM, all of the subchannels are assigned to a single data signal. Furthermore, OFDM specifies the subcarriers to maintain orthogonality of their corresponding time domain waveforms. This technigue allows OFDM to minimize guard-band overhead even though signal spectra that corresponds to the subcarriers overlap in the frequency domain. OFDM can be used to convert a broadband and a wireless channel with frequency-selective fading into multiple frequency-flat subcarrier channels (i.e., transmitted signals in subcarrier channels experience narrowband fading). The multi-carrier modulation aspect of OFDM has been discussed in a previous section.

Multiplexed Transmission Network: Synchronous Optical Network (SONET). TDM-based transmission networks employ either back-to-back demultiplexer–multiplexer pairs or add-drop multiplexers (ADMs) to add or to extract lower-rate signals (tributaries) to or from an existing high-rate data stream. Former plesiochronous TDM-based transmission networks require demultiplexing of a whole multiplexed stream to access a single tributary, and then remultiplexing of the reconstituted tributaries via back-to-back demultiplexer–multiplexer pairs. Current synchronous TDM-based transmission networks employ ADMs that allow tributaries addition and extraction without interfering with other bypass tributaries.

The SONET employs electrical ADMs and converts the high-rate data streams into optical carrier signals via electrical-optical converters for transmission over optical fibers. SONET ADMs can be arranged in linear and ring topologies to form a transmission network. SONET standard specifies the base electrical signal or synchronous transport signal level-1 (STS-1) of 51.84 Mbps, and the multiplexed higher-rate STS-n electrical signals with corresponding optical carrier level-n (OC-n) signal. Repeating 8000 times per second, a SONETSTS-1 frame (9×90 byte-array) consists of transport overhead (9×3 byte-array) that relates to the transmission section and line, and to the synchronous payload envelope (9×87 byte-array) including user data and transmission path overhead. A pointer structure in the transport overhead specifies the beginning of a tributary, and this structure enables the synchronization of frames and tributaries even when their clock frequencies differ slightly.

DATA LINK LAYER

The physical layer of data communications provides an exchange of data bits in the form of a signal over a transmission link between two directly connected devices or stations. The data link layer organizes the bit stream into blocks or frames with control information overhead, and provides a reliable exchange of data frames (blocks of bits) over a data communication link between transmitter and receiver devices. Using a signal transmission service provided by the physical layer, the data link layer provides a data communication service to the network layer. Main data link control functions include frame synchronization, flow control and error recovery (particularly important when a transmission link is error prone), and medium access control to coordinate multiple devices to share and to access the medium of a transmission link.

FRAME SYNCHRONIZATION

A data frame consists of a data payload field and control information fields in the form of header, trailer, and flags. Headers may include start of frame delimiter, character or bit constant, control signaling, and sender and receiver address. Trailes may include an error detection code and an end of frame delimiter. The framing operation packages a sending data message (e.g., network layer data packet) into data frames for transmission over the data link. The frame design should enable a receiver to identify an individual frame after an incoming bit stream is organized into a continuous sequence of frames.

The beginning and the ending of a data frame must be identifiable uniquely. Frames can be of fixed or variable size. Fixed size frames can be delimited implicitly. Variable size frames can be delimited explicitly through a size count encoded in a header field. Transmission error could corrupt the count field, so usually the count field is complemented with starting/ending flags to delimit frames.

In a character-oriented protocol, a data frame consists of a variable number of ASCII-coded characters. Special flag characters are used to delimit the beginning and the end of frames. When these special flag characters appear in the data portion of the frame, character stuffing is used by the sender to insert an extra escape character (ESC) character just before each flag character, followed by the receiver to remove the ESC character.

In a bit-oriented protocol, a data frame consists of a variable number of bits. Special 8-bit pattern flag 01111110 is used to delimit the frame boundary. To preserve data transparency through bit stuffing, the sender inserts an extra 0 bit after sending five consecutive 1 bits, and the receiver discards the 0 bit that follows five consecutive 1 bits.

Channel Coding

Channel encoding is the process of introducing structured redundancy in digital data to allow the receiver to detect or to correct data errors caused by to transmission impairments in the channel. The ratio of redundant bits to the data bits and their relationship determines the error detection and the correction capability of a coding scheme. Channel coding schemes include block coding and convolutional coding schemes (5).

In block coding, data bits are grouped into blocks or datawords (each of k bits); and r redundant bits are added to each block to form a codeword (each of $n = k + r$ bits). The number of possible codewords is 2^{n} and 2^{k} of them are valid codewords, which encode the datawords.

The Hamming distance d_H between two codewords is the number of bit positions in which the corresponding bits differ, e.g., d_H (01011, 11110) = 3. The minimum distance $d_{\min}$ of a block code (that consists of a set of valid codewords) is the minimum d_{H} between any two different valid codewords in the set, e.g., $d_{\min}$(00000, 01011, 10101, 11110) = 3. A block code with $d_{\min}$ can detect all combinations of $(d_{\min}-1)$ errors. A block code with $d_{\min}$ can correct all combinations of errors specified by the largest integer that is less than or equal to $(d_{\min}-1)/2$.

Figure 3 illustrates the error detection operation based on the parity check code. The channel encoder adds a parity bit to the 7-bit dataword (1100100) to produce an even-parity 8-bit codeword (11001001). The signal waveform generator maps the codeword into a NRZ-L baseband signal. The received signal was corrupted by channel noise, one of the 0 bits was received and it was detected as a 1 bit. The channel decoder concludes that the received odd-parity codeword (11000001) is invalid.

Block codes that are deployed today are mostly linear, rather than nonlinear. For linear block codes, the modulo-2 addition of two valid codewords creates another valid codeword. Common linear block coding schemes include simple parity check codes, hamming codes, and cyclic redundancy check (CRC) codes. In a CRC code, the cyclic shifted version of a codeword is also a codeword. This allows for simple implementation by using shift registers. Bose–Chaudhuri–Hocqunghem (BCH) codes constitute a large class of powerful cyclic block codes. Reed–Solomon (RS) codes commonly are used in commercial applications, such as in digital subscriber line for Internet access and in video broadcasting for digital video. For integers m and t, RS coding operates in k symbols of data information (with m bit per symbol), n symbols $(2^m - 1)$ of data block, and $2t$ symbols of redundancy with $d_{\min} = 2t + 1$.

If the data source and the sink transmit and receive in a continuous stream, a block code would be less convenient than a code that generates redundant bits continuously without bits blocking. In convolutional coding, the coding structure extends over the entire transmitted data stream effectively, instead of being limited to data blocks or codewords as in block coding. Convolutional or trellis coding is applicable for communication systems configured with simple encoders and sophisticated decoders; such as space and satellite communication systems.

The channel coding selection for a channel should account for the channel condition, including channel error characteristics. All block and convolutional codes can be used in AWGN channels that produce random errors. However, convolutional codes tend to be ineffective in fading channels that produce burst errors. On the other hand, RS block codes are much more capable of correcting burst errors. For block codes designed for correcting random

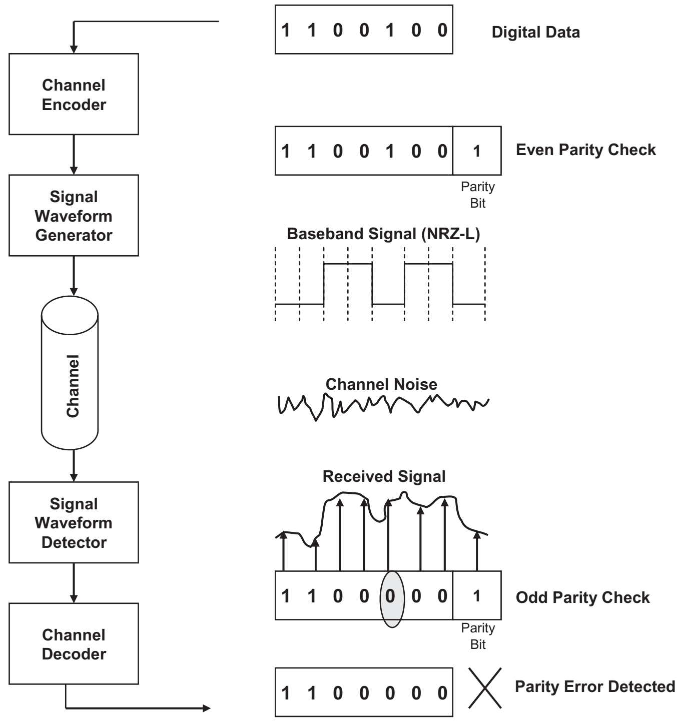

Figure 3. Example of parity-based error detection.

errors, they can be combined with block interleaving to enhance the capability of burst error correction. In block interleaving, L codewords of n-bit block to be transmitted are stored row-by-row in a rectangular $L \times n$ array buffer, and then data is transmitted over the channel column-by-column. The interleaving depth L determines the distribution of the errors of a burst over the codewords. Burst error correction is effective if the resulting number of errors to be distributed in each codeword is within the block code's error correction capability.

Flow Control

Flow control enables the receiver to slow down the sender so that the data frames are not sent at a rate higher than the receiver could handle. Otherwise, the receive buffers would overflow, which results in data frame loss. The sender is allowed to send a maximum number of frames without receiving acknowledgment from the receiver. Those frames sent but not yet acknowledged (outstanding) would be buffered by the sender in case they need to be retransmitted because of transmission error. The receiver can flow control the sender by either passively withholding acknowledgment, or actively signaling the sender explicitly that it is not ready to receive.

Error Control

Transmission errors can result in either lost frames or damaged frames with corrupted bits because of noise and interference in the channel. Error recovery enables a reliable data transfer between the sender and the receiver. When a return channel is available for data acknowledgment and recovery control, the receiver employs error detection via channel coding violation; and then requests for retransmission via automatic repeat request (ARQ) procedure. When the return channel is not available, the receiver employs forward error correction that detects an error via channel coding violation; and then the receiver corrects it by estimating the most likely data transmitted by sender.

ARQ Protocols

ARQ is a general error recovery approach that includes retransmission procedures at the sender to recover from data frames detected with error at receiver, or missing data frames (i.e., very corrupted frames not recognized by receiver). It also includes a procedure to recover from missing acknowledgment frames. With data frames that incorporate error detection codes, the receiver discards data frames with detected errors. The receiver sends an acknowledgment (ACK) frame to indicate the successful reception of one or more data frames. The receiver sends an negative acknowledgment (NAK) frame to request retransmission of one or more data frames in error. The sender sets a transmit timer when a data frame is sent, and retransmits a frame when the timer expires to account for a potentially missing data frame.

Data frames and corresponding ACK/NAK frames are identified by k-bit modulo-2 sequence numbers (N_s). The sequence numbers enable the receiver to avoid receiving duplicate frames because of lost acknowledgments. Data frames could carry a piggyback acknowledgment for data frames transmitted in the opposite direction. Acknowledgment sequence number (N_r) identifies the next data frame expected by the receiver, and acknowledges all outstanding frames up to $N_r - 1$. Outstanding data frames that have been sent but not yet acknowledged would be buffered in transmit buffers in case they need to be retransmitted because of a transmission error.

ARQ protocols combine error recovery control with *sliding-window* flow control. The sender can send multiple consecutive data frames without receiving acknowledgment from the receiver. The sender and the receiver maintain flow control state information through sending and receiving windows.

The sending window contains sequence numbers of data frames that the sender is allowed to send, and it is partitioned into two parts. From the trailing edge to the partition, the first part consists of outstanding frames. From the partition to the leading edge, the second part consists of frames yet to be sent. The sending window size (Ws) equals the maximum number of outstanding frames or the number of transmit buffers. The sender stops accepting data frames for transmission because of flow control when the partition overlaps the leading edge, i.e., all frames in window are outstanding. When an ACK is received with N_r, the window slides forward so that the trailing edge is at N_r.

The receiving window contains the sequence numbers of the data frames that the receiver is expecting to receive. Receiving window size (W_r) is equal to the number of receive buffers. The receive data frames with sequence numbers outside receive window are discarded. The accepted data frames are delivered to the upper layer (i.e., network layer) if their sequence numbers follow immediately that of the last frame delivered; or else they are stored in receive buffers. The acknowledgment procedures are as follows. First, the receiver sets an acknowledgment timer when a frame is delivered. If it is possible to piggyback an ACK, the receiver does so and resets the timer. Second, when an acknowledgment timer expires, it will send a self-contained ACK frame. For both cases, the receiver sets N_r to be the sequence number at the trailing edge of the window at the time the ACK is sent.

Common ARQ protocols include the stop-and-wait ARQ, and the sliding-window based go-back-n ARQ and selective-repeat ARQ. The sending and receiving window sizes specified for these protocols are summarized in Table 1.

Stop-and-Wait ARQ. The stop-and-wait ARQ specifies that both the sending and the receiving window sizes are limited to one. Single-bit modulo-2 sequence numbers are used. The sender and receiver process one frame at a time. This ARQ is particularly useful for the half-duplex data link as the two sides never transmit simultaneously. After sending one data frame, the sender sets the transmit timer and waits for an ACK before sending the next data frame. The sender retransmits the data frame if NAK is received or if the transmit timer expires.

Go-Back-N ARQ. The go-back-n ARQ specifies that the sending window size can range from one to $2^k - 1$; whereas the receiving window size is limited to one. If a data frame is received in error, all subsequent frames will not fall within the receiving window and will be discarded. Consequently, retransmission of all these frames will be necessary. The receiver may seek retransmission actively by sending an NAK with N_r being set to sequence number of the receive window, and then resetting the running acknowledgment timer.

The sender retransmission procedures are as follows. First, the sender sets a transmit timer when a frame is transmitted or retransmitted and resets the timer when frame is acknowledged. Second, when the transmit timer for the oldest outstanding frame expires, the sender retransmits all of the outstanding frames in the sending window. Third, if NAK with Nr is received, the sender slides a sending window to Nr and retransmits all of the outstanding frames in the new window.

Selective-Repeat ARQ. The selective-repeat ARQ specifies that the sending window size can range from one to $2^{(k-1)}$; whereas the receiving window size is less than or equal to the sending window size. Instead of retransmitting every frame in pipeline when a frame is received in error, only the frame in error is retransmitted. Received frames with a sequence number inside receiving window but out of order are stored in buffers. Then the receiver sends a NAK with N_r set to the trailing edge of the receive window, and resets the acknowledgment timer.

The sender retransmission procedures are as follows: The sender retransmits each outstanding frame when the transmit timer for that frame times out. If NAK is received, the sender retransmits the frame indicated by the Nr field in the NAK, slides the window forward if necessary, and sets the transmit timer.

Medium Access Control (MAC)

For the multiaccess or the shared-medium link as illustrated in Fig. 4, the OSI reference model divides the data link layer into the upper logical link control (LLC) sublayer and the lower medium access control (MAC) sublayer. Like the standard data link layer that provides services to the network layer, the LLC sublayer enables transmission control between two directly connected data devices. The MAC sublayer provides services to the LLC sublayer, and enables distributed data devices to access a shared-medium. Although the MAC protocols are medium specific, the LLC protocols are medium independent. The MAC protocol can be classified based on its *multiple access* and *resource sharing* methodologies.

Multiple Access Methodology. In multiplexing control, data devices access a link synchronously through a single multiplexer. In multiple access control, distributed data devices access a link synchronously or asynchronously through distributed controllers. An example *of synchronous* multiple access would be down-link transmissions from a cellular base station to wireless mobile devices. An example of *asynchronous* multiple access would be an up-link transmission from a wireless mobile device to a cellular base station. Like multiplexing, multiples access divides the resource of a transmission channel into accessible portions or subchannels identified by frequency subbands, time-slots, or spreading codes.

Frequency division multiple access (FDMA) schemes divide the frequency-domain resource of a link into portions of spectrum bands that are separated by guard-bands to reduce inter-channel interference. Data devices can transmit simultaneously and continuously on assigned subbands. For a wireless fading channel with mobile devices, FDMA requires a larger guard-band between the adjacent frequency channels to counteract the Doppler frequency spread caused by the data sources mobility.

Time division multiple access (TDMA) schemes divide the time-domain resource of a link into time-slots, separated by guard-times. Data devices take turn and transmit in assigned time-slots, which makes use of the entire link bandwidth. For the wireless fading channel, TDMA requires a larger guard-time for each time slot to counteract the delay spread caused by the multi-path fading.

Code division multiple access (CDMA) schemes divide the code-domain resource of a link into a collection of spreading codes. Data devices transmit their spread spectrum signals via assigned codes. In *synchronous CDMA*, orthogonal spreading codes are employed in which all pairwise cross-correlations are zero. In *asynchronous CDMA*, data devices access the code channels via distributed access controls without coordination, which prohibit the employment of orthogonal spreading codes because of arbitrary random transmission instants. Spreading pseudo-noise sequences are employed instead, which are statistically uncorrelated. This causes multiple access interference

Table 1. Window Sizes for ARQ Protocols

ARQ Protocol	Sending Window Size (W_s)	Receiving Window Size (W_r)
Stop-and-wait	1	1
Go-Back-N	$1 < W_s < 2^k - 1$	1
Selective Repeat	$1 < W_s < 2^{(k-1)}$	$1 < W_r < W_s$

Note: k = Number of bits available for frame sequence number.

(MAI), which is proportional directly to the number of spreading signals received at the same power level.

Orthogonal frequency division multiple access (OFDMA) schemes divide the frequency-domain resource into multiple frequency channels with orthogonal subcarriers. As discussed in a previous section, OFDM is considered as a multi-carrier modulation technique, rather than a multiplexing technique, when all of the subchannels are assigned to a single user signal. In OFDMA, multiple subsets of subchannels are assigned to different user signals.

Resource Sharing Methodology. Resource sharing control can occur either through a *centralized* resource scheduler with global resource availability information, or a *distributed* scheduler with local or isolated resource availability information. Resource sharing schemes include *preassignment, random access (contention), limited-contention*, and *on-demand assignment*. Preassignment allows devices with predetermined and fixed allocation of link resources regardless of their needs to transmit data. Random access allows devices to contend for the link resources by transmitting data whenever available. On-demand assignment allows devices to reserve data for link resources based on their dynamic needs to transmit data.

Preassignment MAC Protocols. These protocols employ static channelization. Link capacity is preassigned or allocated a priori to each station in the frequency domain via FDMA or in the time domain via TDMA. With FDMA-based protocols, disjointed frequency bands (separated by guard bands) are assigned to the links that connect the stations. For a single channel per carrier assignment, each frequency band carries only one channel of nonmultiplexed traffic. With TDMA-based protocols, stations take turns to transmit a burst of data over the same channel. Stations must synchronize with the network timing and the TDMA frame structure. These protocols achieve high efficiency if continuous streams of traffic are exchanged between stations, but they incur poor efficiency under bursty traffic.

Random Access (Contention) MAC Protocols. With random access or contention MAC protocols, no scheduled times exist for stations to transmit and all stations compete against each other to access to the full capacity of the data link. Thus, it is a distributed MAC protocol. Simultaneous transmissions by two or more stations result in a collision that causes all data frames involved to be either destroyed or modified. Collision is recovered by retransmissions after some random time. Delay may become unbounded under heavy traffic, and channel use is relatively poor compared with other MAC protocols that avoid collision, resolve collision, or limit contention. Common random access MAC protocols include Pure ALOHA, Slotted ALOHA, carrier sense multiple access (CSMA), and CSMA with collision detection or with collision avoidance.

Pure ALOHA protocol allows the station to send data frame whenever it is ready, with no regard for other stations (6). The station learns about the collision of its data frame by monitoring its own transmission (distributed control), or by a lack of acknowledgment from a control entity within a time-out period (centralized control). The station retransmits the collided data frame after a random delay or a back-off time. Suppose a station transmits a frame at time t_o, and all data frames are of equal duration T_{frame}. Collision occurs if one of more stations transmit frames within the time interval $(t_o - T_{\text{frame}}, t_o + T_{\text{frame}})$, which is referred to as the vulnerable period of length $2T_{\text{frame}}$.

Heavy traffic causes high collision probability, which increases traffic because of retransmission. In turn, this traffic increases collision probability, and the vicious cycle would cause system instability because of the loss of collision recovery capability. Short term load fluctuations could knock the system into instability. Stabilizing strategies include increasing the range of back-off with increasing number of retransmissions (e.g., *binary exponential back-off*), and limiting the maximum number of retransmissions.

Slotted ALOHA protocol is similar to that of pure ALOHA, but stations are synchronized to time slots of duration equal to the frame duration T_{frame}. Stations may access the medium only at the start of each time slot. Thus, arrivals during each time slot are transmitted at the beginning of the next time slot. Collision recovery is the same as pure ALOHA. Collisions are in the form of a complete frame overlap, and the vulnerable period is of length T_{frame}, which is half that of pure ALOHA. The maximum throughput achieved is twice that of pure ALOHA.

CSMA protocols reduce the collision probability by *sensing* the state of the medium before transmission. Each station proceeds to transmit the data frame if the medium is sensed to be *idle*. Each station defers the data frame transmission and repeats sensing if the medium is sensed to be *busy*. Collision still could occur because the propagation delay must be accounted for the first bit to reach every station and for every station to sense it. The vulnerable period is the maximum propagation delay incurred for a signal to propagate between any two stations. It can be shown that CSMA protocols outperform ALOHA protocols if propagation delay is much smaller than the frame duration. Depending on how they react when the medium is sensed to be busy or idle, CSMA schemes are classified additionally into nonpersistent CSMA, 1-persistent CSMA, and p-persistent CSMA.

With *nonpersistent CSMA* (slotted or unslotted), a station waits for a random delay to sense again if the medium is busy; it transmits as soon as medium is idle. With *1-persistent CSMA* (slotted or unslotted), a station continues to sense if the medium is busy; it transmits as soon as

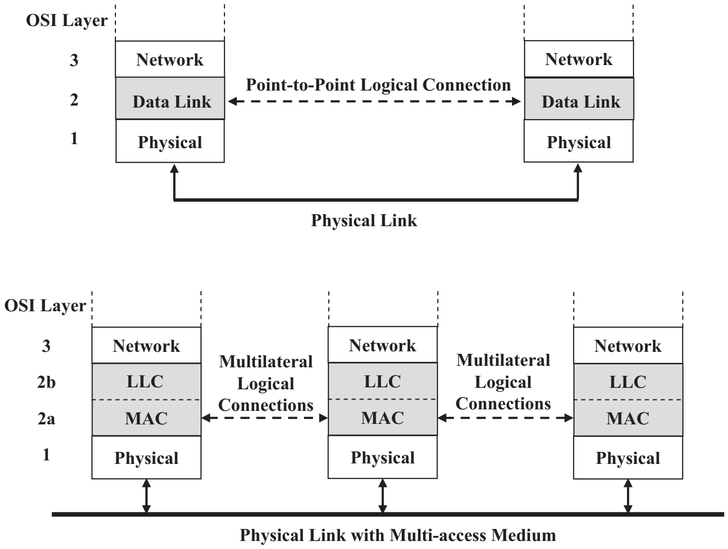

Figure 4. Data link layer.

the medium is idle. With *p-persistent CSMA* (slotted), a station continues sensing if the medium is busy; it transmits in the next slot with probability p, and delay one slot with probability (1-p) if the medium is idle.

The similarities and the differences between these CSMA schemes are summarized in Table 2.

CSMA with Collision Detection (CSMA/CD) protocol enhances the additionally CSMA operations by enabling the stations to continue sensing the channel and detecting collision while transmitting data frames (7). If a collision is *detected* (e.g., received signal energy is greater than that of sent signal, and encoding violation), the involved station would abort frame transmission. After transmitting a brief jamming signal to assure other stations would detect the collision, the involved station would back off and repeat the carrier sensing. Successful frame transmission is assured if no collision is detected within round-trip propagation delay (with regard to the furthest station) of frame transmission.

CSMA with Collision Avoidance (CSMA/CA) protocol enables stations to avoid collisions in wireless networks, where collision detection is not practical because the dynamic range of wireless signals is very large. If the medium is sensed to be idle, a station continues to monitor the medium for a time interval known as the inter-frame space (IFS). If the medium remains idle after IFS, the station chooses the time after a binary exponential back off to schedule its transmission, and then continues to monitor the medium. If the medium is sensed to be busy either during IFS or back off waiting, the station continues to monitor the medium until the medium becomes idle. At the scheduled time, the station transmits the data frame and waits for its positive acknowledgment. The station increases the back off if its transmission fails, and continues to monitor the medium until the medium becomes idle.

Limited-Contention MAC Protocols. These MAC protocols limit the number of contending stations per slot to maximize the probability of success. Different groups of stations contend for repetitive series of different slots. The large group size and the high repetition rate are assigned for light traffic, whereas a small group size and low repetition rate are assigned for heavy traffic. These protocols combine the best properties of contention and contention-free protocols. It achieves low access delay under light traffic and high throughput under heavy traffic. It is applicable to slotted ALOHA and slotted CSMA.

The splitting algorithms (8) are employed commonly by limited-contention MAC protocols. These algorithms split the colliding stations into two groups or subsets; one subset is allowed to transmit in the next slot. The splitting continues until the collision is resolved. Each station can choose whether or not to transmit in the successive slots (i.e., belong to the transmitting subset) according to the random selection, the arrival time of its collided data, or the unique identifier of the station.

On-Demand Assignment MAC. These types of protocols set up an orderly access to the medium. These protocols require the stations to exchange status information of readiness to transmit data frames, and a station can transmit only when it has been authorized by other stations or a centralized control entity. Common on-demand assignment MAC protocols include reservation-based protocols and token-passing protocols.

Reservation-based protocols require a station to reserve link resources before transmitting data. The reservation request could be signaled to other distributed stations or to a centralized reservation control entity. For example, in TDMA-based channelization, each TDMA frame could consist of data slots and reservation slots (usually smaller in size). Each station could signal a request in its own reservation slot, and transmit data in the next TDMA frame.

Token-passing protocols require a special bit pattern (token) to be passed from station to station in a round robin fashion. The token can be passed via a point-to-point line that connects one station to the next (token ring), or via a broadcast bus that connects all stations (token bus). Only a station that posses a token is allowed to send data. A station passes the token to the next station after sending data, or if it has no data to send. Each station is given the chance to send data in turns, and no contention occurs. The average access delay is the summation of the time to pass token through half the stations and the frame transmission time. The average access delay could be fairly long, but it is bounded even under heavy traffic. Token-passing protocols rely on distributed control with no need for network synchronization.

MULTI-INPUT MULTI-OUTPUT (MIMO) TRANSMISSION

MIMO and MIMO-OFDM have emerged as the next generation wireless transmission technologies with antenna arrays for mobile broadband wireless communications. As illustrated in Fig. 5, MIMO (9) is a multi-dimensional wireless transmission system with a transmitter that has multiple waveform generators (i.e., transmit antennas), and a receiver that has multiple waveform detectors (i.e., receive antennas). Multiplexing and channel coding in a MIMO channel would operate over the temporal dimension and the spatial dimension of transmit antennas. MIMO systems can be used either to achieve a diversity gain through space time coding (STC) to counteract multipath fading, or to achieve a throughput capacity gain through space division multiplexing (SDM) to counteract the bandwidth limitation of a wireless channel.

STC

STC is a two-dimensional channel coding method to maximize spectral efficiency in a MIMO channel by coding over the temporal dimension and the spatial dimension of transmit antennas. STC schemes can be based on either space time block codes (STBCs) or by space time trellis codes (STTCs). For a given number of transmit antennas (N_{TA}), an STBC scheme maps a number of modulated symbols (N_{MS}) into a two-dimensional $N_{TA} \times N_{MS}$ codeword that spans in the temporal and the spatial dimensions. On the other hand, the STTC scheme encodes a bit stream through a convolutional code, and then maps the coded bit stream into the temporal and the spatial dimensions.

SDM

SDM is a two-dimensional multiplexing method to increase data throughput in a MIMO channel by enabling simultaneous transmissions of different signals at the same carrier frequency through multiple transmit antennas. The mixed signals that arrived at the receiver can be demultiplexed by employing spatial sampling via multiple receive antennas and corresponding signal processing algorithms.

Combined MIMO–OFDM Transmission

As discussed in a previous section, OFDM can be used to convert a broadband wireless channel with frequency-selective fading into a several frequency-flat, subcarrier channels. A combined MIMO–OFDM system performs MIMO transmission per subcarrier channel with narrowband fading, thus enabling MIMO systems to operate with more optimality in broadband communications. Multiplexing and coding in a MIMO–OFDM system would operate over three dimensions (i.e., temporal, spatial, and subcarrier dimensions).

CONCLUSION

The maximum error-free data rate or capacity of an AWGN channel with a given channel bandwidth is determined by the Shannon capacity. Continuous improvements have been made to design modulation and coding schemes to approach the theoretical error-free capacity limit under the limitations of channel bandwidth and transmission power. Design objectives have always been to increase the spectral efficiency and the link reliability. Modulation can be used to increase spectral efficiency by sacrificing link reliability through modulation, whereas channel coding can be used to increase link reliability by sacrificing spectral efficiency. The performance of modulation and channel coding schemes depend on channel conditions. Existing AWGN-based modulation and coding schemes do not perform optimally in Rayleigh fading channels, whose error-free capacity are considerably less than that of AWGN channels. As fading channels have been increasing used to deploy cellular and Wi-Fi access applications, increasingly needs exist to deploy the next-generation wireless mobile technologies that are best suited for fading channels under all sorts of channel conditions (i.e., flat, frequency-selective, and time-selective fading). The emerging MIMO-OFDM technologies are promising. MIMO optimizes throughput

Table 2. CSMA Schemes Classification

	CSMA Schemes		
Medium Sensing Status	Non-Persistent (Slotted or Unslotted)	l-Persistent (Slotted or Unslotted)	p-Persistent (Slotted)
Idle	Send with Probability = 1	Send with Probability = 1	Send with Probability = p
Busy	Wait random delay, then sense channel	Continue sensing channel until idle	Continue sensing channel until idle
Collision	Wait random delay, then start over carrier sensing		

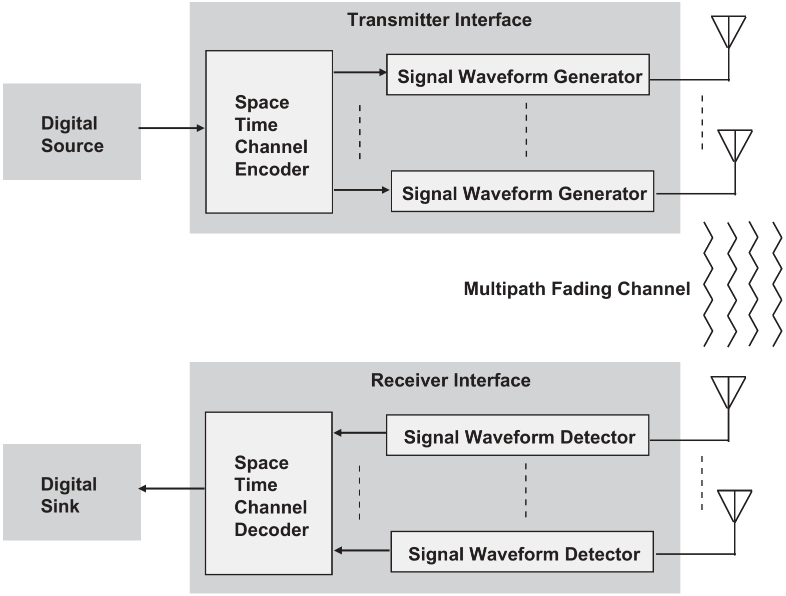

Figure 5. MIMO transmission.

capacity and link reliability by using antenna arrays; whereas OFDM optimizes spectral efficiency and link reliability by converting a broadband frequency-selective fading channel into a set of frequency flat fading channels with less signal distortions.

DATA COMPRESSION CODES, LOSSY

INTRODUCTION

In many data compression applications, one does not insist that the reconstructed data (= decoder output) is absolutely identical to the original source data (= encoder input). Such applications typically involve image or audio compression or compression results of various empirical measurements. Small reconstruction errors may be indistinguishable to a human observer, or small compression artifacts may be tolerable to the application. For example, human eye and ear are not equally sensitive to all frequencies, so information may be removed from less important frequencies without visual or audible effect.

The advantage of lossy compression stems from the fact that allowing reconstruction errors typically results in much higher compression rates than is admitted by lossless methods. This higher compression rate is understandable because several similar inputs now are represented by the same compressed file; in other words, the encoding process is not one to one. Hence, fewer compressed files are available, which results in the reduction in the number of bits required to specify each file.

It also is natural that a tradeoff exists between the amounts of reconstruction error and compression: Allowing bigger error results in higher compression. This tradeoff is studied by a subfield of information theory called the rate-distortion theory.

Information theory and rate-distortion theory can be applied to general types of input data. In the most important lossy data compression applications, the input data consists of numerical values, for example, audio samples or pixel intensities in images. In these cases, a typical lossy compression step is the quantization of numerical values. Quantization refers to the process of rounding some numerical values into a smaller range of values. Rounding an integer to the closest multiple of 10 is a typical example of quantization. Quantization can be performed to each number separately (scalar quantization), or several numbers can be quantized together (vector quantization). Quantization is a lossy operation as several numbers are represented by the same value in the reduced range.

In compression, quantization is not performed directly on the original data values. Rather, the data values are transformed first in such a way that quantization provides maximal compression gain. Commonly used transformations are orthogonal linear transformations (e.g., discrete cosine transform DCT). Also, prediction-based transformations are common: Previous data values are used to form a prediction for the next data value. The difference between the actual data value and the predicted value is the transformed number that is quantized and then included in the compressed file. The purpose of these transformations is to create numerical representations where many data values are close to zero and, hence, will be quantized to zero. The quantized data sets have highly uneven distributions, including many zeroes, and therefore they can be effectively compressed using entropy coding methods such as Huffman or arithmetic coding. Notice that quantization is the only operation that destroys information in these algorithms. Otherwise they consist of lossless transformations and entropy coders.

For example, the widely used lossy image compression algorithm JPEG is based on DCT transformation of 8×8 image blocks and scalar quantization of the transformed values. DCT transformation separates different frequencies so the transformed values are the frequency components of the image blocks. Taking advantage of the fact that the human visual system is more sensitive to low than high frequencies, the high frequency components are quantized more heavily than the low frequency ones. Combined with the fact that typical images contain more low than high frequency information, the quantization results in very few non zero high-frequency components. The components are ordered according to the frequency and entropy coded using Huffman coding.

The following sections discuss in more detail the basic ideas of lossy information theory, rate-distortion theory, scalar and vector quantization, prediction-based coding, and transform coding. Image compression algorithm JPEG is presented also.

THEORY

The Shannon information theory (1) allows one to analyze achievable rate-distortion performance for lossy compression. For simplicity, in the following illustration of the key concepts we assume a finite, independent, and identically distributed (or *iid*) source X. This means that the input data to be compressed consists of a sequence x_1,x_2,x_3,... of symbols from a finite source alphabet X where each member $x_i \in X$ of the sequence is produced with the same fixed probability distribution P on X, independent of other members of the sequence. The *entropy* of such a source is

$$H(X) = -\sum_{x \in X} P(x) \log P(x)$$

that is, the weighted average of the *self-information* $I(x) = -\log P(x)$ of elements $x \in X$. All logarithms are taken in base two, assuming that the compressed data is expressed in bits. The entropy measures the average amount of uncertainty that we have about the output symbol emitted by the source. It turns out that the entropy $H(X)$ is the best expected bitrate per source symbol that any lossless code for this source can

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

achieve (1). See Ref. 2 or any other standard information theory text for more details.

Lossy Information Theory

Suppose then that we allow errors in the reconstruction. In the general set-up we can assume an arbitrary reconstruction alphabet Y. Typically $Y = X$, as it is natural to reconstruct into the original symbol set, but this is not required. Let us specify desired *conditional reconstruction probabilities* $P(y|x)$ for all $x \in X$ and $y \in Y$, where for every $x \in X$ we have

$$\sum_{y \in Y} P(y|x) = 1$$

Value $P(y|x)$ is the probability that source symbol x will be reconstructed as y. Our goal is to design a code that realizes these conditional reconstruction probabilities and has as low an expected bitrate as possible. Note that the code can reconstruct source symbol x into various reconstruction symbols $y \in Y$, depending on the other elements of the input sequence. This is due to the fact that we do not encode individual symbols separately, but coding is done on longer segments of source symbols. Conditional probabilities $P(y|x)$ provide the desired reconstruction distribution. Formula for the best achievable bitrate, as provided by the Shannon theory (1,3), is presented below. See also Refs. 2 and 4.

Example 1. Consider a binary *iid* source X with source alphabet {0, 1} and source probabilities $P(0) = P(1) = \frac{1}{2}$. We encode source sequences in segments of three bits by assigning code c_0 to segments with more 0s than 1s and code c_1 to segments with more 1s than 0s. The entropy of the code is 1 bit per code, or $\frac{1}{3}$ bits per source symbol. Hence, we obtain compression ratio 1:3.

Let us reconstruct code c_0 as segment 000 and c_1 as 111. Then, source segments 000,001,010, and 100 get all reconstructed as 000, whereas segments 111,110,101, and 011 get reconstructed as 111. The encoding/decodong process is deterministic, but source symbols 0 get reconstructed as 1 one quarter of the time (whenever they happen to be in the same segment with two 1s). We say that the conditional reconstruction probabilities are

$$\begin{aligned} P(0|0) = P(1|1) &= \tfrac{3}{4} \\ P(1|0) = P(0|1) &= \tfrac{1}{4} \end{aligned} \qquad \square$$

For every fixed $x \in X$, the conditional reconstruction probabilities $P(y|x)$ are a probability distribution on Y, whose entropy

$$H(Y|x) = -\sum_{y \in Y} P(y|x) \log P(y|x)$$

measures the amount of uncertainty about the reconstruction if the source symbol is known to be x. Their average, weighted by the source probabilities $P(x)$, is the *conditional entropy*

$$H(Y|X) = \sum_{x \in X} P(x) H(Y|x) = -\sum_{x \in X} \sum_{y \in Y} P(x,y) \log P(y|x)$$

where $P(x,y) = P(x)P(y|x)$ is the joint probability of $x \in X$ and $y \in Y$. Conditional entropy $H(Y|X)$ measures the expected amount of uncertainty about the reconstruction to an observer that knows the corresponding source symbol.

The source probabilities $P(x)$ and the conditional reconstruction probabilities $P(y|x)$ also induce an overall probability distribution on the reconstruction alphabet Y, where for every $y \in Y$

$$P(y) = \sum_{x \in X} P(x) P(y|x)$$

We additionally can calculate the conditional source probabilities given the reconstruction symbol $y \in Y$ as

$$P(x|y) = \frac{P(x,y)}{P(y)}$$

The reconstruction entropy $H(Y)$ and the conditional source entropy $H(X|Y)$ in this direction are calculated as follows:

$$\begin{aligned} H(Y) &= -\sum_{y \in Y} P(y) \log P(y) \\ H(X|Y) &= -\sum_{x \in X} \sum_{y \in Y} P(x,y) \log P(x|y) \end{aligned}$$

They key concept of *average mutual information* is defined as the difference

$$I(X,Y) = H(X) - H(X|Y)$$

between the source entropy $H(X)$ and the conditional source entropy $H(X|Y)$. It measures the expectation of how much the uncertainty about the source symbol is reduced if the corresponding reconstruction symbol is known. It can be proved easily that $I(X,Y) \geq 0$ and that $I(X,Y) = I(Y,X)$ where we denote $I(Y,X) = H(Y) - H(Y|X)$ (2). Hence, the average mutual information also is the amount by which the uncertainty about the reconstruction is reduced if the source symbol is known.

It turns out that $I(X,Y)$ is the best bitrate that any code realizing the desired conditional reconstruction probabilities $P(y|x)$ can achieve. More precisely, this statement contains two directions: the direct statement that states that $I(X,Y)$ is a bitrate that can be achieved, and the converse statement that states that no code can have a bitrate below $I(X, Y)$. More precisely, the *direct lossy source coding theorem* can be formulated as follows: For every positive number $\varepsilon > 0$, no matter how small, a code exists such that

(i) For every $x \in X$ and $y \in Y$ the probability that x gets reconstructed as y is within ε of the desired $P(y|x)$, and

(ii) Source sequences are compressed into at most $I(X, Y) + \varepsilon$ expected bits per source symbol.

The *converse of the lossy source coding theorem* states that no code that realizes given reconstruction probabilities $P(y|x)$ can have an expected bitrate below $I(X, Y)$.

The proof of the converse statement is easier. The direct theorem is proved using the Shannon random coding technique. This technique is an example of the *probabilistic argument*, successfully applied in many areas in combinatorics and graph theory. The proof shows the existence of good codes, but it does not provide practical means of constructing such codes. Approaching the limit $I(X, Y)$ requires that long segments of the input sequence are encoded together.

Example 2. Let us return to the setup of Example 1, and let us use the obtained conditional reconstruction probabilities

$$P(0|0) = P(1|1) = \tfrac{3}{4}$$
$$P(1|0) = P(0|1) = \tfrac{1}{4}$$

as our target. The average mutual information is then

$$I(X, Y) = \frac{3}{4}\log_2 3 - 1 \approx 0.1887$$

This value is significantly lower than the rate $\frac{1}{3}$ bits obtained by the code of Example1 . According to the Shannon theory, by increasing the block length of the codes, one can approach rate $I(X, Y) \approx 0.1887$ while keeping the conditional reconstruction probabilities arbitrarily close to the target values. □

This section only discussed the source coding of finite *iid* sources. The main theorem remains valid in more general setups as well, in particular for continuous valued sources and ergodic, stationary Markov sources, that is, sources with memory.

Rate-Distortion Theory

In lossy compression, usually one does not want to specify for each source symbol the whole conditional probability distribution of reconstruction symbols. Rather, one is concerned with the amount of distortion made in the reconstruction. A *distortion function* on source alphabet X and reconstruction alphabet Y is a mapping

$$d : X \times Y \rightarrow R_+$$

into the non-negative real numbers. The value $d(x,y)$ represents the amount of distortion caused when source symbol x gets reconstructed as y. Typically (but not necessarily) $X = Y$, $d(x,x) = 0$ for all $x \in X$, and $d(x,y) > 0$ when $x \neq y$. Common distortion functions in the continuous valued case $X = Y = \mathbb{R}$ are the *squared error distortion*

$$d(x,y) = (x - y)^2$$

and the *absolute error distortion*

$$d(x,y) = |x - y|$$

Hamming distortion refers to the function

$$d(x,y) = \begin{cases} 0, & \text{if } x = y \\ 1, & \text{if } x \neq y \end{cases}$$

The distortion between two sequences of symbols is defined as the average of the distortions between the corresponding elements. One talks about the *mean squared error* (MSE) or the *mean absolute error* (MAE) if the distortion function is the squared error or the absolute error distortion, respectively. These measures are the most widely used error measures in digital signal processing.

Consider the setup of the previous section where source symbols x are reconstructed as symbols y with probabilities $P(y|x)$. This setup imposes distortion $d(x,y)$ with probability $P(x,y) = P(x)P(y|x)$, so the *expected distortion* is

$$\sum_{x \in X} \sum_{y \in Y} P(x)P(y|x)d(x,y)$$

The goal is to find the highest achievable compression rate for a given target distortion D, which leads to the problem of identifying conditional reconstruction probabilities $P(y|x)$ such that the expected distortion is at most D while $I(X, Y)$ is as small as possible. Note how we no longer "micromanage" the reconstruction by preselecting the conditional probabilities. Instead, we only care about the overall reconstruction error induced by the probabilities and look for the probabilities that give the lowest bitrate $I(X, Y)$.

This process leads to the definition of the *rate-distortion function* $R(D)$ of the source:

$$R(D) = \min\{I(X, Y)|P(y|x) \text{ such that } \sum_{x \in X}\sum_{y \in Y} P(x)P(y|x)d(x,y) \leq D\}$$

The minimization is over all conditional probabilities $P(y|x)$ that induce at most distortion D. According to the source coding statement of the previous section, $R(D)$ is the best achievable rate at distortion D.

Example 3. (2) Consider a binary source that emits symbols 0 and 1 with probabilities p and $1-p$, respectively, and let us use the Hamming distortion function. By symmetry we do not lose generality if we assume that

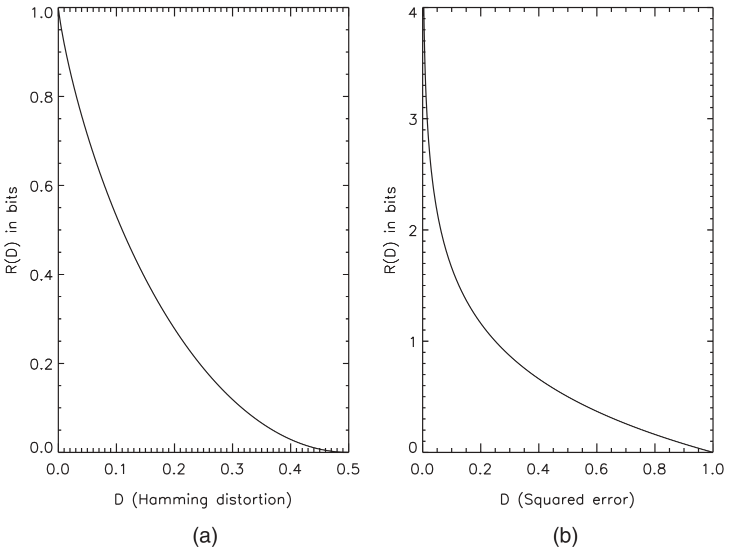

Figure 1. The rate-distortion function of (a) binary source with $p = 0.5$ and (b) Gaussian source with $\sigma = 1$. Achievable rates reside above the curve.

$p \leq 1 - p$. The rate-distortion function of this source is

$$R(D) = \begin{cases} h(p) - h(D), & \text{for } 0 \leq D \leq p \\ 0, & \text{for } D > p \end{cases}$$

where $h(r) = -r\log(r) - (1-r)\log(1-r)$ is the binary entropy function. See Fig. 1(a) for a plot of function $R(D)$.

For a continuous valued example, consider a source that emits real numbers *iid* under the Gaussian probability distribution with variance σ^2, that is, the probability density function of the source is

$$p(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{\frac{-x^2}{2\sigma^2}}$$

Consider the squared error distortion function. The corresponding rate distortion function is

$$R(D) = \begin{cases} \log(\sigma) - \frac{1}{2}\log(D), & \text{for } 0 < D \leq \sigma^2 \\ 0, & \text{for } D > \sigma^2 \end{cases}$$

see Fig. 1(b). □

Denote by D_{min} the smallest possible expected distortion at any bitrate (i.e., the distortion when the bitrate is high enough for lossless coding) and by D_{max} the smallest expected distortion corresponding to bitrate zero (i.e., the case where the reconstruction is done without receiving any information from the source). In the Gaussian example above, $D_{min} = 0$ and $D_{max} = \sigma^2$, and in the binary source example, $D_{min} = 0$ and $D_{max} = p$. Values of $R(D)$ are interesting only in the interval $D_{min} \leq D \leq D_{max}$. Function $R(D)$ is not defined for $D < D_{min}$, and it has value zero for all $D > D_{max}$. It can be proved that in the open interval $D_{min} < D < D_{max}$ the rate-distortion function $R(D)$ is strictly decreasing, continuously differentiable and convex downward. Its derivative approaches $-\infty$ when D approaches D_{min}(3,5,4).

In Example 3 , we had analytic formulas for the rate-distortion functions. In many cases such formulas cannot be found, and numerical calculations of rate-distortion functions become important. Finding $R(D)$ for a given finite *iid* source is a convex optimization problem and can be solved effectively using, for example, the Arimoto–Blahut algorithm (6,7).

QUANTIZATION

In the most important application areas of lossy compression, the source symbols are numerical values. They can be color intensities of pixels in image compression or audio samples in audio compression. Quantization is the process of representing approximations of numerical values using a small symbol set. In scalar quantization each number is treated separately, whereas in vector quantization several numbers are quantized together. Typically, some numerical transformation first is applied to initialize the data into a more suitable form before quantization. Quantization is the only lossy operation in use in many compression algorithms. See Ref. 8 for more details on quantization.

Scalar Quantization

A *scalar quantizer* is specified by a finite number of available *reconstruction values* $r_1, \ldots, r_n \in \mathbb{R}$, ordered $r_1 < r_2 < \ldots < r_n$, and the corresponding *decision intervals*. Decision intervals are specified by their boundaries $b_1, b_2, \ldots,$

$b_{n-1} \in \mathbb{R}$, also ordered $b_1 < b_2 < \ldots < b_{n-1}$. For each $i = 1, \ldots, n$, all input numbers in the decision interval (b_{i-1}, b_i) are quantized into r_i, where we use the convention that $b_0 = -\infty$ and $b_n = +\infty$. Only index i needs to be encoded, and the decoder knows to reconstruct it as value r_i. Note that all numerical digital data have been quantized initially from continuous valued measurements into discrete values. In digital data compression, we consider, additional quantization of discrete data into a more coarse representation to improve compression.

The simplest form of quantization is *uniform quantization*. In this case, the quantization step sizes $b_i - b_{i-1}$ are constant. This process can be viewed as the process of rounding each number x into the closest multiple of some positive constant b. Uniform quantizers are used widely because of their simplicity.

The choice of the quantizer affects both the distortion and the bitrate of a compressor. Typically, quantization is the only lossy step of a compressor, and quantization error becomes distortion in the reconstruction. For given distortion function and probability distribution of the input values, one obtains the expected distortion. For the analysis of bitrate, observe that if the quantizer outputs are entropy coded and take advantage of their uneven probability distribution, then the entropy of the distribution provides the achieved bitrate. The quantizer design problem then is the problem of selecting the decision intervals and reconstruction values in a way that provides minimal entropy for given distortion.

The classic Lloyd–Max (9,10) algorithm ignores the entropy and only minimizes the expected distortion of the quantizer output for a fixed number n of reconstruction values. The algorithm, hence, assumes that the quantizer output is encoded using fixed length codewords that ignore the distribution. The Lloyd–Max algorithm iteratively repeats the following two steps:

(i) Find reconstruction values r_i that minimize the expected distortion, while keeping the interval boundaries b_i fixed, and

(ii) Find optimal boundaries b_i, while keeping the reconstruction values fixed.

If the squared error distortion is used, the best choice of r_i in step (i) is the centroid (mean) of the distribution inside the corresponding decision interval $[b_{i-1}, b_i)$. If the error is measured in absolute error distortion, then the best choice of r_i is the median of the distribution in $[b_{i-1}, b_i)$. In step (ii), the optimal decision interval boundaries b_i in both distortions are the midpoints $\frac{r_i + r_{i+1}}{2}$ between consecutive reconstruction values.

Each iteration of (i) and (ii) lowers the expected distortion so the process converges toward a local minimum. A Lloyd–Max quantizer is any quantizer that is optimal in the sense that (i) and (ii) do not change it.

Modifications of the Lloyd–Max algorithm exist that produce entropy-constrained quantizers (8). These quantizers incorporate the bitrate in the iteration loop (i)–(ii). Also, a shortest path algorithm in directed acyclic graph can be used in optimal quantizer design (11).

Vector Quantization

From information theory, it is known that optimal lossy coding of sequences of symbols requires that long blocks of symbols are encoded together, even if they are independent statistically. This means that scalar quantization is suboptimal. In *vector quantization*, the input sequence is divided into blocks of length k, and each block is viewed as an element of $\mathbb{R}^k$, the k-dimensional real vector space. An n-level vector quantizer is specified by n reconstruction vectors $\vec{r}_1, \ldots, \vec{r}_n \in \mathbb{R}^k$ and the corresponding decision regions. Individual reconstruction vectors are called *code vectors*, and their collection often is called a *code book*.

Decision regions form a partitioning of $\mathbb{R}^k$ into n parts, each part representing the input vectors that are quantized into the respective code vector. Decision regions do not need to be formed explicitly, rather, one uses the distortion function to determine for any given input vector which of the n available code vectors $\vec{r}_i$ gives optimal representation. The encoder determines for blocks of k consecutive input values the best code vector $\vec{r}_i$ and communicates the index i to the decoder. The decoder reconstructs it as the code vector $\vec{r}_i$. Typically, each vector gets quantized to the closest code vector available in the code book, but if entropy coding of the code vectors is used, then the bitrate also may be incorporated in the decision.

Theoretically, vector quantizers can encode sources as close to the rate-distortion bound as desired. This encoding, however, requires that the block length k is increased, which makes this fact have more theoretical than practical significance.

The Lloyd–Max quantizer design algorithm easily generalizes into dimension k. The generalized Lloyd–Max algorithm, also known as the LBG algorithm after Linde, Buzo, and Gray (12), commonly is used with training vectors $\vec{t}_1, \ldots \vec{t}_m \in \mathbb{R}^k$. These vectors are sample vectors from representative data to be compressed. The idea is that although the actual probability distribution of vectors from the source may be difficult to find, obtaining large collections of training vectors is easy, and it corresponds to taking random samples from the distribution.

The LBG algorithm iteratively repeats the following two steps. At all times the training vectors are assigned to decision regions.

(i) For each decision region i find the vector $\vec{r}_i$ that minimizes the sum of the distortions between $\vec{r}_i$ and the training vectors previously assigned to region number i.

(ii) Change the assignment of training vectors: Go over the training vectors one by one and find for each training vector $\vec{t}_j$ the closest code vector $\vec{r}_i$ under the given distortion. Assign vector $\vec{t}_j$ in decision region number i.

In step (i), the optimal choice of $\vec{r}_i$ is either the coordinate wise mean or median of the training vectors in decision region number i, depending on whether the squared error or absolute error distortion is used.

Additional details are needed to specify how to initialize the code book and what is done when a decision region becomes empty. One also can incorporate the bitrate in the iteration loop, which creates entropy-constrained vector quantizers. For more details on vector quantization see, for example, Ref. 13.

DATA TRANSFORMATIONS

In data compression situations, it is rarely the case that the elements of source sequences are independent of each other. For example, consecutive audio samples or neighboring pixel values in images are highly correlated. Any effective compression system must take advantage of these correlations to improve compression—there is no sense in encoding the values independently of each other as then their common information gets encoded more than once. Vector quantization is one way to exploit correlations. Scalar quantization, however, requires some additional transformations to be performed on the data to remove correlation before quantization.

Prediction-Based Transformations

One way to remove correlation is to use previously processed data values to calculate a *prediction* $\hat{x}_i \in \mathbb{R}$ for the next data value $x_i \in \mathbb{R}$. As the decoder calculates the same prediction, it is enough to encode the *prediction error*

$$e_i = x_i - \hat{x}_i$$

In lossy compression, the prediction error is scalar quantized. Let $\bar{e}_i$ denote e_i quantized. Value $\bar{e}_i$ is entropy coded and included in the compressed file. The decoder obtains $\bar{e}_i$ and calculates the reconstruction value

$$\bar{x}_i = \bar{e}_i + \hat{x}_i$$

Note that the reconstruction error $x_i - \bar{x}_i$ is identical to the quantization error $e_i - \bar{e}_i$ so the quantization directly controls the distortion.

In order to allow the encoder and decoder to calculate an identical prediction $\hat{x}_i$, it is important that the predictions are based on the previously reconstructed values $\bar{x}_j$, not the original values $x_j, j < i$. In other words,

$$\hat{x}_i = f(\bar{x}_{i-1}, \bar{x}_{i-2}, \bar{x}_{i-3}, \ldots)$$

where f is the prediction function. In *linear prediction*, function f is a linear function, that is,

$$\hat{x}_i = a_1\bar{x}_{i-1} + a_2\bar{x}_{i-2} + \ldots + a_k\bar{x}_{i-k}$$

for some constants $a_1, a_2, \ldots, a_k \in \mathbb{R}$. Here, k is the *order* of the predictor. Optimal values of parameters $a_1, a_{2,} \ldots, a_k$ that minimize the squared prediction error can be found by solving a system of linear equations, provided autocorrelation values of the input sequences are known (14).

In prediction-based coding, one has strict control of the maximum allowed reconstruction error in individual source elements x_i. As the reconstruction error is identical to the quantization error, the step size of a uniform quantizer provides an upper bound on the absolute reconstruction error. Compression where a tight bound is imposed on the reconstruction errors of individual numbers rather than an average calculated over the entire input sequence is termed *near-lossless compression*.

Linear Transformations

An alternative to prediction-based coding is to perform a linear transformation on the input sequence to remove correlations. In particular, *orthogonal transformations* are used because they keep mean squared distances invariant. This method allows easy distortion control: The MSE quantization error on the transformed data is identical to the MSE reconstruction error on the original data.

Orthogonal linear transformation is given by an orthogonal square matrix, that is, an $n \times n$ matrix M whose rows (and consequently also columns) form an orthonormal basis of $\mathbb{R}^n$. Its inverse matrix is the same as its transpose M^T. The rows of M are the *basis vectors* of the transformation.

A data sequence of length n is viewed as an n-dimensional column vector $\vec{x} \in \mathbb{R}^n$. This vector can be the entire input, or, more likely, the input sequence is divided into blocks of length n, and each block is transformed separately. The transformed vector is $M\vec{x}$, which is also a sequence of n real numbers. Notice that the elements of the transformed vector are the coefficients in the expression of $\vec{x}$ as a linear combination of the basis vectors.

The inverse transformation is given by matrix M^T. In the following, we denote the i'th coordinate of $\vec{x}$ by $\vec{x}(i)$ for $i = 1$, 2,..., n. If the transformed data is quantized into $\vec{y} \in \mathbb{R}^n$, then the reconstruction becomes $M^T\vec{y}$. Orthogonality guarantees that the squared quantization error $\|M\vec{x} - \vec{y}\|^2$ is identical to the squared reconstruction error $\|\vec{x} - M^T\vec{y}\|^2$. Here, we use the notation

$$\|\vec{r}\|^2 = \sum_{i=1}^{n} \vec{r}(i)^2$$

for the square norm in $\mathbb{R}^n$.

KLT Transformation. The goal is to choose a transformation that maximally decorrelates the coordinates of the data vectors. At the same time, one hopes that as many coordinates as possible become almost zero, which results in low entropy in the distribution of quantized coordinate values. The second goal is called energy compaction.

Let us be more precise. Consider a probability distribution on the input data vectors with mean $\vec{m} \in \mathbb{R}^n$. The *variance* in coordinate i is the expectation of $(\vec{x}(i) - \vec{m}(i))^2$ when $\vec{x} \in \mathbb{R}^n$ is drawn from the distribution. The *energy* in coordinate i is the expectation of $\vec{x}(i)^2$. The total variance (energy) of the distribution is the sum of the n coordinate-wise variances (energies). Orthogonal transformation keeps the total variance and energy unchanged, but a shift of variances and energies between coordinates can occur. Variance (energy) compaction means that as much variance (energy) as possible gets shifted into as few coordinates as possible.

The *covariance* in coordinates i and j is the expectation of

$$(\vec{x}(i) - \vec{m}(i))(\vec{x}(j) - \vec{m}(j))$$

Coordinates are called uncorrelated if the covariance is zero. Decorrrelation refers to the goal of making the coordinates uncorrelated. Analogously, we can call the expectation of $\vec{x}(i)\vec{x}(j)$ the "coenergy" of the coordinates. Notice that the variances and covariances of a distribution are identical to the energies and coenergies of the translated distribution of $\mathbb{R}^n$ by the mean $\vec{m}$.

Example 4. Let $n = 2$, and let us build a distribution of vectors by sampling blocks from a grayscale image. The image is partitioned into blocks of 1×2 pixels, and each such block provides a vector $(x, y) \in \mathbb{R}^2$ where x and y are the intensities of the two pixels. See Fig. 2 (a) for a plot of the distribution. The two coordinates are highly correlated, which is natural because neighboring pixels typically have similar intensities. The variances and energies in the two coordinates are

	Energy	Variance
x	17224	2907
y	17281	2885
total	34505	5792

The covariance and coenergy between the x and y coordinates are 17174 and 2817, respectively.

Let us perform the orthogonal transformation

$$\frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$$

that rotates the points 45 degrees clockwise, see Fig. 2 (b) for the transformed distribution. The coordinates after the transformation have the following variances and energies:

	Energy	Variance
x	34426	5713
y	79	79
total	34505	5792

Energy and variance has been packed in the first coordinate, whereas the total energy and variance remained invariant. The effect is that the second coordinates became very small (and easy to compress), whereas the first coordinates increased.

After the rotation, the covariance and the coenergy are -29 and 11, respectively. The transformed coordinates are uncorrelated almost, but not totally. □

The two goals of variance compaction and decorrelation coincide. An orthogonal transformation called KLT (Karhunen–Loève transformation) makes all covariances between different coordinates zero. It turns out that at the same time KLT packs variance in the following, optimal way: For every $k \leq n$ the variance in coordinates 1,2,. . ., k after KLT is as large as in any k coordinates after any orthogonal transformation. In other words, no orthogonal transformation packs more variance in the first coordinate than KLT nor more variance in two coordinates than KLT, and so forth. The rows of the KLT transformation matrix are orthonormal eigenvectors of the *covariance matrix*, that is, the matrix whose element i,j is the covariance in coordinates i and j for all $1 \leq i, j \leq n$. If energy compaction rather than variance compaction is the goal, then one should replace the covariance matrix by the analogous coenergy matrix.

Example 5. In the case of Example 4 the covariance matrix is

$$\begin{pmatrix} 2907 & 2817 \\ 2817 & 2885 \end{pmatrix}$$

The corresponding KLT matrix

$$\begin{pmatrix} 0.708486 & 0.705725 \\ -0.705725 & 0.708486 \end{pmatrix}$$

consists of the orthonormal eigenvectors. It is the clockwise rotation of $\mathbb{R}^2$ by 44.88 degrees. □

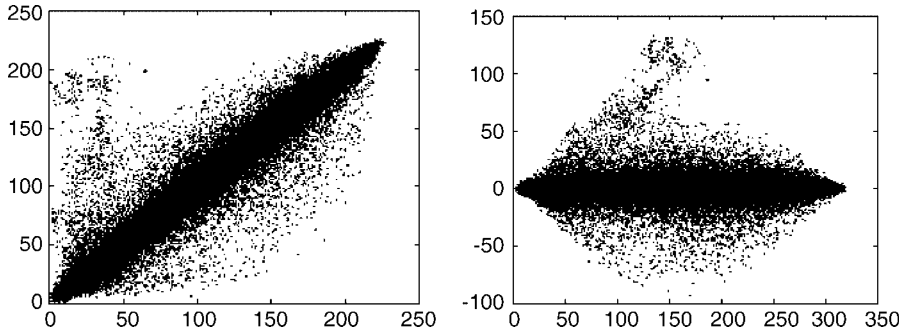

Figure 2. The sample distribution (a) before and (b) after the orthogonal transformation.

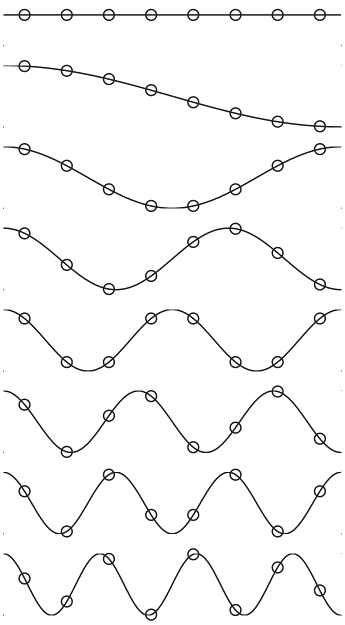

Figure 3. Size $n = 8$ DCT basis vectors.

KLT transformation, although optimal, is not used widely in compression applications. No fast way exists to take the transformation of given data vectors—one has to multiply the data vector by the KLT matrix. Also, the transformation is distribution dependent, so that the KLT transformation matrix or the covariance matrix has to be communicated to the decoder, which adds overhead to the bitrate. In addition, for real image data it turns out that the decorrelation performance of the widely used DCT transformation is almost as good. KLT is, however, an important tool in data analysis where it is used to lower the dimension of the data set by removing the less significant dimensions. This method also is known as the principal component analysis.

DCT Transformation. The *discrete cosine transform* (DCT) is an orthogonal linear transformation whose basis vectors are obtained by uniformly sampling the cosine function, see Fig. 3. More precisely, the element i, j of the $n \times n$ DCT matrix is

$$C_i \cos(i\pi \frac{2j+1}{2n})$$

where $i,j = 0,1,\ldots, n\text{–}1$ and C_i is the normalization factor

$$C_i = \begin{cases} \sqrt{1/n}, & \text{if } i = 0 \\ \sqrt{2/n}, & \text{otherwise} \end{cases}$$

Different basis vectors of DCT capture different frequencies present in the input. The first basis vector ($i = 0$) is constant, and the corresponding transformed value is called the DC coefficient. The DC coefficient gives the average of the input. Other transformed values are AC coefficients. DCT has good energy compaction properties where typically most energy is packed into the low frequency coefficients.

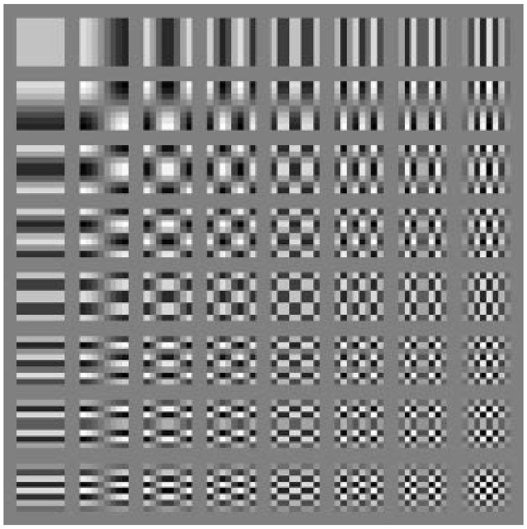

Figure 4. Basis vectors of the 8×8 DCT.

There are fast DCT algorithms that perform the transformation faster than the straightforward multiplication of the data by the transformation matrix. See Ref. 15 for these and other details on DCT.

Linear Transformations in Image Compression. In image data, the pixels have a two-dimensional arrangement. Correlations between pixels also are current in both horizontal and vertical directions. DCT, however, is natively suitable for one-dimensional signals because it separates frequencies in the direction of the signal. Also, other common transformations are designed for signals along a one-dimensional line. To use them on images, the transformation is done twice: first along horizontal lines of the image and then again on vertical lines on the output of the first round. (The same result is obtained if the vertical transformation is executed first, followed by the horizontal direction.) The combined effect again is an orthogonal transformation of the input image.

For example, the basis vectors of DCT on 8×8 image data is shown in Fig. 4. The transformation decomposes an input image into a linear combination of the shown basis vectors. Typically, high-frequency coefficients corresponding to basis vectors at the lower right corner are very small, whereas the low frequency basis vectors at the upper left corner capture most of the image energy. This fact is exploited in the JPEG image compression algorithm discussed below.

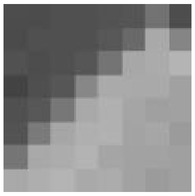
JPEG

This section outlines the JPEG (Joint Photographic Experts Group) image compression standard as an illustration of the concepts discussed in previous sections. JPEG is based on the DCT transformation of 8×8 image blocks;

uniform scalar quantization of the transformed values, where different step sizes can be used at different frequency components; ordering of the quantized values from the low frequency to the high frequency; and Huffman coding of the ordered, quantized coefficients. The bitrate and the quality are controlled through the selection of the quantizer step sizes. For details of JPEG, see Ref. 16.

If the input image is a color image, it has three color components, each of which is compressed as a grayscale image. But the commonly used RGB (red, green, and blue) color representation first is converted into a luminance–chrominance representation where the luminance component is the intensity and two chrominance components give the color. The chrominance components typically compress much better than the luminance component that contains most of the image information. In addition, the human visual system is not as sensitive to the chrominance data, so the chrominance components often are subsampled by removing half of the rows and/or columns. Also, the chrominance components can be quantized more heavily.

Next, the image is partitioned into non overlapping 8 × 8 squares. As an example, take the image block



or

77	76	80	80	83	85	114	77
75	80	80	80	87	105	169	133
81	77	80	86	116	167	171	180
67	79	86	135	170	169	169	161
80	87	119	168	176	165	159	161
83	122	166	175	177	163	166	155
117	168	172	179	165	162	162	159
168	174	180	169	172	162	155	160

extracted from a test picture. The intensity values are integers in the interval 0...255. First, 128 is subtracted from all intensities, and the result is transformed using the 8 × 8 DCT. The transformed values of the sample block—rounded to the closest integer—are

28	−158	−47	−5	−14	8	−17	5
−212	−61	56	32	−9	22	−9	7
−27	104	44	−12	−23	7	−6	9
−30	29	−50	−25	−1	11	−10	5
−11	21	−23	19	25	0	0	1
−3	2	−12	4	−4	−12	−2	−9
2	0	1	6	−1	−5	19	3
0	0	11	2	3	−2	11	−11

Notice that the high frequency values at the lower right corner are relatively small. This phenomenon is common as typical images contain more low than high frequencies. The next step is the lossy step of scalar quantization. Different frequencies may be quantized differently. Typically, the high-frequency values are quantized more coarsely than the low frequencies because the human visual system is less sensitive to high frequencies. The quantizer step sizes are specified in an 8 × 8 array, called the quantization table. In our example, let us use the following quantization table:

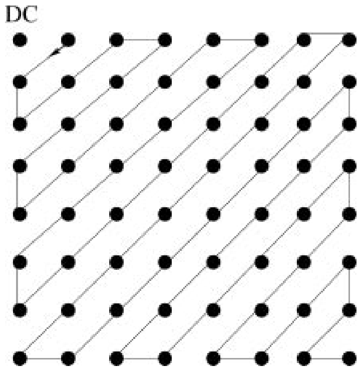
16	11	10	16	24	40	51	61
12	12	14	19	26	58	60	55
14	13	16	24	40	57	69	56
14	17	22	29	51	87	80	62
18	22	37	56	68	109	103	77
24	35	55	64	81	104	113	92
49	64	78	87	103	121	120	101
72	92	95	98	112	100	103	99

The transformed data values are divided by the corresponding element of the quantization table and rounded to the closest integer. The result is

2	−14	−5	0	−1	0	0	0
−18	−5	4	2	0	0	0	0
−2	8	3	0	−1	0	0	0
−2	2	−2	−1	0	0	0	0
−1	1	−1	0	0	0	0	0
0	0	0	0	0	0	0	0
0	0	0	0	0	0	0	0
0	0	0	0	0	0	0	0

Notice the large number of zeroes in the high-frequency part of the table. This large number is because of two factors: Higher frequencies were quantized more, and the input contain less high frequency information (energy) in the first place.

Next, the quantized values need to be entropy coded. Huffman coding (or arithmetic coding) is used. The DC coefficient (number 2 in our example) simply is subtracted from the DC coefficient of the previous block, and the difference is entropy coded. The other 63 values—the AC coefficients—are lined up according to the following zigzag order:



The purpose is to have the large low-frequency values first, and hopefully many zeroes at the end. In our example, this produces the sequence

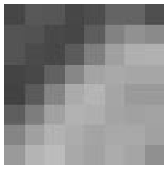
$$-14,\ -18,\ -2,\ -5,\ -5, 0, 4, 8,\ -2,\ -1, 2, 3, 2, -1, 0, 0, 0,$$
$$-2, 1, 0, 0, 0,\ -1,\ -1,\ -1, 0, 0, \ldots$$

where the end of the sequence contains only zeroes. Huffman coding is used where each Huffman code word represents a non zero value and the count of zeroes before it. In other words, Huffman code words are used for the non zero values only, although these code words also specify the positions of zeroes. A specific code word also exists for the end of the block that is inserted after the last non zero value. In this way, the long sequence of zeroes at the end can be skipped.

From the compressed file, the decoder obtains the quantized DCT output. Multiplying the values by the entries of the quantization table and applying the inverse DCT produces the reconstructed image block. In our example, this block is

70	87	86	71	77	100	100	78
84	82	72	69	93	130	145	138
84	74	71	91	127	160	175	177
68	72	97	135	163	169	166	166
66	90	133	171	180	165	154	154
94	125	161	178	174	164	161	163
132	160	178	172	164	168	168	161
154	180	188	169	162	172	165	144

or



The level of the compression artifacts is controlled by the selection of the quantization table. Typical artifacts in JPEG with coarse quantization are: blocking along the boundaries of the 8 × 8 blocks, blending of colors because of high quantization of chrominance components, and ringing on edges because of the loss of high-frequency information.

SUBBAND CODING AND WAVELETS

Typical image data contains localized high frequencies on the boundaries of objects. Within an object, usually large low frequency areas exist. Classical transformations into the frequency domain, such as DCT, measure the total amounts of various frequencies in the input. To localize the effect of sharp edges, DCT commonly is applied on relatively small image blocks. In this way, image edges only affect the compression of the block that contains the edge. This method, however, leads to blocking artifacts seen in JPEG.

Alternative linear, even orthogonal, transformations exist that measure frequencies locally. A simple example is the Haar transformation. It is based an a multilevel application of a 45 degree rotation of $\mathbb{R}^2$, specified by the matrix

$$M = \frac{1}{\sqrt{2}}\begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$$

On the first level, the input signal of length n is partitioned into segments of two samples and each segment is transformed using M. The result is shuffled by grouping together the first and the second coefficients from all segments, respectively. This shuffling provides two signals of length $n/2$, where the first signal consists of moving averages and the second signal of moving differences of the input. These two signals are called subbands, and they also can be viewed as the result of filtering the input signal by FIR filters whose coefficients are the rows of matrix M, followed by subsampling where half of the output values are deleted.

The high-frequency subband that contains the moving differences typically has small energy because consecutive input samples are similar. The low-frequency subband that contains the moving averages, however, is a scaled version of the original signal. The second level of the Haar transformation repeats the process on this low-frequency subband. This process again produces two subbands (signals of length $n/4$ this time) that contain moving averages and differences. The process is repeated on the low-frequency output for as many levels as desired.

The combined effect of all the levels is an orthogonal transformation that splits the signal into a number of subbands. Notice that a sharp transition in the input signal now only affects a small number of values in each subband, so the effect of sharp edges remains localized in a small number of output values.

Haar transformation is the simplest subband transformation. Other subband coders are based on the similar idea of filtering the signal with two filters—one low-pass and one high-pass filter—followed by subsampling the outputs by a factor of two. The process is repeated on the low-pass output and iterated in this fashion for as many levels as desired. Different subband coders differ in the filters they use. Haar transformation uses very simple filters, but other filters with better energy compaction properties exist. See, for example, Ref. 17 for more details on wavelets and subband coding.

When comparing KLT (and DCT) with subband transformations on individual inputs, one notices that although KLT packs energy optimally in fixed, predetermined coefficients, subband transformations pack the energy better in fewer coefficients, however, the positions of those coefficients depend on the input. In other words, for good compression one cannot order the coefficients in a predetermined zigzag order as in JPEG, but one has to specify also the position of each large value.

Among the earliest successful image compression algorithms that use subband transformations are the embedded zerotree wavelet (EZW) algorithm by J. M. Shapiro (18) and the set partitioning in hierarchical trees (SPIHT) algorithm by A. Said and W. A. Pearlman (19). The JPEG 2000 image compression standard is based on subband coding as well (20).

CONCLUSION

A wide variety of specific lossy compression algorithms based on the techniques presented here exist for audio, speech, image, and video data. In audio coding, linear prediction commonly is used. Also, subband coding and wavelets are well suited. If DCT type transformations are used, they are applied commonly on overlapping segments of the signal to avoid blocking artifacts.

In image compression, JPEG has been dominant. The wavelet approach has become more popular after the introduction of the wavelet-based JPEG 2000. At high quantization levels, JPEG 2000 exhibits blurring and ringing on edges, but it does not suffer from the blocking artifacts typical to JPEG.

Video is an image sequence, so it is not surprising that the same techniques that work in image compression also work well with video data. The main difference is the additional temporal redundancy: Consecutive video frames are very similar, and this similarity can be used to get good compression. Commonly, achieving this good compression is done through block-based motion compensation, where the frame is partitioned into blocks (say of size 16 × 16) and for each block a motion vector that refers to a reconstructed block in a previously transmitted frame is given. The motion vector specifies the relative location of the most similar block in the previous frame. This reference block is used by the decoder as the first approximation. The difference of the correct block and the approximation then is encoded as a still image using DCT. Common standards such as MPEG-2 are based on this principle. At high compression, the technique suffers from blocking artifacts, especially in the presence of high motion. This difficulty is because the motion vectors of neighboring blocks can differ significantly, which results in visible block boundaries, and because at high-motion areas the motion compensation leaves large differences to be encoded using DCT, which can be done within available bit budget only by increasing the level of quantization.

See Refs. 21–24 for more information on lossy compression and for details of specific algorithms.

DATA HANDLING IN INTELLIGENT TRANSPORTATION SYSTEMS

INTRODUCTION

Within the domain of computer science, *data handling* is the coordinated movement of data within and between computer systems. The format of the data may be changed during these movements, possibly losing information during conversions. The data may also be filtered for privacy, security, or efficiency reasons. For instance, some information transmitted from an accident site may be filtered for privacy purposes before being presented to the general public (e.g., license numbers and names). The motivation for this article is to be an updated reference of the various mechanisms and best practices currently available for handling *intelligent transportation systems* (ITSs) data. In the sections that follow, data handling within ITS is discussed in detail.

What are Intelligent Transportation Systems?

Intelligent transportation systems apply computer, communication, and sensor technologies in an effort to improve surface transportation. The application of these technologies within surface transportation typically has been limited (e.g., car electronics and traffic signals). One goal of ITS is to broaden the use of these technologies to integrate more closely travelers, vehicles, and their surrounding infrastructure. Used effectively, ITS helps monitor and manage traffic flow, reduce congestion, provide alternative routes to travelers, enhance productivity, respond to incidents, and save lives, time, and money. Over the past ten years, the public and private sectors have invested billions of dollars in ITS research and development and in initial deployment of the resulting products and services.

Given the potential benefits of ITS, the U.S. Congress specifically supported an ITS program in the Transportation Equity Act for the 21st Century (TEA-21) in 1998. As defined by TEA-21, the ITS program provides for the research, development, and operational testing of ITSs aimed at solving congestion and safety problems, improving operating efficiencies in transit and commercial vehicles, and reducing the environmental impact of growing travel demand. Technologies that were cost effective were deployed nationwide within surface transportation systems as part of TEA-21.

Intelligent transportation systems can be broken down into three general categories: advanced traveler information systems, advanced traffic management systems, and incident management systems.

Advanced Traveler Information Systems (ATISs) deliver data directly to travelers, empowering them to make better choices about alternative routes or modes of transportation. When archived, this historical data provide transportation planners with accurate travel pattern information, optimizing the transportation planning process.

Advanced Traffic Management Systems (ATMSs) employ a variety of relatively inexpensive detectors, cameras, and communication systems to monitor traffic, optimize signal timings on major arterials, and control the flow of traffic.

Incident Management Systems, for their part, provide traffic operators with the tools to allow a quick and efficient response to accidents, hazardous spills, and other emergencies. Redundant communications systems link data collection points, transportation operations centers, and travel information portals into an integrated network that can be operated efficiently and “intelligently.”

Some example ITS applications include on-board navigation systems, crash notification systems, electronic payment systems, roadbed sensors, traffic video/control technologies, weather information services, variable message signs, fleet tracking, and weigh in-motion technologies.

MAJOR CHALLENGES

One major challenge in handling ITS data involves managing the broad spectrum of requirements inherent in a transportation system. ITS data must flow from and between a variety of locations and devices such as in-vehicle sensors, police dispatch centers, infrastructure sensors, computers, and databases. Each of these options has different bandwidth, formatting, and security requirements. A “one-solution-fits-all” approach is not appropriate in this type of environment. Fortunately, many standards can be applied in concert with one another to cover all requirements. These standards and how they are used are discussed in the sections that follow.

DATA HANDLING IN ITS

Data within an ITS originates at various sensors, such as in-pavement inductive loop detectors for measuring the presence of a vehicle, transponders for collecting toll fees, video cameras, and operator input. These data typically are collected and aggregated by a transportation agency for use in managing traffic flow and in detecting and responding to accidents. These data are often archived, and later data-mining techniques are used to detect traffic trends. These data also make their way to information providers for use in radio, television, and Web traffic reports.

The different requirements for ITS data handling depend on the medium used. For instance, the requirements for data handling in communications stress the efficient use of bandwidth and low latency, whereas data handling for data-mining applications require fast lookup capabilities.

Data Types and Formats

Various types of data are stored and manipulated by an ITS. The types of data are discussed in the sections that follow.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Traffic Statistics. Speed, travel time, volume, and occupancy data or other numeric measurements are used to characterize the flow of vehicles at a specific point or over a specific segment of roadway. These data can be generated from many types of detection systems, such as loop detectors, microwaves, infrared or sonic detectors, video image detection, automatic vehicle identification, license plate matching systems, and wireless phone probes.

Weather/Environmental. Wind speed, wind direction, temperature, humidity, visibility, and precipitation data are collected by weather stations. This information can be used to determine whether road salt is needed because of icing conditions or whether danger exists to large vehicles because of high wind speeds.

Video/Images. Video cameras are mounted high to provide unobstructed views of traffic. Video data are in the form of encoded data streams or still images. Video feeds are used to determine the cause and location of incidents and to determine the overall level of service (congestion).

Incident/Event Reports. Incidents, construction/ maintenance, events, and road conditions are some types of data collected. This information usually is entered manually into the "system" because an automated means of detecting an incident has yet to be developed. The reports provide descriptive information on planned or unplanned occurrences that affect or may affect traffic flow.

Data Attributes. The following attributes are common within ITS data: *Accuracy*—How precise is the data? *Detail*—Is the data a direct measurement or an estimated/indirect measurement? *Timeliness*—How fresh is the data? *Availability/Reliability*—How dependable is the flow of data? *Density*—How close together/far apart are the data collection sources? *Accessibility*—How easy is the data accessed by a data consumer? *Confidence*—Is the data trustworthy? *Coverage*—Where is the data collected?

Standards for Data Handling

Standards provide a mechanism to ensure compatibility among various disparate systems. These standards reduce costs because software and hardware can be developed to make use of a handful of standards rather than of hundreds of proprietary protocols.

The following organizations are involved in the development of ITS standards: the American Association of State Highway and Transportation Officials (AASHTO), American National Standards Institute (ANSI), American Society for Testing & Materials (ASTM), Consumer Electronics Association (CEA), Institute of Electrical and Electronics Engineers (IEEE), Institute of Transportation Engineers (ITE), Society of Automotive Engineers (SAE), National Electrical Manufacturers Association (NEMA), and the National Transportation Communications for ITS Protocol (NTCIP). Note that NTCIP is a joint effort among AASHTO, ITE, and NEMA.

The Federal Geographic Steering Committee (FGSC) provides staff to support the U.S. Department of the Interior to manage and facilitate the National Spatial Data Infrastructure (NSDI) (1).

Data Formats and Communication Protocols. Standards are built off of one another. For instance, ITS standards make use of standards for data formatting and communications, such as Extensible Markup Language (XML), Common Object Request Broker Architecture (CORBA), or Abstract Syntax Notation number One (ASN.1). To better understand ITS standards, these underlying standards will be discussed first.

Extensible Markup Language. XML is a standard of the World Wide Web Consortium (W3C) (2). XML is a means of encoding data so that computers can send and receive information. XML allows computers to understand the information content of the data and act on that content (e.g., process the information, display the information to a human, store the information in a database, and issue a command to a field device). Unlike most computer encoding standards (e.g., Basic Encoding Rules, Octet Encoding Rules, Packed Encoding Ruled, Common Data Representation, and Hypertext Markup Language), no single set of encoding rules exists for XML. Instead, XML encoding rules are customized for different applications. Furthermore, XML encoding rules include a mechanism for identifying each element of an XML document or message. See Ref. 3 for an overview of XML use in ITS applications.

The advantages of using XML for ITS data handling are for communications. It has pervasive support among software companies, standards organizations, and government agencies. Also, XML formatted data are often bundled with Web services over Hyper-Text Transmission Protocol (HTTP) via SOAP (4) or XML-RPC (5). This bundling allows the data and associated commands to traverse firewalls more easily. Some may see this process as a disadvantage, however, because it basically is hiding the services from network administrators and granting potentially unsecured access to important functions.

XML format is not well suited for data storage, however, because its hierarchal data structure does not lend itself to easy storage and retrieval from relational databases. However, XML databases, which natively can store, query, and retrieve XML-formatted documents, are now available (6).

A disadvantage to XML-formatted data is that the tags and the textual nature of the documents tend to make them much more verbose. This verbosity, in turn, requires higher bandwidth communication links and more data processing to encode and decode ITS data as compared with CORBA or ASN.1 (7,8).

Common Object Request Broker Architecture. CORBA is an Object Management Group (OMG) standard for communications between computers (9). As part of CORBA, the interface definition language (IDL) provides a platform and computer language-independent specification of the data to be transmitted and the services that are available to a CORBA application. The OMG requires CORBA implementations to make use of the Internet Inter-ORB Protocol

(IIOP) for encoding messages over the Internet. This protocol ensures that CORBA implementations from different vendors running on different operating systems can interact with one another. NTCIP has a CORBA-based standard for communications between transportation centers, NTCIP 2305 (10). CORBA inherently is object oriented, which allows for the definition of both data structures and for commands in the form of interfaces.

One advantage to using CORBA are its relatively lower bandwidth requirements as compared with XML-based communications. CORBA has wide industry support, and many open-source implementations are available (11,12). Because CORBA is based on the IIOP communications standard, the various commercial and open-source implementations can interoperate with one another. CORBA has the advantage, as compared with ASN.1 or XML, in that it describes both the structure of the data to be transmitted and what is to be done with the data. Finally, many counterpart extensions to CORBA handle such things as authentication.

The disadvantages to CORBA are that it requires specialized knowledge to integrate it into ITS data handling systems. Also, because CORBA does not make use of the HTTP protocol, it does not traverse Web firewalls as easily as XML-RPC or SOAP.

Abstract Syntax Notation. ASN.1 is a standard of the International Standards Organization (ISO) that defines a formalism for the specification of abstract data types. ASN.1 is a formal notation used for describing data transmission protocols, regardless of language implementation and physical representation of these data, whatever the application, whether complex or very simple. ASN/DATEX is a NTCIP standard (NTCIP 2304). ASN.1 is not a communication or data storage mechanism, but it is a standard for expressing the format of complex data structures in a machine-independent manner. Many encoding rules can encode and decode data via ASN.1 such as the basic encoding rules (BERs), canonical encoding rules (CERs), and distinguished encoding rules (DERs) (13).

ASN.1 has the advantage that it unambiguously defines the structure for ITS data and the various encoding schemes allow for efficient transmission of the data over even lower bandwidth communication systems. Many software libraries are also available that handle the encoding and decoding of ASN.1 data structures (14).

ITS Data Bus. Chartered in late 1995, the Data Bus Committee is developing the concept of a dedicated ITS data bus that may be installed on a vehicle to work in parallel with existing automotive electronics (15). When complete, the data bus will facilitate the addition of ITS electronics devices to vehicles without endangering any of its existing systems.

The ITS data bus will provide an open architecture to permit interoperability that will allow manufacturers, dealers, and vehicle buyers to install a wide range of electronics equipment in vehicles at any time during the vehicle's lifecycle, with little or no expert assistance required. The goal of the Data Bus Committee is to develop SAE recommended practices and standards that define the message formats, message header codes, node IDs, application services and service codes, data definitions, diagnostic connectors, diagnostic services and test mode codes, ITS data bus–vehicle bus gateway services and service codes, network management services/functionality, and other areas as may be needed.

National ITS Architecture. The National ITS Architecture provides a common framework for planning, defining, and integrating intelligent transportation systems (16). It is a mature product that reflects the contributions of a broad cross section of the ITS community: transportation practitioners, systems engineers, system developers, technology specialists, and consultants. The architecture provides high-level definitions of the functions, physical entities, and information flows that are required for ITS. The architecture is meant to be used as a planning tool for state and local governments.

Traffic Management Data Dictionary. The Data Dictionary for Advanced Traveler Information Systems, Society of Automotive Engineers (SAE) standard J2353, provides concise definitions for the data elements used in advanced traveler information systems (ATIS) (17). These definitions provide a bit-by-bit breakdown of each data element using ASN.1. The traffic management data dictionary is meant to be used in conjunction with at least two other standards, one for defining the message sets (e.g., SAE J2354 and SAE J2369) and the other for defining the communication protocol to be used.

TransXML. XML Schemas for the exchanges of Transportation Data (TransXML) is a fledgling standard with the goal to integrate various standards such as LandXML, aecXML, ITS XML, and OpenGIS into a common framework. This project has not had any results yet; see Ref. 18 for more information.

Geography Markup Language. Geography markup language (GML) is an OpenGIS standard based on XML that is used for encoding and storing geographic information, including the geometry and properties of geographic features (19). GML was developed by an international, nonprofit standards organization, the Open GIS Consortium, Inc. GML describes geographic features using a variety of XML elements such as features, coordinate referencing systems, geometry, topology, time, units of measure, and generalized values.

Spatial Data Transfer Standard. The Spatial Data Transfer Standard (SDTS) is a National Institute of Standards (NIST) standard for the exchange of digitized spatial data between computer systems (20). SDTS uses ISO 8211 for its physical file encoding and breaks the file down into modules, each of which is composed of records, which in turn are composed of fields. Thirty-four different types of modules currently are defined by the standard, some of which are specialized for a specific application.

LandXML. LandXML is an industry-developed standard schema for the exchange of data created during land planning, surveying, and civil engineering design processes by different applications software. LandXML was developed by an industry consortium of land developers, universities, and various government agencies. LandXML is used within GIS applications, survey field instruments, civil engineering desktop and computer aided design (CAD)-based applications, instant three-dimensional (3-D) viewers, and high-end 3D visualization rendering applications. LandXML has provisions for not only the storage of a feature's geometry, but also for its attributes, such as property owner and survey status. LandXML can be converted readily to GML format.

Scalable Vector Graphics. Scalable vector graphics (SVG) is an XML-based standard for the storage and display of graphics using vector data and graphic primitives. It primarily is used in the design of websites, but also it has application for the display and transfer of vector-based geographic data. It does not, however, have specific provisions for the attributes that are associated with geographic data such as road names and speed limits.

Location Referencing Data Model. The location referencing data model is a National Cooperative Highway Research Program (NCHRP) project that defines a location referencing system. Within this system, a location can be defined in various formats such as mile points or addresses. It also provides for the conversion of a location between the various formats and for the definition of a location in one, two, or more dimensions (21).

International Standards Organization Technical Committee 211. The International Standards Organization Technical Committee 211 (ISO TC/211) has several geographic standards that are of importance to intelligent transportation systems: Geographic information—Rules for Application Schema; ISO 19123, Geographic information—Schema for coverage geometry and functions; and ISO 19115, Geographic information—Metadata.

Data Mining and Analysis

Data mining and analysis of transportation data are useful for transportation planning purposes (e.g., transit development, safety analysis, and road design). Data quality especially is important because the sensors involved can malfunction and feed erroneous data into the analysis process (22). For this reason, ITS data typically needs to be filtered carefully to assure data quality. This filtering is accomplished by throwing out inconsistent data. For instance, a speed detector may be showing a constant free flow speed while its upstream and downstream counterparts show much slower speeds during peak usage hours. In this case, the inconsistent detector data would be thrown out and an average of the up and downstream detectors would be used instead.

DATA PRIVACY

The definition of privacy varies greatly among societies, across time, and even among individuals; with so much variation and interpretation, providing a single concrete definition is difficult. Several concepts that are related to privacy are as follows:

Solitude: The right of an individual to be undisturbed by, or invisible from, some or all other members of society, including protection of the home, work, or a public place from unwanted intrusion.

Secrecy: The ability to keep personal information secret from some or all others, including the right to control the initial and onward distribution of personal information and the ability to communicate with others in private.

Anonymity: The right to anonymity by allowing an individual to remain nameless in social or commercial interaction.

LEGAL BACKGROUND

In their influential article entitled "The Right to Privacy" published in the Harvard Law Review in 1890, Samuel D. Warren and Louis D. Brandeis described how "[i]nstantaneous photographs and newspaper enterprise have invaded the sacred precincts of private and domestic life; and numerous mechanical devices threaten to make good the prediction that 'what is whispered in the closet shall be proclaimed from the house-tops.'"

Warren and Brandeis described how U.S. common law could be used to protect an individual's right to privacy. The article has been very influential in the subsequent development of legal instruments to protect data privacy. In 1948, the General Assembly of the United Nations passed the Declaration of Human Rights, of which Article 12 states, "[n]o one shall be subjected to arbitrary interference with his privacy, family, home or correspondence, nor to attacks upon his honour and reputation. Everyone has the right to the protection of the law against such interference or attacks." The majority of countries in the world now consider privacy as a right and have enacted laws describing how and when citizens can expect privacy.

The level of legal protection of privacy varies from one country to another. In the United States, there is no general privacy protection law to regulate private industry; instead specific federal legislation is introduced to deal with particular instances of the collection and processing of personal information. In addition, some states have amended their consititutions to include specific rights to privacy. In areas not covered by specific federal or state laws, companies are left to self-regulate. The new executive post of Chief Privacy Officer has been adopted by some companies, with responsibilities including the development of privacy policy, tracking legislation, monitoring competitors, training employees, and if necessary, performing damage control in the press.

The European Union has a comprehensive framework to control the collection and distribution of personally identifiable information by both state and private-sector institutions. The 1998 EU Data Protection Directive is the latest piece of European legislation that follows on from a series of national laws initially developed in the 1970s and earlier EU directives and OECD guidelines.

The EU Directive requires that all personal data are as follows:

- Processed fairly and lawfully
- Collected for explicit purposes and not further processed in any way incompatible with those purposes
- Relevant and not excessive in relation to the collected purposes
- Accurate and up to date
- Kept in a form that identifies an individual for no longer than neccessary to meet the stated purpose

Companies, governments, and in some cases individuals who process personal information must register their intent to do so with an independent supervisory authority and outline the requirement for, and purpose of, data processing. The supervisory authority has the power to investigate the processing of personal data and impose sanctions on those who do not adhere to the Directive. Individuals are entitled to receive a copy of their personal data held by a third-party "at reasonable intervals and without excessive delay or expense."

The European model has been widely copied elsewhere, in part because the Directive requires adequate levels of protection for the processing of personal data be available in all countries that receive personal data from within the EU. The provision of adequate protection is open to interpretation, and in some cases, it has been condemned for being too low; for example, the 2004 agreement between the European Commission and the United States to share airline passenger screening data has been widely criticized.

THE EFFECT OF TECHNOLOGY ON PRIVACY

Developments in science and technology continue to provide individuals, governments, and private industry with new ways to invade the privacy of others. In particular, the ability of computers to record, process, and communicate personal data has increased exponentially during the latter decades of the twentieth century. This increase in computing power has been used by governments, companies, and individuals to process an increasing quantity of personally identifiable data. Globalization has driven the desire to distribute personal information to different parts of the world and has encouraged the development of standards

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

such as the Internet Protocol suite and XML, enabling an efficient exchange of digital information on a global scale.

The widespread use of the personal computer and the Internet has provided a variety of both legitimate and malicous reasons for individuals to process personal data. Social networking websites allow people to search for user profiles matching certain criteria. Similarly, querying a Web search engine for an individual's name reveals a wealth of information about the person, including archived posts on mailing lists and newsgroups, personal home pages, business web pages, and telephone numbers. Often this information is intentionally published by, or on behalf of, the individual, but this copious amount of information can be easily misused. More serious invasions of privacy are possible when personal computers are connected to the Internet and contain sensitive personal data, for example, financial records and medical information. Many computers today are relatively insecure and are easy prey for malicious code in the form of viruses, trojans, and worms. Once compromised, a computer falls under the complete control of an attacker who may freely access any private data stored there.

The quantity and quality of personal information available on the Internet can be sufficient for a malicious person to perform *identity theft*, allowing them to impersonate a victim for illicit financial gain. *Cyberstalkers* use information available online to harrass their victims, sometimes with violent consequences. Anti-abortion activists have created websites detailing the home addresses of abortion doctors and photos of women who receive an abortion; these details have then been used by violent extremists, sometimes resulting in murder.

Governments process personal data for a variety of different purposes. Census data are collected from citizens in many countries to enable strategic planning of state and private sector services. Financial data such as bank account transactions are examined in the fight against organized crime, and biological data such as photographs, fingerprints, iris scans, and DNA profiles can be collected for both research and forensic analysis purposes. Traditionally, different government departments, like separate companies, have kept separate databases, but in some cases, disparate systems are in the process of, or have already been merged, enabling far more in-depth citizen profiling.

Companies compile personal information about customers to process orders, determine effective marketing strategies, and direct advertisements toward individuals who are likely to be receptive to them. Targetted advertisements are often used to increase consumer loyalty by providing discount points, tokens, or coupons on products of interest to a specific individual.

In economics, the act of charging different prices to different customers is known as *price discrimination* and is common practice in many markets worldwide. There are several different mechanisms by which sellers can perform price discrimination, including individual bartering, schemes of quantity discounts, and market segmentation. Sellers who have collected detailed personal information on buyers can employ a fourth mechanism. They can compute directly how much a user *can* pay for a product.

In markets with large up-front costs and low production costs, sellers can sacrifice the privacy of buyers to good effect, maximizing their profits without having to unnecessarily inconvenience anyone. For example, sellers no longer need to employ market segmentation to force poorer buyers to purchase third-class tickets; instead everyone can get the same high-quality service but for different prices: a potential social benefit. Societies have yet to decide whether this represents a reasonable invasion of privacy or something requiring government regulation.

Small and mobile computational devices are becoming increasingly popular. The GSM Association estimated that in early 2004, more than one billion people—one sixth of the world's population—had a GSM mobile phone. As devices like these continue to proliferate, the volume of personal information processed by computers will continue to increase, not just because there are more devices, but because these devices increasingly need to collect more personal information to function effectively (see UBIQUITOUS COMPUTING). As a consequence, providing privacy in the twenty-first century will become increasingly difficult and important.

USING TECHNOLOGY TO PROTECT PRIVACY

Although computer-related technologies are increasing the ability of individuals, companies, and governments to invade personal privacy, technology can also be used to increase the level of privacy available to individuals. Several solutions can be used depending on the level of trust placed in the recipients of private information.

Secrecy

Developments in cryptography have enabled information and communications to be encrypted, maintaining their secrecy in the presence of attacks by other individuals, companies, and even governments. In the latter part of the twentieth century, governments were reluctant to allow individuals access to strong encryption and therefore attempted to control the distribution of strong encryption technology. The development of the personal computer made governmental restriction on strong encryption ultimately impossible, because individuals could purchase computers powerful enough to perform both symmetric and public key cryptography in software.

Pretty Good Privacy (PGP) was one of the first programs developed to take advantage of the power of personal computers and offer individuals access to strong encryption schemes to keep documents secret from corporations and governments; it was so successful at this that its author, Phil Zimmerman, was charged with (but later acquitted of) violating U.S. export laws. More recently, Transport Layer Security (TLS) has been developed for the World Wide Web to enable end-to-end privacy of communications between two participants. As such, TLS has been a key enabling technology in the development of e-commerce over the Internet, enabling buyers and sellers to exchange credit card information in a secure way.

Access Control

Cryptography is excellent at protecting privacy when the data are controlled by its owner and it is shared with relatively few other parties who trust each other to keep the data secret. Sharing data with a larger set of participants increases the likelihood that trust is misplaced in at least one party, thereby jeopardizing data secrecy. The number of participants with access to private information can often be reduced by implementing *multilateral security*, where information is stored in compartments accessable to only a few individuals, and the flow of information between compartments is restricted (see COMPUTER SECURITY).

A recent example of using multilateral security to protect privacy is the British Medical Association model for controlling access to electronic patient records. In the model, patients do not have a single electronic record; rather, they have a set of records (or compartments), each of which has a separate list of health-care workers who have the permission to read or append information to it. The flow of information between different records is restricted to prevent particularly sensitive information detailed in one record, such as a positive HIV test, from being introduced into other records.

Reciprocity

Configuring fine-grained access control parameters can be time consuming and difficult to get right. An alternative solution is to use *reciprocity*, where two or more entities agree to the mutual exchange of private data. The exchange of information is symmetric if each party in the reciprocal transaction reveals the same piece of private data to all other parties; for example, three friends share their current mobile phone location with each other through their mobile phone operator. An exchange of data is asymmetric if information is provided in return for the knowledge of the recepient's identity. For example, in the United Kingdom, consumer credit ratings employ reciprocity: If a company queries a credit rating of an individual, that fact is recorded in the database so that when an individual queries their credit rating at a later date, they can see which companies examined their record.

Asymmetric reciprocity requires those requesting data to have a reputation worth protecting so that they obey acceptable social conventions when asking for information. Therefore, an abusive information request should reduce the attacker's reputation so that a requester with a poor reputation forfeits all future access. Symmetric reciprocity requires that the information shared by each participant is of similar value and therefore constitutes a fair exchange. This is not always true; for example, the home phone number of a famous individual may be considered more valuable than the phone number of an ordinary citizen.

A centralized authority is usually required to enforce reciprocity by authenticating both the identities of those who access private data and the actual content of the mutually shared information. Authentication guarantees the identities of the parties, and the content of the exchanged information cannot be forged; therefore, the central authority must be trusted by all parties who use the system.

Anonymity

Sometimes there no trust relationship exists between the owner of personal information and a third-party, and yet they still want to exchange information. For example, individuals may not want to reveal the contents of their medical records to drug companies; yet the development of pharmaceutical products clearly benefits from access to the information contained within such documents. It is often possible to provide access to a *subset* of the data that satisfies the demands of the third party and simultaneously protects the privacy of an individual through *anonymization*.

Anonymization protects an individual's privacy by removing all personally identifiable data before delivering it to an untrusted third party. Therefore, once data are successfully anonymized an adversary cannot infer the real-world individual represented by the data set. Anonymization is not an easy process; it is not sufficient to simply remove explicit identifiers such as a name or telephone number, because a combination of other attributes may enable a malicious data recipient to infer the individual represented by the data set. For example, in the set of medical records for Cambridge, England, there may be only one 42-year-old professor who has lost sight in one eye. If the data presented to the third party contains information concerning the individual's home city, profession, date of birth, and ophthalmology in sufficient detail, then it may be possible to associate this data with a real-world entity and therefore associate any other data in this record with a concrete identity. In this case, the privacy of the professor is effectively lost and the contents of his medical record, as presented to the third party, are revealed.

Successful anonymization may require the values in the released data set to be modified to prevent the third party from inferring the real-world identity associated with a record. For example, reducing the accuracy of the individual's age from 42 to the range (40–50) may prevent an attacker associating an identity with the record. Whether this reduction alone is sufficient depends on the data held in the other records (in the example above, it depends on the number of other professors between the ages of 40 and 50 with sight in only one eye). In general, anonymization of data is achieved through a thorough statistical analysis of the data set that takes into account the amount of information known by an attacker; such analysis is called Statistical Disclosure Control.

IS PRIVACY ALWAYS WORTH PROTECTING?

The rigorous protection of privacy is not always of benefit to the individual concerned or society at large. Professor Anita Allen observed that privacy in the home and workplace has been a problem for women where it led to "imposed modesty, chastity, and domestic isolation." Such enforced solitude can prevent the exposure of criminal acts such as domestic abuse. Allowing government ministers and departments privacy in their professional duties is at odds with the principles of openness and accountability. Most people would agree on the need for secrecy and privacy in the realm of international espionage but would hesitate in restricting the freedom of the press to uncover corruption and financial irregularities.

Similarly, company directors are ultimately accountable to shareholders; however, the desire for openness with investors must be reconciled with the need to protect business secrets from competitors. Most countries use legal measures to force businesses to make certain information publically available, for example, the filing of public accounts; yet financial scandals are still not uncommon. In many instances, an individual's right to privacy must be balanced with the need to protect themselves or others.

DATA SEARCH ENGINE

INTRODUCTION

The World Wide Web was first developed by Tim Berners-Lee and his colleagues in 1990. In just over a decade, it has become the largest information source in human history. The total number of documents and database records that are accessible via the Web is estimated to be in the hundreds of billions (1). By the end of 2005, there were already over 1 billion Internet users worldwide. Finding information on the Web has become an important part of our daily lives. Indeed, searching is the second most popular activity on the Web, behind e-mail, and about 550 million Web searches are performed every day.

The Web consists of the Surface Web and the Deep Web (Hidden Web or Invisible Web). Each page in the Surface Web has a logical address called Uniform Resource Locator (URL). The URL of a page allows the page to be fetched directly. In contrast, the Deep Web contains pages that cannot be directly fetched and database records stored in database systems. It is estimated that the size of the Deep Web is over 100 times larger than that of the Surface Web (1).

The tools that we use to find information on the Web are called *search engines*. Today, over 1 million search engines are believed to be operational on the Web (2). Search engines may be classified based on the type of data that are searched. Search engines that search text documents are called *document search engines*, whereas those that search structured data stored in database systems are called *database search engines*. Many popular search engines such as Google and Yahoo are document search engines, whereas many e-commerce search engines such as Amazon.com are considered to be database search engines. Document search engines usually have a simple interface with a textbox for users to enter a query, which typically contains some key words that reflect the user's information needs. Database search engines, on the other hand, usually have more complex interfaces to allow users to enter more specific and complex queries.

Most search engines cover only a small portion of the Web. To increase the coverage of the Web by a single search system, multiple search engines can be combined. A search system that uses other search engines to perform the search and combines their search results is called a *metasearch engine*. Mamma.com and dogpile.com are metasearch engines that combine multiple document search engines whereas addall.com is a metasearch engine that combines multiple database search engines for books. From a user's perspective, there is little difference between using a search engine and using a metasearch engine.

This article provides an overview of some of the main methods that are used to create search engines and metasearch engines. In the next section, we describe the basic techniques for creating a document search engine. Then we sketch the idea of building a database search engine. Finally, we introduce the key components of metasearch engines, including both document metasearch engines and database metasearch engines, and the techniques for building them.

DOCUMENT SEARCH ENGINE

Architecture

Although the architectures of different Web search engines may vary, a typical document search engine generally consists of the following four main components as shown in Fig. 1: Web crawler, Indexer, Index database, and Query engine. A Web crawler, also known as a Web spider or a Web robot, traverses the Web to fetch Web pages by following the URLs of Web pages. The Indexer is responsible for parsing the text of each Web page into word tokens and then creating the Index database using all the fetched Web pages. When a user query is received, the Query engine searches the Index database to find the matching Web pages for the query.

Crawling the Web

A Web crawler is a computer program that fetches Web pages from remote Web servers. The URL of each Web page identifies the location of the page on the Web. Given its URL, a Web page can be downloaded from a Web server using the HTTP (HyperText Transfer Protocol). Starting from some initial URLs, a Web crawler repeatedly fetches Web pages based on their URLs and extracts new URLs from the downloaded pages so that more pages can be downloaded. This process ends when some termination conditions are satisfied. Some possible termination conditions include (1) no new URL remains and (2) a preset number of pages have been downloaded. As a Web crawler may interact with numerous autonomous Web servers, it is important to design scalable and efficient crawlers.

To crawl the Web quickly, multiple crawlers can be applied. These crawlers may operate in two different manners (i.e., centralized and distributed). Centralized crawlers are located at the same location running on different machines in parallel. Distributed crawlers are distributed at different locations of the Internet, and controlled by a central coordinator; each crawler just crawls the Web sites that are geographically close to the location of the crawler. The most significant benefit of distributed crawlers is the reduction in communication cost incurred by crawling activity. Centralized crawlers, however, are easier to implement and control than distributed crawlers.

As the Web grows and changes constantly, it is necessary to have the crawlers regularly re-crawl the Web and make the contents of the index database up to date. Frequent re-crawling of the Web will waste significant resources and make the network and Web servers over-

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

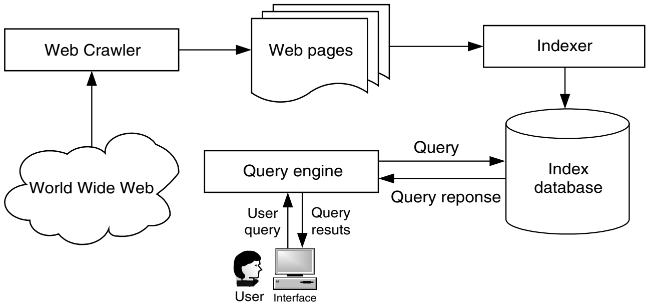

Figure 1. The general architecture of a document search engine.

loaded. Therefore, some incremental crawling strategies should be employed. One strategy is to re-crawl just the changed or newly added Web pages since the last crawling. The other strategy is to employ topic-specific crawlers to crawl the Web pages relevant to a pre-defined set of topics. Topic-specific crawling can also be used to build specialized search engines that are only interested in Web pages in some specific topics.

Conventional Web crawlers are capable of crawling only Web pages in the Surface Web. Deep Web crawlers are designed to crawl information in the Deep Web (3). As information in the Deep Web is often hidden behind the search interfaces of Deep Web data sources, Deep Web crawlers usually gather data by submitting queries to these search interfaces and collecting the returned results.

Indexing Web Pages

After Web pages are gathered to the site of a search engine, they are pre-processed into a format that is suitable for effective and efficient retrieval by search engines. The contents of a page may be represented by the words it has. Non-content words such as "the" and "is" are usually not used for page representation. Often, words are converted to their stems using a stemming program to facilitate the match of the different variations of the same word. For example, "comput" is the common stem of "compute" and "computing". After non-content word removal and stemming are performed on a page, the remaining words (called *terms* or *index terms*) are used to represent the page. Phrases may also be recognized as special terms. Furthermore, a weight is assigned to each term to reflect the importance of the term in representing the contents of the page.

The weight of a term t in a page p within a given set P of pages may be determined in a number of ways. If we treat each page as a plain text document, then the weight of t is usually computed based on two statistics. The first is its *term frequency* (*tf*) in p (i.e., the number of times t appears in p), and the second is its *document frequency* (*df*) in P (i.e., the number of pages in P that contain t). Intuitively, the more times a term appears in a page, the more important the term is in representing the contents of the page. Therefore, the weight of t in p should be a monotonically increasing function of its term frequency. On the other hand, the more pages that have a term, the less useful the term is in differentiating different pages. As a result, the weight of a term should be a monotonically decreasing function of its document frequency. Currently, most Web pages are formatted in HTML, which contains a set of tags such as *title* and *header*. The tag information can be used to influence the weights of the terms for representing Web pages. For example, terms in the title of a page or emphasized using bold and italic fonts are likely to be more important in representing a page than terms in the main body of the page with normal font.

To allow efficient search of Web pages for any given query, the representations of the fetched Web pages are organized into an *inverted file structure*. For each term t, an inverted list of the format $[(p_1, w_1), \ldots, (p_k, w_k)]$ is generated and stored, where each p_j is the identifier of a page containing t and w_j is the weight of t in p_j, $1 \leq j \leq k$. Only entries with positive weights are kept.

Ranking Pages for User Queries

A typical query submitted to a document search engine consists of some keywords. Such a query can also be represented as a set of terms with weights. The degree of match between a page and a query, often call the *similarity*, can be measured by the terms they share. A simple approach is to add up the products of the weights corresponding to the matching terms between the query and the page. This approach yields larger similarities for pages that share more important terms with a query. However, it tends to favor longer pages over shorter ones. This problem is often addressed by dividing the above similarity by the product of the lengths of the query and the page. The function that computes such type of similarities is called the *Cosine* function (4). The length of each page can be computed beforehand and stored at the search engine site.

Many methods exist for ranking Web pages for user queries, and different search engines likely employ different ranking techniques. For example, some ranking methods also consider the proximity of the query terms within a page. As another example, a search engine may keep track of the number of times each page has been accessed by users and use such information to help rank pages. Google (www.google.com) is one of the most popular search engines on the Web. A main reason why Google is successful is its powerful ranking method, which has the capability to differentiate more important pages from less important ones even when they all contain the query terms the same number of times. Google uses the linkage information among Web pages (i.e., how Web pages are linked) to derive the importance of each page. A link from page A to page B is placed by the author of page A. Intuitively, the existence of such a link is an indication that the author of page A considers page B to be of some value. On the Web, a page may be linked from many other pages and these links can be aggregated in some way to reflect the overall importance of the page. For a given page, *PageRank* is a measure of the relative importance of the page on the Web, and this measure is computed based on the linkage information (5). The following are the three main ideas behind the definition and computation of PageRank. (1) Pages that are linked from more pages are likely to be more important. In other words, the importance of a page should be reflected by the popularity of the page among the authors of all Web pages. (2) Pages that are linked from more important pages are likely to be more important themselves. (3) Pages that have links to more pages have less influence over the importance of each of the linked pages. In other words, if a page has more child pages, then it can only propagate a smaller fraction of its importance to each child page. Based on the above insights, the founders of Google developed a method to calculate the importance (PageRank) of each page on the Web (5). The PageRanks of Web pages can be combined with other, say content-based, measures to indicate the overall relevance of a page with respect to a given query. For example, for a given query, a page may be ranked based on a weighted sum of its similarity with the query and its PageRank. Among pages with similar similarities, this method will rank those that have higher PageRanks.

Effective and Efficient Retrieval

For a given query, a page is said to be *relevant* if the sender of the query finds the page useful. For a given query submitted by a user against a fixed set of pages, the set of relevant pages is also fixed. A good retrieval system should return a high percentage of relevant pages to the user and rank them high in the search result for each query. Traditionally, the effectiveness of a text retrieval system is measured using two quantities known as *recall* and *precision*. For a given query and a set of documents, recall is the percentage of the relevant documents that are retrieved and precision is the percentage of the retrieved documents that are relevant. To evaluate the effectiveness of a text retrieval system, a set of test queries is often used. For each query, the set of relevant documents is identified in advance. For each test query, a precision value at a different recall point is obtained. When the precision values at different recall values are averaged over all test queries, an average recall-precision curve is obtained, which is used as the measure of the effectiveness of the system. A system is considered to be more effective than another system if the recall-precision curve of the former is above that of the latter. A perfect text retrieval system should have both recall and precision equal to 1 at the same time. In other words, such a system retrieves exactly the set of relevant documents for each query. In practice, perfect performance is not achievable for many reasons, for example, a user's information needs usually cannot be precisely specified by the used query and the contents of documents and queries cannot be completely represented by weighted terms.

Using both recall and precision to measure the effectiveness of traditional text retrieval systems requires knowing all the relevant documents for each test query in advance. This requirement, however, is not practical for independently evaluating large search engines because it is impossible to know the number of relevant pages in a search engine for a query unless all the pages are retrieved and manually examined. Without knowing the number of relevant pages for each test query, the recall measure cannot be computed. As a result of this practical constraint, search engines are often evaluated using the average precision based on the top k retrieved pages for a set of test queries, for some small integer k, say 20, or based on the average position of the first relevant page among the returned results for each test query (6).

A large search engine may index hundreds of millions or even billions of pages, and process millions of queries on a daily basis. For example, by the end of 2005, the Google search engine has indexed about 10 billion pages and processed over 200 million queries every day. To accommodate the high computation demand, a large search engine often employs a large number of computers and efficient query processing techniques. When a user query is received by a search engine, the inverted file structure of the pre-processed pages, not the pages themselves, are used to find matching pages. Computing the similarity between a query and every page directly is very inefficient because the vast majority of the pages likely do not share any term with the query and computing the similarities of these pages with the query is a waste of resources. To process a query, a *hash table* is first used to locate the storage location of the inverted file list of each query term. Based on the inverted file lists of all the terms in the query, the similarities of all the pages that contain at least one term in common with the query can be computed efficiently.

Result Organization

Most search engines display search results in descending order of their matching scores with respect to a given query. Some search engines, such as the Vivisimo search engine (www.vivisimo.com), organize their results into groups such that pages that have certain common features are placed into the same group. Clustering/categorizing search results is known to be effective in helping users identify relevant results in two situations. One is when the number of results returned for a query is large, which is mostly true for large search engines, and the other is when a query submitted by a user is short, which is also mostly true as the average number of terms in a search engine query is slightly over two. When the number of results is large, clustering allows the searcher to focus the attention on a small number of promising groups. When a query is short, the query may be interpreted in different ways, in this case, clustering can group results based on different interpretations that allow the searcher to focus on the group with desired interpretation. For example, when query "apple" is submitted to the Vivisimo search engine, results related to Apple computer (Macintosh) forms one group and results related to fruit forms another group, which makes it easy for a user to focus on the results he/she wants.

Challenges of Document Search Engines

Although Web search engines like Google, Yahoo, and MSN are widely used by numerous users to find the desired information on the Web, there are still a number of challenges for enhancing their quality (7,8). In the following, we briefly introduce some of these challenges.

Freshness. Currently, most search engines depend on Web crawlers to collect Web pages from numerous Web sites and build the index database based on the fetched Web pages. To refresh the index database so as to provide up-to-date pages, they periodically (e.g., once every month) *recollect* Web pages from the Internet and *rebuild* the index database. As a result, pages that are added/deleted/changed since the last crawling are not reflected in the current index database, which makes some pages not accessible via the search engine, some retrieved pages not available on the Web (i.e., deadlinks), and the ranking of some pages based on obsolete contents. How to keep the index database up-to-date for large search engines is a challenging issue.

Coverage. It was estimated that no search engine indexes more than one-third of the "publicly indexable Web" (9). One important reason is that the Web crawlers can only crawl Web pages that are linked to the initial seed URLs. The "Bow Tie" theory about the Web structure (10) indicates that only 30% of the Web pages are strongly connected. This theory further proves the limitation of Web crawlers. How to fetch more Web pages, including those in the Deep Web, is a problem that needs further research.

Quality of Results. Quality of results refers to how well the returned pages match the given keywords query. Given a keywords query, a user wants the most relevant pages to be returned. Suppose a user submits "apple" as a query, a typical search engine will return all pages containing the word "apple" no matter if it is related to an apple pie recipe or Apple computer. Both the keywords-based similarity and the lack of context compromise the quality of returned pages. One promising technique for improving the quality of results is to perform a personalized search, in which a profile is maintained for each user that contains the user's personal information, such as specialty and interest, as well as some information obtained by tracking the user's Web surfing behaviors, such as which pages the user has clicked and how long the user spent on reading them; a user's query can be expanded based on his/her profile, and the pages are retrieved and ranked based on how well they match the expanded query.

Natural Language Query. Currently, most search engines accept only keywords queries. However, keywords cannot precisely express users' information needs. Natural language queries, such as "Who is the president of the United States?" often require clear answers that cannot be provided by most current search engines. Processing natural language queries requires not only the understanding of the semantics of a user query but also a different parsing and indexing mechanism of Web pages. Search engine ask.com can answer some simple natural language queries such as "Who is the president of the United States?" and "Where is Chicago?" using its *Web Answer* capability. However, ask.com does not yet have the capability to answer general natural language queries. There is still a long way to go before general natural language queries can be precisely answered.

Querying Non-Text Corpus. In addition to textual Web pages, a large amount of image, video, and audio data also exists on the Web. How to effectively and efficiently index and retrieve such data is also an open research problem in data search engines. Although some search engines such as Google and Yahoo can search images, their technologies are still mostly keywords-match based.

DATABASE SEARCH ENGINE

In comparison with document search engines, database search engines are much easier to build because they do not need crawlers to crawl the Web to build the index database. Instead, traditional database systems such as Oracle or SQL-server are usually used by database search engines to store and manage data. The stored data are often compiled and entered by human users. Unlike Web pages that have little structure, the data in database search engines are generally well structured. For example, the database of an online Web bookstore contains various books, and every book has attributes such as title, author, ISBN, publication date, and so on.

To make the data in a database search engine Web-accessible, an HTML form-based Web search interface like Fig. 2 is created on top of the underlying database system. The Web search interface often has multiple fields for users to specify queries that are more complex than the keywords queries for document Web search engines. For example, the search interface of bn.com (Fig. 2) contains fields like title, author, price, format, and so on. A user query submitted through the Web search interface of a database search engine is usually converted to a database query (e.g., SQL) that can be processed by the underlying database system; after the results that satisfy the query conditions are returned by the database system, they are wrapped by appropriate HTML tags and presented to the user on the dynamically generated Web page.

Database search engines are often used by organizations or companies that want to publish their compiled data on the Web for information sharing or business benefits. For example, a real estate company may employ a database search engine to post housing information, and an airline may use a database search engine to allow travelers to search and purchase airplane tickets.

It should be noted that structured data that are stored in database systems and are accessible via database search engines constitute a major portion of the Deep Web. A

recent survey (2) estimated that, by April 2004, among the 450,000 search engines for the Deep Web, 348,000 were database search engines.

METASEARCH ENGINE

A metasearch engine is a system that provides unified access to multiple existing search engines. When a metasearch engine receives a query from a user, it sends the query to multiple existing search engines, and it then combines the results returned by these search engines and displays the combined results to the user. A metasearch engine makes it easy for a user to search multiple search engines simultaneously while submitting just one query. A big benefit of a metasearch engine is its ability to combine the coverage of many search engines. As metasearch engines interact with the search interfaces of search engines, they can use Deep Web search engines just as easily as Surface Web search engines. Therefore, metasearch engine technology provides an effective mechanism to reach a large portion of the Deep Web by connecting to many Deep Web search engines.

Metasearch Engine Architecture

A simple metasearch engine consists of a user interface for users to submit queries, a search engine connection component for programmatically submitting queries to its employed search engines and receiving result pages from them, a result extraction component for extracting the search result records from the returned result pages, and a result merging component for combining the results (11). If a metasearch engine employs a large number of search engines, then a search engine selection component is needed. This component determines which search engines are likely to contain good matching results for any given user query so that only these search engines are used for this query. Search engine selection is necessary for efficiency considerations. For example, suppose only the 20 best-matched results are needed for a query and there are 1000 search engines in a metasearch engine. It is clear that the 20 best-matched results will come from at most 20 search engines, meaning that at least 980 search engines are not useful for this query. Sending a query to useless search engines will cause serious inefficiencies, such as heavy network traffic caused by transmitting unwanted results and the waste of system resources for evaluating the query.

We may have metasearch engines for document search engines and metasearch engines for database search engines. These two types of metasearch engines, though conceptually similar, need different techniques to build. They will be discussed in the next two subsections.

Document Metasearch Engine

A document metasearch engine employs document search engines as its underlying search engines. In this subsection, we discuss some aspects of building a document metasearch engine, including search engine selection, search engine connection, result extraction, and merging.

Search Engine Selection. When a metasearch engine receives a query from a user, the metasearch engine makes a determination on which search engines likely contain useful pages to the query and therefore should be used to process the query. Before search engine selection can be performed, some information representing the contents of the set of pages of each search engine is collected. The information about the pages in a search engine is called the *representative* of the search engine (11). The representatives of all search engines used by the metasearch engine are collected in advance and are stored with the metasearch engine. During search engine selection for a given query, search engines are ranked based on how well their representatives match with the query.

Different search engine selection techniques exist and they often employ different types of search engine representatives. A simple representative of a search engine may contain only a few selected key words or a short description. This type of representative is usually produced manually by someone who is familiar with the contents of the search engine. When a user query is received, the metasearch engine can compute the similarities between the query and the representatives, and then select the search engines with the highest similarities. Although this method is easy to implement, this type of representative provides only a general description about the contents of search engines. As a result, the accuracy of the selection may be low.

More elaborate representatives collect detailed statistical information about the pages in each search engine. These representatives typically collect one or several pieces of statistical information for each term in each search engine. As it is impractical to find out all the terms that appear in some pages in a search engine, an approximate vocabulary of terms for a search engine can be used. Such an approximate vocabulary can be obtained from pages retrieved from the search engine using sample queries (12). Some of the statistics that have been used in proposed search engine selection techniques include, for each term, its *document frequency*, its average or maximum weight in all pages having the term, and the number of search engines that have the term. With the detailed statistics, more accurate estimation of the usefulness of each search engine with respect to any user query can be obtained. The collected statistics may be used to compute the similarity between a query and each search engine, to estimate the number of pages in a search engine whose similarities with the query are above a threshold value, and to estimate the similarity of the most similar page in a search engine with respect to a query (11). These quantities allow search engines to be ranked for any given query and the top-ranked search engines can then be selected to process the query.

It is also possible to generate search engine representatives by learning from the search results of past queries. In this case, the representative of a search engine is simply the knowledge indicating its past performance with respect to different queries. In the SavvySearch metasearch engine (13) (now www.search.com), the learning is carried out as follows. For a search engine, a weight is maintained for each term that has appeared in previous queries. The weight of a term for a search engine is increased or decreased depending on whether the search engine returns useful results for a query containing the term. Over time, if a search engine has a large positive (negative) weight for a term, the search engine is considered to have responded well (poorly) to the term in the past. When a new query is received by the metasearch engine, the weights of the query terms in the representatives of different search engines are aggregated to rank the search engines. The ProFusion metasearch engine also employs a learning-based approach to construct the search engine representatives (14). ProFusion uses training queries to find out how well each search engine responds to queries in 13 different subject categories. The knowledge learned about each search engine4 from training queries is used to select search engines to use for each user query and the knowledge is continuously updated based on the user's reaction to the search result (i.e., whether a particular page is clicked by the user).

Search Engine Connection. Usually, the search interface of a search engine is implemented using an HTML *form* tag with a query textbox. The form tag contains all information needed to connect to the search engine via a program. Such information includes the name and the location of the program (i.e., the search engine server) that processes user queries as well as the network connection method (i.e., the HTTP request method, usually GET or POST). The query textbox has an associated name and is used to fill out the query. The form tag of each search engine interface is pre-processed to extract the information needed for program connection. After a query is received by the metasearch engine and the decision is made to use a particular search engine, the query is assigned to the name of the query textbox of the search engine and sent to the server of the search engine using the HTTP request method supported by the search engine. After the query is processed by the search engine, a result page containing the search results is returned to the metasearch engine.

Search Result Extraction. A result page returned by a search engine is a dynamically generated HTML page. In addition to the search result records for a query, a result page usually also contains some unwanted information/ links such as advertisements, search engine host information, or sponsored links. It is essential for the metasearch engine to correctly extract the search result records on each result page. A typical search result record corresponds to a Web page found by the search engine and it usually contains the URL and the title of the page as well as some additional information about the page (usually the first few sentences of the page plus the date at which the page was created, etc.; it is often called the *snippet* of the page).

As different search engines organize their result pages differently, a separate result extraction program (also called *extraction wrapper*) needs to be generated for each search engine. To extract the search result records of a search engine, the structure/format of its result pages needs to be analyzed to identify the region(s) that contain the records and separators that separate different records (15). As a result, a wrapper is constructed to extract the results of any query for the search engine. Extraction wrappers can be manually, semi-automatically, or automatically constructed.

Result Merging. Result merging is the task of combining the results returned from multiple search engines into a single ranked list. Ideally, pages in the merged result should be ranked in descending order of the global matching scores of the pages, which can be accomplished by fetching/downloading all returned pages from their local servers and computing their global matching scores in the metasearch engine. For example, the Inquirus metasearch engine employs such an approach (7). The main drawback of this approach is that the time it takes to fetch the pages might be long.

Most metasearch engines use the local ranks of the returned pages and their snippets to perform result merging to avoid fetching the actual pages (16). When snippets are used to perform the merging, a matching score of each snippet with the query can be computed based on several factors such as the number of unique query terms that appear in the snippet and the proximity of the query terms in the snippet. Recall that when search engine selection is performed for a given query, the usefulness of each search engine is estimated and is represented as a score. The search engine scores can be used to adjust the matching scores of retrieved search records, for example, by multiplying the matching score of each record by the score of the search engine that retrieved the record. Furthermore, if the same result is retrieved by multiple search engines, the multiplied scores of the result from these search engines are aggregated, or added up, to produce the final score for the result. This type of aggregation gives preference to those results that are retrieved by multiple search engines. The search results are then ranked in descending order of the final scores.

Database Metasearch Engine

A database metasearch engine provides a unified access to multiple database search engines. Usually, multiple database search engines in the same application domain (e.g., auto, book, real estate, flight) are integrated to create a database metasearch engine. Such a metasearch engine over multiple e-commerce sites allows users to do comparison-shopping across these sites. For example, a metasearch engine on top of all book search engines allows users to find desired books with the lowest price from all booksellers.

A database metasearch engine is similar to a document metasearch engine in architecture. Components such as search engine connection, result extraction, and result merging are common in both types of metasearch engines, but the corresponding components for database metasearch engines need to deal with more structured data. For example, result extraction needs to extract not only the returned search records (say books) but also lower level semantic data units within each record such as the titles and prices of books. One new component needed for a database metasearch engine is the search interface integration component. This component integrates the search interfaces of multiple database search engines in the same domain into a unified interface, which is then used by users to specify queries against the metasearch engine. This component is not needed for document metasearch engines because document search engines usually have very simple search interfaces (just a textbox). In the following subsections, we present some details about the search interface integration component and the result extraction component. For the latter, we focus on extracting lower level semantic data units within records.

Search Interface Integration. To integrate the search interfaces of database search engines, the first step is to extract the search fields on the search interfaces from the HTML Web pages of these interfaces. A typical search interface of a database search engine has multiple search fields. An example of such an interface is shown in Fig. 2. Each search field is implemented by text (i.e., field label) and one or more HTML form control elements such as textbox, selection list, radio button, and checkbox. The text indicates the semantic meaning of its corresponding search field. A search interface can be treated as a partial schema of the underlying database, and each search field can be considered as an attribute of the schema. Search interfaces can be manually extracted but recently there have been efforts to develop techniques to automate the extraction (17). The main challenge of automatic extraction of search interfaces is to group form control elements and field labels into logical attributes.

After all the search interfaces under consideration have been extracted, they are integrated into a unified search interface to serve as the interface of the database metasearch engine. Search interface integration consists of primarily two steps. In the first step, attributes that have similar semantics across different search interfaces are identified. In the second step, attributes with similar semantics are mapped to a single attribute on the unified interface. In general, it is not difficult for an experienced human user to identify matching attributes across different search interfaces when the number of search interfaces under consideration is small. For applications that need to integrate a large number of search interfaces or need to perform the integration for many domains, automatic integration tools are needed. WISE-Integrator (18) is a tool that is specifically designed to automate the integration of search interfaces. It can identify matching attributes across different interfaces and produce a unified interface automatically.

Result Extraction and Annotation. For a document search engine, a search result record corresponds to a retrieved Web page. For a database search engine, however, a search result record corresponds to a structured entity in the database. The problem of extracting search result records from the result pages of both types of search engines is similar (see search result extraction section). However, a search result record of a database entity is more structured than that of a Web page, and it usually consists of multiple lower level semantic data units that need to be extracted and annotated with appropriate labels to facilitate further data manipulation such as result merging.

Wrapper induction in (19) is a semi-automatic technique to extract the desired information from Web pages. It needs users to specify what information they want to extract, and then the wrapper induction system induces the rules to construct the wrapper for extracting the corresponding data. Much human work is involved in such wrapper construction. Recently, research efforts (20,21) have been put on how to automatically construct wrapper to extract structured data. To automatically annotate the extracted data instances, currently there are three basic approaches: ontology-based (22), search interface schema-based, and physical layout-based. In the ontology-based approach, a task-specific ontology (i.e., conceptual model instance) is usually predefined, which describes the data of interest, including relationships, lexical appearance, and context keywords. A database schema and recognizers for constants and keywords can be produced by parsing the ontology. Then the data units can be recognized and structured using the recognizers and the database schema. The search interface schema-based approach (23) is based on the observation that the complex Web search interfaces of database search engines usually partially reflect the schema of the data in the underlying databases. So the data units in the returned result record may be the values of a search field on search interfaces. The search field labels are thereby assigned to corresponding data units as meaningful labels. The physical layout-based approach assumes that data units usually occur together with their class labels; thus it annotates the data units in such a way that the closest label to the data units is treated as the class label. The headers of a visual table layout are also another clue for annotating the corresponding column of data units. As none of the three approaches is perfect, a combination of them will be a very promising approach to automatic annotation.

Challenges of Metasearch Engines

Metasearch engine technology faces very different challenges compared with search engine technology, and some of these challenges are briefly described below.

Automatic Maintenance. Search engines used by metasearch engines may change their connection parameters and result display format, and these changes can cause the search engines not usable from the metasearch engines unless the corresponding connection programs and result extraction wrappers are changed accordingly. It is very expensive to manually monitor the changes of search engines and make the corresponding changes in the metasearch engine. Techniques that can automatically detect search engine changes and make the necessary adjustments in the corresponding metasearch engine components are needed.

Scalability. Most of today's metasearch engines are very small in terms of the number of search engines used. A typical metasearch engine has only about a dozen search engines. The current largest metasearch engine AllInOneNews (www.allinonenews.com) connects to about 1500 news search engines. But it is still very far away from building a metasearch engine that uses all of the over half million document search engines currently on the Web. There are number of challenges in building very large-scale metasearch engines, including automatic maintenance described above, and automatic generation and maintenance of search engine representatives that are needed to enable efficient and effective search engine selection.

Entity Identification. For database metasearch engines, data records retrieved from different search engines that correspond to the same real-world entities must be correctly identified before any meaningful result merging can be performed. Automatic entity identification across autonomous information sources has been a very challenging issue for a long time. A related problem is the automatic and accurate data unit annotation problem as knowing the meanings of different data units in a record can greatly help match the records. Although research on both entity identification and data unit annotation is being actively pursued, there is still long way to go to solve these problems satisfactorily.

ACKNOWLEDGMENT

This work is supported in part by the following NSF grants: IIS-0414981, IIS-0414939, and CNS-0454298. We also would like to thank the anonymous reviewers for valuable suggestions to improve the manuscript.

DATA SECURITY

INTRODUCTION

The term *data security* refers to the protection of information against possible violations that can compromise its *secrecy* (or confidentiality), *integrity,* or *availability.* Secrecy is compromised if information is disclosed to users not authorized to access it. Integrity is compromised if information is improperly modified, deleted, or tampered. Availability is compromised if users are prevented from accessing data for which they have the necessary permissions. This last problem is also known as *denial-of-service.*

The problem of protecting information has existed since information has been managed. However, as technology advances and information management systems become more and more powerful, the problem of enforcing information security also becomes more critical. The increasing development of information technology in the past few years, which has led to the widespread use of computer systems to store and manipulate information and greatly increased the availability and the processing and storage power of information systems, has also posed new serious security threats and increased the potential damage that violations may cause. Organizations more than ever today depend on the information they manage. A violation to the security of the information may jeopardize the whole system working and cause serious damages. Hospitals, banks, public administrations, and private organizations, all of them depend on the accuracy, availability, and confidentiality of the information they manage. Just imagine what could happen, for instance, if a patient's data were improperly modified, were not available to the doctors because of a violation blocking access to the resources, or were disclosed to the public domain.

Many are the threats to security to which information is exposed. Threats can be *nonfraudulent* or *fraudulent.* The first category comprises all threats resulting in nonintentional violations, such as natural disasters, errors or bugs in hardware or software, and human errors. The second category comprises all threats causing intentional violations. Such threats can be represented by authorized users *(insiders),* who can misuse their privileges and authority, or external users *(intruders),* who can improperly get access to the system and its resources. Ensuring protection against these threats requires the application of different protection measures. This article focuses, in particular, on the protection of information against possible violations by users, insiders, or intruders. The following services are crucial to the protection of data within this context (1):

1. *Identification and Authentication.* It provides the system with the ability of identifying its users and confirming their identity.
2. *Access Control.* It evaluates access requests to the resources by the authenticated users, and based on some access rules, it determines whether they must be granted or denied.
3. *Audit.* It provides a post facto evaluation of the requests and the accesses occurred to determine whether violations have occurred or have been attempted.
4. *Encryption.* It ensures that any data stored in the system or is sent over the network can be deciphered only by the intended recipient. In network communication, it can also be used to ensure the authenticity of the information transmitted and of the parties involved in the communication.

Figure 1 illustrates the position of these services within the system working. Their treatment is the focus of this article.

IDENTIFICATION AND AUTHENTICATION

Authentication is the process of certifying the identity of a party to another. In the most basic form, authentication certifies the identity of a human user to the computer system. Authentication is a prerequisite for a correct access control, because the correctness of the access control relies on the correctness of the identity of the subject requesting access. Good authentication is also important for *accountability,* whereby users can be retained accountable for the actions accomplished when connected to the system. In the authentication process, we can generally distinguish an *identification* phase, where users declare their identity to the computer and submit a proof for it; and an actual *authentication* phase, where the declared identity and the submitted proof are evaluated. The most common ways to enforce user to computer authentication are based on the use of:

- *Something the user knows,* such as a password.
- *Something the user possesses,* such as a magnetic card.
- *Something the user is or does,* such as her physical characteristics.

These techniques can be used in alternative or in combination, thus providing a stronger protection. For instance, a smartcard may require that a password be entered to unlock it.

Authentication Based on Knowledge

The most common technique based on user's knowledge uses secret keywords, named *passwords.* A password, known only to the user and the system, proves the identity of the user to the system. Users wishing to log into the computer enter their identity *(login)* and submit a secret keyword *(password)* as proof of their identity. Passwords

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

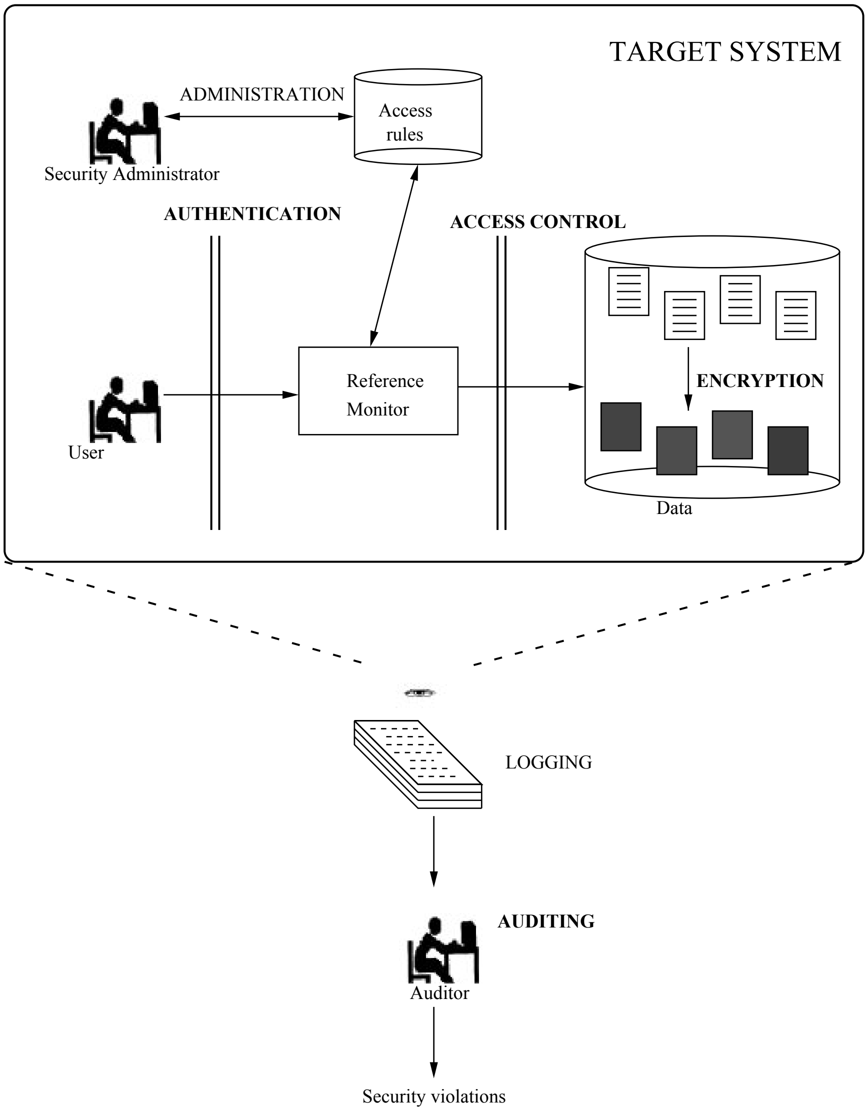

Figure 1. Authentication, access control, audit, and encryption.

are the most commonly used authentication techniques for controlling access to computers. The wide use of this technique is because it is very simple, cheap, and easily enforceable. As a drawback, however, this technique is vulnerable. Passwords can often be easily *guessed, snooped* by people observing the legitimate user keying it in, *sniffed* during transmission, or *spoofed* by attackers impersonating login interfaces. By getting a user's password, an attacker can then "impersonate" this user and enter the system. An important aspect necessary to limit the vulnerability of passwords is a good password management. A good password management requires users to change their password regularly, choose passwords that are not easy to guess, and keep the password private. Unfortunately these practices are not always followed. Having to remember passwords can become a burden for a user, especially when multiple passwords, necessary to access different accounts, need to be remembered. To avoid this problem, many systems enforce automatic controls regulating the specification and use of passwords. For instance, it is possible to enforce restrictions on the minimum number of digits a password must have, possibly requiring the use of both alphanumeric and non-alphanumeric characters. Also, often systems check passwords against language dictionaries and reject passwords corresponding to words of the language (which would be easily retrieved by attackers enforcing dictionary attacks). It is also possible to associate a maximum lifetime with passwords and require users to change their password when it expires. Passwords that remain unchanged for a long time are more vulnerable, and, if guessed and never changed, would allow attackers to freely access the system impersonating the legitimate users. A history log can also be kept to make sure users do not just pretend to change the password while reusing instead the same one. Sometimes a minimum lifetime can also be associated with passwords. The reason is for users to avoid reusing the same password over and over again despite the presence of lifetime and history controls. Without a minimum lifetime, a user required to change password but unwilling to do so could simply change it and then change it back right away to the old value. A minimum lifetime restriction would forbid this kind of operation.

Authentication Based on Possession

In this category, also called *token-based*, all techniques exist that require users to present a *token* as a proof of their identity. A token is a credit-size card device storing some information establishing and proving the token's identity. The simplest form of token is a memory card containing magnetically recorded information, which can be read by an appropriate card reader. Essentially, this technique authenticates the validity of the token, not of the user: Possession of the token establishes identity for the user. The main weakness of such an approach is that tokens can be forged, lost, or stolen. To limit the risk of security breaches due to such occurrences, often memory cards are used together with a *personal identification number (PIN),* generally composed of four numeric digits, that works like a password. To enter the system, a user needs both to present the token and to enter the PIN. Like passwords, PIN can be guessed or spoofed, thus possibly compromising authentication, because an attacker possessing the token and knowing the PIN will be able to impersonate the legitimate user and enter the system. To limit the vulnerability from attackers possessing a token and trying to guess the corresponding PIN to enter the system, often the authentication server terminates the authentication process, and possibly seizes the card, upon submission of few bad tries for a PIN. Like passwords, tokens can be shared among users, thus compromising accountability. Unlike with passwords, however, because possession of the token is necessary to enter the system, only one user at a time is able to enter the system. Memory cards are very simple and do not have any processing power. They cannot therefore perform any check on the PIN or encrypt it for transmission. This requires sending the PIN to the authentication server in the clear, exposing the PIN to sniffing attacks and requiring trust in the authentication server. The ATM (Automatic Teller Machine) cards are provided with processing power, which allows the checking and encrypting of the PIN before its transmission to the authentication server.

In token devices provided with processing capabilities, authentication is generally based on a challenge-response handshake. The authentication server generates a challenge that is keyed into the token by the user. The token computes a response by applying a cryptographic algorithm to the secret key, the PIN, and the challenge, and returns it to the user, who enters this response into the workstation interfacing the authentication server. In some cases, the workstation can directly interface the token, thus eliminating the need for the user to type in the challenge and the response. Smartcards are sophisticated token devices that have both processing power and direct connection to the system. Each smartcard has a unique private key stored within it. To authenticate the user to the system, the smartcard verifies the PIN. It then enciphers the user's identifier, the PIN, and additional information like date and time, and it sends the resulting ciphertext to the authentication server. Authentication succeeds if the authentication server can decipher the message properly.

Authentication Based on Personal Characteristics

Authentication techniques in this category establish the identity of users on the basis of their biometric characteristics. Biometric techniques can use physical or behavioral characteristics, or a combination of them. Physical characteristics are, for example, the retina, the fingerprint, and the palmprint. Behavioral characteristics include handwriting, voiceprint, and keystroke dynamics (2). Biometric techniques require a first phase in which the characteristic is measured. This phase, also called *enrollment,* generally comprises several measurements of the characteristic. On the basis of the different measurements, a template is computed and stored at the authentication server. A User's identity is established by comparing their characteristics with the stored templates. It is important to note that, unlike passwords, biometric methods are not exact. A password entered by a user either matches the one stored at the authentication server or it does not. A biometric characteristic instead cannot be required to exactly match the stored template. The authentication result is therefore based on how closely the characteristic matches the stored template. The acceptable difference must be determined in such a way that the method provides a high rate of successes (i.e., it correctly authenticates legitimate users and rejects attackers) and a low rate of unsuccesses. Unsuccesses can either deny access to legitimate users or allow accesses that should be rejected. Biometric techniques, being based on personal characteristics of the users, do not suffer of the weaknesses discusses above for password or token-based authentication. However, they require high-level and expensive technology, and they may be less accurate. Moreover, techniques based on physical characteristics are often not well accepted by users because of their intrusive nature. For instance, retinal scanners, which are one of the most accurate biometric methods of authentication, have raised concerns about possible harms that the infrared beams sent to the eye by the scanner can cause. Measurements of other characteristics, such as fingerprint or keystroke dynamics, have instead raised concerns about the privacy of the users.

ACCESS CONTROL

Access control evaluates the requests to access resources and services and determines whether to grant or deny them. In discussing access control, it is generally useful to distinguish between *policies* and *mechanisms*. Policies are high-level guidelines that determine how accesses are controlled and access decisions are determined. Mechanisms are low-level software and hardware functions implementing the policies. There are several advantages in abstracting policies from their implementation. First, it is possible to compare different policies and evaluate their properties without worrying about how they are actually implemented. Second, it is possible to devise mechanisms that enforce different policies so that a change of policy does not necessarily require changing the whole implementation. Third, it is possible to devise mechanisms that can enforce multiple policies at the same time, thus allowing users to choose the policy that best suits their needs when stating protection requirements on their data (3–6). The definition and formalization of a set of policies specifying the working of the access control system, providing thus an abstraction of the control mechanism, is called a *model.*

Access control policies can be divided into three major categories: *discretionary access control* (DAC), *mandatory access control* (MAC), and the most recent *role-based access control* (RBAC).

Discretionary Policies

Discretionary access control policies govern the access of users to the system on the basis of the user's identity and of rules, called *authorizations,* that specify for each user (or group of users) the types of accesses the user can/cannot exercise on each object. The objects to which access can be requested, and on which authorizations can be specified, may depend on the specific data model considered and on the desired granularity of access control. For instance, in operating systems, objects can be files, directories, or programs. In relational databases, objects can be databases, relations, views, and, possibly tuples or attributes within a relation. In object-oriented databases, objects include classes, instances, and methods. Accesses executable on the objects, or on which authorizations can be specified, may correspond to primitive operations like read, write, and execute, or to higher level operations or applications. For instance, in a bank organization, operations like, debit, credit, inquiry, an extinguish can be defined on objects of type accounts.

Policies in this class are called discretionary because they allow users to specify authorizations. Hence, the accesses to be or not to be allowed are at the discretion of the users. An authorization in its basic form is a triple ⟨`user`, `object`, `mode`⟩ stating that the `user` can exercise the access `mode` on the `object`. Authorizations of this form represent permission of accesses. Each request is controlled against the authorizations and allowed only if a triple authorizing it exists. This kind of policy is also called *closed* policy, because only accesses for which an explicit authorization is given are allowed, whereas the default decision is to deny access. In an *open* policy, instead, (negative) authorizations specify the accesses that should not be allowed. All access requests for which no negative authorizations are specified are allowed by default. Most systems support the closed policy. The open policy can be applied in systems with limited protection requirements, where most accesses are to be allowed and the specification of negative authorizations results is therefore more convenient.

Specification of authorizations for each single user, each single access mode, and each single object can become an administrative burden. By grouping users, modes, and objects, it is possible to specify authorizations holding for a group of users, a collection of access modes, and/or a set of objects (4,7–9). This grouping can be user defined or derived from the data definition or organization. For instance, object grouping can be based on the type of objects (e.g., files, directories, executable programs); on the application/activity in which they are used (e.g., ps-files, tex-files, dvi-files, ascii); on data model concepts (e.g., in object-oriented systems, a group can be defined corresponding to a class and grouping all its instances); or on other classifications defined by users. Groups of users generally reflect the structure of the organization. For instance, examples of groups can be `employee`, `staff`, `researchers`, or `consultants`. Most models considering user groups allow groups to be nested and nondisjoint. This means that users can belong to different groups and groups themselves can be members of other groups, provided that there are no cycles in the membership relation (i.e., a group cannot be a member of itself). Moreover, a basic group, called `public`, generally collects all users of the system.

The most recent authorization models supports grouping of users and objects, and both positive and negative authorizations (4,6,8,10–14). These features, toward the development of mechanisms able to enforce different policies, allow the support of both the closed and the open policy within the same system. Moreover, they represent a convenient means to support exceptions to authorizations. For instance, it is possible to specify that a group of users, with the exception of one of its members, can execute a particular access by granting a positive authorization for the access to the group and a negative authorization for the same access to the user. As a drawback for this added expressiveness and flexibility, support of both positive and negative authorizations complicates authorization management. In particular, conflicts may arise. To illustrate, consider the case of a user belonging to two groups. One group has a positive authorization for an access; the other has a negative authorization for the same access. Conflict control policies should then be devised that determine whether the access should in this case be allowed or denied. Different solutions can be taken. For instance, deciding on the *safest* side, the negative authorizations can be considered to hold *(denials take precedence).* Alternatively, conflicts may be resolved on the basis of possible relationships between the involved groups. For instance, if one of the groups is a member of the other one, then the authorization specified for the first group may be considered to hold *(most specific authorization takes precedence).* Another possible solution consists in assigning explicit priorities to authorizations; in the case of conflicts, the authorization with greater priority is considered to hold.

DAC Mechanisms. A common way to think of authorizations at a conceptual level is by means of an *access matrix.* Each row corresponds to a user (or group), and each column corresponds to an object. The entry crossing a user with an object reports the access modes that the user can exercise on the object. Figure 2(a) reports an example of an access matrix. Although the matrix represents a good conceptualization of authorizations, it is not appropriate for implementation. The access matrix may be very large and sparse. Storing authorizations as an access matrix may therefore prove inefficient. Three possible approaches can be used to represent the matrix:

- *Access Control List (ACL).* The matrix is stored by column. Each object is associated with a list, indicating, for each user, the access modes the user can exercise on the object.

- *Capability*. The matrix is stored by row. Each user has associated a list, called a capability list, indicating for each object in the system the accesses the user is allowed to exercise on the object.
- *Authorization Table*. Nonempty entries of the matrix are reported in a three-column table whose columns are users, objects, and access modes, respectively. Each tuple in the table corresponds to an authorization.

Figure 2(b)–(d) illustrates the ACLs, capabilities, and authorization table, respectively, corresponding to the access matrix in Fig. 2(a).

Capabilities and ACLs present advantages and disadvantages with respect to authorization control and management. In particular, with ACLs, it is immediate to check the authorizations holding on an object, whereas retrieving all authorizations of a user requires the examination of the ACLs for all objects. Analogously, with capabilities, it is immediate to determine the privileges of a user, whereas retrieving all accesses executable on an object requires the examination of all different capabilities. These aspects affect the efficiency of authorization revocation upon deletion of either users or objects.

In a system supporting capabilities, it is sufficient for a user to present the appropriate capability to gain access to an object. This represents an advantage in distributed systems because it avoids multiple authentication of a subject. A user can be authenticated at a host, acquire the appropriate capabilities and present them to obtain accesses at the various servers of the system. Capabilities suffers, however, from a serious weakness. Unlike tickets, capabilities can be copied. This exposes capabilities to the risk of forgery, whereby an attacker gains access to the system by copying capabilities. For these reasons, capabilities are not generally used. Most commercial systems use ACLs. The Linux file system uses a primitive form of authorizations and ACLs. Each user in the system belongs to exactly one group, and each file has an owner (generally the user who created it). Authorizations for each file can be specified for either the owner, the group to which she belongs, or "the rest of the world." Each file has associated a list of nine privileges: *read, write*, and *execute,* each defined three times, at the level of *user, group,* and *other.* Each privilege is characterized by a single letter: `r` for *read;*`w` for *write;*`x` for *execute;* the absence of the privilege is represented by character -. The string presents first the *user* privileges, then *group,* and finally *other.* For instance, the ACL `rwxr-x--x` associated with a file indicates that the file can be read, written, and executed by its owner; read and executed by the group to which the owner belongs; and executed by all other users.

Weakness of Discretionary Policies: The Trojan Horse Problem. In discussing discretionary policies, we have referred to users and to access requests on objects submitted by users. Although it is true that each request is originated because of some user's actions, a more precise examination of the access control problem shows the utility

of separating *users* from *subjects*. Users are passive entities for whom authorizations can be specified and who can connect to the system. Once connected to the system, users originate processes (subjects) that execute on their behalf and, accordingly, submit requests to the system. Discretionary policies ignore this distinction and evaluate all requests submitted by a process running on behalf of some user against the authorizations of the user. This aspect makes discretionary policies vulnerable from processes executing malicious programs exploiting the authorizations of the user on behalf of whom they are executing. In particular, the access control system can be bypassed by Trojan Horses embedded in programs. A Trojan Horse is a computer program with an apparently or actually useful function, which contains additional *hidden* functions that surreptitiously exploit the legitimate authorizations of the invoking process. A Trojan Horse can improperly use any authorization of the invoking user; for example, it could even delete all files of the user (this destructive behavior is not uncommon in the case of viruses). This vulnerability to Trojan Horses, together with the fact discretionary policies do not enforce any control on the flow of information once this information is acquired by a process, makes it possible for processes to leak information to users not allowed to read it. This can happen without the cognizance of the data administrator/owner, and despite the fact that each single access request is controlled against the authorizations. To understand how a Trojan Horse can leak information to unauthorized users despite the discretionary access control, consider the following example. Assume that within an organization, Vicky, a top-level manager, creates a file Market containing important information about releases of new products. This information is very sensitive for the organization and, according to the organization's policy, should not be disclosed to anybody besides Vicky. Consider now John, one of Vicky's subordinates, who wants to acquire this sensitive information to sell it to a competitor organization. To achieve this, John creates a file, let's call it Stolen, and gives Vicky the authorization to write the file. Note that Vicky may not even know about the existence of Stolen or about the fact that she has the write authorization on it. Moreover, John modifies an application generally used by Vicky, to include two hidden operations, a read operation on file Market and a write operation on file Stolen [Fig. 3(a)]. Then, he gives the new application to his manager. Suppose now that Vicky executes the application. As the application executes on behalf of Vicky, every access is checked against Vicky's authorizations, and the read and write operations above will be allowed. As a result, during execution, sensitive information in Market is transferred to Stolen and thus made readable to the dishonest employee John, who can then sell it to the competitor [Fig. 3(b)].

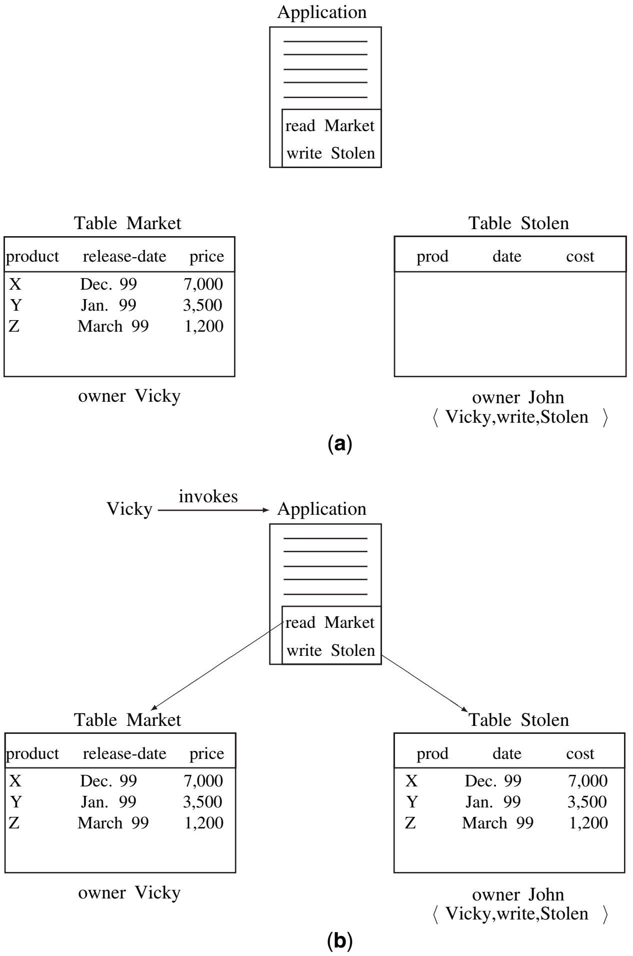

Figure 3. An example of a Trojan Horse.

The reader may object that there is little point in defending against Trojan Horses leaking information flow: Such an information flow could have happened anyway, by having Vicky explicitly tell this information to John, possibly even off-line, without the use of the computer system. Here is where the distinction between users and subjects operating on their behalf comes in. Although users are trusted to obey the access restrictions, subjects operating on their behalf are not. With reference to our example, Vicky is trusted not to release the sensitive information she knows to John, because, according to the authorizations, John cannot read it. However, the processes operating on behalf of Vicky cannot be given the same trust. Processes run programs that, unless properly certified, cannot be trusted for the operations they execute, as illustrated by the example above. For this reason, restrictions should be enforced on the operations that processes themselves can execute. In particular, protection against Trojan Horses leaking information to unauthorized users requires controlling the flows of information within process execution and possibly restricting them (13–18). Mandatory policies provide a way to enforce information flow control through the use of labels.

Mandatory Policies

Mandatory security policies enforce access control on the basis of classifications of *subjects* and *objects* in the system. Objects are the passive entities storing information, such as files, records, records' fields, in operating systems; or databases, tables, attributes, and tuples in relational database systems. Subjects are active entities that request access to the objects. An *access class* is defined as consisting of two components: a *security level* and a *set of categories*. The

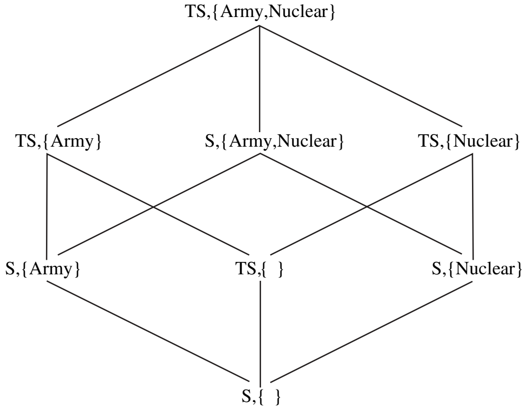

Figure 4. An example of a classification lattice.

security level is an element of a hierarchically ordered set. The levels generally considered are Top Secret (TS), Secret (S), Confidential (C), and Unclassified (U), where TS > S > C > U. The set of categories is a subset of an unordered set, whose elements reflect functional or competence areas (e.g., NATO, Nuclear, Army for military systems; Financial, Administration, Research, for commercial systems). Access classes are partially ordered as follows: an access class c_1 *dominates* ($\geq$) an access class c_2 iff the security level of c_1 is greater than or equal to that of c_2 and the categories of c_1 include those of c_2. Two classes c_1 and c_2 are said to be incomparable if neither $c_1 \geq c_2$ nor $c_2 \geq c_1$ holds. Access classes together with the dominance relationship between them form a lattice. Figure 4 illustrates the security lattice for the security levels TS and S and the categories Nuclear and Army. Each object and each user in the system is assigned an access class. The security level of the access class associated with an object reflects the sensitivity of the information contained in the object, that is, the potential damage that could result from the unauthorized disclosure of the information. The security level of the access class associated with a user, also called *clearance,* reflects the user's trustworthiness not to disclose sensitive information to users not cleared to see it. Categories are used to provide finer grained security classifications of subjects and objects than classifications provided by security levels alone, and they are the basis for enforcing *need-to-know* restrictions. Users can connect to their system at any access class dominated by their clearance. A user connecting to the system at a given access class originates a subject at that access class. For instance, a user cleared `(Secret,Ø)` can connect to the system as a `(Secret,Ø)`, `(Confidential,Ø)`, or `(Unclassified,Ø)` subject. Requests by a subject to access an object are controlled with respect to the access class of the subject and the object and granted only if some relationship, depending on the requested access, is satisfied. In particular, two principles, first formulated by Bell and LaPadula (19), must be satisfied to protect information confidentiality:

No Read Up. A subject is allowed a read access to an object only if the access class of the subject dominates the access class of the object.

No Write Down. A subject is allowed a write access to an object only if the access class of the subject is dominated by the access of the object. (In most applications, subjects are further restricted to write only at their own level, so that no overwriting of sensitive information by low subjects not even allowed to see it can take place.)

Satisfaction of these two principles prevents information to flow from high-level subjects/objects to subjects/objects at lower levels, thereby ensuring the satisfaction of the protection requirements (i.e., no process will be able to make sensitive information available to users not cleared for it). This is illustrated in Fig. 5. Note the importance of controlling both read and write operations, because both can be improperly used to leak information. Consider the example of the Trojan Horse in Fig. 3. Possible classifications reflecting the specified access restrictions could be Secret for Vicky and Market, and Unclassified for John and Stolen. In the respect of the no-read-up and no-write-down principles, the Trojan Horse will never be able to complete successfully. If Vicky connects to the system as a Secret (or Confidential) subject, and thus the application runs with a Secret (or Confidential) access class, the write operation would be blocked. If Vicky invokes the application as an Unclassified subject, the read operation will be blocked instead.

Given the no-write-down principle, it is clear now why users are allowed to connect to the system at different access classes, so that they are able to access information at different levels (provided that they are cleared for it). For instance, Vicky has to connect to the system at a level below

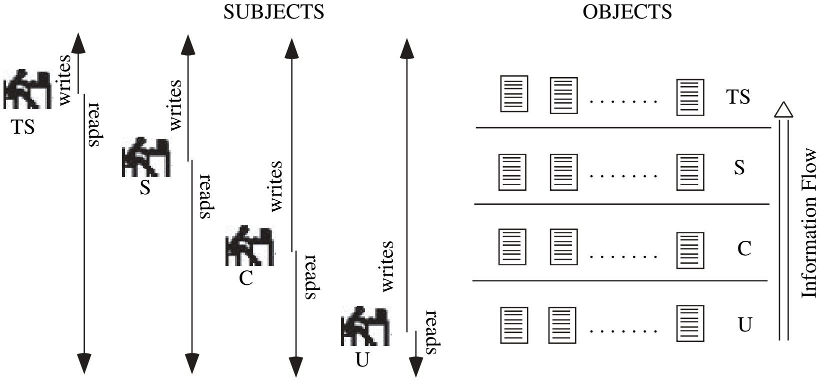

Figure 5. Controlling information flow for secrecy.

her clearance if she wants to write some Unclassified information, such as working instructions for John. Note also that a lower class does not mean “less” privileges in absolute terms, but only less reading privileges, as it is clear from the example above.

The mandatory policy that we have discussed above protects the confidentiality of the information. An analogous policy can be applied for the protection of the integrity of the information, to avoid untrusted subjects from modifying information they cannot write and compromise its integrity. With reference to our organization example, for example, integrity could be compromised if the Trojan Horse implanted by John in the application would write data in the file Market. Access classes for integrity comprise an integrity level and a set of categories. The set of categories is as seen for secrecy. The integrity level associated with a user reflects the user’s trustworthiness for inserting, modifying, or deleting information. The integrity level associated with an object reflects both the degree of trust that can be placed on the information stored in the object and the potential damage that could result from an unauthorized modification of the information. An example of integrity levels includes Crucial (C), Important (I), and Unknown (U). Access control is enforced according to the following two principles:

No Read Down. A subject is allowed a read access to an object only if the access class of the subject is dominated by the access class of the object.

No Write Up. A subject is allowed a write access to an object only if the access class of the subject is dominates the access class of the object.

Satisfaction of these principles safeguards integrity by preventing information stored in low objects (and therefore less reliable) to flow to high objects. This is illustrated in Fig. 6.

As it is visible from Figs. 5 and 6, secrecy policies allow the flow of information only from lower to higher (security) levels, whereas integrity policies allow the flow of information only from higher to lower security levels. If both secrecy and integrity have to be controlled, objects and subjects have to be assigned two access classes, one for secrecy control and one for integrity control.

The main drawback of mandatory protection policies is the rigidity of the control. They require the definition and application of classifications to subjects and objects. This may not always be feasible. Moreover, accesses to be allowed are determined only on the basis of the classifications of subjects and objects in the system. No possibility is given to the users for granting and revoking authorizations to other users. Some approaches have been proposed that complement flow control with discretionary access control (13,15,17).

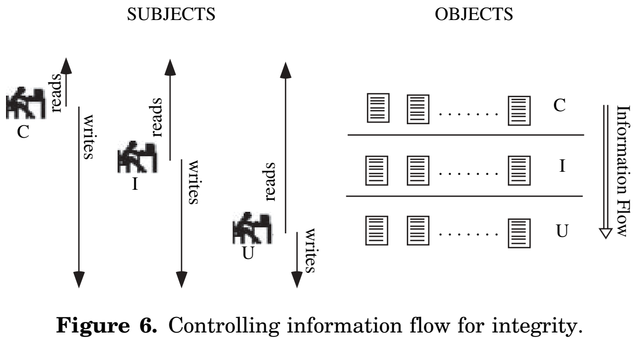

Figure 6. Controlling information flow for integrity.

Role-based Policies

A class of access control policies that has been receiving considerable attention recently is represented by role-based policies (20–22). Role-based policies govern the access of users to the information on the basis of their organizational role. A role can be defined as a set of actions and responsibilities associated with a particular working activity. Intuitively, a role identifies a task, and corresponding privileges, that users need to execute to perform organizational activities. Example of roles can be `secretary`, `dept-chair`, `programmer`, `payroll-officer`, and so on. Authorizations to access objects are not specified directly for users to access objects: Users are given authorizations to activate roles, and roles are given authorizations to access objects. By activating a given role (set of roles), a user will be able to execute the accesses for which the role is (set of roles are) authorized. Like groups, roles can also be organized in a hierarchy, along which authorizations can be propagated.

Note the different semantics that groups, presented in Section 3.1, and roles carry. Roles can be “activated” and “deactivated” by users at their discretion, whereas group membership always applies; that is, users cannot enable and disable group memberships (and corresponding authorizations) at their will. Note, however, that a same “concept” can be seen both as a group and as a role. To understand the difference between groups and roles, consider the following example. We could define a group, called `G_programmer`, consisting all users who are programmers. Any authorization specified for `G_programmer` is propagated to its members. Thus, if an authorization to read `tech-reports` is given to `G_programmer`, its members can exercise this right. We could also define a role, called `R_programmer`, and associate with it those privileges that are related to the programming activity and necessary for the programmers to perform their jobs (such as compiling, debugging, and writing reports). These privileges can be exercised by authorized users only when they choose to assume the role `R_programmer`. It is important to note that roles and groups are two complementary concepts; they are not mutually exclusive.

The enforcement of role-based policies present several advantages. Authorization management results are simplified by the separation of the users’ identity from the authorizations they need to execute tasks. Several users can be given the same set of authorizations simply by assigning them the same role. Also, if a user’s responsibilities change (e.g., because of a promotion), it is sufficient to disable her for the previous roles and enable her for a new set of roles, instead of deleting and inserting the many access authorizations that this responsibility change implies. A major advantage of role-based policies is represented by the fact that authorizations of a role are enabled only when the role is active for a user. This allows the enforcement of the least privilege principle, whereby a process is given only the authorizations it needs to complete successfully. This confinement of the process in a defined workspace is an important defense against attacks aiming at exploiting authorizations (as the Trojan Horse example illustrated). Moreover, the definition of roles and related authorizations fits with the information system organization and allows us to support related constraints, such as, for example, separation of duties (23–25). Separation of duties requires that no user should be given enough privileges to be able to misuse the system. For instance, the person authorizing a paycheck should not be the same person who prepares it. Separation of duties can be enforced statically, by controlling the specification of roles associated with each user and authorizations associated with each role, or dynamically, by controlling the actions actually executed by users when playing particular roles (4,24).

AUDIT

Authentication and access control do not guarantee complete security. Indeed, unauthorized or improper uses of the system can still occur. The reasons for this are various. First, security mechanisms, like any other software or hardware mechanism, can suffer from flaws that make them vulnerable to attacks. Second, security mechanisms have a cost, both monetary and in loss of system's performances. The more protection to reduce accidental and deliberate violations is implemented, the higher the cost of the system will be. For this reason, often organizations prefer to adopt less secure mechanisms, which have little impact on the system's performance, with respect to more reliable mechanisms, that would introduce overhead processing. Third, authorized users may misuse their privileges. This last aspect is definitely not the least, as misuse of privileges by internal users is one major cause of security violations.

This scenario raises the need for *audit control*. Audit provides a post facto evaluation of the requests and the accesses occurred to determine whether violations have occurred or have been attempted. To detect possible violations, all user requests and activities are registered in an *audit trail* (or *log),* for their later examination. An audit trail is a set of records of *computer events,* where a computer event is any action that happens on a computer system (e.g., logging into a system, executing a program, and opening a file). A computer system may have more than one audit trail, each devoted to a particular type of activity. The kind and format of data stored in an audit trail may vary from system to system; however, the information that should be recorded for each event includes the subject making the request, the object to which access is requested, the operation requested, the time and location at which the operation was requested, the response of the access control, and the amount of resources used. An audit trail is generated by an *auditing system* that monitors system activities. Audit trails have many uses in computer security:

- *Individual Accountability* An individual's actions are tracked in an audit trail making users personally accountable for their actions. Accountability may have a deterrent effect, as users are less likely to behave improperly if they know that their activities are being monitored.
- *Reconstructing Events* Audit trails can be used to reconstruct events after a problem has occurred. The amount of damage that occurred with an incident can be assessed by reviewing audit trails of system activity to pinpoint how, when, and why the incident occurred.
- *Monitoring* Audit trails may also be used as on-line tools to help monitoring problems as they occur. Such real-time monitoring helps in detecting problems like disk failures, over utilization of system resources, or network outages.
- *Intrusion Detection* Audit trails can be used to identify attempts to penetrate a system and gain unauthorized access.

It is easy to see that auditing is not a simple task, also due to the huge amount of data to be examined and to the fact that it is not always clear how violations are reflected in the users' or system's behaviors. Recent research has focused on the development of automated tools to help audit controls. In particular, a class of automated tools is represented by the so-called *intrusion detection systems,* whose purpose is to automate the data acquisition and their analysis. The issues to be addressed in data acquisition and analysis are as folows:

- *Audit data retention:* If the audit control is based on history information, then audit records al ready examined must be maintained. However, to avoid the "history log" to grow indefinitely, pruning operations should be executed removing records that do not need to be considered further.
- *Audit level:* Different approaches can be taken with respect to the level of events to be recorded. For instance, events can be recorded at the command level, at the level of each system call, at the application level, and so on. Each approach has some advantages and disadvantages, represented by the violations that can be detected and by the complexity and volume of audit records that have to be stored, respectively.
- *Recording time:* Different approaches can be taken with respect to the time at which the audit records are to be recorded. For instance, accesses can be recorded at the time they are requested or at the time they are completed. The first approach provides a quick response to possible violations, and the second provides more complete information for analysis.
- *Events monitored:* Audit analysis can be performed on any event or on specific events such as the events regarding a particular subject, object, operation, or occurring at a particular time or in a particular situation.

- *Audit control execution time:* Different approaches can be taken with respect to the time at which the audit control should be executed.
- *Audit control mechanism location:* The intrusion detection system and the monitored system may reside on the same machine or on different machines. Placing the audit control mechanism on different machines has advantages both in terms of performances (audit control does not interfere with normal system operation) and security, as the audit mechanism will not be affected by violations to the system under control.

DATA ENCRYPTION

Another measure for protecting information is provided by cryptography. Cryptographic techniques allow users to store, or transmit, encoded information instead of the actual data. An *encryption* process transforms the *plaintext* to be protected into an encoded *ciphertext,* which can then be stored or transmitted. A *decryption* process allows us to retrieve the *plaintext* from the *ciphertext.* The encryption and decryption functions take a *key* as a parameter. A user getting access to data, or sniffing them from the network, but lacking the appropriate decryption key, will not be able to understand them. Also, tampering with data results is difficult without the appropriate encryption key.

Cryptographic techniques must be proved resistant to attacks by cryptoanalysts trying to break the system to recover the plaintext or the key, or to forge data (generally, messages transmitted over the network). Cryptanalysis attacks can be classified according to how much information the cryptanalyst has available. In particular, with respect to secrecy, attacks can be classified as *ciphertext only, known-plaintext,* and *chosen-plaintext.* In ciphertext-only attacks, the cryptanalyst only knows the ciphertext, although she may know the encryption algorithm, the plaintext language, and possibly some words that are probably used in the plaintext. In known-plaintext attacks, the cryptanalyst also knows some plaintext and corresponding ciphertext. In chosen-plaintext attacks, the cryptanalyst can acquire the ciphertext corresponding to a selected plaintext. Most cryptographic techniques are designed to withstand chosen-plaintext attacks. The robustness of cryptographic algorithms relies on the amount of work and time that would be necessary to a cryptanalyst to break the system, using the best available techniques. With respect to protecting the authenticity of the information, there are two main classes of attacks: *impersonation attack,* in which the cryptanalyst creates a fraudulent ciphertext without knowledge of the authentic cipher-text; and *substitution attacks*, in which the cryptanalyst intercepts the authentic ciphertext and improperly modifies it.

Encryption algorithms can be divided into two main classes: *symmetric,* or *secret key,* and *asymmetric,* or *public key.* Symmetric algorithms encrypt and decrypt text by using the same key. Public key algorithms use, instead, two different keys. A *public* key is used to encrypt, and a *private* key, which cannot be guessed by knowing the public key, is used to decrypt. This is illustrated in Fig. 7. Symmetric algorithms rely on the secrecy of the key. Public key algorithms rely on the secrecy of the private key.

Symmetric Key Encryption

Most symmetric key encryption algorithms are *block ciphers*; that is, they break up the plaintext into blocks of a fixed length and encrypt one block at a time. Two well-known classes of block ciphers are based on substitution techniques and transposition techniques.

Substitution Algorithms. Substitution algorithms define a mapping, based on the key, between characters in the plaintext and characters in the ciphertext. Some substitution techniques are as follows.

Simple Substitution. Simple substitution algorithms are based on a one-to-one mapping between the plaintext alphabet and the ciphertext alphabet. Each character in the plaintext alphabet is therefore replaced with a fixed substitute in the ciphertext alphabet. An example of simple substitution is represented by the algorithms based on *shifted* alphabets, in which each letter of the plaintext is mapped onto the letter at a given fixed distance from it in the alphabet (wrapping the last letter with the first). An example of such algorithms is the Caesar cipher in which each letter is mapped to the letter three positions after it in the alphabet. Thus, A is mapped to D, B to E, and Z to C. For instance, `thistext` would be encrypted as `wklvwhaw`. Simple substitution techniques can be broken by analyzing single-letter frequency distribution (26).

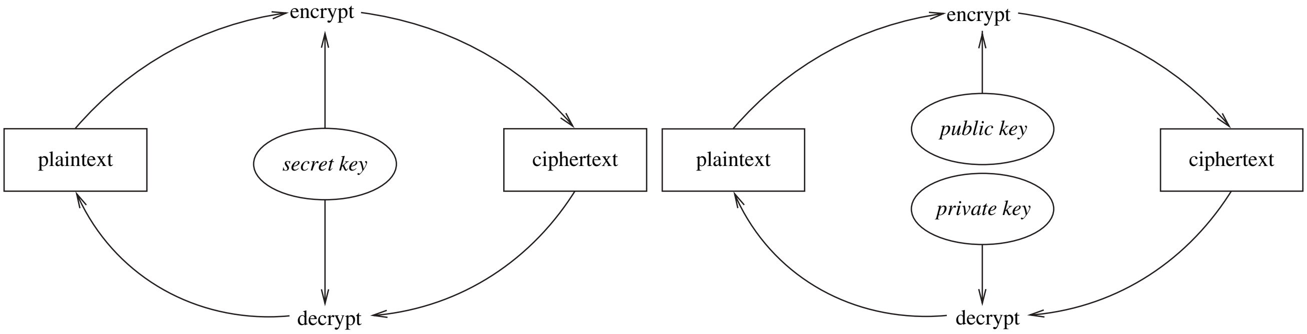

Figure 7. Secret key versus public key cryptography.

Homophonic Substitution. Homophonic substitution algorithms map each character of the plaintext alphabet onto a set of characters, called its *homophones,* in the ciphertext alphabet. There is therefore a one-to-many mapping between a plaintext character and the corresponding characters in the ciphertext. (Obviously, the vice versa is not true as decrypting cannot be ambiguous.) In this way, different occurrences of the same character in the plaintext may be mapped to different characters in the ciphertext. This characteristic allows the flattening of the letter frequency distribution in the ciphertext and proves a defense against attacks exploiting it. A simple example of homophonic substitution (although not used for ciphering) can be seen in the use of characters for phone numbers. Here, the alphabet of the plaintext are numbers, the alphabet of the ciphertext are the letters of the alphabet, but Q and Z which are not used, plus numbers 0 and 1 (which are not mapped to any letter). Number 2 maps to the first three letters of the alphabet, number 3 to the second three letters, and so on. For instance, number 6974663 can be enciphered as myphone, where the three occurrences of character 6 have been mapped to three different letters.

Polyalphabetic Substitution. Polyalphabetic substitution algorithms overcome the weakness of simple substitution through the use of multiple substitution algorithms. Most polyalphabetic algorithms use periodic sequences of alphabets. For instance, the Vigenère cipher uses a word as a key. The position in the alphabet of the *i*th character of the key gives the number of right shifts to be enforced on each *i*th element (modulo the key length) of the plaintext. For instance, if key crypt is used, then the first, sixth, eleventh, . . . , character of the plaintext will be shifted by 3 (the position of c in the alphabet); the second, seventh, twelfth, . . . , character will be shifted by 17 (the position of **r** in the alphabet); and so on.

Polygram Substitution. Although the previous algorithms encrypt a letter at the time, polygram algorithms encrypt blocks of letters. The plaintext is divided into blocks of letters. The mapping of each character of a block depends on the other characters appearing in the block. As an example, the Playfair cipher uses as key a 5 × 5 matrix, where the 25 letters of the alphabet (J was not considered) are inserted in some order. The plaintext is divided into blocks of length two. Each pair of characters is mapped onto a pair of characters in the ciphertext, where the mapping depends on the position of the two plaintext characters in the matrix (e.g., whether they are in the same column and/ or row). Polygram substitution destroys single-letter frequency distribution, thus making cryptanalysis harder.

Transposition Algorithms. Transposition algorithms determine the ciphertext by permuting the plaintext characters according to some scheme. The ciphertext, therefore, contains exactly the same characters as the plaintext but in different order. Often, the permutation scheme is determined by writing the plaintext in some geometric figure and then reading it by traversing the figure in a specified order. Some transposition algorithms, based on the use of matrixes, are as follows.

Column Transposition. The plaintext is written in a matrix by rows and re-read by columns according to an order specified by the key. Often the key is a word: The number of characters in the key determines the number of columns, and the position of the characters considered in alphabetical order determines the order to be considered in the reading process. For instance, key crypt would imply the use of a five-column matrix, where the order of the columns to be read is 14253 (the position in the key of the key characters is considered in alphabetical order). Let's say now that the plaintext to be encrypted is acme has discovered a new fuel. The matrix will look like as follows:

c	r	y	p	t
1	3	5	2	4
a	c	m	e	h
a	s	d	i	s
c	o	v	e	r
e	d	a	n	e
w	f	u	e	l

The corresponding ciphertext is aaceweienecsodfhsrelmdvau.

Periodic Transposition. It is a variation of the previous technique, where the text is also read by rows (instead of by columns) according to a specified column order. More precisely, instead of indicating the columns to be read, the key indicates the order in which the characters in each row must be read, and the matrix is read row by row. For instance, by using key crypt, the ciphertext is obtained by reading the first, fourth, second, fifth, and third character of the first row, then the second row is read in the same order, the third row, and so on. This process is equivalent to breaking the text in blocks with the same length as the key, and to permuting the characters in each block according to the order specified by the key. In this case, the ciphertext corresponding to the plaintext acme has discovered a new fuel is aechmaissdceorvendeaweflu.

Pure transposition and substitution techniques prove very vulnerable. For instance, transposition algorithms can be broken through anagramming techniques, because the characters in the ciphered text correspond exactly to the characters in the plaintext. Also, the fact that a transposition method has been used to encrypt can be determined by the fact that the ciphertext respects the frequency letter distribution of the considered alphabet. Simple substitution algorithms are vulnerable from attacks exploiting single-letter frequency distribution. Among them, shifted alphabet ciphers are easier to break, given that the mapping function applies the same transformation to all characters. Stronger algorithms can be obtained by combining the two techniques (27).

Advanced Encryption Standard (AES). In November 2001, the National Institute of Standards and Technology announced the approval of a new secret key cipher standard chosen among 15 candidates. This new standard algorithm was meant to replace the old DES algorithm (28), whose key

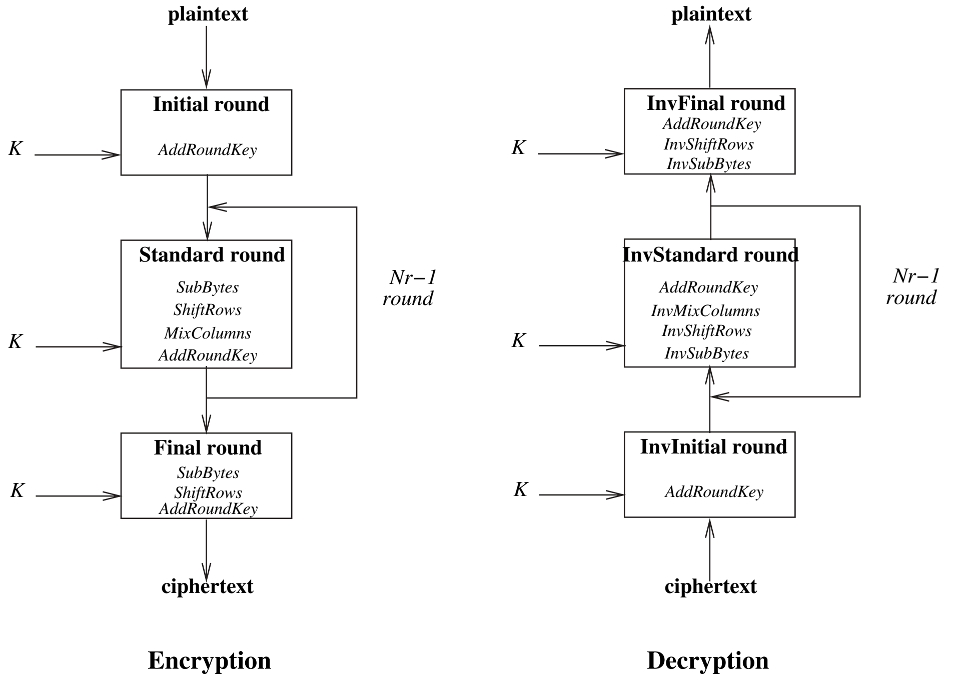

Figure 8. Encryption and decryption phases of the AES algorithm.

sizes were becoming too small. Rijndael, a compressed name taken from its inventors Rijmen and Daemen, was chosen to become the future Advanced Encryption Standard (AES) (29). AES is a block cipher that can process 128-bit block units using cipher keys with lengths of 128, 192, and 256 bits. Strictly speaking, AES is not precisely Rijndael (although in practice they are used interchangeably) as Rijndael supports a larger range of block and key sizes. Figure 8 illustrates the AES operational mode. It starts with an initial round followed by a number of standard rounds and ends with a final round. The number of standard round is dependent on the key length as illustrated in Table 1. AES operates on a 4 × 4 array of bytes (the intermediate cipher result), called the *state*.

AddRoundKey. The *AddRoundKey* operation is a simple EXOR operation between the *state* and the *roundkey*. The *roundkey* is derived from the secret key by means of a key schedule. The number of *roundkey* necessary to encrypt one block of the plaintext depends on the key length as this determines the number of rounds. For instance, for a key length of 128 bits, 11 *roundkeys* are needed. The keys are generated recursively. More precisely, key k_i of the ith round is obtained from the key expansion routine using subkey k_{i-1} of round $i - 1$-th and the secret key.

Table 1. Number of rounds

	Key length (words)	Number of rounds (Nr)
AES-128	4	10
AES-192	6	12
AES-256	8	14

[1]A word is 32 bits.

SubBytes. In the *SubBytes* operation, each byte in the state is updated using an 8-bit S-box. This operation provides the nonlinearity in the cipher. The AES S-box is specified as a matrix $M16 \times 16$. The first digit d_1 of the hexadecimal number corresponding to a state byte is used as a row index and the second digit d_2 as a column index. Hence, cell $M[d_1, d_2]$ contains the new hexadecimal number.

Shift Rows. In the *ShiftRows* operation, the rows of *state* are cyclically shifted with different offsets. The first row is shifted over 1 byte, the second row over 2 bytes, and the third row over 3 bytes.

MixColumns. The *MixColumns* operation operates on the columns of the state, combining the four bytes in each column using a linear transformation. Together with *ShiftRows, MixColumns* provides diffusion[1] in the cipher.

Note that in the AES algorithm encipherment and decipherment consists of different operations. Each operation that is used for encryption must be inverted to make it possible to decrypt a message (see Fig. 8).

Asymmetric Key Encryption

Asymmetric key encryption algorithms use two different keys for encryption and decryption. They are based on the application of one-way functions. A one-way function is a

[1] Diffusion refers to the property that redundancy in the statistics of the plaintext is "dissipated" in the statistics of the ciphertext (27). In a cipher with good diffusion, flipping an input bit should change each output bit with a probability of one half.

function that satisfies the property that it is computationally infeasible to compute the input from the result. Asymmetric key encryption algorithms are therefore based on hard-to-solve mathematical problems, such as computing logarithms, as in the proposals by Diffie and Hellman (30), (the proponents of public key cryptography) and by ElGamal (31), or factoring, as in the RSA algorithm illustrated next.

The RSA Algorithm. The most well-known public key algorithm is the RSA algorithm, whose name is derived from the initials of its inventor (Rivest, Shamir, and Adleman) (32). It is based on the idea that it is easy to multiply two large prime numbers, but it is extremely difficult to factor a large number. The establishment of the pair of keys works as follows. The user wishing to establish a pair of keys chooses two large primes p and q (which are to remain secret) and computes $n = pq$ and $\phi(n) = (p-1)(q-1)$, where $\phi(n)$ is the number of elements between 0 and $n-1$ that are relatively prime to n. Then, the user chooses an integer e between 1 and $\phi(n)-1$ that is relatively prime to $\phi(n)$, and computes its inverse d such that $ed \equiv 1 \bmod \phi(n)$. d can be easily computed by knowing $\phi(n)$. The encryption function E raises the plaintext M to the power e, modulo n. The decryption function D raises the ciphertext C to the power d, modulo n. That is, $E(M) = M^e \bmod n$ and $D(C) = C^d \bmod n$. Here, the public key is represented by the pair (e, n) and the private key by d. Because $\phi(n)$ cannot be determined without knowing the prime factors p and q, it is possible to keep d secret even if e and n are made public. The security of the algorithm depends therefore on the difficulty of factoring n into p and q. Usually a key with n of 512 bits is used, whose factorization would take a half-million MIPS-years with the best techniques known today. The algorithm itself, however, does not constraint the key length. The key length is variable. A longer key provides more protection, whereas a shorter key proves more efficient. The authors of the algorithm suggested using a 100-digit number for p and q, which would imply a 200-digit number for n. In this scenario, factoring n would take several billion years. The block size is also variable, but it must be smaller than the length of the key. The ciphertext block is the same length as the key.

Application of Cryptography

Cryptographic techniques can be used to protect the secrecy of information stored in the system, so that it will not be understandable to possible intruders bypassing access controls. For instance, password files are generally encrypted. Cryptography proves particularly useful in the protection of information transmitted over a communication network (33). Information transmitted over a network is vulnerable from *passive* attacks, in which intruders sniff the information, thus compromising its secrecy, and from *active* attacks, in which intruders improperly modify the information, thus compromising its integrity. Protecting against passive attacks means safeguarding the confidentiality of the message being transmitted. Protecting against active attacks requires us to be able to ensure the *authenticity of the message, its sender, and its receiver.* Authentication of the receiver means that the sender must be able to verify that the message is received by the recipient for which it was intended. Authentication of the sender means that the recipient of a message must be able to verify the identity of the sender. Authentication of the message means that sender and recipient must be able to verify that the message has not been improperly modified during transmission.

Both secret and public key techniques can be used to provide protection against both passive and active attacks. The use of secret keys in the communication requires the sender and the receiver to share the secret key. The sender encrypts the information to be transmitted by using the secret key and then sends it. Upon reception, the receiver decrypts the information with the same key and recovers the plaintext. Secret key techniques can be used if there is confidence in the fact that the key is only known by the sender and recipient and no disputes can arise (e.g., a dispute can arise if the sender of a message denies having ever sent it). Public keys, like secret keys, can provide authenticity of the sender, the recipient, and the message as follows. Each user establishes a pair of keys: The private key is known only to her, and the public key can be known to everybody. A user wishing to send a message to another user encrypts the message by using the public key of the receiver and then sends it. Upon reception, the receiver decrypts the message with his/her private key. Public keys can also be used to provide *nonrepudiation,* meaning the sender of a message cannot deny having sent it. The use of public keys to provide nonrepudiation is based on the concept of *digital signatures,* which, like handwritten signatures, provide a way for a sender to sign the information being transmitted. Digital signatures are essentially encoded information, a function of the message and the key, which are appended to a message. Digital signatures can be enforced through public key technology by having the sender of a message encrypting the message with her private key before transmission. The recipient will retrieve the message by decrypting it with the public key of the sender. Nonrepudiation is provided because only the sender knows her public key and therefore only the sender could have produced the message in question. In the application of secret keys, instead, the sender can claim that the message was forged by the recipient herself, who also knows the key. The two uses of public keys can be combined, thus providing sender, message, and recipient authentication, together with nonrepudiation.

Public key algorithms can do everything that secret key algorithms can do. However, all known public key algorithms are orders of magnitude slower than secret key algorithms. For this reason, often public key techniques are used for things that secret key techniques cannot do. In particular, they may be used at the beginning of a communication for authentication and to establish a secret key with which to encrypt information to be transmitted.

AUTHENTICATION AND ACCESS CONTROL IN OPEN SYSTEMS

Throughout this chapter, we illustrated the services crucial to the protection of data. In this section, we present ongoing work addressing authentication and access control in emerging applications and new scenarios.

Authentication in Open Environments

Today, accessing information on the global Internet has become an essential requirement of the modern economy. Recently, the focus has shifted from access to traditional information stored in WWW sites to access to large *e-services* (34). *Global e-services* are also coming of age, designed as custom applications exploiting single e-services already available on the Internet and integrating the results. In such a context, users normally have to sign-on to several distributed systems where e-services were built up in a way that they act independently as isolated security domains. Therefore, each user who wants to enter one of these domains has to authenticate herself at each of these security domains by the use of separate credentials (see Fig. 9). However, to realize the cooperation of services located in different domains, there is a need to have some authentication mechanism that does not require the user to authenticate and enter her user credentials several times. On corporate networks as well as on the global Net, access to services by *single-sign-on authentication* is now becoming a widespread way to authenticate users. Single-sign-on authentication relying on *digital certificates* (35) is currently the most popular choice for e-business applications. The widespread adoption of advanced *Public-Key Infrastructure* (PKI) technology and PKI-based solutions has provided secure techniques for outsourcing digital certificate management. Basically, any certificate-based authentication language needs a *subject description*, including a set of attributes. Several standardization efforts are aimed at exploiting such descriptions; for example, the Liberty Alliance (www.projectliberty.org) consortium is promoting a set of open standards for developing federated identity management infrastructures. However, the most successful standard is SAML (36), an authentication protocol handling authentication information across transactions between parties. Such an authentication information, which is wrapped into a SAML document, is called an *assertion* and it belongs to an entity (i.e., a human person, a computer, or any other subject as well). According to the specifications, an assertion may carry information about:

- Authentication acts performed by the subject.
- Attributes of the subject.
- Authorization decisions relating to the subject.

SAML assertions are usually transferred from *identity providers* (i.e., authorities that provide the user's identity to the affiliated services) to *service providers* (i.e., entities that simply offer services) and consist of one or more *statements*. Three kinds of statements are allowed: authentication statements, attribute statements, and authorization decision statements. Authentication statements assert to the service provider that the principal did indeed authenticate with the identity provider at a particular time using a particular method of authentication. Other information about the principal may be disclosed in an authentication statement. For instance, in the authentication statement in Fig. 10, the e-mail address of the principal is disclosed to the service provider. Note that the three statement types are not mutually exclusive. For instance, both

authentication statements and attribute statements may be included in a single assertion. Beside the format of the assertion, the SAML specifications include an XML-based request-response protocol for interchanging the assertions. By the use of this protocol, an assertion consuming service can request a specified assertion belonging to a given subject or entity. This protocol can be based on various existing transport protocols such as HTTP or SOAP over HTTP.

Attribute-based Access Control

As said, in open environments, resource/service requesters are not identified by unique names but depend on their *attributes* (usually substantiated by certificates) to gain accesses to resources. Basing authorization on attributes of the the resource/service requester provides flexibility and scalability that is essential in the context of large distributed open systems, where subjects are identified by using a certificate-based authentication language. Attribute-based access control differs from the traditional discretionary access control model by replacing both the *subject* by a set of attributes and the *objects* by descriptions in terms of available properties associated with them. The meaning of a stated attribute may be a granted capability for a service, an identity, or a nonidentifying characteristic of a user (e.g., a skill). Here, the basic idea is that not all access control decisions are identity based. For instance, information about a user's current role (e.g., physician) or a client's ability to pay for a resource access may be more important than the client's identity.

Several proposals have been introduced for access control to distributed heterogeneous resources from multiple sources based on the use of attribute certificates (37–40). In such a context, two relevant access control languages using XML are WS-Policy (41) and XACML (42). Based on the WS-Security (43), WS-Policy provides a grammar for expressing Web service policies. The WS-Policy includes a set of general messaging related assertions defined in WS-Policy Assertions (44) and a set of security policy assertions related to supporting the WS-Security specification defined in WS-SecurityPolicy (45). In addition to the WS-Policy, WS-Policy Attachment (46) defines how to attach these policies to Web services or other subjects (e.g., service locators). The eXtensible Access Control Markup Language (XACML) (42) is the result of a recent OASIS standardization effort proposing an XML-based language to express and interchange access control policies. XACML is designed to express authorization policies in XML against objects that are themselves identified in XML. The language can represent the functionalities of most policy representation mechanisms. The main conceptual difference between XACML and WS-Policy is that although XACML is based on a model that provides a *formal* representation of the access control security policy and its workings, WS-Policy has been developed without taking into consideration this modeling phase. The result is an ambiguous language that is subject to different interpretations and uses. This means that given a set of policies expressed by using the syntax and semantics of WS-Policy, their evaluation may have a different result depending on how the ambiguities of the language have been resolved. This is obviously a serious problem, especially in the access control area, where access decisions have to be deterministic (47,48). In the remainder of this section, we focus on XACML.

XACML Policy Language Model. XACML describes both an access control policy language and a request/response language. The policy language is used to express access control policies (who can do what when). The request/response language expresses queries about whether a particular access (request) should be allowed and describes answers (responses) to those queries (see the next subsection). Figure 11 formally illustrates the *XACML policy language model,* where the main concepts of interests are *rule, policy,* and *policy set.* An XACML policy has as a root element, either a `Policy or a PolicySet`. A `PolicySet` is a collection of `Policy` or `PolicySet`. An XACML policy consists of a *target,* a set of *rules,* an optional set of *obligations,* and a *rule combining algorithm.*

Target. A `Target` basically consists of a simplified set of conditions for the subject, resource, and action that must be satisfied for a policy to be applicable to a given access request: If all conditions of a `Target` are satisfied, its

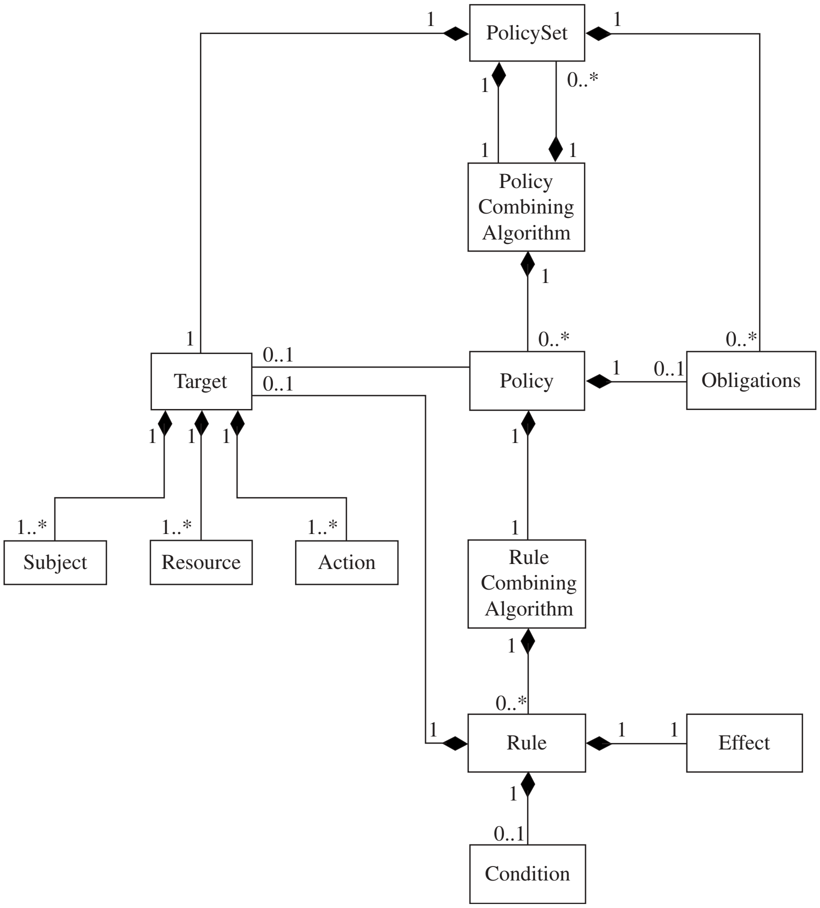

Figure 11. XACML policy language model 42.

associated `Policy` (or `Policyset`) applies to the request. If a policy applies to all subjects, actions, or resources, an empty element, named `AnySubject`, `AnyAction`, and `AnyResource`, respectively, is used.

Rule. A Rule specifies a permission (`permit`) or a denial (`deny`) for a subject to perform an action on an object. The components of a rule are a *target,* an *effect,* and a *condition.* The target defines the set of resources, subjects, and actions to which the rule is intended to apply. The effect of the rule can be `permit` or `deny`. The condition represents a boolean expression that may further refine the applicability of the rule. Note that the `Target` element is an optional element: A rule with no target applies to all possible requests. An important feature of XACML is that a rule is based on the definition of attributes corresponding to specific characteristics of a subject, resource, action, or environment. For instance, a physician at a hospital may have the attribute of being a researcher, a specialist in some field, or many other job roles. According to these attributes, that physician can perform different functions within the hospital. As another example, a particular function may be dependent on the time of the day (e.g., access to the patient records can be limited to the working hours of 8:00 am to 6:00 pm). An access request is mainly composed of attributes that will be compared with attribute values in a policy to make an access decision. Attributes are identified by the `SubjectAttributeDesignator, ResourceAttributeDesignator, ActionAttributeDesignator`, and `EnvironmentAttributeDesignator` elements. These elements use the `AttributeValue` element to define the value of a particular attribute. Alternatively, the `AttributeSelector` element can be used to specify where to retrieve a particular attribute. Note that both the attribute designator and the attribute selector elements can return multiple values. For this reason, XACML provides an attribute type called *bag*. A bag is an unordered collection and it can contain duplicates values for a particular attribute. In addition, XACML defines other standard value types such as string, boolean, integer, and time. Together with these attribute types, XACML also defines operations to be performed on the different types, such as equality operation, comparison operation, and string manipulation.

Obligation. An `Obligation` is an operation that has to be performed in conjunction with the enforcement of an authorization decision. For instance, an obligation can state that all accesses on medical data have to be logged. Note that only policies that are evaluated and have returned a response of `permit` or `deny` can return obligations. More precisely, an obligation is returned only if the effect of the policy matches the value specified in the `FullfillOn` attribute associated with the obligation. This means that if a policy evaluates to `indeterminate` or `not applicable`, then the associated obligations are not returned.

Rule Combining Algorithm. Each `Policy` also defines a rule combining algorithm used for reconciling the decisions each rule makes. The final decision value, called the *authorization decision,* inserted into the XACML context is the value of the policy as defined by the rule combining algorithm. XACML defines different combining algorithms. Examples of these are as follows:

- *Deny overrides.* If a rule exists that evaluates to `deny` or, if all rules evaluate to `not applicable`, then the result is `deny`. If all rules evaluate to `permit`, then the result is `permit`. If some rules evaluate to `permit` and some evaluate to `not applicable`, then the result is `permit`.
- *Permit overrides.* If a rule exists that evaluates to `permit`, then the result is `permit`. If all rules evaluate to `not applicable`, then the result is `deny`. If some rules evaluate to `deny` and some evaluate to `not applicable`, then the result is `deny`.
- *First applicable.* Each rule is evaluated in the order in which it appears in the `Policy`. For each rule, if the target matches and the conditions evaluate to true, then the result is the effect (`permit` or `deny`) of such a rule. Otherwise, the next rule is considered.

</Policy>
```

Figure 12. An example of XACML policy.

- *Only-one-applicable.* If more than one rule applies, then the result is `indeterminate`. If no rule applies, then the result is not `applicable`. If only one policy applies, the result coincides with the result of evaluating that rule.

In summary, according to the selected combining algorithm, the authorization decision can be `permit, deny, not applicable` (when no applicable policies or rules could be found), or `indeterminate` (when some errors occurred during the access control process).

The `PolicySet` element consists of a set of *policies,* a *target,* an optional set of *obligations,* and a *policy combining algorithm.* The policy, target, and obligation components are as described above. The policy combining algorithms define how the results of evaluating the policies in the policy set have to be combined when evaluating the policy set. This value is then inserted in the XACML response context. As an example of policy, suppose that there is a hospital where a high-level policy states that:

Any member of the `SeniorResearcher` group can read the research report web page www.hospital.com/research report/reports.html.

Figure 12 shows the XACML policy corresponding to this high-level policy. The policy applies to requests on the web page http://www.hospital.com/research report/reports.html. It has one rule with a target that requires an action of read and a condition that applies only if the subject is a member of the group `SeniorResearcher`.

XACML Request and Response

XACML defines a standard format for expressing requests and responses. More precisely, the original request is translated, through the context handler, in a canonical form and is then evaluated. Such a request contains attributes for the subject, resource, action, and optionally, for the environment. Each request includes exactly one set of attributes for the resource and action and at most one set of environment attributes. There may be multiple sets of subject attributes, each of which is identified by a category URI. Figure 13(a) illustrates the XSD Schema of the request. A response element contains one or more results, each of which correspond to the result of an evaluation. Each result contains three elements, namely `Decision`, `Status`, and `Obligations`. The `Decision` element specifies the authorization decision (i.e., `permit, deny, indeterminate, not applicable`), the `Status` element indicates if some error occurred during the evaluation process, and the optional `Obligations` element states the obligations that must be fulfilled. Figure 13(b) illustrates the XSD Schema of the response.

As an example of request and response, suppose now that a user belonging to group `SeniorResearcher` and with email user1@hospital.com wants to read the www.example.com/forum/private.html web page. The corresponding XACML request is illustrated in Fig. 14(a). This request is compared with the XACML policy in Fig. 12. The result is that the user is allowed to access the requested web page. The corresponding XACML response is illustrated in Fig. 14(b).

CONCLUSIONS

Ensuring protection to information stored in a computer system means safeguarding the information against possible violations to its secrecy, integrity, or availability. This is a requirement that any information system must satisfy and that requires the enforcement of different protection methods and related tools. Authentication, access control, auditing, and encryption are all necessary to this task. As it should be clear from this article, these different measures are not independent but strongly dependent on each other. Access control relies on good authentication, because accesses allowed or denied depend on the identity of the user requesting them. Strong authentication supports good auditing, because users can be held accountable for their actions. Cryptographic techniques are necessary to ensure strong authentication, for example, to securely store or transmit passwords. A weakness in any of these measures may compromise the security of the whole system (a chain is as strong as its weakness link). Their correct and coordinated enforcement is therefore crucial to the protection of the information.

DATA STRUCTURES AND ALGORITHMS

INTRODUCTION

An *algorithm* is a finite procedure, with a well-defined set of steps, aimed at solving a specific problem. Algorithms are present in any problem-solving task involving the use of computers in numerical or nonnumerical applications. An algorithm is usually required to stop in a finite number of steps, although some useful procedures are meant to be run continuously, such as operating systems and related system software. These procedures are sometimes not regarded as algorithms, but simply as programs. In general, a *program* is a set of machine-readable and executable codes used to implement algorithms.

These definitions make clear the fact that an algorithm is a high-level description, which should be independent of the underlying machine that is used to implement it. This requirement is important to simplify the task of analysis of the properties of an algorithm: We do not need to consider all possible machine details necessary to implement it, but only the properties common to all such implementations.

Algorithms can be classified and studied according to their performance characteristics. Among all algorithms to solve a specific problem, we clearly want the ones that have better performance, according to established performance measurements for an application. Among the performance parameters used for classification purposes, the most important are *time* and *space*. For a specified problem, the time and space taken by the algorithm with best possible performance are called the *time* and *space complexity* measures for the problem.

Space is a simpler measure to analyze, as it is clearly tied to time: An algorithm cannot use more than t units of space, where t is the total time spent by the algorithm. Usually, the space used by an algorithm is clearly identifiable from the data structures used in its operation. For example, if an algorithm operates using only a vector that depends on the size of the input, the space complexity of the algorithm can be bounded by a function of the input size.

On the other hand, time complexity is difficult to characterize in general. In fact, the most fundamental question about an algorithm, whether it stops in finite time or not, is known to be undecidable (i.e., it cannot be answered in general). Although this result is a very negative result, it is still possible to analyze the time complexity of several classes of practical algorithms, which is the main objective of the area of *analysis of algorithms*. This type of analysis is important because time complexity is the main restriction on applying an algorithm in practice. Consider, for example, an algorithm that takes time exponential in the size of the input. Such an algorithm is not practical, unless the size of the inputs for the considered problem is always very small. For general inputs, such algorithm will easily surpass any reasonable time limit.

More formally, the *time complexity* of an algorithm is usually defined as the total number of elementary operations (arithmetic operations, comparisons, branching instructions, etc.) performed. The time complexity is generally quantified as a function of the *input size*. The input size of a problem is the total number of bits required to represent all data necessary for solving the problem. For example, if an algorithm receives as input a vector with n integer values, each value represented in binary notation, then the number of bits required to represent the input is $n[\log K]$, where K is an upper bound on the maximum value stored on any position of the input vector (note that all logarithms discussed in this article are taken with respect to the base 2). It is common to assume that integer numbers used in an algorithm are all limited in size to a given upper bound, unless it is an important parameter (for example, in numerical algorithms such as factorization). Thus, it is usual to say that the input size for a vector of n integers is equal to n.

When analyzing an algorithm, the main concern is in understanding its performance under different conditions. Most common conditions considered are the following:

- *Worst case:* By the worst case of an algorithm, we mean the maximum time necessary to compute its result, for some fixed input size. The worst case analysis is usually considered the best way of analyzing algorithms, because it gives a time complexity bound that is independent of the input. It is also surprisingly easy to compute for most problems.
- *Average case:* The average case analysis of an algorithm is concerned with the expected time necessary for the algorithm to run, for all data inputs with fixed size. Average case analysis generally requires some assumptions about the probabilistic distribution of input data, and therefore the results are dependent on such assumptions, which are not easy to guess in most cases. Moreover, the stochastic analysis of even the simplest algorithms may become a daunting task.
- *Best case:* It is the time complexity of an algorithm under the best conditions for a specific input size. Although simple to compute in most cases, the best case analysis is not very useful to predict the actual performance of an algorithm in real situations.

From the three types of analysis shown above, worst case analysis is the most interesting from the theoretical as well as practical point of view. As an example of the above complexity cases, consider the classic problem of searching a specific value x in a list of n elements. The simplest algorithm consists of comparing x with each element in sequence, from positions 1 to n. The worst case of this algorithm occurs when the element searched is not present, or when present in the last position. The best case occurs when the searched element is in position 1. The average case of the algorithm, however, depends on the distribution

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

of the input. If we assume that each value has the same probability to occur in each position and there are no repeated values, then, on average, $n/2$ comparisons are necessary to find the desired element.

To simplify the study of time and space requirements of algorithms, asymptotic notation is usually employed. This notation allows one to ignore constant factors in the running time, making the analysis independent of different specific details developing from the algorithm implementation. Given the integer functions f and g, we say that $f(n) = \mathcal{O}(g(n))$ (which is read as "$f(n)$ is of the order of $g(n)$") if there are constants $c > 0$ and $N > 0$, such that $f(n) \leq c \cdot g(n)$ for all $n \geq N$. Similarly, given the integer functions f and g, we say that $f(n) = \Omega(n)$ if there are constants $c > 0$ and $N > 0$, such that $f(n) \geq c \cdot g(n)$ for all $n \geq N$. The notations for O and Ω can be also combined by saying that $f(n) = \Theta(n)$ if and only if $f(n) = \mathcal{O}(n)$ and $f(n) = \Omega(n)$.

DATA STRUCTURES

Data structures are a fundamental aspect of algorithms, because they describe how data will be manipulated in the computer's memory. The organization of data can make the difference between effcient and inefficient algorithms. Consider, for example, the problem of inserting a number in the middle of an ordered list with n elements. This operation can be done in constant ($\mathcal{O}(1)$) time if the list is manipulated as a set of linked elements. On the other hand, if it is represented as an array with fixed positions, it is necessary to create space in the array for the required position, which requires at least $n/2$ elements to be moved. Thus, the time complexity in this case is $\mathcal{O}(n)$.

Data structures can be studied from a high-level standpoint, where we consider only the operations performed on data. Data structures described in this way are called *abstract data types* (ADT). ADTs are important because they allow an abstraction of the properties of a data structure, which can have several implementations. Thus, a second way of looking at data structures is through the analysis of the actual implementation of its ADT, as data is organized in the computer's memory.

Queues and Stacks

As an example of ADT, consider the concept of queue. A queue can receive new elements at its end. Elements can be removed only at the beginning of the queue. The concept leads to the formulation of the following natural operations: ADD(ELEMENT): adds ELEMENT to the end of the queue; REMOVE(ELEMENT): removes ELEMENT from the beginning of the queue.

The ADT queue can be implemented using several data structures. The simplest implementation uses an array a with n positions to hold the elements, considering that n is the maximum size of the queue. This implementation has the following properties: The ADD operation can be performed in constant time, as we need only to update the location of the last element (in this implementation, the array is circular, for example, element $a[1]$ comes right after position $a[n]$). Similarly, the REMOVE operation can be implemented just by decreasing the position of the front of the queue, and therefore it can be performed in constant time. A second implementation of queue uses doubly linked lists. This implementation has similar time complexity, because it needs only to add or remove an element and its corresponding links. However, it has the advantage that it is not restricted to the size of a preallocated array.

A second useful ADT is the stack. It has the same operations as a queue, but the semantic of the operations is different: ADD puts a new element on the top of a stack, and REMOVE takes the element that is at its top. Similarly to queues, implementations can be based on arrays or linked lists, operating in constant time.

Queues and stacks are examples of more general data structures that support a set of operations, in this case ADD and REMOVE. This class of data structures include all general *lists*, where insertion and removal can occur in any position of the list.

A well-known class of data structures is the *dictionary*, with the operations INSERT, DELETE, and SEARCH. Still another class is the *priority queue*, where the desired operations are FIND-MIN, DELETE-MIN, and INSERT.

Binary Trees

A binary tree is a recursive structure that can be either empty or have a root node with two children, which are themselves binary trees. Binary trees are important data structures used to implement abstract data types. An example of abstract structure that can be implemented with binary trees are dictionaries.

A special node in the binary tree is the *root* node, which is the top level node. At the lower level of the tree are the *leaves*, defined as subtrees with empty children. The level of a node x is an indicator of distance from x to the root node. The level of the root is defined to be 1, and the level a child node is defined as 1 plus the level of its parent node. The *height* of a tree is the maximum level of any of its nodes.

The main feature of binary trees is that they can be used to segment the domain of elements stored in their nodes into two subdomains at each node, which allows some algorithms running in binary trees to operate on time $\mathcal{O}(\log n)$. Consider a binary tree implementing a dictionary, where the elements are integer numbers. We can store a number x in the tree using the following strategy: Check initially the root node. If it is empty, store x in the root of the subtree. Otherwise, let the value stored there be equal to r. If $x < r$, then check recursively the left child tree; if $x > r$, then check recursively the left child tree. Searching the binary tree (instead of inserting a node) is similar, but we just need to check if $x = r$ and return when this is true. Note that we are partitioning the solution space into two subsets at each step of the algorithm. The resulting data structure is called a *binary search tree*.

As an example of binary tree, consider Fig. 1. We assume that we want to insert the value 36 into the tree. The first comparison with the root node will determine that the position of the value must be on the right subtree. The second comparison with 45 will then result in the selection of the left subtree. Comparing with the value 38, we see that the element must be on the left subtree. Finally, the comparison with the empty subtree shows that it is the position at which the node with value 36 should be inserted.

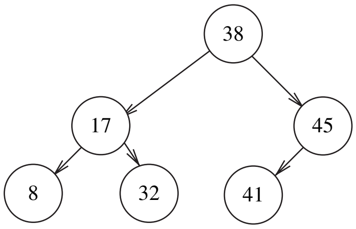

Figure 1. An example of binary tree.

A closer examination of the tree in Fig. 1 reviews that a possible order for insertion of the values in the tree is 38, 17, 45, 8, 32, and 41 when starting from an empty binary tree. Any other ordering of these numbers according to *nondecreasing levels* in the final tree would produce the same result. However, some orderings of these values may produce trees with large height, which is not desirable as we discuss below. For example, the ordering 8, 17, 32, 38, 41, and 45 will generate a tree that has only one branch with height 6.

It is easy to check that operations in binary trees such as Find or Insert have to perform at most h comparisons, where h is the height of the tree. It is also simple to show that the height of a binary tree satisfies $h = \Omega(\log n)$. Therefore, it is an important goal for any algorithm applied to binary trees to keep the height as close as possible to the lower bound of $\log n$. If true, then the algorithms for binary tree operations discussed above will also take time $\Theta(\log n)$.

Several methods have been developed to guarantee that binary trees produced by insertion and searching procedures have the height $\mathcal{O}(\log n)$. These methods, which include *red-black* trees, 2-3 trees, and AVL trees, provide elaborate techniques for rotating an existing configuration of nodes in the tree, such that the final binary tree is balanced (i.e., it has height close to $\mathcal{O}(\log n)$). These ideas can be stated as in the following theorem:

Theorem 1. *A dictionary and a priority queue can be implemented such that the* Find *and* Insert *operations take time* $\Theta(\log n)$.

Graphs

A graph is a data structure that represents a set of nodes (possibly with labels), together with relations between pairs of nodes. Graphs are denoted as $G = (V, E)$, where V is a nonempty set and $E \subseteq V \times V$. They are a fundamental data structure for processing discrete information, because a large number of combinatorial problems can be expressed using graphs. A well-known example is the *traveling salesman problem*. Consider a set of n cities, with a set of roads connecting pairs of cities. This system can be represented as a graph $G = (V, E)$, where V is the set of cities and E is the set of all pairs $(u, v) \in V \times V$ such that there is a road between cities u and v with cost $c(u, v)$. The problem requires finding a tour through all cities with minimum cost.

Graphs are classified into *directed* and *undirected* graphs. In a directed graph, the edge (i, j) has an associated direction. In an undirected graph, however, the direction is not specified, and therefore $\{i, j\}$ and $\{j, i\}$ are notations for the same edge.

A graph is an abstract data type with the following basic operations: InsertEdge, RemoveEdge, Find, Adjacent, and Connected. Other operations are also interesting, but they vary according to the application. Graphs can be represented using different data structures. The simplest representation is called the *node incidence matrix* representation. In this case, the graph $G = (V, E)$ with n nodes is represented by a $n \times n$ matrix $A = (a_{ij})$, such that $a_{ij} = 1$ if $(i, j) \in E$ and $a_{ij} = 0$ otherwise. A graph is called *sparse* when the number of edges is $\mathcal{O}(|V|)$. The node incidence matrix is a convenient representation, but it usually leads to suboptimal algorithm performance, especially when the graph is sparse, which happens, for example, when the algorithm needs to find all edges in a graph, which requires $\Theta(n^2)$ in the matrix representation, as all pairs $(i, j) \in V \times V$ need to be probed for adjacency.

A variation of the first representation for graphs is the *node-edge* incidence matrix. This representation is more useful for directed graphs, although it can also be used with undirected graphs by simultaneously considering both the edges (i, j) and (j, i). In the node-edge incidence matrix representation, a graph $G = (V, E)$ with n nodes and m edges is represented by an $n \times m$ matrix $A = (a_{ie})$, where $a_{ie} = -1$ if $e = (i, j) \in E$, $a_{ie} = 1$ if $e = (j, i) \in E$, and $a_{ie} = 0$ otherwise.

A third representation for graphs, which is more useful when the graph is sparse, is called the *adjacency list* representation. In this representation, an array a with n positions is used, where $a[i]$ keeps a link to a list of nodes that are adjacent to node i. With this data representation, it is possible to iterate over all edges of the graph by looking at each linked list, which takes time $\Omega(|E|)$, instead of $\Omega(|V|^2)$ as in the node incidence matrix representation, which means that all algorithms that need to iterate over the edges of a graph will have improved performance on sparse graphs, when compared with the matrix representations.

ADVANCED DATA STRUCTURES

Problems involving data manipulation can usually benefit from the use of more advanced data structures. Examples can be found in areas such as computational geometry, search and classification of Internet content, and fast access to external memory. Although the complex techniques employed in such applications cannot be fully described here because of space constraints, we provide references for some problems that employ advanced data structures to be solved.

External memory algorithms have application whenever there is a large amount of data that cannot fit in the computer's main memory. Examples of such applications include manipulation of scientific data, such as meteorologic, astrophysical, geological, geographical, and medical databases. The general problem, however, is the same encountered in any computer system with memory hierarchies levels, such as cache memory, main memory, and external disk storage.

A data structure frequently used to access out-of-memory data is the B-tree. A B-tree is a type of balanced tree designed to perform optimally when large parts of the stored data is out of the computer's main memory. The challenge in this kind of application is that accessing secondary storage, such as a hard disk, is many orders of magnitude slower than accessing the main memory. Thus, the number of accesses to secondary storage is the bottleneck that must be addressed. The basic design strategy of B-trees is to reduce the amount of blocks of the hard disk that must be read, in order to locate some specific information in the data structure. This strategy minimizes the time lost in accessing secondary storage. Several improvements to B-trees have been proposed in the last decades, with the objective of making this adequate for new applications. For example, cache-oblivious B-trees (1,2) are extensions of the B-tree model where the algorithm has no information about the sizes of the main memory cache or secondary storage block.

Another example of external memory data structure that tries to reduce the number of disk accesses is the *buffer tree* (3). The basic idea of a buffer tree is that elements of the tree are considered to be blocks of the secondary storage medium, so that access to these blocks is minimized.

An example of application of external memory algorithms to geographical databases is the problem of processing line segments (4). In such databases, large amounts of data must be processed, and questions must be answered fast, with the minimum number of accesses to secondary storage. The type of questions occurring here include how to find if two line segments stored in the database intersect, or how to optimally triangulate a specific area.

Data structures for external memory algorithms also play an important role in the solution of some graph theory problems, occurring in applications such as telecommunications, financial markets, medicine, and so on. An example of large network database is provided by the so-called *call graph*, created from information about calls among users of AT&T (5). The call graph is defined as having nodes representing the users of the telephony system. Edges connect nodes whenever there is a call between the corresponding users during some specified period of time. The resulting database had several million nodes and a similar number of edges. The whole amount of data had to be held on special data structures for fast processing.

Questions that are interesting in this kind of graph are, for example, the number of connected components, the average size of such connected components, and the maximum size of cliques (groups of completely connected users) in the graph. In this application, special data structures had to be created to explore the sparsity of the graph and avoid the access to secondary storage, which resulted in an algorithm with efficient performance that was able to find large sets of completely connected nodes in the call graph.

ALGORITHMS

General Techniques

The development of a new algorithm for a problem is always a creative effort, because there is no easy, general way of doing that (note also, that some problems may have not a finite algorithm (6)). However, some general approaches used for the construction of algorithms have demonstrated their usefulness and applicability for solving different problems of varied natures and origins. Next, we briefly describe some of these techniques.

Divide and conquer is a strategy for development of algorithms in which the problem is divided into smaller parts that are then solved *recursively* (a recursive algorithm is an algorithm that calls itself). This strategy has been successful in several areas, such as sorting, searching, and computational geometry algorithms. In the next section, we discuss examples of this approach. The simplicity of this type of algorithm stems from its recursive nature: We do not have to regard the solution of large problems, because the recursion will break the input data into smaller pieces.

Dynamic programming is a technique that also tries to divide the problem into smaller pieces; however, it does it in the way that solutions of smaller problems can be orderly reused, and therefore they do not need to be computed more than once. An example of such an algorithm is the Floid's method for finding all shortest paths in a graph. The algorithm basically computes solutions where paths can pass only through some subset of nodes. Then, the final solution is built using this information.

Greedy methods have been frequently used for the construction of efficient algorithms. A greedy algorithm always makes decisions that will maximize a short-term goal, and employs the results to build a complete solution for the problem. Using again the shortest path problem as an example, the Dijkstra's algorithm is a type of greedy method. In this case, the function that is minimized at each step is the distance to the set of nodes previously considered by the algorithm.

Finally, we can mention some other important algorithm construction methods such as *backtracking*, *enumeration*, and *randomization*. The use of such techniques has allowed to develop many efficient algorithms, which provides optimal or approximate solutions to a great variety of problems in numerous areas.

Algorithms for Some Basic Problems

In this section, we discuss some basic algorithms for problems such as binary search, sorting, matrix multiplication, and minimum weight spanning tree.

Sorting. Suppose we are given an array of numbers $a_1, \ldots, a_n$. Our task is to sort this array in nondecreasing order such that $a_1 \leq a_2 \leq \ldots \leq a_n$. Probably the most obvious algorithm for this problem is the so-called *selection sort*. Its main idea is the following. First, we find the smallest number of these n elements and interchange it with a_1. The number of comparisons we need is exactly (n−1). Next, we repeat this procedure with the array $a_2, \ldots, a_n$, then with the array $a_3, \ldots, a_n$, and so on. The total number of required comparisons is

$$(n-1) + (n-2) + \ldots + 1 = \Theta(n^2)$$

A better algorithm called the *merge sort* can be developed using the divide and conquer strategy. Initially, we divide the input vector into two parts, say from a_1 to $a_{n/2}$ and from $a_{n/2+1}$ to a_n. Then, we can call the sorting algorithm *recursively* for the smaller vectors $a_1, \ldots, a_{n/2}$ and $a_{n/2+1}, \ldots, a_n$ (the recursion can be solved very easily when the vectors to be sorted have size 1 or 2; therefore, the algorithm will always end with a correctly sorted vector). Finally, we need to *merge* these two sorted arrays into one sorted array. This procedure can be done in $\Theta(n)$ time. If $T(n)$ is the total number of comparisons made by an algorithm for the input array of size n, then for the described algorithm $T(n)$ satisfies $T(n) = 2T(n/2) + \Theta(n)$, which results in $T(n) = \Theta(n \log n)$.

Next, we show that merging two arrays respectively with l and m elements can be done in $\Theta(l + m)$ time. Let $X = x_1, \ldots, x_l$ and $Y = y_1, \ldots, y_m$ be our two input arrays sorted in nondecreasing order and Z be an auxiliary vector of length $l + m$. As X and Y are sorted, if we compare x_1 and y_1, then the smallest of these two numbers is also the smallest number of X and Y combined. Suppose, for example, $x_1 \leq y_1$. Let $z_1 = x_1$ and remove x_1 from X. Repeating the procedure described above with new X and Y, we obtain z_2. Proceed this way until one of the arrays becomes empty. Finally, keeping the order, we can output all the elements of the remaining array to Z. Obviously, the obtained array Z contains the needed result. It is also easy to observe that every time we move an element to Z we remove one of the elements of X or Y and make exactly one comparison. Therefore, the number of comparisons we perform is $\Theta(l + m)$.

Proposition 1. *We can sort an array with n elements in* $\Theta(n \log n)$ *time*.

It can also be shown that any sorting algorithm requires at least $\Omega(n \log n)$ comparisons. Therefore, the merge sort is asymptotically optimal.

Binary Search. In the binary search problem, for an array $a_1, \ldots, a_n$ sorted in nondecreasing order, we need to check if a given element x is present in this array. A divide-and-conquer strategy can be used to design a simple and effective algorithm for solving this problem.

As the first step of the algorithm, we check whether $x = a_{n/2}$. If it is true, then the problem is solved. Otherwise, because the array is sorted in nondecreasing order, if $x > a_{n/2}$, then we conclude that x cannot be in the first part of the array, for example, x cannot be present in $a_1, \ldots, a_{n/2}$. Applying the same argument, if $x < a_{n/2}$, then the second part of the array, which is $a_{n/2}, \ldots, a_n$, can be excluded from our consideration. Next, we repeat the procedure described above with the remaining half of the initial array. At every step, the size of the array reduces by a factor of 2. Therefore, denoting by $T(n)$ the number of comparisons, we obtain that $T(n) = 2T(n/2) + 1$. Solving the recurrence equation, we have $T(n) = \Theta(\log n)$.

Matrix Multiplication. Suppose that, given two $n \times n$ matrices A and B, we need to calculate their product $C = AB$. Let a_{ij}, b_{ij}, and c_{ij} be the elements of matrices A, B, and C, respectively. Then, by definition, for all i and j, we have $c_{ij} = \sum_{k=1}^{n} a_{ik} b_{kj}$. Using this formula, every element c_{ij} of C can be calculated in $\Theta(n)$ time. As there are n^2 elements in the matrix C, the matrix C can be computed in $\Theta(n^3)$ time.

Strassen developed an algorithm based on a divide-and-conquer strategy, which requires only $\Theta(n^{\log_2 7})$ time. The main idea of the algorithm is based on the simple observation that two matrices of size 2×2 can be multiplied using only 7 multiplications (instead of 8) and 18 additions (fortunately, the running time of the algorithm asymptotically is not sensible to increasing the number of additions). Let the matrices A and B in the problem be partitioned as follows:

$$A = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix}$$

$$B = \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix}$$

where the size of matrices A_{ij} and B_{ij} is $(n/2) \times (n/2)$. Then calling the algorithm recursively and applying the Strassen formulas, we obtain the following formula for the running time $T(n)$ of the algorithm:

$$T(n) = 7T(n/2) + \Theta(n^2)$$

The solution of the recursive formula above is $T(n) = \Theta(n^{\log_2 7})$. A more detailed description of the algorithm can be found in textbooks on algorithms, which are listed in the last section of this article.

Minimum Weight Spanning Tree. A *tree* is a connected graph without cycles; that is, it contains a path between every pair of nodes, and this path is unique. Consider an undirected connected graph $G = (V, E)$, where each edge (i, j) has a weight w_{ij}. A spanning tree T_G of the graph G is a subgraph of G that is a tree and spans (i.e., contains) all nodes in V. The *minimum spanning tree* (MST) problem is to find a spanning tree with minimum total sum of its edge weights.

The following algorithm for solving this problem is designed using the greedy approach. Initially, we sort all the edges of the given graph G in nondecreasing order and create a list of edges L. Let T be an empty subgraph of G. Pick an element of L with minimum weight (say e), add e to T, and remove it from L. Proceed with this procedure checking at every step that adding the new edge does not create a cycle in T (if this happens, then we do not add the corresponding edge to T). After $n - 1$ edges are added to T, where n is the number of nodes in G, stop. Denote the obtained subgraph by T_G. The following proposition can be proved:

Proposition 2. *The greedy algorithm described above returns a minimum weight spanning tree* T_G.

Analysis of Algorithms and Complexity Issues

As mentioned above, worst case analysis is probably the most widely used criteria for evaluating algorithms. The basic algorithms discussed (binary search, sorting, selection, matrix multiplication) require only a polynomial number of elementary operations in the size of the input data. In the area of analysis of algorithms and complexity theory, the set of all problems that can be solved in polynomial time (i.e., by a polynomialtime algorithm) is usually denoted by P. Another important class of problems is NP, defined as the collection of all problems for which the correctness of a solution, described using a polynomial-sized encoding, can be verified in polynomial time. Obviously, P is a subset of NP (i.e., $\mathrm{P} \subseteq \mathrm{NP}$). On the other hand, deciding whether $\mathrm{P} \neq \mathrm{NP}$ is probably the most famous open problem in theoretical computer science.

We say that problem II is *polynomial-time reducible* to problem II_1 if given an instance $I(\mathrm{II})$ of problem II, we can, in polynomial time, obtain an instance $I(\mathrm{II}_1)$ of problem II_1 such that by solving $I(\mathrm{II}_1)$ one can compute in polynomial time an optimal solution to $I(\mathrm{II})$. In other words, under this type of reduction, the existence of a polynomial algorithm for solving II_1 will imply the existence of a polynomial algorithm for II. A problem II is called *NP-complete* if $\mathrm{II} \in \mathrm{NP}$, and any problem in NP can be reduced in polynomial time to II, therefore, the class of NP-complete problems consists of the hardest problems in NP. Notice that if any NP-complete problem can be solved in polynomial time, then all problems in NP can be solved in polynomial time (i.e., $\mathrm{P} = \mathrm{NP}$).

In 1971, Steve Cook provided the foundation of NP-completeness theory, proving that the SATISFIABILITY problem is NP-complete (7) (a formal definition of this problem is omitted here). Since that time, the number of NP-complete problems has been significantly increased. Another classic NP-complete problem is the so-called SUBSET SUM problem: Given a set of positive integers $S = \{s_1, s_2, \ldots, s_n\}$ and a positive integer K, does there exist a vector $\mathbf{x} \in \{0,1\}^n$, such that $\sum_{i=1}^{n} s_i x_i = K$? Other examples of NP-complete problems include the TSP (see section Graphs), SET COVER, VERTEX COVER, PARTITION, and so on.

Although it is not known whether $\mathrm{P} \neq \mathrm{NP}$, it is generally assumed that all NP-complete problems are hard to solve. In other words, proving that some problem belongs to the class of NP-complete problems implies that it cannot be solved in polynomial time. The standard procedure of proving that a problem II_1 is NP-complete consists of two steps: (1) proving that $\mathrm{II}_1 \in \mathrm{NP}$ and (2) reducing in polynomial time some known NP-complete problem II to the problem II_1.

Finally, let us also consider the definition of NP-hardness. We say that a problem II belongs to the class of NP-hard problems if there exists an NP-complete problem that can be reduced in polynomial time to II. Therefore, the problem II is at least as hard to solve as any other NP-complete problem, but it is not known whether this problem belongs to NP.

For more detailed information on the theory of NP-completeness and rigorous definitions (including the formal Turing machine model), we refer to the famous book by Garey and Johnson (8) or to the more recent book by Papadimitriou (6).

Approximation Algorithms

The notion of NP-hardness (8) leads researchers to consider alternative strategies to solve problems that are intractable. A possible technique in this case is to solve the problem in an approximate way by not requiring an exact solution, but a solution with an *approximation guarantee*.

An *approximation algorithm* is defined as follows. Let II be a minimization problem, f be the objective function that is minimized by II, and $OPT(x)$ be the optimum solution cost for instance x of II (i.e., $OPT(x)$ is the minimum value (over all feasible solutions s of II) of $f(s)$). Given a minimization problem II and an algorithm A for II, we say that A is an approximation algorithm with approximation guarantee (or performance guarantee, or performance ratio) $\delta > 1$ if, for every instance x of II, the resulting solution s returned by A on instance x has value $f(s) \leq \delta OPT(x)$. A similar definition applies when II is a maximization problem, but in this case $0 < \delta < 1$ and we want $f(s) \geq \delta OPT(x)$.

Approximation algorithms have been studied since the 1970s (9,10). In the last few years, however, the area has received more attention due to great advances in the understanding of approximation complexity. Other recent advances include the use of mathematical programming techniques (linear programming, semidefinite programming) to study the quality of relaxations for some problems and determining approximation guarantees.

A simple example of approximation algorithm was proposed by Christofides (10) for the *traveling salesman problem* (see Graphs section). The TSP is known to be strongly NP-hard, and therefore no polynomial time exact algorithm is known for solving it. It is also known that the problem cannot be approximated in general. However, if the distances considered are Euclidean, therefore obeying the triangular inequality, we can use Christofides' algorithm to find an approximate solution in the following way:

```
1. Algorithm Christofides
2. Input: Graph $G = (V, E)$
3. Find a minimum spanning tree $T$ connecting $V(G)$
4. Double each edge in $T$, resulting in $T'$
5. Find a circuit $C$ in $T'$ starting from any node
6. Shortcut $C$ whenever a node is repeated (i.e., substitute $(a, b, c) \subset C$ for $(a, c)$, whenever $b$ was visited previously)
7. return $C$
```

Theorem 2. *Christofides' algorithm has an approximation guarantee of* 2.

Proof. Just notice that the cost of a minimum spanning tree is a lower bound of the cost of the optimum solution, because, given a solution to TSP, we can find a minimum spanning tree by removing one of its edges. Thus, doubling the edges of T will only multiply the bound by two. Then, the shortcuting operation in line 6 is guaranteed not to increase the cost of the solution, because of the triangular inequality satisfied by G. □

The algorithm above shows that simple strategies may lead to good guarantees of approximation. However, it is known that many problems have no constant approximation guarantee, such as the SET COVER problem, unless $P = NP$ (a large list of impossibility results for approximation is given in Ref. (11)). More elaborate algorithms are based on linear programming (LP) duality and semidefinite programming. These two mathematical programming techniques are frequently useful to provide lower bounds for the solutions obtained by combinatorial algorithms.

Randomized Algorithms

Randomized algorithms correspond to a different way of looking at the task of solving a problem using computers. The usual way of thinking about algorithms is to design a set of steps that will correctly solve the problem whenever the input is given correctly, within a pre-established time, which, however, may not be the simplest or even the more effective way of solving a problem. We might consider algorithms that give the right solution for the problem with some known probability. We can also consider algorithms that always provide the right solution, but with a running time that as known just through its probabilistic distribution. Such algorithms are called *randomized algorithms*.

Randomized algorithms are usually described as algorithms that use “coin tossing” (i.e., a randomizer) or a random number generator. There are two major types of randomized algorithms: *Las Vegas* and *Monte Carlo*.

A *Las Vegas* algorithm is defined as a randomized algorithm, which always provides the correct answer but whose running time is a random variable. A *Monte Carlo* algorithm is a randomized algorithm that always has a predetermined running time (which, of course, may depend on the input size) but whose output is correct with high probability. If n is the input size of the algorithm, then by the *high probability* we imply a probability, which is equal to or greater than $1 - n^{-\alpha}$ for some fixed $\alpha \geq 1$.

Next we describe a simple example of a Monte-Carlo algorithm. Suppose we are given an array $A = a_1, \ldots, a_n$ of n numbers, where all elements are distinct and n is even. The task is to find an element of A greater than the median M of the given array.

In the first step of the algorithm, we randomly choose $\alpha \log n$ elements of the input array A. Let us denote this subset by $\tilde{A}$. Thus, $|\tilde{A}| = \alpha \log n$ and $\tilde{A} \subset A$. Then, we find the largest number from the selected subset. Obviously, we can do it in $\Theta(\log n)$ time. We argue that this element is the correct answer with high probability. The algorithm fails if all elements of the randomly selected subset are less than or equal to the median M. As elements of $\tilde{A}$ are randomly selected, it is easy to observe that any element of $\tilde{A}$ is less than or equal to the median M with probability 1/2. Therefore, the probability of failure is $P_f = (1/2)^{\alpha \log n} = n^{-\alpha}$. In summary, we can conclude that if the size of the subset $\tilde{A}$ satisfies $|\tilde{A}| \geq \alpha \log n$, then the largest element of $\tilde{A}$ is a correct result with probability at least $1 - n^{-\alpha}$. Applying the randomized algorithm, we solve the problem in $\Theta(\log n)$ time with high probability.

Parallel Algorithms

Parallel algorithms provide methods to harness the power of multiple processors working together to solve a problem. The idea of using parallel computing is natural and has been explored in multiple ways. Theoretical models for parallel algorithms have been developed, including the shared memory and message passing (MP) parallel systems.

The PRAM (Parallel Random Access Machine) is a simple model in which multiple processors access a shared memory pool. Each read or write operation is executed asynchronously by the processors. Different processors collaborate to solve a problem by writing information that will be subsequently read by others. The PRAM is a popular model that captures the basic features of parallel systems, and there is a large number of algorithms developed for this theoretical model. However, the PRAM is not a realistic model: Real systems have difficulty in guaranteeing concurrent access to memory shared by several processors.

Variations of the main model have been proposed to overcome the limitations of PRAM. Such models have additional features, including different memory access policies. For example, the EREW (exclusive read, exclusive write) allows only one processor to access the memory for read and write operations. The CREW model (concurrent read, exclusive write) allows that multiple processors read the memory simultaneously, whereas only one processor can write to memory at each time.

MP is another basic model that is extensively used in parallel algorithms. In MP, all information shared by processors is sent via messages; memory is local and accessed by a single processor. Thus, messages are the only mechanism of cooperation in MP. A major result in parallel programming is that the two mechanisms discussed (shared memory and MP) are equivalent in computational power.

The success of a parallel algorithm is measured by the amount of work that it can evenly share among processors. Therefore, we need to quantify the *speedup* of a parallel algorithm, given the size of the problem, the time $T_S(n)$ necessary to solve the problem in a sequential computer, and the time $T_P(n, p)$ needed by the parallel algorithm with p processors. The speedup $\phi(n, p)$ can be computed as $\phi(n, p) = T_S(n)/T_P(n, p)$, and the *asymptotic speedup* $\phi_\infty(p)$ is the value of $\phi(n, p)$ when n approaches infinity (i.e., $\phi_\infty(p) = \lim_{n \to \infty} \phi(n, p)$). The desired situation is that all processors can contribute to evenly reduce the computational time. In this case, $\phi(n, p) = \mathcal{O}(p)$, and we say that the algorithm has *linear speedup*.

We show a simple example of parallel algorithm. In the *prefix computation* problem, a list $L = \{l_1, \ldots, l_n\}$ of numbers is given, and the objective is to compute the sequence of values $\sum_{i=1}^{j} l_i$ for $j \in \{1, \ldots, n\}$. The following algorithm uses n processors to compute the parallel prefix of n numbers in $\mathcal{O}(\log n)$ time.

```
Algorithm Parallel-prefix
Input: $L = \{l_1, \ldots, l_n\}$
for $k \leftarrow 0$ to $\lfloor \log n \rfloor - 1$ do
    Execute the following instructions in parallel:
    for $j \leftarrow 2^k + 1$ to $n$ do
        $l_j \leftarrow l_{j-2^k} + l_j$
    end
end
```

As a sequential algorithm for this problem has complexity $\Theta(n)$, the speedup of using the parallel algorithm is $\phi(n, n) = \Theta(n/\log n)$.

Heuristics and Metaheuristics

One of the most popular techniques for solving computationally hard problems is to apply the so-called *heuristic* approaches. A heuristic is an ad hoc algorithm that applies a set of rules to create or improve solutions to an NP-hard problem. Heuristics give a practical way of finding solutions that can be satisfactory for most purposes. The main distinctive features of these type of algorithms are fast execution time and the goal of finding good-quality solutions without necessarily providing any guarantee of quality. Heuristics are particularly useful for solving in practice hard large-scale problems for which more exact solution methods are not available.

As an example of a simple heuristic, we can consider a *local search* algorithm. Suppose we need to solve a combinatorial optimization problem, where we minimize an objective function $f(x)$, and the decision variable x is a vector of n binary variables (i.e., $x_i \in \{0, 1\}$ for $i \in \{1, \ldots, n\}$). For each problem, we define a *neighborhood* $N(x)$ of a feasible solution x as the set of feasible solutions x' that can be created by a well-defined modification of x. For example, let $x \in \{0, 1\}^n$ be a feasible solution, then $N(x)$ can be defined as the set of solutions x^k such that

$$x_i^k = \begin{cases} 1 - x_i & \text{if } i = k \\ x_i & \text{otherwise} \end{cases}$$

for $k \in \{1, \ldots, n\}$. A point $x \in \{0, 1\}^n$ is called a *local optimum* if it does not have a neighbor whose objective value is strictly better than $f(x)$. In our example, which we suppose is a minimization problem, it means that if x is a local optimum, then $f(x) \leq f(x^k)$ for all $k \in \{1, \ldots, n\}$. In this case, if we can generate a feasible solution x, then we can check if x is locally optimal in time $\mathcal{O}(n)$ (notice that other neighborhoods may lead to different search times). Let $\tilde{x} \in N(x)$, with $f(\tilde{x}) < f(x)$. Assigning $x \leftarrow \tilde{x}$, we can repeat the afore-mentioned procedure that searches for a locally optimal solution while the optimality criterion is reached. For many problems, local search-based approaches similar to the one described above proved to be very successful.

A *metaheuristic* is a family of heuristics that can be applied to find good solutions for difficult problems. The main difference between metaheuristics and heuristics is that, while a heuristic is an ad hoc procedure, a metaheuristic must follow a well-defined sequence of steps and use some specified data structures. However, the exact implementation of some of the steps in a metaheuristic may be customized, according to the target problem. Therefore, a concrete implementation of a metaheuristic provides a heuristic for a specific problem (hence, the use of the prefix "meta"). Elements of heuristics such as local search or greedy methods are usually combined in metaheuristics in order to find solutions of better quality.

Examples of metaheuristic methods include simulated annealing, genetic algorithms, tabu search, GRASP, path relinking, reactive search, ant colony optimization, and variable neighborhood search.

BIBLIOGRAPHIC NOTES

Algorithms and data structures have a vast literature, and we provide only some of the most important references. Popular books in algorithms and data structures include the ones by Cormen et al. (12), Horowitz et al. (13), Sedgewick (14), and Knuth (15). Networks and graph algorithms are covered in depth in Ahuja et al. (16). Books on data structures include the classics by Aho et al. (17) and Tarjan (18).

NP-hard problems have been discussed in several books, but the best-known reference is the compendium by Garey and Johnson (8). A standard reference on randomized algorithms is Ref. (19). For more information on parallel algorithms, and especially PRAM algorithms, see the book by Jaja (20). Good reviews of approximation algorithms are presented in the book edited by Hochbaum (21), and by Vazirani (22). For a more detailed discussion of different metaheuristics and related topics, the reader is referred to Ref. (23).

Information about the complexity of numerical optimization problems is available in the paper by Pardalos and Vavasis (24) and the books listed in Refs. (25) and (26).

DATA WAREHOUSE

INTRODUCTION

For a few decades, the role played by database technology in companies and enterprises has only been that of storing operational data, that is data generated by daily, routine operations carried out within business processes (such as selling, purchasing, and billing). On the other hand, managers need to access quickly and reliably the strategic information that supports decision making. Such information is extracted mainly from the vast amount of operational data stored in corporate databases, through a complex selection and summarization process.

Very quickly, the exponential growth in data volumes made computers the only suitable support for the decisional process run by managers. Thus, starting from the late 1980s, the role of databases began to change, which led to the rise of *decision support systems* that were meant as the suite of tools and techniques capable of extracting relevant information from a set of electronically recorded data. Among decision support systems, data warehousing systems are probably those that captured the most attention from both the industrial and the academic world.

A typical decision-making scenario is that of a large enterprise, with several branches, whose managers wish to quantify and evaluate the contribution given from each of them to the global commercial return of the enterprise. Because elemental commercial data are stored in the enterprise database, the traditional approach taken by the manager consists in asking the database administrators to write an ad hoc query that can aggregate properly the available data to produce the result. Unfortunately, writing such a query is commonly very difficult, because different, heterogeneous data sources will be involved. In addition, the query will probably take a very long time to be executed, because it will involve a huge volume of data, and it will run together with the application queries that are part of the operational workload of the enterprise. Eventually, the manager will get on his desk a report in the form of a either summary table, a diagram, or a spreadsheet, on which he will base his decision.

This approach leads to a useless waste of time and resources, and often it produces poor results. By the way, mixing these ad hoc, analytical queries with the operational ones required by the daily routine causes the system to slow down, which makes all users unhappy. Thus, the core idea of data warehousing is to separate analytical queries, which are commonly called OLAP *(On-Line Analytical Processing)* queries, from the operational ones, called OLTP *(On-Line Transactional Processing)* queries, by building a new information repository that integrates the elemental data coming from different sources, organizes them into an appropriate structure, and makes them available for analyses and evaluations aimed at planning and decision making.

Among the areas where data warehousing technologies are employed successfully, we mention but a few: trade, manufacturing, financial services, telecommunications, and health care. On the other hand, the applications of data warehousing are not restricted to enterprises: They also range from epidemiology to demography, from natural sciences to didactics. The common trait for all these fields is the need for tools that enable the user to obtain summary information easily and quickly out of a vast amount of data, to use it for studying a phenomenon and discovering significant trends and correlations—in short, for acquiring useful knowledge for decision support.

BASIC DEFINITIONS

A *data warehousing system* can be defined as a collection of methods, techniques, and tools that support the so-called *knowledge worker* (one who works primarily with information or develops and uses knowledge in the workplace: for instance, a corporate manager or a data analyst) in decision making by transforming data into information. The main features of data warehousing can be summarized as follows:

- Easy access to nonskilled computer users.
- Data integration based on a model of the enterprise.
- Flexible querying capabilities to take advantage of the information assets.
- Synthesis, to enable targeted and effective analysis.
- Multidimensional representation to give the user an intuitive and handy view of information.
- Correctness, completeness, and freshness of information.

At the core of this process, the *data warehouse* is a repository that responds to the above requirements. According to the classic definition by Bill Inmon (see Further Reading), a data warehouse is a collection of data that exhibits the following characteristics:

1. Subject-oriented, which means that all the data items related to the same business object are connected.
2. Time-variant, which means that the history of business is tracked and recorded to enable temporal reports.
3. Nonvolatile, which means that data are read-only and never updated or deleted.
4. Integrated, which means that data from different enterprise applications are collected and made consistent.

Although operational data commonly span a limited time interval, because most business transactions only involve recent data, the data warehouse must support

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

analyses that cover some years. Thus, the data warehouse is refreshed periodically starting from operational data. According to a common metaphor, we can imagine that photographs of operational data are periodically taken; the sequence of photos is then stored in the data warehouse, where a sort of movie is generated that depicts the history of business up to the current time.

Because in principle data are never deleted, and refreshes are made when the system is offline, a data warehouse can be considered basically as a read-only database. This feature, together with the importance given to achieving good querying performances, has two main consequences. First, the database management systems (DBMSs) used to manage the data warehouse do not need sophisticated techniques for supporting transactions. Second, the design techniques used for data warehouses are completely different from those adopted for operational databases.

As mentioned, another relevant difference between operational databases and data warehouses is related to the types of queries supported. OLTP queries on operational databases typically read and write a relatively small number of records from some tables related by simple relationships (e.g., search for customers' data to insert new orders). Conversely, OLAP queries on data warehouses commonly read a huge number of records to compute a few pieces of summary information. Most importantly, although the OLTP workload is "frozen" within applications and only occasionally ad hoc queries are formulated, the OLAP workload is intrinsically interactive and dynamic.

ARCHITECTURES

To preserve the separation between transactional and analytical processing, most data warehousing architectures are based on at least two data levels: the data sources and the data warehouse.

Data sources are heterogeneous; they may be part of the corporate information system (operational databases, legacy systems, spreadsheets, flat files, etc.). or even reside outside the company (Web databases, streams, etc.). These data are extracted, cleaned, completed, validated, integrated into a single schema, and loaded into the data warehouse by the so-called *ETL (Extraction, Transformation, and Loading)* tools.

The data warehouse is the centralized repository for the integrated information. Here, different from the sources, data are stored in multidimensional form, and their structure is optimized to guarantee good performance for OLAP queries. In practice, most often, the data warehouse is replaced physically by a set of *data marts* that include the portion of information that is relevant to a specific area of business, division of the enterprise, and category of users. Note the presence of a *metadata repository* that contains the "data about data," for example, a description of the logical organization of data within the sources, the data warehouse, and the data marts.

Finally, the information in the data warehouse is accessed by users by means of different types of tools: reporting tools, OLAP tools, data-mining tools, and what-if analysis tools.

Some architectures include an additional level called the *reconciled level* or *operational data-store*. It materializes the operational data obtained by extracting and cleaning source data: Thus, it contains integrated, consistent, correct, detailed, and current data. These reconciled data are then used to feed the data warehouse directly. Although the reconciled level introduces a significant redundancy, it also bears some notable benefits. In fact, it defines a reference data model for the whole company, and at the same time, it introduces a clear separation between the issues related to data extraction, cleaning and integration and those related to data warehouse loading. Remarkably, in some cases, the reconciled level is also used to better accomplish some operational tasks (such as producing daily reports that cannot be prepared satisfactorily using the corporate applications).

In the practice, these ingredients are blended differently to give origin to the five basic architectures commonly recognized in the literature:

- Independent data marts architecture
- Bus architecture
- Hub-and-spoke architecture
- Centralized data warehouse architecture
- Federated architecture

In the *independent data mart architecture*, different data marts are designed separately and built in a nonintegrated fashion (Fig. 1). This architecture, although sometimes initially adopted in the absence of a strong sponsorship toward an enterprise-wide warehousing project or when the organizational divisions that make up the company are coupled loosely, tends to be soon replaced by other architectures that better achieve data integration and cross-reporting.

The *bus architecture* is apparently similar to the previous one, with one important difference: A basic set of conformed dimension and facts, derived by a careful analysis of the main enterprise processes, is adopted and shared as a common design guideline to ensure logical integration of data marts and an enterprise-wide view of information.

In the *hub-and-spoke architecture*, much attention is given to scalability and extensibility and to achieving an enterprise-wide view of information. Atomic, normalized data are stored in a reconciled level that feeds a set of data marts containing summarized data in multidimensional form (Fig. 2). Users mainly access the data marts, but they occasionally may query the reconciled level.

The *centralized architecture* can be viewed as a particular implementation of the hub-and-spoke architecture where the reconciled level and the data marts are collapsed into a single physical repository.

Finally, *the federated architecture* is sometimes adopted in contexts where preexisting data warehouses/data marts are to be integrated noninvasively to provide a single, cross-organization decision support environment (e.g., in the case of mergers and acquisitions). Each data warehouse/data mart is either virtually or physically integrated with the

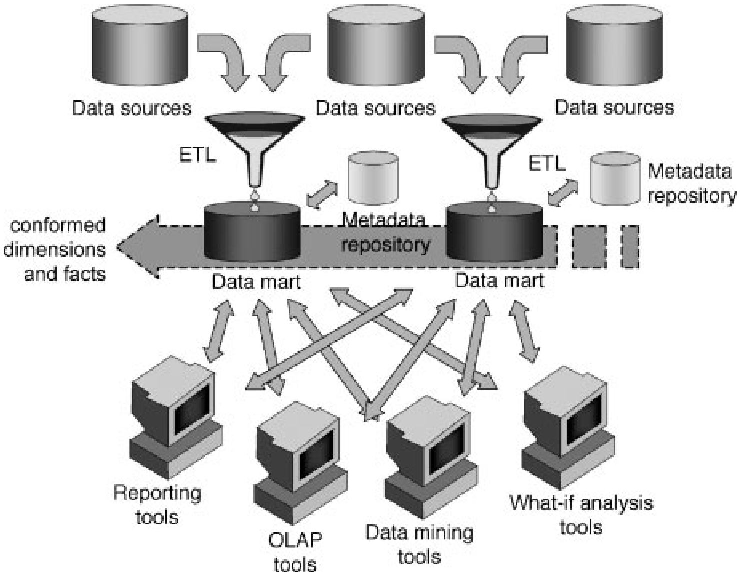

Figure 1. Independent data marts and bus architectures (without and with conformed dimensions and facts).

others by leaning on a variety of advanced techniques such as distributed querying, ontologies, and metadata interoperability.

ACCESSING THE DATA WAREHOUSE

This section discusses how users can exploit information stored in the data warehouse for decision making. In the following subsection, after introducing the particular features of the multidimensional model, we will survey the two main approaches for analyzing information: reporting and OLAP.

The Multidimensional Model

The reasons why the multidimensional model is adopted universally as the paradigm for representing data in data warehouses are its simplicity, its suitability for business analyses, and its intuitiveness for nonskilled computer users, which are also caused by the widespread use of spreadsheets as tools for individual productivity. Unfortunately, although some attempts have been made in the literature to formalize the multidimensional model (e.g., Ref. 1), none of them has emerged as a standard so far.

The multidimensional model originates from the observation that the decisional process is ruled by the *facts* of the business world, such as sales, shipments, bank transactions, and purchases. The occurrences of a fact correspond to *events* that occur dynamically: For example, every sale or shipment made is an event. For each fact, it is important to know the values of a set of *measures* that quantitatively describe the events: the revenue of a sale, the quantity shipped, the amount of a bank transaction, and the discount on a purchase.

The events that happen in the enterprise world are obviously too many to be analyzed one by one. Thus, to make them easily selectable and groupable, we imagine arranging them within an n-dimensional space whose axes, called *dimensions* of analysis, define different perspectives for their identification. Dimensions commonly are discrete, alphanumeric attributes that determine the minimum granularity for analyzing facts. For instance, the sales in a chain of stores can be represented within a three-dimensional space whose dimensions are the products, the stores, and the dates.

The concepts of dimension gave birth to the well-known *cube* metaphor for representing multidimensional data. According to this metaphor, events correspond to cells of a cube whose edges represents the dimensions of analysis. A cell of the cube is determined uniquely by assigning a value to every dimension, and it contains a value for each measure. Figure 3 shows an intuitive graphical representation of a cube centered on the sale fact. The dimensions are **product, store**, and **date**. An event corresponds to the selling of a given product in a given store on a given day, and it is described by two measures: the quantity sold and the revenue. The figure emphasizes that the cube is sparse, i.e., that several events did not happen at all: Obviously, not all products are sold every day in every store.

Normally, each dimension is structured into a *hierarchy* of *dimension levels* (sometimes called *roll-up hierarchy*) that group its values in different ways. For instance, products may be grouped according to their type and their brand, and types may be grouped additionally into categories. Stores are grouped into cities, which in turn are grouped into regions and nations. Dates are grouped into months and years. On top of each hierarchy, a final level exists that groups together all possible values of a hierarchy (all products, all stores, and all dates). Each dimension level may be described even more by one or more *descriptive attributes* (e.g., a product may be described by its name, its color, and its weight).

A brief mention to some alternative terminology used either in the literature or in the commercial tools is useful.

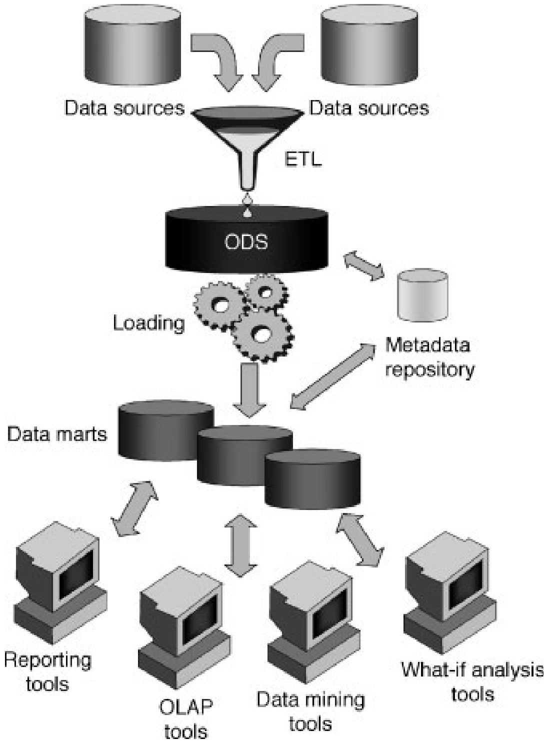

Figure 2. Hub-and-spoke architecture; ODS stands for operational data store.

Although with the term *dimension* we refer to the attribute that determines the minimum fact granularity, sometimes the whole hierarchies are named as dimensions. Measures are sometimes called *variables, metrics, categories, properties*, or *indicators*. Finally, dimension levels are sometimes called *parameters* or *attributes*.

We now observe that the cube cells and the data they contain, although summarizing the elemental data stored within operational sources, are still very difficult to analyze because of their huge number. Two basic techniques are used, possibly together, to reduce the quantity of data and thus obtain useful information: *restriction* and *aggregation*. For both, hierarchies play a fundamental role because they determine how events may be aggregated and selected.

Restricting data means cutting out a portion of the cube to limit the scope of analysis. The simplest form of restriction is *slicing*, where the cube dimensionality is reduced by focusing on one single value for one or more dimensions. For instance, as depicted in Fig. 4, by deciding that only sales of store "S-Mart" are of interest, the decision maker actually cuts a slice of the cube obtaining a two-dimensional subcube. *Dicing* is a generalization of slicing in which a subcube is determined by posing Boolean conditions on hierarchy levels. For instance, the user may be interested in sales of products of type "Hi-Fi" for the stores in Rome during the days of January 2007 (see Fig. 4).

Although restriction is used widely, aggregation plays the most relevant role in analyzing multidimensional data. In fact, most often users are not interested in analyzing events at the maximum level of detail. For instance, it may be interesting to analyze sale events not on a daily basis but by month. In the cube metaphor, this process means grouping, for each product and each store, all cells corresponding to the days of the same month into one macro-cell. In the aggregated cube obtained, each macro-cell represents a synthesis of the data stored in the cells it aggregates: in our example, the total number of items sold in each month and the total monthly revenue, which are calculated by summing the values of **quantity** and **revenue** through the corresponding cells. Eventually, by aggregating along the time hierarchy, an aggregated cube is obtained in which each macro-cell represents the total sales over the whole time period for each product and store. Aggregation can also be operated along two or more hierarchies. For instance, as shown in Fig. 5, sales can be aggregated by month, product type, and city.

Noticeably, not every measure can be aggregated consistently along all dimensions using the sum operator. In some cases, other operators (such as average or minimum) can be used instead, whereas in other cases, aggregation is not possible at all. For details on the two related problems of *additivity* and *summarizability*, the reader is referred to Ref. 2.

Reporting

Reporting is oriented to users who need to access periodically information structured in a fixed way. For instance, a hospital must send monthly reports of the costs of patient stays to a regional office. These reports always have the same form, so the designer can write the query that generates the report and "freeze" it within an application so that it can be executed at the users' needs.

A report is associated with a query and a presentation. The query typically entails selecting and aggregating multidimensional data stored in one or more facts. The presentation can be in tabular or graphical form (a diagram, a histogram, a cake, etc.). Most reporting tools also allow for automatically distributing periodic reports to interested users by e-mail on a subscription basis or for posting reports in the corporate intranet server for downloading.

OLAP

OLAP, which is probably the best known technique for querying data warehouses, enables users to explore interactively and analyze information based on the multidimensional model. While the users of reporting tools essentially play a passive role, OLAP users can define actively a complex analysis session where each step taken follows from the results obtained at previous steps. The impromptu character of OLAP sessions, the deep knowledge of data required, the complexity of the possible queries, and the orientation toward users not skilled in computer science maximize the importance of the employed tool, whose interface necessarily has to exhibit excellent features of flexibility and friendliness.

An OLAP session consists in a "navigation path" that reflects the course of analysis of one or more facts from different points of view and at different detail levels. Such a path is realized into a sequence of queries, with each differentially expressed with reference to the previous

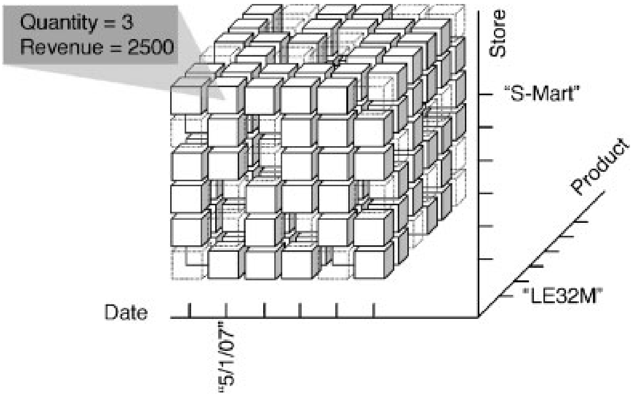

Figure 3. The three-dimensional cube that models the sales in a chain of shops. In the S-Mart store, on 5/1/2007, three LE32M TVs were sold, for a total revenue of $2500.

query. Query results are multidimensional; like for reporting, OLAP tools typically represent data in either tabular or graphical form.

Each step in the analysis session is marked by the application of an *OLAP operator* that transforms the previous query into a new one. The most common OLAP operators are as follows:

- *Roll-up*, which aggregates data even more (e.g., from sales by product, nation, and month to sales by category, nation, and year).
- *Drill-down*, which adds detail to data (e.g., from sales by category, nation, and year to sales by category, city, and year).
- *Slice-and-dice*, which selects data by fixing values or intervals for one or more dimensions (e.g., sales of products of type "Hi-Fi" for stores in Italy).
- *Pivoting*, which changes the way of visualizing the results by rotating the cube (e.g., swaps rows with columns).
- *Drill-across*, which joins two or more correlated cubes to compare their data (e.g., join the sales and the promotions cubes to compare revenues with discounts).

We close this section by observing that, in several applications, much use is made of an intermediate approach commonly called *semistatic reporting*, in which only a reduced set of OLAP navigation paths are enabled to avoid obtaining inconsistent or wrong results by incorrectly using aggregation, while allowing for some flexibility in manipulating data.

IMPLEMENTATIONS OF THE MULTIDIMENSIONAL MODEL

Two main approaches exist for implementing a data warehouse: *ROLAP*, which stands for *relational OLAP*, and *MOLAP*, which stands for *multidimensional OLAP*. Recently a third, intermediate approach has been adopted in some commercial tools: *HOLAP*, that is, *hybrid OLAP*.

Relational OLAP

On a ROLAP platform, the relational technology is employed to store data in multidimensional form. This approach is motivated by the huge research work made on the relational model, by the widespread knowledge of relational databases and their administration, and by the excellent level of performance and flexibility achieved by relational DBMSs. Of course, because the expressiveness of the relational model does not include the basic concepts of the multidimensional model, it is necessary to adopt specific schema structures that allow the multidimensional model to be mapped onto the relational model. Two main such structures are commonly adopted: the *star schema* and the *snowflake schema*.

The star schema is a relational schema composed of a set of relations called *dimension tables* and one relation called a *fact table*. Each dimension table models a hierarchy; it includes a surrogate key (i.e., a unique progressive number generated by the DBMS) and one column for each level and descriptive attribute of the hierarchy. The fact table includes a set of foreign keys, one that references each dimension table, which together define the primary key, plus one column for each measure. Figure 6 shows a star schema for the sales example. Noticeably, dimension tables are denormalized (they are not in the third normal form); this is aimed at reducing the number of relational joins to be computed when executing OLAP queries, so as to improve performance.

A snowflake schema is a star schema in which one or more dimension tables have been partially or totally normalized to reduce redundancy. Thus, a dimension table can be split into one *primary* dimension table (whose surrogate key is references by the fact table) and one or more

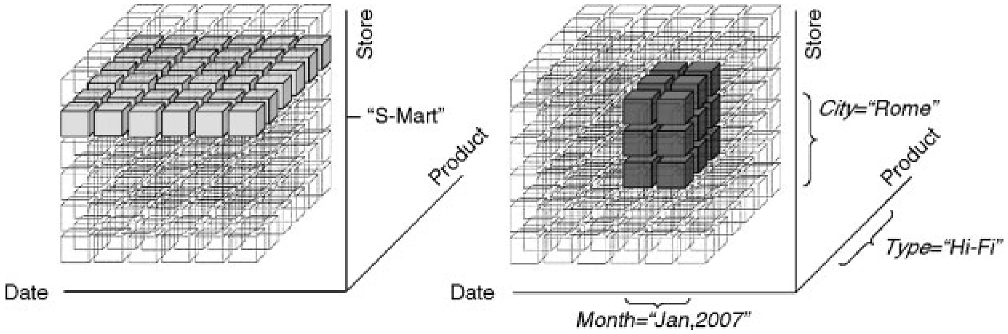

Figure 4. Slicing (left) and dicing (right) on the sales cube.

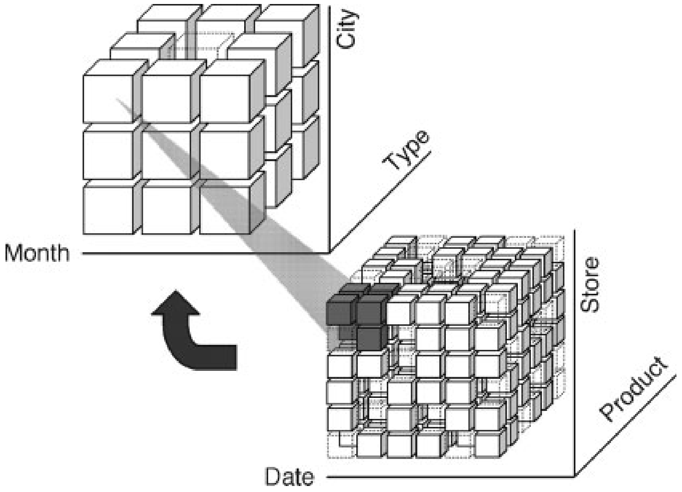

Figure 5. Aggregation on the sales cube.

secondary dimension tables (each including a surrogate key and referencing the key of another dimension table). Figure 7 shows an example for the sale schema, in which the product dimension has been normalized partially.

Multidimensional OLAP

Differently from ROLAP, a MOLAP system is based on a native logical model that directly supports multidimensional data and operations. Data are stored physically into multidimensional arrays, and positional techniques are used to access them.

The great advantage of MOLAP platforms is that OLAP queries can be executed with optimal performances, without resorting to complex and costly join operations. On the other hand, they fall short when dealing with large volumes of data, mainly because of the problem of sparseness: In fact, when a large percentage of the cube cells are empty, a lot of memory space is wasted uselessly unless ad hoc compression techniques are adopted.

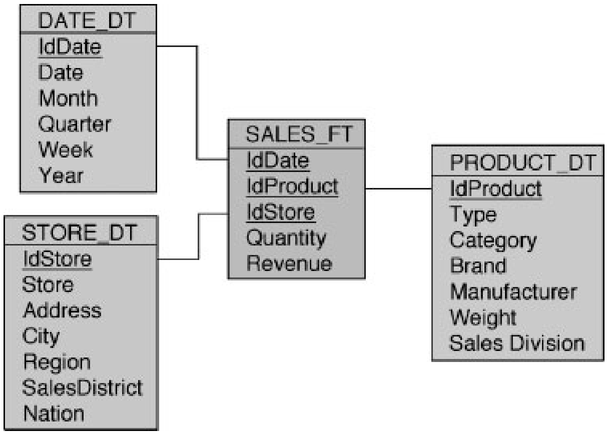

Figure 6. Star schema for the sales example (primary keys are underlined).

Hybrid OLAP

HOLAP can be viewed as an intermediate approach between ROLAP and MOLAP, because it tries to put together their advantages into a single platform. Two basic strategies are pursued in commercial tools to achieve this goal. In the first strategy, detailed data are stored in a relational database, whereas a set of useful preaggregates are stored on proprietary multidimensional structures. In the second strategy, cubes are partitioned into dense and sparse subcubes, with the former being stored in multidimensional form, and the latter in relational form.

DESIGN TECHNIQUES

Despite the basic role played by a well-structured methodological framework in ensuring that the data warehouse designed fully meets the user expectations, a very few *comprehensive* design methods have been devised so far (e.g., Refs. 3 and 4). None of them has emerged as a standard, but all agree on one point: A bottom-up approach is preferable to a top-down approach, because it significantly reduces the risk of project failure. While in a top-down approach the data warehouse is planned and designed initially in its entirety, in a bottom-up approach, it is built incrementally by designing and prototyping one data mart at a time, starting from the one that plays the most strategic business role. In general terms, the macro-phases for designing a data warehouse can be stated as follows:

- *Planning*, based on a feasibility study that assesses the project goals, estimates the system borders and size, evaluates costs and benefits, and analyzes risks and users' expectations.
- *Infrastructure design*, aimed at comparing the different architectural solutions, at surveying the available technologies and tools, and at preparing a draft design of the whole system.
- *Data mart development*, which iteratively designs, develops, tests and deploys each data mart and the related applications.

As concerns the design of each data mart, the methodology proposed in Ref. 3 encompasses eight closely related, but not necessarily strictly sequential, phases:

1. *Data source analysis*. The source schemata are analyzed and integrated to produce a reconciled schema describing the available operational data.
2. *Requirement analysis*. Business users are interviewed to understand and collect their goals and needs, so as to generate requirement glossaries and a preliminary specification of the core workload.
3. *Conceptual design*. Starting from the user requirements and from the reconciled schema, a conceptual schema that describes the data mart in an implementation-independent manner is derived.
4. *Schema validation*. The preliminary workload is better specified and tested against the conceptual schema to validate it.

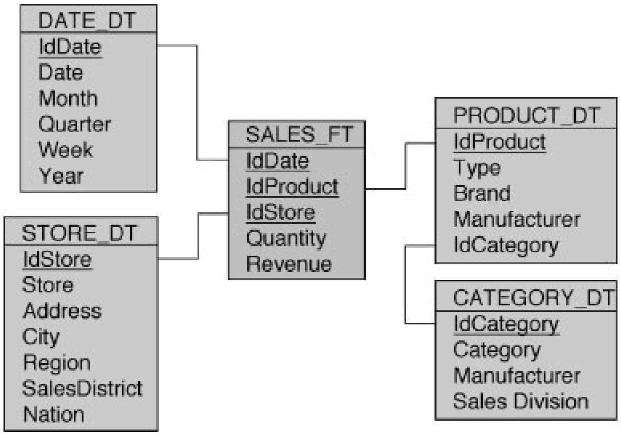

Figure 7. Snowflake schema for the sales example.

5. *Logical design*. The conceptual schema is translated into a logical schema according to the target logical model (relational or multidimensional), considering the expected workload and possible additional constraints related to space occupation and querying performances.
6. *ETL design*. The ETL procedures used to feed the data mart starting from the data sources via the reconciled level are designed.
7. *Physical design*. Physical optimization of the logical schema is done, depending on the specific characteristic of the platform chosen for implementing the data mart.
8. *Implementation*. The physical schema of the data mart is deployed, ETL procedures are implemented, and the applications for data analysis are built and tested.

Several techniques for supporting single phases of design have been proposed in the literature; a brief survey of the most relevant approaches is reported in the following subsections.

Data Source Analysis

A huge literature about schema integration has been accumulating over the last two decades. Integration methodologies have been proposed (e.g., Ref. 5), together with formalisms to code the relevant information (e.g., Ref. 6). However, the integration tools developed so far [such as TSIMMIS (7) and MOMIS (8)] should still be considered research prototypes rather than industrial tools, with the notable exception of Clio (9), which is supported by IBM.

Requirement Analysis

A careful requirement analysis is one of the keys to reduce dramatically the risk of failure for warehousing projects. From this point of view, the approaches to data warehouse design usually are classified in two categories:

- *Supply-driven* (or *data-driven*) approaches design the data warehouse starting from a detailed analysis of the data sources (e.g., Ref. 10). User requirements impact design by allowing the designer to select which chunks of data are relevant for the decision-making process and by determining their structuring according to the multidimensional model.
- *Demand-driven* (or *requirement-driven*) approaches start from determining the information requirements of business users (like in Ref. 11). The problem of mapping these requirements onto the available data sources is faced only *a posteriori*, by designing proper ETL routines, and possibly by accommodating data sources to accomplish the information needs.

A few *mixed* approaches were also devised (12,13), where requirement analysis and source inspection are carried out in parallel, and user requirements are exploited to reduce the complexity of conceptual design.

Conceptual Design

Although no agreement exists on a standard conceptual model for data warehouses, most authors agree on the importance of a conceptual design phase providing a high level of abstraction in describing the multidimensional schema of the data warehouse aimed at achieving independence of implementation issues. To this end, conceptual models typically rely on a graphical notation that facilitates writing, understanding, and managing conceptual schemata by designers and users.

The existing approaches may be framed into three categories: extensions to the entity-relationship model (e.g, Ref. 14), extensions to UML (e.g., Ref. 15), and ad hoc models (e.g., Ref. 16). Although all models have the same core expressivity, in that they all allow the basic concepts of the multidimensional model to be represented graphically, they significantly differ as to the possibility of representing more advanced concepts such as irregular hierarchies, many-to-many associations, and additivity.

Logical Design

The goal of logical design is to translate a conceptual schema into a logical schema for the data mart. Although on MOLAP platforms this task is relatively simple, because the target logical model is multidimensional like the source conceptual one, on ROLAP platforms, two different models (multidimensional and relational) have to be matched. This is probably the area of data warehousing where research has focused the most during the last decade (see, for instance, Ref. 17); in particular, a lot has been written about the so-called view materialization problem.

View materialization is a well-known technique for optimizing the querying performance of data warehouses by physically materializing a set of (redundant) tables, called *views*, that store data at different aggregation levels. In the presence of materialized views, an ad hoc component of the underlying DBMS (often called *aggregate navigator*) is entrusted with the task of choosing, for each query formulated by the user, the view(s) on which the query can be answered most cheaply. Because the number of potential views is exponential in the number of hierarchy levels, materializing all views would be prohibitive. Thus, research has focused mainly on effective techniques for determining the optimal subset of views to be materialized under different kinds of constraints (e.g., Ref. 18).

Another optimization technique that is sometimes adopted to improve the querying performance is *fragmentation* (also called*partitioning* or *striping*). In particular, in *vertical* fragmentation, the fact tables are partitioned into smaller tables that contain the key and a subset of measures that are often accessed together by the workload queries (19).

ETL Design

This topic has earned some research interest only in the last few years. The focus here is to model the ETL process either from the functional, the dynamic, or the static point of view. In particular, besides techniques for conceptual design of ETL (20), some approaches are aimed at automating (21) and optimizing (22) the logical design of ETL. Although the research on ETL modeling is probably less mature than that on multidimensional modeling, it will probably have a very relevant impact on improving the overall reliability of the design process and on reducing its duration.

Physical Design

Physical design is aimed at filling the gap between the logical schema and its implementation on the specific target platform. As such, it is concerned mainly with the problem of choosing which types of indexes should be created on which columns of which tables. Like the problem of view selection, this problem has exponential complexity. A few papers on the topic can be found in the literature: For instance, Ref. 23 proposes a technique that jointly optimizes view and index selection, whereas Ref. 24 selects the optimal set of indexes for a given set of views in the presence of space constraints. The problem is made even more complex by the fact that ROLAP platforms typically offer, besides classic B-trees, other types of indexes, such as star indexes, projection indexes, and bitmap indexes (25).

Note that, although some authors consider both view selection and fragmentation as part of physical design, we prefer to include them into logical design for similarity with the design of operational databases (26).

ADVANCED TOPICS

Several other topics besides those discussed so far have been addressed by the data warehouse literature. Among them we mention:

- *Query processing*. OLAP queries are intrinsically different from OLTP queries: They are read-only queries requiring a very large amount of data, taken from a few tables, to be accessed and aggregated. In addition, DBMSs oriented to data warehousing commonly support different types of specialized indexes besides B-trees. Finally, differently from the OLTP workload, the OLAP workload is very dynamical and subject to change, and very fast response times are needed. For all these reasons, the query processing techniques required by data warehousing systems are significantly different from those traditionally implemented in relational DBMSs.
- *Security*. Among the different aspects of security, confidentiality (i.e., ensuring that users can only access the information they have privileges for) is particularly relevant in data warehousing, because business information is very sensitive. Although the classic security models developed for operational databases are used widely by data warehousing tools, the particularities of OLAP applications ask for more specific models centered on the main concepts of multidimensional modeling—facts, dimensions, and measures.
- *Evolution*. The continuous evolution of the application domains is bringing to the forefront the dynamic aspects related to describing how the information stored in the data warehouse changes over time. As concerns changes in values of hierarchy data (the so-called *slowly changing dimensions*), several approaches have been devised, and some commercial systems allow us to track changes and to query cubes effectively based on different temporal scenarios. Conversely, the problem of managing changes on the schema level has only been explored partially, and no dedicated commercial tools or restructuring methods are available to the designer yet.
- *Quality*. Because of the strategic importance of data warehouses, it is absolutely crucial to guarantee their quality (in terms of data, design, technology, business, etc.) from the early stages of a project. Although some relevant work on the quality of data has been carried out, no agreement still exists on the quality of the design process and its impact on decision making.
- *Interoperability*. The wide variety of tools and software products available on the market has lead to a broad diversity in metadata modeling for data warehouses. In practice, tools with dissimilar metadata are integrated by building complex metadata bridges, but some information is lost when translating from one form of metadata to another. Thus, a need exists for a standard definition of metadata in order to better support data warehouse interoperability and integration, which is particularly relevant in the recurrent case of mergers and acquisitions. Two industry standards developed by multivendor organizations have originated in this context: the Open Information Model (OIM) by the Meta Data Coalition (MDC) and the Common Warehouse Metamodel (CWM) by the OMG.
- *New architectures and applications*. Advanced architectures for business intelligence are emerging to support new kinds of applications, possibly involving new and more complex data types. Here we cite *spatial data warehousing, web warehousing, real-time data warehousing, distributed data warehousing, and scientific data warehousing*. Thus, it becomes necessary to adapt

and specialize the existing design and optimization techniques to cope with these new applications.

See Ref. 26 for an up-to-date survey of open research themes.

DECISION SUPPORT SYSTEMS: FOUNDATIONS AND VARIATIONS

INTRODUCTION

Over the past quarter century, economic and technological forces have produced radical redefinitions of work, the workplace, and the marketplace. They have ushered in the era of knowledge workers, knowledge-based organizations, and the knowledge economy. People have always used the knowledge available to them to make decisions that shape the world in which they live. Decisions of workers, consumers, and organizations range from those affecting the world in some small or fleeting way to those of global and lasting proportions. In recent times, the number of decisions being made per time period and the complexity of factors involved in decision activities have grown dramatically. As the world's supply of knowledge continues to accelerate, the amount of knowledge used in making decisions has exploded. Computer-based systems that help decision makers deal with both the knowledge explosion and the incessant demands for decisions in a fast-paced, complicated world are called decision support systems (DSSs). Such systems have become practically indispensable for high performance, competitiveness, and even organizational survival.

Imagine an organization in which managers and other workers cannot use computers to aid any of their decisional activities. Contrast this fantasy with the vision of an organization whose managers and other knowledge workers routinely employ computers to get at and process knowledge that has a bearing on decisions being made. These DSSs store and process certain kinds of knowledge in much higher volumes and at much higher speeds than the human mind. In addition to such efficiency advantages, they can also be more effective for certain kinds of knowledge handling because they are not subject to such common human conditions as oversight, forgetfulness, miscalculation, bias, and stress. Failure to appreciate or exploit such decision support capabilities puts individuals and organizations at a major disadvantage

As a prelude to considering the characteristics of DSSs, we need to examine a couple of preliminaries: decision making and knowledge. Understanding what it means to make a decision provides a useful basis for exploring decision support possibilities. Understanding salient aspects of knowledge gives a starting point for appreciating ways in which computers can support the use of knowledge during decision making.

DECISION MAKING

General agreement in the management literature exists that a *decision* is a choice. It may be a choice about a "course of action" (1,2), choice of a "strategy for action" (3), or a choice leading to a certain desired objective"(4). Thus, we can think of *decision making* as an activity culminating in the selection of one from among multiple alternative courses of action.

In general, the number of alternatives identified and considered in decision making could be very large. The work involved in becoming aware of alternatives often makes up a major share of a decision-making episode. It is concerned with such questions as "Where do alternatives come from?" "How many alternatives are enough?" "How can large numbers of alternatives be managed so none is forgotten or garbled?" A computer-based system (i.e, a DSS) can help a decision maker cope with such issues.

Ultimately, one alternative is selected. But, which one? This choice depends on a study of the alternatives to understand their various implications as well as on a clear appreciation of what is important to the decision maker. The work involved in selecting one alternative often makes up a major share of a decision-making episode. It is concerned with such questions as: "To what extent should each alternative be studied?" "How reliable is our expectation about an alternative's impacts?" "Are an alternative's expected impacts compatible with the decision maker's purposes?" "What basis should be used to compare alternatives with each other?" "What strategy will be followed in arriving at a choice?" Computer-based systems (i.e., DSSs) can be very beneficial in supporting the study of alternatives. Some systems even recommend the selection of a particular alternative and explain the rationale underlying that advice.

Complementing the classic view of decisions and decision making, there is the *knowledge-based view* that holds that a decision is knowledge that indicates the nature of an action commitment (5). When we regard a decision as a piece of knowledge, making a decision means we are making a new piece of knowledge that did not exist before, manufacturing new knowledge by transforming or assembling existing pieces of knowledge. The manufacturing process may yield additional new knowledge as byproducts (e.g., knowledge derived as evidence to justify the decision, knowledge about alternatives that were not chosen, knowledge about improving the decision manufacturing process itself). Such byproducts can be useful later in making other decisions. A DSS is a computer-based system that aids the manufacturing process, just as machines aid in the manufacturing of material goods.

According to Mintzberg (6), there are four decisional roles: entrepreneur, disturbance handler, resource allocator, and negotiator. When playing the entrepreneur role, a decision maker searches for opportunities to advance in new directions aligned with his/her/its purpose. If such an opportunity is discovered, the decision maker initiates and devises controlled changes in an effort to seize the opportunity. As a disturbance handler, a decision maker initiates and devises corrective actions when facing an unexpected disturbance. As a resource allocator, a decision maker determines where efforts will be expended and how assets

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

will be deployed. This decision can be thought of as determining a strategy for structuring available resources. When playing the negotiator role, a decision maker bargains with others to try to reach a joint decision. Decision support systems are capable of supporting these four roles, although a particular DSS can be oriented more toward one role than the others.

A DSS can also vary to suit other particularities of contexts in which it is to be used. For instance, the context could be strategic decision making (concerned with deciding on purposes to fulfill, objectives to meet, changes in objectives, policies to adopt) decision making to ensure objectives are met and policies are observed, or operational decision making about performing specific tasks. These contexts vary along such dimensions as time horizons for deciding, extent of precision and detailed knowledge needed, narrow to wide-ranging knowledge, rhythm to decision-making activities, and degree of creativity or qualitative judgment required.

As another example of decision context, consider the maturity of the situation in which a decision is being made. Some decisions are made in established situations, whereas others are made in emergent situations. Well-established situations imply considerable experience in previously having made similar kinds of decisions, with a relatively high level of knowledge existing about the current state of affairs and the history of previous decisions of a similar nature. In contrast, emergent situations are characterized not only by some surprising new knowledge, but also often by a scarcity of relevant knowledge as well, often with intense effort required to acquire needed knowledge. The type of support likely to be most useful for established contexts could be quite different than what is valuable in the case of emergent settings.

Simon (2,7) says that decisions comprise a continuum ranging from structured to unstructured. The structuredness of a decision is concerned with how routine and repetitive is the process that produced it. A highly structured decision is one that has been manufactured in an established context. Alternatives from which the choice is made are clear-cut, and each can be readily evaluated in light of purposes and goals. All knowledge required to make the decision is available in a form that makes it straightforward to use. Unstructured decisions tend to be produced in emergent contexts. Issues pertinent to producing a decision are not well understood. Some issues may be entirely unknown to the decision maker; alternatives from which a choice will be made are vague or unknown, are difficult to compare and contrast, or cannot be easily evaluated. In other words, the knowledge required to produce a decision is unavailable, difficult to acquire, incomplete, suspect, or in a form that cannot be readily used by the decision maker. Semistructured decisions lie between the two extremes.

DSSs of varying kinds can be valuable aids in the manufacture of semistructured and unstructured decisions (8), as well as structured decisions (9). For the former, DSSs can be designed to facilitate the exploration of knowledge, help synthesize methods for reaching decisions, catalog and examine the results of brainstorming, provide multiple perspectives on issues, or stimulate a decision maker's creative capabilities. For structured decisions, DSSs automatically carry out some portion of the process used to produce a decision.

Because decisions are not manufactured in a vacuum, an appreciation of decision contexts and types can help us understand what features would be useful to have in a DSS. The same can be said for an appreciation of decision makers and decision processes, which we now consider in turn.

Decision making can involve an individual participant or multiple participants. In the multiparticipant case, the power to decide may be vested in a single participant, with other participants having varying degrees of influence over what the decision will be and how efficiently it will be produced. They do so by specializing in assorted knowledge processing tasks assigned to them during the making of the decision. These supporting participants function as extensions to the deciding participant's own knowledge processing capabilities. At the other extreme of multiparticipant decision making, participants share equal authority over the decision being made, with little formal specialization in knowledge processing tasks. This is referred to as a group decision maker, whereas the other extreme is called an organization decision maker. There are many variations between these extremes. Correspondingly, DSSs for these different kinds of multiparticipant decision makers can be expected to exhibit some different kinds of features. Moreover, a particular DSS may assist a specific participant, some subset of participants, or all participants involved in a multiparticipant decision.

Now, as for the process of decision making, Simon (2) says there are three important phases, which he calls intelligence, design, and choice. Moreover, running through the phases in any decision-making process, a decision maker is concerned with recognizing and solving some problems in some sequence (10). A decision-making process is governed by the decision maker's strategy for reaching a choice (11).

The intelligence phase is a period when the decision maker is alert for occasions to make decisions, preoccupied with collecting knowledge, and concerned with evaluating it in light of a guiding purpose. The design phase is a period wherein the decision maker formulates alternative courses of action, analyzes those alternatives to arrive at expectations about the likely outcomes of choosing each, and evaluates those expectations with respect to a purpose or objective. During the design phase, the decision maker may find that additional knowledge is needed, triggering a return to the intelligence phase to satisfy that need before continuing with the design activity. Evaluations of the alternatives are carried forward into the choice phase of the decision process, where they are compared and one is chosen. This choice is made in the face of internal and external pressures related to the nature of the decision maker and the decision context. It may happen that none of the alternatives are palatable, that several competing alternatives yield very positive evaluations, or that the state of the world has changed significantly since the alternatives were formulated and analyzed. So, the decision maker may return to one of the two earlier phases to collect more up-to-date knowledge, formulate new alternatives, reanalyze alternatives, reevaluate them, and so forth. Any phase is susceptible to computer-based support.

Recognizing and solving problems is the essence of activity within intelligence, design, and choice phases. For structured decisions, the path toward the objective of producing a decision is well charted. Problems to be surmounted are recognized easily, and the means for solving them are readily available. Unstructured decisions take us into uncharted territory. Problems that will be encountered along the way are not known in advance. Even when stumbled upon, they may be difficult to recognize and subsequently solve. Ingenuity and an exploratory attitude are vital for coping with these types of decisions.

Thus, a decision-making process can be thought of as a flow of problem-recognition and problem-solving exercises. In the case of a multiparticipant decision maker, this flow has many tributaries, made up of different participants working on various problems simultaneously, in parallel, or in some necessary sequence. Only if we solve its subproblems can we solve an overall decision problem. DSSs can help decision makers in recognizing and/or solving problems.

A decision-making process, and associated knowledge processing, are strongly colored by the strategy being used to choose an alternative. Well-known decision-making strategies include optimizing, satisficing, elimination-by-aspects, incrementalism, mixed scanning, and the analytic hierarchy process. As a practical matter, each strategy has certain strengths and limitations (9). A DSS designed to support an optimizing strategy may be of little help when a satisficing strategy is being adopted and vice versa.

We close this brief overview of decision making by considering two key questions about decision support: Why does a decision maker need support? What is the nature of the needed support? Computer systems to support decision makers are not free. Not only is there the cost of purchasing or developing a DSS, costs are also associated with learning about, using, and maintaining a DSS. It is only reasonable that the benefits of a DSS should be required to outweigh its costs. Although some DSS benefits can be difficult to measure in precise quantitative terms, all benefits are the result of a decision maker's need for support in overcoming cognitive, economic, or time limits (9).

Cognitive limits refer to limits in the human mind's ability to store and process knowledge. A person does not know everything all the time, and what is known cannot always be recalled in an instantaneous, error-free fashion. Because decision making is a knowledge-intensive activity, cognitive limits substantially restrict an individual's problem-solving efficiency and effectiveness. They may even make it impossible for the individual to reach some decisions. If these limits are relaxed, decision-maker productivity should improve. The main reason multiparticipant decision makers exist is because of this situation. Rather than having an individual find and solve all problems leading to a decision, additional participants serve as extensions to the deciding participant's own knowledge-handling skills, allowing problems to be solved more reliably or rapidly. A DSS can function as a supporting participant in decision making, essentially extending a person's cognitive capabilities.

To relax cognitive limits as much as possible, we could consider forming a very large team of participants. But this can be expensive not only in terms of paying and equipping more people, but also with respect to increased communication and coordination costs. At some point, the benefits of increased cognitive abilities are outweighed by the costs of more people. Decision support systems can soften the effects of economic limits when they are admitted as decision-making participants. If properly conceived and used, added DSSs increase the productivity of human participants and allow the organization decision maker to solve problems more efficiently and effectively.

A decision maker may be blessed with extraordinary cognitive abilities and vast economic resources but very little time. Time limits can put severe pressure on the decision maker, increasing the likelihood of errors and poor-quality decisions. There may not be sufficient time to consider relevant knowledge, to solve relevant problems, or to employ a desirable decision-making strategy. Because computers can process some kinds of knowledge much faster than humans, are not error-prone, work tirelessly, and are immune to stresses from looming deadlines, DSSs can help lessen the impacts of time limits.

To summarize, the support that a DSS offers normally includes at least one of the following:

- Alerts user to a decision-making opportunity or challenge
- Recognizes problems that need to be solved as part of the decision-making process
- Solves problems recognized by itself or by the user
- Facilitates or extends the user's ability to process (e.g., acquire, transform, and explore) knowledge
- Offers advice, expectations, evaluations, facts, analyses, and designs to users
- Stimulates the user's perception, imagination, or creative insight
- Coordinates/facilitates interactions within multiparticipant decision makers

Because knowledge forms the fabric of decision making, all the various kinds of support that a DSS can provide are essentially exercises in knowledge management. Thus, we now take a closer look at the matter of knowledge.

KNOWLEDGE MATTERS

Now, consider the notion of knowledge in more detail. A decision maker possesses a storehouse of knowledge, plus abilities to both alter and draw on the contents of that inventory (12). This characterization holds for all types of decision makers—individuals, groups, and organizations. In the multiparticipant cases, both knowledge and processing abilities are distributed among participants. Knowledge is extracted on an as-needed basis from the inventory and manipulated to produce solutions for the flow of problems that constitutes a decision manufacturing process. When the inventory is inadequate for solving some problem, outgoing messages are used in an effort to acquire the additional knowledge. The solution to each problem arising during the manufacturing process is itself a piece of knowledge. In turn, it may be used to find or solve other problems, whose solutions are knowledge allowing still other problems to be solved, and so forth, until the overall problem of producing a decision is solved (10). Thus, knowledge is the raw material, work-in-process, byproduct, and finished good of decision making.

If a system has and can use a representation of "something (an object, a procedure, . . . whatever), then the system itself can also be said to have knowledge, namely, the knowledge embodied in that representation about that thing" (13). Knowledge is embodied in *usable representations*, where a representation is a pattern of some kind: symbolic, digital, mental, behavioral, audio, visual, etc. To the extent that we can make use of that representation, it embodies knowledge. Of particular interest for DSSs are the representations that a computer can use and the knowledge processing ability corresponding to each knowledge representation approaches permitted in its portion of the knowledge storehouse. A DSS cannot process knowledge that it cannot represent. Conversely, a DSS cannot know what is represented by some pattern that it cannot process.

When designing or encountering a particular DSS, we should examine it in terms of the possibilities it presents for representing and processing knowledge—that is, the knowledge-management abilities it has to supplement human cognitive abilities. Over the years, several computer-based techniques for managing knowledge have been successfully applied to support decision makers, including text/hypertext/document management, database management, data warehousing, solver management spreadsheet analysis, rule management, message management, process management, and so forth (5). Each of these techniques can represent and process one or more of the three basic types of knowledge important for study of DSSs: descriptive, procedural, and reasoning knowledge (12,14).

Knowledge about the state of some world is called descriptive knowledge. It includes descriptions of past, present, future, and hypothetical situations. This knowledge includes data and information. In contrast, procedural knowledge is concerned with step-by-step procedures for accomplishing some task. Reasoning knowledge specifies conclusions that can be drawn when a specified situation exists. Descriptive, procedural, and reasoning knowledge can be used together within a single DSS to support decision making (10). For example, a DSS may derive (e.g., from past data) descriptive knowledge (e.g., a forecast) as the solution to a problem by using procedural knowledge indicating how to derive the new knowledge (e.g., how to calculate a forecast from historical observations). Using reasoning knowledge (e.g., rules) about what procedures are valid under different circumstances, the DSS infers which procedure is appropriate for solving the specific forecasting problem or to infer a valid sequence of existing procedures that, when carried out, would yield a solution.

Aside from knowledge type, knowledge has other attribute dimensions relevant to DSSs (15,16). One of these dimensions is knowledge orientation, which holds that a processor's knowledge can be oriented in the direction of the decision domain, of other related processors with which it interacts, and/or itself. A DSS can thus possess domain knowledge, which is descriptive, procedural, and/or reasoning (DPR) knowledge that allows the DSS to find or solve problems about a domain of interest (e.g., finance). It can possess relational knowledge, which is DPR knowledge that is the basis of a DSS's ability to effectively relate to (e.g., interact with) its user and other processors in the course of decision making. A DSS may also have self-knowledge, which is DPR knowledge about what it knows and what it can do. An adaptive DSS is one for which DPR knowledge for any of these three orientations can change by virtue of the DSS's experiences.

DECISION SUPPORT SYSTEM ROOTS, CHARACTERISTICS, AND BENEFITS

Rooted in an understanding of decision making, appreciating the purposes of DSSs serves as a starting point for identifying possible characteristics and benefits that we might expect a DSS to exhibit. These purposes include:

- Increase a decision maker's efficiency and/or effectiveness
- Help a decision maker successfully deal with the decisional context
- Aid one or more of the three decision-making phases
- Help the flow of problem-solving episodes proceed more smoothly or rapidly
- Relax cognitive, economic, and/or temporal constraints on a decision maker
- Help manage DPR knowledge that is important for reaching decisions

Decision support systems are deeply rooted in the evolution of business computing systems (aka information systems). Another way to appreciate characteristics and benefits of DSSs is to compare/contrast them with traits of their two predecessors in this evolution: data processing systems (DPS) and management information systems (MIS). All three share the traits of being concerned with record keeping; however, they differ in various ways, because each serves a different purpose in managing knowledge resources.

The main purpose of DPS was and is to automate the handling of large numbers of transactions. For example, a bank must deal with large volumes of deposit and withdrawal transactions every day, properly track each transaction's effect on one or more accounts, and maintain a history of all transactions to give a basis for auditing its operations. At the heart of a DPS lies a body of descriptive knowledge—computerized records of what is known as a result of transactions having happened. A data processing system has two major abilities related to the stored data: record keeping and transaction generation. The former keeps the records up-to-date in light of incoming transactions and can cause creation of new records, modification of existing records, deletion of obsolete records, or alteration of relationships among records. The second DPS ability is production of outgoing transactions based on stored descriptive knowledge, and transmitted to such targets as customers, suppliers, employees, or governmental regulators.

Unlike DPS, the central purpose of MIS was and is to provide periodic reports that recap certain predetermined aspects of past operations. They give regular snapshots of what has been happening. For instance, MIS might provide manufacturing managers with daily reports on parts usage and inventory levels, weekly reports on shipments received and parts ordered, a monthly report of production expenditures, and an annual report on individual workers' levels of productivity. Whereas DPS concern is with transforming transactions into records and generating transactions from records, MIS concern with record keeping focuses on using this stored descriptive knowledge as a base for generating recurring standard reports. Of course, an MIS also has facilities for creating and updating the collection of records that it keeps. Thus, an MIS can be regarded as extending the DPS idea to emphasize production of standard reports rather than producing voluminous transactions for customers, suppliers, employees, or regulators.

Information contained in standard MIS reports certainly can be factored into their users' decision-making activities. When this is the case, MIS can be fairly regarded as a kind of DSS. However, the nature of such support is very limited in light of our understanding of decision making. Reports generated by MIS are defined before the system is created. However, the situation surrounding a decision maker can be very dynamic. Except for the most structured kinds of decisions, information needs can arise unexpectedly and change more rapidly than MIS can be built or revised. Even when some needed information exists in a stack of reports accumulated from MIS, it may be buried within other information held by a report, scattered across several reports, and presented in a fashion not suitable for a user. Moreover, relevant information existing in MIS reports may not only be incomplete, difficult to dig out, unfocused, or difficult to grasp, it may also be in need of additional processing. For instance, a series of sales reports may list daily sales levels for various products, when a user actually needs projections of future sales based on data in these reports. Decision making proceeds more efficiently and effectively when a user can easily get complete, fully processed, focused descriptive knowledge (or even procedural and reasoning knowledge) presented in the desired way.

Standard reports generated by MIS are typically issued at set time intervals. But decisions that are not fully structured tend to be required at irregular, unanticipated times. The knowledge needed for manufacturing decisions must be available on an ad hoc, spur-of-the-moment, as-needed basis. Another limit on MIS ability to support decisions stems from their exclusive focus on managing descriptive knowledge. Decision makers frequently need procedural and/or reasoning knowledge as well. While an MIS deals with domain knowledge, decision making can often benefit from relational and self-knowledge possessed by its participants.

Decision support capabilities can be built on top of DPS and MIS functions. For instance, so-called digital dashboards are a good example. A digital dashboard integrates knowledge from multiple sources (e.g., external feeds and departmental DPSs and MISs) and can present various measures of key performance indicators (e.g., sales figures, operations status, balanced scorecards, and competitor actions) as an aid to executives in identifying and formulating problems in the course of decision making. Executives can face decisions, particularly more strategic decisions, that involve multiple inter-related issues involving marketing, strategy, competition, cash flow, financing, outsourcing, human resources, and so forth. In such circumstances, it is important for the knowledge system contents to be sufficiently wide ranging to help address cross-functional decisions.

DSS Characteristics

Ideally, a decision maker should have immediate, focused, clear access to whatever knowledge is needed on the spur-of-the-moment. Pursuit of this ideal separates decision support systems from their DPS and MIS ancestors. It also suggests characteristics we might expect to observe in a DSS:

- A DSS includes a body of knowledge that describes some aspects of the decision domain, that specifies how to accomplish various tasks, and/or that indicates what conclusions are valid in various circumstances.
- A DSS may also possess DPR knowledge of other decision-making participants and itself as well.
- A DSS has an ability to acquire, assimilate, and alter its descriptive, procedural, and/or reasoning knowledge.
- A DSS has an ability to present knowledge on an ad hoc basis in various customized ways as well as in standard reports.
- A DSS has an ability to select any desired subset of stored knowledge for either presentation or deriving new knowledge in the course of problem recognition and/or problem solving.
- DSS can interact directly with a participant in a decision maker in such a way that there is flexibility in choosing and sequencing knowledge manipulation activities.

There are, of course, variations among DSSs with respect to each of these characteristics. For instance, one DSS may possess descriptive and procedural knowledge, another holds only descriptive and reasoning knowledge, and another DSS may store only descriptive knowledge. As another example, there can be wide variations in the nature of users' interactions with DSSs (push versus pull interactions). Regardless of such variations, these characteristics combine to amplify a decision maker's knowledge management capabilities.

The notion of DSSs arose in the early 1970s (17,18). Within a decade, each of the characteristics cited had been identified as an important DSS trait (8,19–21). In that period, various DSSs were proposed or implemented for specific decision-making applications such as those for corporate planning (22), water-quality planning (23), banking (24), and so forth (19). By the late 1970s, new technological developments were emerging that would prove to give tremendous impetus to the DSS field. These developments included the microcomputer, electronic spreadsheets, management science packages, and ad hoc query interfaces (9). Technological advances impacting the DSS field have continued, including progress in artificial intelligence, collaborative technologies, and the Internet.

It is also notable that DSS characteristics are increasingly appearing in software systems not traditionally thought of as providing decision support, such as enterprise systems (25). They also commonly appear in websites, supporting decisions of both users and providers of those sites (26).

DSS Benefits

Benefits of a particular DSS depend not only on its precise characteristics, but also on the nature of the user and on the decision context. A good fit among these three factors must exist if potential benefits of the DSS are to become practical realities. A DSS that one user finds very beneficial may be of little value to another user, even though both are facing similar decisions. Or, a DSS that is beneficial to a user in one decision context may not be so valuable to that user in another context.

Nevertheless, we can identify potential DSS benefits (9,27), one or more of which is exhibited by any specific DSS:

- In a most fundamental sense, a DSS augments a user's own innate knowledge and knowledge manipulation skills by extending the user's capacity for representing and processing knowledge in the course of decision making.
- A DSS may be alert for events that lead to problem recognition, that demand decisions, or that present decisional opportunities and notify users.
- A user can have the DSS solve problems that the user alone would not even attempt or that would consume a great deal of time because of their complexity and magnitude.
- Even for relatively simple problems encountered in decision making, a DSS may be able to reach solutions faster and/or more reliably than the user.
- Even though a DSS may be unable to find or solve a problem facing a user, it may be used to guide the user into a rational view of the problem or otherwise stimulate the user's thoughts about the problem. For instance, the DSS may be used in an exploratory way to browse selectively through stored data or to analyze selectively the implications of ideas related to the problem. The user may ask the DSS for advice about dealing with the problem. Perhaps the user can have the DSS solve a similar problem to trigger insights about the problem actually being faced.
- The very activity of constructing a DSS may reveal new ways of thinking about the decision domain, relational issues among participants, or even partially formalize various aspects of decision making.
- A DSS may provide additional compelling evidence to justify a user's position, helping secure agreement or cooperation of others. Similarly, a DSS may be used by the decision maker to check on or confirm the results of problems solved independently of the DSS.
- Because of the enhanced productivity and/or agility a DSS fosters, it may give users or their organizations competitive advantages or allow them to stay competitive.

Empirical evidence supporting the actual existence of these benefits is examined in Ref. 28. Because no one DSS provides all these benefits to all decision makers in all decision situations, frequently many DSSs within an organization help to manage its knowledge resources. A particular decision maker may also make use of several DSSs within a single decision-making episode or across different decision-making situations.

DECISION SUPPORT SYSTEM ARCHITECTURE

We are now in a good position to examine the architecture of DSSs, which identifies four essential elements of a DSS and explains their interrelationships. A DSS has a language system, presentation system, knowledge system, and problem-processing system (9,10,29). By varying the makeup of these four elements, different DSSs are produced. Special cases of the generic DSS architecture vary in terms of the knowledge representation and processing approaches they employ giving DSS categories such as text-oriented DSSs, database-oriented DSSs, spreadsheet-oriented DSSs, solver-oriented DSSs, rule-oriented DSSs, compound DSSs, and collaborative DSSs (9).

The Generic Architecture

A decision support system can be defined in terms of three systems of representation:

- A language system (LS) consists of all messages the DSS can accept.
- A presentation system (PS) consists of all messages the DSS can emit.
- A knowledge system (KS) consists of all knowledge the DSS has assimilated and stored.

By themselves, these three kinds of systems can do nothing. They simply represent knowledge, either in the sense of messages that can be passed or representations that have been accumulated for possible processing. Yet they are essential elements of a DSS. Each is used by the fourth element: the problem-processing system (PPS). This system is the active part of a DSS, its software engine. As its name suggests, a PPS is what tries to recognize and solve problems (i.e., process problems) during the making of a decision.

Figure 1 illustrates how the four subsystems are related to each other and to a DSS user. The user is typically a human participant in the decision making but could also be the DSS developer, administrator, knowledge-entry person/device, or even another DSS. In any case, a user makes a

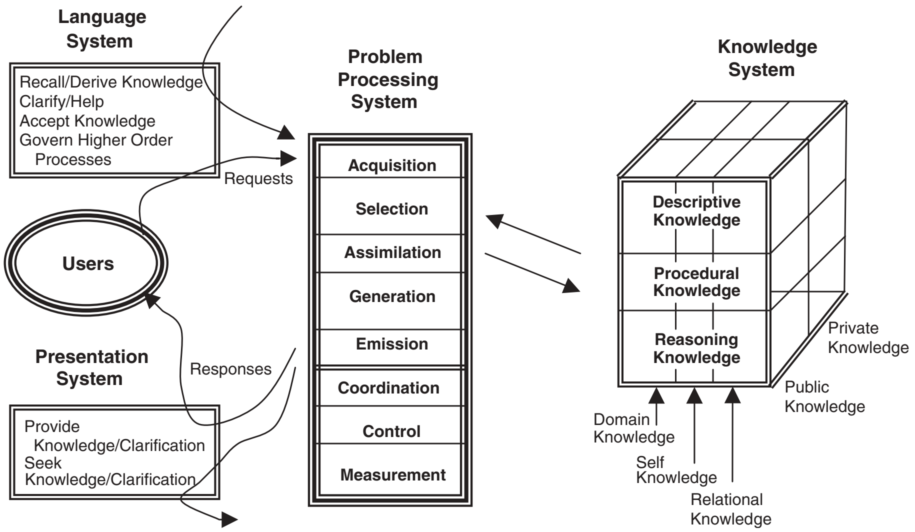

Figure 1. Decision support system architecture.

request by selecting an element of the LS. It could be a request to accept/provide knowledge, clarify previous requests/responses, and find/solve a problem. Once the PPS has been requested to process a particular LS element, it does so. This processing may very well require the PPS to draw on KS contents in order to interpret the request and develop a response to it. The processing may also change the knowledge held in the KS. In either event, the PPS may issue a response to the user. It does so by choosing to present one PS element to the user. The presentation choice is determined by the processing carried out with KS contents in response to the user's request. In some cases, PPS activity is triggered by an event rather than by a user's request, with the processing result being pushed to the user.

This simple architecture captures crucial and fundamental aspects common to all DSSs. To more fully appreciate the nature of a specific DSS, we must know about the requests that make up its LS, the responses that make up its PS, the knowledge representations allowed and existing in its KS, and the knowledge-processing capabilities of its PPS. Developers of DSSs must pay careful attention to all these elements when they design and build DSSs.

Requests that comprise a LS include those seeking:

- Recall or derivation of knowledge (i.e., solving a problem)
- Clarification of prior responses or help in making subsequent responses
- Acceptance of knowledge from the user or other external sources
- To govern a higher order process (e.g., launch a workflow)

Similarly, PS subsets include those that:

- Provide knowledge or clarification
- Seek knowledge or clarification from the user or other external sources

These LS and PS categorizations are based on message semantics. Yet another way of categorizing LS requests and PS responses could be based on distinctions in the styles of messages (e.g., menu, command, text, form, graphic, audio, direct manipulation, video, and animation).

A KS can include DPR knowledge for any of the orientations (domain, relational, and/or self), although the emphasis is commonly on domain-oriented knowledge. Many options are available to DSS developers for representations to employ in a KS, including text, hypertext, forms, datasets, database, spreadsheet, solvers, programs, rules, case bases, grammars, dictionaries, semantic nets, frames, documents, and video/audio records. The key point is that, for any of these representations to convey knowledge, it must be a representation that is usable by the DSS's problem processing system. That is, a PPS must have processing capabilities that correspond the each knowledge representation technique employed in its KS.

Regardless of the particular knowledge processing technique(s) it uses, a PPS tends to have the following knowledge manipulation abilities (9,10,16):

- Acquire knowledge from outside itself (interpreting it along the way)
- Select knowledge from its KS (e.g., for use in acquiring, assimilating, generating, and emitting knowledge)
- Assimilate knowledge into its KS (e.g., incorporate acquired or generated knowledge subject to maintenance of KS quality)
- Generate knowledge (e.g., derive or discover new knowledge)
- Emit knowledge to the outside (packaging it into suitable presentations along the way)

Some PPSs do not have all five abilities (e.g., can select knowledge, but not generate it). In addition, a PPS may have some higher order abilities that guide/govern the patterns of acquisition, selection, generation, assimilation, and emission activities that occur during a decisional episode (9,16):

- Measurement of knowledge and processing (allowing subsequent evaluation and learning)
- Control of knowledge and processing (ensuring integrity, quality, security, and privacy)
- Coordination of knowledge and processing (e.g., routing communications among participants, guiding workflows, promoting incentives to participants, intervening in negotiations, and enforcing processing priorities across concurrent decisional episodes)

The generic DSS architecture gives us a common base and fundamental terms for discussing, comparing, and contrasting specific DSSs and classes of DSSs.

DSS Classes

A useful way to look at KS contents and PPS abilities is in terms of the knowledge management techniques employed by a DSS (5,9). This gives rise to many special cases of the generic DSS architecture, several classes of these being considered here.

A text-oriented DSS supports decision makers by keeping track of textually represented DPR knowledge that could have a bearing on decisions (30,31). It allows documents to be created, revised, and reviewed by decision makers on an as-needed basis. The viewing can be exploratory browsing in search of stimulation or a focused search for some particular piece of knowledge needed in the manufacture of a decision. In either event, there is a problem with traditional text management: It is not convenient to trace a flow of ideas through separate pieces of text in the KS, as there are no explicit relationships among them.

This limitation is remedied in a hypertext-oriented DSS, whose KS is comprised of pieces of text explicitly linked to other pieces of text that are conceptually related to it. The PPS capabilities include creation, deletion, and traversal of nodes and links. The hypertext-oriented DSS supplements a decision maker's own associative capabilities by accurately storing and recalling large volumes of concepts and connections (32,33).

Another special case of the DSS architecture uses the database technique of knowledge management, especially relational and multidimensional approaches. Database-oriented DSSs have been used since the early years of the DSS field (34–36), tending to handle rigidly structured, often extremely voluminous, descriptive knowledge. The PPS is a database control system, plus an interactive query processing system and/or various custom-built processing systems, to satisfy user requests. Data warehouses (37) and data marts belong to this DSS class.

Well known for solving "what-if" problems, spreadsheet-oriented DSSs are in widespread use (38). The KS holds descriptive and procedural knowledge in spreadsheets. Using the spreadsheet technique, a DSS user not only can create, view, and modify procedural knowledge held in the KS but also can tell the PPS to carry out the instructions they contain. This capability gives DSS users much more power in handling procedural knowledge than is typical with either text management or database management. However, it is not nearly as convenient as database management in handling large volumes of descriptive knowledge, or text management in representing and processing unstructured textual passages.

Another class of DSSs is based on the notion of a solver—an executable algorithm that solves any member of a particular class of problems. Solver management is concerned with storage and use of a collection of solvers. Two approaches to solver-oriented DSS are fixed and flexible. In the fixed approach, solvers are part of the PPS, which means that a solver cannot be easily added to, or deleted from, the DSS nor readily modified. With the flexible approach, the PPS is designed to manipulate (e.g., create, delete, update, combine, and coordinate) solver modules held in the KS according to user requests.

The KS for a fixed solver-oriented DSS is typically able to hold datasets (groupings of numbers organized according to conventions required by the solvers). Many solvers can use a dataset, and a given solver can feed on multiple datasets. It is not uncommon for the KS to also hold editable problem statements and report format descriptions. In addition to solver modules, the KS flexible approach also accommodates datasets and perhaps problem statements or report formats. Each module requires certain data to be available for its use before its instructions can be carried out. Some of that data may already exist in KS datasets. The remaining data must either be furnished by the user (i.e., in the problem statement) or produced by executing other modules. In other words, a single module may not be able to solve some problems. Yet they can be solved by executing a certain sequence of modules. The results of carrying out instructions in the first module are used as data inputs in executing the second module, whose results become data for the third or subsequent module executions, and so forth, until a solution is achieved. Thus, the PPS coordinates the executions of modules that combine to make up the solver for a user's problem statement.

Another special case of the generic DSS architecture involves representing and processing rules (i.e., reasoning knowledge), (21,39). The KS of a rule-oriented DSS holds one or more rule sets, each pertaining to reasoning about what recommendation to give a user seeking advice on some subject. In addition to rule sets, it is common for the KS to contain descriptions of the current state. A user can request advice and explanation of the rationale for that advice. The PPS can do logical inference (i.e., to reason) with a set of rules to produce advice sought by a user. The problem processor examines pertinent rules in a rule set, looking for those whose premises are true for the current situation. This situation is defined by current state descriptions and the user's request for advice. When the PPS finds a true premise, it takes the actions specified in that rule's conclusion. This action sheds additional light on the situation, which allows premises of still other rules to be established as true, which causes actions in their conclusions to be taken. Reasoning continues in this way until some action is taken that yields the request advice or the PPS gives up because of insufficient knowledge in its KS. The PPS also has the ability to explain its behavior both during and after conducting the inference.

Rule-based inference is an artificial intelligence technique. A rule-oriented DSS is an example of what is called an intelligent DSS (21,39). Generally, any of the DSS categories can include systems that incorporate artificial intelligence mechanisms to enhance their problem processing capabilities. These mechanisms include natural language processing (for understanding and interpreting natural language), intelligent tutoring features (for offering help to users), machine learning approaches such as genetic algorithms or neural networks (for giving a DSS the ability to adapt its behavior based on its experiences), knowledge representation approaches such as semantic networks (for KS enrichment), search strategies (for knowledge selection and acquisition), and intelligent agent architectures (for event monitoring, collaborative processing, etc).

Each foregoing DSS class emphasizes a single knowledge management technique, supporting users in ways that cannot be easily replicated by DSSs based on different techniques. If a user needs the kinds of support offered by multiple knowledge management techniques, there are two basic options:

- Use multiple DSSs, each oriented toward a particular technique.
- Use a single DSS that encompasses multiple techniques.

The latter is a compound DSS, having a PPS equipped with the knowledge manipulation abilities of two or more techniques. The KS holds knowledge representations associated with all of these techniques. A good example of a compound DSS is evident in the architecture introduced by Sprague and Carlson (40), which combines database management and solver management into a single system, so that solvers (aka models) can operate against full-scale databases instead of datasets. Online analytic processing systems when operating against data warehouses belong to this class of compound DSSs. Software tools such as KnowledgeMan (aka the Knowledge Manager) and Guru have been used as prefabricated PPSs for building compound DSSs, synthesizing many knowledge management techniques in a single system (5,35,39). Such prefabricated PPSs are a realization of the concept of a generalized problem processing system (9,10).

Another important class, multiparticipant decision support systems (MDSSs), involves DSSs specifically designed to support decision-making efforts of a decision maker comprised of multiple participants. An MDSS that supports a group decision maker is called a group decision support system (GDSS). An MDSS that supports other kinds of multiparticipant decision makers, such as hierarchic teams, project teams, firms, agencies, or markets, is called an organizational decision support system (ODSS). Compared with a group, an organization has greater differentiation/specialization of participant roles in the decision making, greater coordination among these roles, greater differentiation in participants' authority over the decision, and more structured message flows among participants (9). It is possible that an MDSS supports negotiations among participants to resolve points of contention. If so, it is a negotiation support system (NSS) as well as being a GDSS or ODSS.

The KS and/or PPS of an MDSS can be distributed across multiple computers, which may be in close physical proximity (e.g., an electronic meeting room) or dispersed worldwide (e.g., as Internet nodes). Participants in the decision may interact at the same time or asynchronously. Although MDSSs can take on any of the characteristics and employ any of the knowledge management techniques discussed above, their hallmark is a focus on strong PPS coordination ability, perhaps with some control and measurement abilities as well. Examples of such ability includes (41-43):

- PPS controls what communication channels are open for use at any given time.
- PPS guides deliberations in such ways as monitoring and adjusting for the current state of participants' work, requiring input from all participants, permitting input to be anonymous, enforcing a particular coordination method (e.g., nominal group technique), and handling/tabulating participant voting.
- PPS continually gathers, organizes, filters, and formats public materials generated by participants during the decision-making process, electronically distributing them to participants periodically or on demand; it permits users to transfer knowledge readily from private to public portions of the KS (and vice versa) and perhaps even from one private store to another.
- PPS continually tracks the status of deliberations as a basis for giving cues to participants (e.g., who has viewed or considered what, where are the greatest disagreements, where is other clarification or analysis needed, when is there a new alternative to be considered, and who has or has not voted).
- PPS regulates the assignment of participants to roles (e.g., furnishing an electronic market in which they bid for the opportunity to fill roles).
- PPS implements an incentive scheme designed to motivate and properly reward participants for their contributions to decisions.
- By tracking what occurred in prior decision-making sessions, along with recording feedback on the results for those sessions (e.g., decision quality, process innovation), a PPS enables the MDSS to learn how to coordinate better or to avoid coordination pitfalls in the future.

For each of these abilities, a PPS may range from offering relatively primitive to relatively sophisticated features.

Thus, the KS of an MDSS typically includes a group/organization memory of what has occurred in decisional episodes. In addition to public knowledge that can be selected by any/all participants, the KS may also accommodate private knowledge spaces for each participant. Similarly, the LS (and PS) may include both a public language (and presentations) comprising messages suited to all participants and private languages (and presentations) available to specific participants. In addition to the kinds of users noted in Fig. 1, an MDSS may also interact with a facilitator(s), who helps the participants (individually and collectively) make effective use of the MDSS.

A GDSS seeks to reduce losses that can result from working as a group, while keeping (or enhancing) the gains that group work can yield (44). DeSanctis and Gallupe (45) identify three levels of GDSSs, differing in terms of features they offer for supporting a group decision maker. A Level-1 GDSS reduces communication barriers that would otherwise occur among participants, stimulating and hastening messages exchanges. A Level-2 GDSS reduces uncertainty and "noise" that can occur in a group's decision process via various systematic knowledge manipulation techniques like those encountered in the DSS classes previously described. A Level-3 GDSS governs timing, content, or patterns of messages exchanged by participants, actively driving or regulating a group's decision process.

Nunamaker et al. (44) draw the following conclusions from their observations of GDSSs in the laboratory and the field:

- Parallel communication encourages greater participation and reduces the likelihood of a few participants dominating the proceedings.
- Anonymity reduces apprehensions about participating and lessens the pressure to conform, allowing for more candid interactions.
- Existence of a group memory makes it easier for participants to pause and ponder the contributions of others during the session, as well as preserving a permanent record of what has occurred.
- Process structuring helps keep the participants focused on making the decision, reducing tendencies toward digression and unproductive behaviors.
- Task support and structuring give participants the ability to select and derive needed knowledge.

The notion of an ODSS has long been recognized, with an early conception viewing an organizational decision maker as a knowledge processor having multiple human and multiple computer components, organized according to roles and relationships that divide their individual labors in alternative ways in the interest of solving a decision problem facing the organization (46). Each component (human or machine) is an intelligent processor capable of solving some class of problems either on its own or by coordinating the efforts of other components—passing messages to them and receiving messages from them. The key ideas in this early framework for ODSS are the notions of distributed problem solving by human and machine knowledge processors, communication among these problem solvers, and coordination of interrelated problem-solving efforts in the interest of solving an overall decision problem. To date, organizational DSSs have not received nearly as much attention as group DSSs.

George (47) identifies three main ODSS themes:

- Involves computer-based technologies and may involve communication technology
- Accommodates users who perform different organizational functions and who occupy different positions in the organization's hierarchical levels
- Is primarily concerned with decisions that cut across organizational units or impact corporate issues

and organizes candidate technologies for ODSS development into several categories:

- Technologies to facilitate communication within the organization and across the organization's boundaries
- Technologies to coordinate use of resources involved in decision making
- Technologies to filter and summarize knowledge (e.g., intelligent agents)
- Technologies to track the status of the organization and its environment
- Technologies to represent and process diverse kinds of knowledge needed in decision making
- Technologies to help the organization and its participants reach decisions

Computer systems designed for specific business processes, such as customer relationship management, product lifecycle management, and supply chain management are evolving from an initial emphasis on transaction handling and reporting, to increasingly offer decision support characteristics. As such, they can be considered to be ODSSs. The most extensive of these systems are enterprise resource planning systems, which seek to integrate traditionally distinct business applications into a single system with a common knowledge store. Although these systems often regarded from the perspectives of data processing and management information systems, research indicates that enterprise systems do have some ODSS features and do provide decision support benefits to organizations (25,28). Their potential as decision support platforms is increasingly reflected in new product offerings of software vendors.

Although some GDSSs and ODSSs have features that can benefit negotiators, these features have not been the central motive or interest of such systems. DSSs designed specifically for supporting negotiation activities are called negotiationsupport systems. Pioneering tools for NSS development include NEGO, a PPS designed to help negotiators change their strategies, form coalitions, and evaluate compromises (48), and NEGOPLAN, an expert system shell that represents negotiation issues and decomposes negotiation goals to help examine consequences of different negotiation scenarios (49). See Refs. 50 and 51 for surveys of NSS software and Ref. 52 for a formal theoretical foundation of NSSs.

CONCLUSION

Decision support systems have major socioeconomic impacts and are so pervasive as to be practically invisible. The study and application of DSSs comprises a major subject area within the information systems discipline.

This extensive area, has unifying principles rooted in knowledge management and the generic architecture shown in Fig. 1; it is also an area rich in diversity, nuances, and potential for additional advances. For a thorough, in-depth appreciation of the DSS area, consult the two-volume *Handbook on Decision Support Systems*(53), the flagship journal *Decision Support Systems*, the DSS applications-intensive *Interfaces*, the *Journal of Decision Systems, Journal of Data Warehousing*, and *Business Intelligence Journal*.

For all their value, we must keep in mind the fact that DSSs have limitations. They cannot make up for a faulty (e.g., irrational) decision maker, and the efficacy of the support they provide is constrained by the extent and quality of their knowledge systems relative to the decision situation being faced (9). Their effectiveness is influenced by such factors as adequacy of a user's problem formulations, capture of relevant variables, and timely and accurate knowledge about the status of these decision parameters. Ultimately, the value of a DSS does not derive simply from its existence, but it depends very much on how it is designed, used, maintained, and evaluated, plus the decision maker's assumptions about the DSS.

DEDUCTIVE DATABASES

INTRODUCTION

The field of deductive databases is based on logic. The objective is to derive new data from facts in the database and rules that are provided with the database. In the Background section, a description is provided of a deductive database, of a *query* and of an *answer* to a query in a deductive database. Also discussed is how deductive databases extend relational databases (see RELATIONAL DATABASES) and form a subset of *logic programming* (see AI LANGUAGES AND PROCESSING). In the Historical Background of Deductive Databases section, we discuss the pre-history, the start of the field, and the major historical developments including the formative years and initial prototype systems. Then we first present Datalog databases with recursion but without negation and also explain semantic query optimization *(SQO)* and cooperative answering; then we introduce default negation for stratified databases; discuss current stratified prototype systems; the introduction of deductive database concepts into the relational database language *SQL:99;* why the deductive database technology has not led to commercial systems; and introduce the concept of nonstratified deductive databases. The Disjunctive Deductive Databases section describes incomplete databases, denoted $Datalog^{\neg}_{disj}$, that permit more expressive knowledge base systems. We discuss the need for disjunction in knowledge base systems; disjunctive deductive databases that do not contain default negation; the extension of disjunctive systems to include default and logical negation; the extension of the answer set semantics to incorporate default negation; and methods to select an appropriate semantics. In the next section, implementations of nonstratified deductive and disjunctive databases are presented and we define a knowledge base system in terms of the extensions to relational databases described in this article. The Applications section has brief descriptions of some of the applications of deductive databases: data integration, handling preferences, updates, AI planning, and handling inconsistencies. The Final section summarizes the work.

BACKGROUND

A deductive database is an extension of a relational database. Formally, a deductive database, (*DDB*) is a triple, < *EDB, IDB, IC* >, where *EDB* is a set of facts, called the *extensional database, IDB* is a set of rules, called the *intensional database,* and *IC* is a set of *integrity constraints*. A *DDB* is based on first-order logic. An atomic formula is a k-place predicate letter whose arguments are constants or variables. Atomic formulas evaluate to *true* or *false*. The *EDB* consists of *ground atomic formulas* or disjunctions of ground atomic formulas. An atomic formula is *ground* if it consists of a predicate with k arguments, where the arguments are constants. Examples of ground atomic formulas are *supplies(acme, shovels),* and *supplies (acme, screws),* whose intended meaning is: "The Acme Corporation supplies shovels and screws." An example of a disjunction is: *supplierloc(acme, boston)* ∨ *supplierloc(acme, washington),* whose intended meaning is: "The Acme Corporation is located either in Boston or in Washington, or in both locations." Corresponding to an atomic formula, there is a *relation* that consists of all tuples whose arguments are in an atomic formula with the same name. For the *supplies* predicate, there is a relation, the *SUPPLIES* relation, that consists of a set of tuples (e.g., {< *acme, shovels* >, < *acme, screws* >}) when the *SUPPLIES* relation consists of the above two facts. In a relational database, the *EDB* consists only of atoms. Throughout the article, predicate letters are written in lower case and arguments of predicates that are constants are also written in lower case, whereas upper-case letters denote variables.

The intensional database consists of a set of rules of the form:

$$L_1, \ldots, L_n \leftarrow M_1, \ldots, M_m,\ not\ M_{m+1}, \ldots,\ not\ M_{m+l} \quad (1)$$

where the L_i and the M_j are atomic formulas and *not* is default negation (discussed below). Intensional rules are universally quantified and are an abbreviation of the formula:

$$\forall X_1 \ldots, X_k (L_1 \vee \ldots \vee L_n \leftarrow M_1 \wedge \ldots \wedge M_m \wedge not\, M_{m+1} \wedge \ldots \wedge not\, M_{m+l})$$

where the $X_1, \ldots, X_k$ lists all free variables.

A rule with $n = 0$ is either a query or an integrity constraint. When $n > 0$, the rule is either an IDB rule used to derive data or it may be an integrity constraint that restricts what tuples may be in the database. Rules for which $n \leq 1$ and $l = 0$ are called *Horn rules*.

DDBs restrict arguments of atomic formulas to constants and variables, whereas in first-order logic atomic formulas may also contain function symbols as arguments, which assures that answers to queries in *DDBs* are finite[1]. Rules may be read either declaratively or procedurally. A declarative reading of Formula (1) is:

L_1 *or* L_2 *or* ... *or* L_n is *true* if M_1 *and* M_2 *and* ... *and* M_m *and not* M_{m+1} *and* ... *and not* M_{m+l} are all *true*.

A procedural reading of Formula (1) is:

[1] When there are function symbols, an infinite number of terms may be generated from the finite number of constants and the function symbols; hence, the answer to a query may be infinite.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

L_1 *or* L_2 *or* ... *or* L_n are solved if M_1 *and* M_2 *and* ... *and* M_m *and not* M_{m+1} *and* ... *and not* M_{m+l} are solved.

The left-hand side of the implication, L_1 *or* ... *or* L_n, is called the *head* of the rule, whereas the right-hand side,

M_1 *and* M_2 *and* ... *and* M_m *and not* M_{m+1} *and* ... *and not* M_{m+l} is called the *body* of the rule.

Queries to a database, $Q(X_1, \ldots, X_r)$, are of the form $\exists X_1 \ldots \exists X_r\,(L_1 \wedge L_2 \ldots \wedge L_s)$, written as $\leftarrow L_1, L_2, \ldots, L_s$, where $s \geq 1$, the L_i are literals and the X_i, $1 \leq i \leq r$, are the free variables in Q. An answer to a query has the form $< a_{11}, \ldots, a_{1r} > + < a_{21}, \ldots, a_{2r} > + \ldots + < a_{k1}, \ldots, a_{kr} >$ such that $Q(a_{11}, \ldots, a_{1r}) \vee Q(a_{21}, \ldots, a_{2r}) \vee \ldots \vee Q(a_{k1}, \ldots, a_{kr})$ is provable from the database, which means that an inference system is used to find answers to queries.

DDBs are closely related to logic programs when the facts are restricted to atomic formulas and the rules have only one atom in the left-hand side of a rule. The main difference is that a logic program query search is for a single answer, proceeding top-down from the query to an answer. In *DDBs,* searches are bottom-up, starting from the facts, to find all answers. A logic program query might ask for an item supplied by a supplier, whereas in a deductive database, a query asks for all items supplied by a supplier. *DDBs* restricted to atoms as facts, and rules that consist of single atoms on the left-hand side of a rule and atoms on the right-hand side of a rule that do not contain the default rule for negation, *not,* are called *Datalog* databases, (i.e., rules in Formula(1), where $n = 1$, $m \geq 0$, and $l = 0$). Rules in *Datalog* databases may be recursive. A traditional relational database is a *DDB* where the *EDB* consists of atoms and *IDB* rules are not recursive.

There are several different concepts of the relationship of integrity constraints to the union of the *EDB* and the *IDB* in the *DDB*. Two such concepts are *consistency* and *theoremhood*. In the consistency approach (proposed by Kowalski), the *IC* must be consistent with $EDB \cup IDB$. In the theoremhood approach (proposed by Reiter and by Lloyd and Topor), each integrity constraint must be a theorem of $EDB \cup IDB$.

To answer queries that consist of conjunctions of positive and default negated atoms in *Datalog* requires that semantics be associated with negation because only positive atoms can be derived from *Datalog* DDBs. How one interprets the semantics of default negation can lead to different answers. Two important semantics for handling default negation are termed the *closed-world assumption* (*CWA*), due to Reiter, and *negation-as-finite-failure* (*NFF*), due to Clark. In the *CW A,* failure to prove the positive atom implies that the negated atom is *true*. In the *NFF,* predicates in the *EDB* and the *IDB* are considered the *if* portion of the database and are closed by effectively reversing the implication to achieve the *only if* part of the database. The two approaches lead to slightly different results. Negation, as applied to disjunctive theories, is discussed later.

Example 1 (Ancestor). *Consider the following database that consists of parents and ancestors. The database consists of two predicates, whose schema are* $p(X, Y)$, *intended to mean that Y is a* parent of *X, and* $a(X, Y)$, *intended to mean that Y is an* ancestor of *X. The database consists of five EDB statements and two IDB rules:*

r1. $p(mike, jack)$
r2. $p(sally, jack)$
r3. $p(katie, mike)$
r4. $p(beverly, mike)$
r5. $p(roger, sally)$
r6. $a(X, Y) \leftarrow p(X, Y)$
r7. $a(X, Y) \leftarrow p(X, Z), a(Z, Y)$

The answer to the question $p(mike, X)$ *is jack. The answer to the question* $a(mike, X)$ *is jack using rule r6. An answer to the query* $a(roger, X)$ *is sally using rule r6. Another answer to the query* $a(roger, X)$*, jack, is found by using rule r7.*

For the query $p(katie, jack)$*, the answer by the* CWA *is* no; *jack is not a* parent of katie. *The reason is that there are only five facts, none of which specify* $p(katie, jack)$*, and there are no rules that can be used to find additional parents.*

More expressive power may be obtained in a *DDB* by allowing negated atoms on the right-hand side of a rule. The semantics associated with such databases depends on how the rule of negation is interpreted, as discussed in the Datalog and Extended Deductive Databases section and the Disjunctive Deductive Databases section.

HISTORICAL BACKGROUND OF DEDUCTIVE DATABASES

The prehistory of *DDBs* is considered to be from 1957 to 1970. The efforts in this period used primarily ad hoc or simple approaches to perform deduction. The period 1970 to 1978 were the formative years, which preceded the start of the field. The period 1979 to 2003 saw the development of a theoretical framework and prototype systems.

Prehistory of Deductive Databases

In 1957, a system called *ACSI-MATIC* was under development to automate work in Army intelligence. An objective was to derive new data based on given information and general rules. Chains of related data were sought and the data contained reliability estimates. A prototype system was implemented to derive new data whose reliability values depended on the reliability of the original data. The deduction used was modus ponens (i.e., from p and $p \rightarrow q$, one concludes q, where p and q are propositions).

Several *DDBs* were developed in the 1960s. Although in 1970 Codd founded the field of *Relational Databases,* relational systems were in use before then. In 1963, using a relational approach, Levien and Maron developed a system, *Relational Data File* (*RDF*), that had an inferential capability, implemented through a language termed *INFEREX*. An *INFEREX* program could be stored in the system (such as in current systems that store views) and re-executed, if necessary. A programmer specified reasoning rules via an *INFEREX* program. The system handled credibility ratings of sentences in forming deductions. Theoretical work by Kuhns on the *RDF* project recognized that there were classes of questions that were, in a sense, not "reasonable." For example, let the database consist of the statement, "Reichenbach wrote *Elements of Symbolic Logic.*" Whereas the question, "What books has Reichenbach written?", is reasonable, the questions, "What books has Reichenbach not written?", or, "Who did not write 'Elements of Symbolic Logic'?", are not reasonable. It is one of the first times that the issue of negation in queries was explored.

In 1964, Raphael, for his Ph.D. thesis at M.I.T., developed a system called *Semantic Information Retrieval (SIR),* which had a limited capability with respect to deduction, using special rules. Green and Raphael subsequently designed and implemented several successors to *SIR:* $QA-1$, a re-implementation of *SIR;* $QA-2$, the first system to incorporate the *Robinson Resolution Principle* developed for automated theorem proving; $QA-3$ that incorporated added heuristics; and $QA-3.5$, which permitted alternative design strategies to be tested within the context of the resolution theorem prover. Green and Raphael were the first to recognize the importance and applicability of the work performed by Robinson in automated theorem proving. They developed the first *DDB* using formal techniques based on the Resolution Principle, which is a generalization of modus ponens to first-order predicate logic. The Robinson Resolution Principle is the standard method used to deduce new data in *DDBs*.

Deductive Databases: The Formative Years 1969–1978

The start of deductive databases is considered to be November 1977, when a workshop, "Logic and Data Bases," was organized in Toulouse, France. The workshop included researchers who had performed work in deduction from 1969 to 1977 and used the Robinson Resolution Principle to perform deduction. The Workshop, organized by Gallaire and Nicolas, in collaboration with Minker, led to the publication of papers from the workshop in the book, "Logic and Data Bases," edited by Gallaire and Minker.

Many significant contributions were described in the book. Nicolas and Gallaire discussed the difference between model theory and proof theory. They demonstrated that the approach taken by the database community was model theoretic (i.e., the database represents the truths of the theory and queries are answered by a bottom-up search). However, in logic programming, answers to a query used a proof theoretic approach, starting from the query, in a top-down search. Reiter contributed two papers. One dealt with compiling axioms. He noted that if the *IDB* contained no recursive axioms, then a theorem prover could be used to generate a new set of axioms where the head of each axiom was defined in terms of relations in a database. Hence, a theorem prover was no longer needed during query operations. His second paper discussed the *CWA*, whereby in a theory, if one cannot prove that an *atomic formula* is *true,* then the negation of the atomic formula is assumed to be *true*. Reiter's paper elucidated three major issues: the definition of a query, an answer to a query, and how one deals with negation. Clark presented an alternative theory of negation. He introduced the concept of *if-and-only-if* conditions that underly the meaning of negation, called negation-as-finite-failure. The Reiter and Clark papers are the first to formally define default negation in logic programs and deductive databases. Several implementations of deductive databases were reported. Chang developed a system called *DEDUCE;* Kellogg, Klahr, and Travis developed a system called *Deductively Augmented Data Management System (DADM);* and Minker described a system called *Maryland Refutation Proof Procedure 3.0 (MRPPS 3.0)*. Kowalski discussed the use of logic for data description. Darvas, Futo, and Szeredi presented applications of *Prolog* to drug data and drug interactions. Nicolas and Yazdanian described the importance of integrity constraints in deductive databases. The book provided, for the first time, a comprehensive description of the interaction between logic and databases.

References to work on the history of the development of the field of deductive databases may be found in Refs. 1 and 2. A brief description of the early systems is contained in Ref. 1.

Deductive Databases: Prototypes, 1979–2004

During the period 1979 through today, a number of prototype systems were developed based on the Robinson Resolution Principle and bottom-up techniques. Most of the prototypes that were developed during this period either no longer exist or are not supported. In this section, we describe several efforts because these systems contributed to developments that were subsequently incorporated into *SQL* as described in the SQL: 1999 section.

These systems include *Validity* developed by Nicolas and Vieille; *Coral,* developed by Ramakrishnan at the University of Wisconsin; and *NAIL!,* developed by Ullman and his group at Stanford University. All of these prototypes introduced new techniques for handling deductive databases.

The *Validity* system's predecessor was developed at the European Computer Research Consortium, was directed by Nicolas, and started in 1984. It led to the study of algorithms and prototypes: deductive query evaluation methods (*QSQ*/*SLD* and others); integrity checking (Soundcheck); hypothetical reasoning and *IC* checking; and aggregation through recursion.

Implementation at Stanford University, directed by Ullman, started in 1985 on *NAIL! (Not Another Implementation of Logic!)*. The effort led to the first paper on recursion using the *magic sets* method. See the Datalog Databases section for a discussion of *magic sets*. Other contributions were aggregation in logical rules and theoretical contributions to negation: stratified negation by Van Gelder, well-founded negation by Van Gelder, Ross and Schlipf, (see the Nonstratified Deductive Databases section for a discussion of stratification and well-foundedness) and modularly stratified negation (3).

Implementation efforts at the University of Wisconsin, directed by Ramakrishnan, on the *Coral* DDBs started in the 1980s. Bottom-up and magic set methods were implemented. The declarative query language supports general Horn clauses augmented with complex terms, set-grouping, aggregation, negation, and relations with tuples that contain universally quantified variables.

DATALOG AND EXTENDED DEDUCTIVE DATABASES

The first generalization of relational databases was to permit function-free recursive Horn rules in a database (i.e., rules in which the head of a rule is an atom and the body of a rule is a conjunction of atoms). So, in Formula (1), $n = 1, m \geq 1$ and $l = 0$. These databases are called *DDBs,* or *Datalog* databases.

Datalog Databases

In 1976, van Emden and Kowalski formalized the semantics of logic programs that consist of Horn rules, where the rules are not necessarily function-free. They recognized that the semantics of Horn theories can be characterized in three distinct ways: by model, fixpoint, or proof theory. These three characterizations lead to the same semantics. When the logic program is function-free, their work provides the semantics for *Datalog* databases.

To better understand model theory we need to introduce the concept of *Herbrand universe*, which is the set of constants of the database. The *Herbrand base* is the set of all atoms that can be constructed from the predicates using only elements from the Herbrand universe for the arguments. A set of atoms from the Herbrand base that satisfies all the rules is called a *Herbrand model*.

Model theory deals with the collection of models that captures the intended meaning of the database. Fixpoint theory deals with a fixpoint operator that constructs the collection of all atoms that can be inferred to be *true* from the database. Proof theory provides a procedure that finds answers to queries with respect to the database. van Emden and Kowalski showed that the intersection of all Herbrand models of a Horn *DDB* is the unique minimal model, which is the same as all of the atoms in the fixpoint and are exactly the atoms provable from the theory.

Example 2 (Example of Semantics). *Consider Example 1. The unique minimal Herbrand model of the database is:*

$M = \{p(mike, jack), p(sally, jack), p(katie, mike), p(beverly, mike), p(roger, sally), a(mike, jack), a(sally, jack), a(katie, mike), a(beverly, mike), a(roger, sally), a(katie, jack), a(beverly, jack), a(roger, jack)\}$.

These atoms are all true, *and when substituted into the rules in Example 1, they make all of the rules* true. *Hence, they form a model. If we were to add another fact to the model M, say, p(jack, sally), it would not contradict any of the rules, and it would also be a model. However, this fact can be eliminated because the original set was a model and is contained in the expanded model. That is, minimal Herbrand models are preferred. It is also easy to see that the atoms in M are the only atoms that can be derived from the rules and the data. In Example 3, below, we show that these atoms are in the fixpoint of the database.*

To find if the negation of a ground atom is *true,* one can subtract from the Herbrand base the minimal Herbrand model. If the atom is contained in this set, then it is assumed *false*. Alternatively, answering queries that consist of negated atoms that are ground may be achieved using negation-as-finite failure as described by Clark.

Initial approaches to answering queries in *DDBs* did not handle recursion and were primarily top-down (or backward reasoning). However, answering queries in relational database systems was bottom-up (or forward reasoning) to find all answers. Several approaches were developed to handle recursion, two of which are called the *Alexander* and *magic set* methods, which make use of constants that appear in a query and perform search by bottom-up reasoning. Rohmer, Lescoeur, and Kerisit introduced the Alexander method. Bancilhon, Maier, Sagiv, and Ullman developed the concept of magic sets. These methods take advantage of constants in the query and effectively compute answers using a combined top-down and bottom-up approach. Bry reconciled the bottom-up and top-down methods to compute recursive queries. He showed that the Alexander and magic set methods based on rewriting and methods based on resolution implement the same top-down evaluation of the original database rules by means of auxiliary rules processed bottom-up. In principle, handling recursion poses no additional problems. One can iterate search (referred to as the *naive method)* until a fixpoint is reached, which can be achieved in a finite set of steps because the database has a finite set of constants and is function-free. However, it is unknown how many steps will be required to obtain the fixpoint. The Alexander and magic set methods improve search time when recursion exists, such as for transitive closure rules.

Example 3 (Fixpoint). *The fixpoint of a database is the set of all atoms that satisfy the EDB and the IDB. The fixpoint may be found in a* naive *manner by iterating until no more atoms can be found. Consider Example 1 again.*

Step$(0) = \phi$. *That is, nothing is in the fixpoint.*

Step$(1) = \{p(mike, jack), p(sally, jack), p(katie, mike), p(beverly, mike), p(roger, sally)\}$.

These are all facts, and satisfy r1, r2, r3, r4, and r5. The atoms in Step$(0) \cup$ *Step*(1) *now constitutes a partial fixpoint.*

Step$(2) = \{a(mike, jack), a(sally, jack), a(katie, mike), a(beverly, mike), a(roger, sally)\}$ *are found by using the results of Step*$(0) \cup$ *Step*(1) *on rules r6 and r7. Only rule r6 provides additional atoms when applied. Step*$(0) \cup$ *Step*$(1) \cup$ *Step*(2) *becomes the revised partial fixpoint.*

Step$(3) = \{a(katie, jack), a(beverly, jack), a(roger, jack)\}$, *which results from the previous partial fixpoint. These were obtained from rule r7, which was the only rule that provided new atoms at this step. The new partial fixpoint is Step*$(0) \cup$ *Step*$(1) \cup$ *Step*$(2) \cup$ *Step*(3).

Step$(4) = \phi$. *No additional atoms can be found that satisfy the EDB* $\cup$ *IDB. Hence, the fixpoint iteration may be terminated, and the fixpoint is Step*$(0) \cup$ *Step*$(1) \cup$ *Step*$(2) \cup$ *Step*(3).

Notice that this result is the same as the minimal model M in Example 2.

Classes of recursive rules exist where it is known how many iterations will be required. These rules lead to what has been called *bounded recursion,* noted first by Minker and Nicolas and extended by Naughton and Sagiv. Example 4 illustrates bounded recursion.

Example 4 (Bounded Recursion). *If a rule is* singular, *then it is bound to terminate in a finite number of steps independent of the state of the database. A recursive rule is* singular *if it is of the form*

$$R \leftarrow F \wedge R_1 \wedge \ldots \wedge R_n$$

where F is a conjunction of possibly empty base relations (i.e., empty EDB*) and R,* $R_1, R_2, \ldots, R_n$ *are atoms that have the same relation name if:*

1. *each variable that occurs in an atom* R_i *and does not occur in R only occurs in* R_i;
2. *each variable in R occurs in the same argument position in any atom* R_i *where it appears, except perhaps in at most one atom* R_1 *that contains all of the variables of R.*

Thus, the rule

$$R(X,Y,Z) \leftarrow R(X,Y',Z), R(X,Y,Z')$$

is singular because (a) Y′ and Z′ appear, respectively, in the first and second atoms in the head of the rule (condition 1), and (b) the variables X, Y, Z always appear in the same argument position (condition 2).

The major use of *ICs* has been to assure that a database update is consistent. Nicolas showed how to improve the speed of update, using techniques from *DDBs*. Reiter showed that *Datalog* databases can be queried with or without *ICs* and the answer to the query is identical, which, however, does not preclude the use of *ICs* in the query process. Although *ICs* do not affect the result of a query, they may affect the efficiency to compute an answer. *ICs* provide *semantic* information about the data in the database. If a query requests a join (see RELATIONAL DATABASES) for which there will never be an answer because of the constraints, this can be used to omit trying to answer the query and return the empty answer set and avoids unnecessary joins on potentially large relational databases, or performing a long deduction in a *DDB*. The use of *ICs* to constrain search is called *semantic query optimization (SQO).* McSkimin and Minker were the first to use *ICs* for *SQO* in *DDBs*. Hammer and Zdonik as well as King first applied *SQO* to relational databases. Chakravarthy, Grant, and Minker formalized *SQO* and developed the *partial subsumption algorithm* and method of *residues*, which provide a general technique applicable to any relational or *DDB*. Godfrey, Gryz, and Minker applied the technique bottom-up. Semantic query optimization is being incorporated into relational databases. In *DB2,* cases are recognized when only one answer is to be found and the search is terminated. In other systems, equalities and other arithmetic constraints are being added to optimize search. One can envision the use of join elimination in *SQO* to be introduced to relational technology. One can now estimate when it will be useful to eliminate a join. The tools and techniques already exist and it is merely a matter of time before users and system implementers have them as part of their database systems.

A topic related to *SQO* is that of *cooperative answering systems*. The objective is to give a user the reason why a particular query succeeded or failed. When a query fails, one generally cannot tell why failure occurred. There may be several reasons: The database currently does not contain information to respond to the user or there will never be an answer to the query. The distinction may be useful. *User constraints (UCs)* are related to *ICs*. A user constraint is a formula that models a user's preferences. It may omit answers to queries in which the user has no interest (e.g., stating that, in developing a route of travel, the user does not want to pass through a particular city) or provide other constraints to restrict search. When *UCs* are identical in form to *ICs,* they can be used for this purpose. Although *ICs* provide the semantics of the entire database, *UCs* provide the semantics of the user. *UCs* may be inconsistent with a database. Thus, a separation of these two semantics is essential. To maintain the consistency of the database, only *ICs* are relevant. A query may then be thought of as the conjunction of the original query and the *UCs*. Hence, a query can be semantically optimized based both on *ICs* and *UCs*.

Other features may be built into a system, such as the ability to relax a query that fails, so that an answer to a related query may be found. This feature has been termed *query relaxation*.

The first article on magic sets may be found in Ref. 4. A description of the magic set method to handle recursion in *DDBs* may be found in Refs. 5 and 6. References to work in bounded recursion may be found in Ref. 2. For work on fixpoint theory of *Datalog,* and the work of van Emden and Kowalski, see the book by Lloyd,(7). A comprehensive survey and references to work in cooperative answering systems is in Ref. 8. References to alternative definitions of *ICs,* semantic query optimization, and the method of partial subsumption may be found in Ref. 2.

Stratified Deductive Databases

Logic programs that use default negation in the body of a clause were first used in 1986. Apt, Blair, and Walker, and Van Gelder introduced the concept of stratification to logic programs in which L_1 and the M_j, $1 \leq j \leq m + l$, in Formula (1) are atomic formulas and there is no recursion through negation. They show that there is a unique preferred minimal model, computed from strata to strata. Przymusinski termed this minimal model the *perfect model*. When a theory is stratified, rules can be placed in different strata, where the definition of a predicate in the head of a rule is in a higher stratum than the definitions of predicates negated in the body of the rule. The definition of a predicate is the collection of rules containing the predicate in their head.

Thus, one can compute positive predicates in a lower stratum and a negated predicate's complement is *true* in the body of the clause if the positive atom has not been computed in the lower stratum. The same semantics is obtained regardless of how the database is stratified. When the theory contains no function symbols, the *DDB* is termed $Datalog^{\neg}$. If a database can be stratified, then there is no recursion through negation, and the database is called $Datalog^{\neg}_{strat}$.

Example 5 (Stratified Program). *The rules,*

$r_1 : p \leftarrow q,\ not\ r$

$r_2 : q \leftarrow p$

$r_3 : q \leftarrow s$

$r_4 : s$

$- - - - - - - -$

$r_5 :\ r \leftarrow t$

comprise a stratified theory in which there are two strata. The rule r_5 *is in the lowest stratum, whereas the other rules are in a higher stratum. The predicate p is in a higher stratum than the stratum for r because it depends negatively on r. q is in the same stratum as p because it depends on p. s is also in the same stratum as q. The meaning of the stratified program is that {s, q, p} are* true, *whereas {t, r} are* false. *t is* false *because there is no defining rule for t. As t is* false, *and there is only one rule for r, r is* false. *s is given as* true, *and hence, q is* true. *As q is* true *and r is* false, *from rule* r$_1$, *p is* true.

Current Prototypes

In this section, we discuss two systems that are currently active: *Aditi* and *LDL++*. In addition, relational databases such as *Oracle* and *IBM DB2* have incorporated deductive features from the language *SQL,* discussed in the next subsection.

Aditi. The *Aditi* system has been under development at the University of Melbourne under the direction of Dr. Ramamohanarao. A beta release of the system took place approximately in December 1997. *Aditi* handles stratified databases and recursion and aggregation in stratified databases. It optimizes recursion with magic sets and semi-naive evaluation. The system interfaces with *Prolog*. *Aditi* continues to be developed. Its programming language is Mercury, which contains Datalog as a subset. *Aditi* can handle transactions and has traditional recovery procedures as normally found in commercial databases. There is currently no security-related implementations in the system, but several hooks are available in the system to add these features, which are contemplated for future releases. However, parallel relational operations have not been implemented. It is unclear if *Aditi* will be developed for commercial use.

LDL++. Implementation efforts at *MCC,* directed by Tsur and Zaniolo, started in 1984 and emphasized bottom-up evaluation methods and query evaluation using such methods as seminaive evaluation, magic sets and counting, semantics for stratified negation and set-grouping, investigation of safety, the finiteness of answer sets, and join order optimization. The *LDL* system was implemented in 1988 and released in the period 1989 to 1991. It was among the first widely available *DDBs* and was distributed to universities and shareholder companies of MCC. This system evolved into *LDL++*. No commercial development is currently planned for the system.

To remedy some of the difficulties discovered in applications of LDL, the system called LDL++ was designed in the early 1990s. This system was finally completed as a research prototype in 2000 at UCLA. LDL++ has many innovative features particularly involving its language constructs for allowing negation and aggregates in recursion; its execution model is designed to support data intensive applications, and its application testbed can be used to evaluate deductive database technology on domains such as middleware and data mining. In this summary, we concentrate on two language features. A thorough overview of the system is given in Ref. 9.

A special construct *choice* is used to enforce a functional dependency integrity constraint. Consider the case with student and professor data in which each student has one advisor who must be in the same department as the student. Suppose we have the following facts:

student(jeff, cs)

professor (grant, cs)

professor(minker, cs)

The rule for eligible advisor is

$elig - adv(S,\ P) \leftarrow student(S,\ Major),$
$\quad professor(P,\ Major)$

Thus, we deduce *elig − adv(jeff, grant)* and *elig − adv(jeff, minker)*. However, a student can have only one advisor. The rule for advisor is

advisor(S, P) ← *student(S, Major), professor(P, Major), choice((S), (P)).*

Thus, *choice* enforces the functional dependency

$advisor : S \rightarrow P$

but the result is nondeterministic. It turns out that the use of *choice* in deductive databases has a well-behaved semantics, works well computationally even in the case of stratified negation, and leads to a simple definition of aggregates, including user-defined aggregates.

In the Stratified Deductive Databases section we discussed stratification. LDL++ introduced the notion of an XY-stratified program. In the Background section we gave an example of the computation of *ancestor*. Here we show how to compute ancestors as well as how to count up the number of generations that separate them from the person, *mike,* in this case.

$$delta - anc(0, mike)$$

$$delta - anc(J+1, Y) \leftarrow delta - anc(J, X),$$
$$\quad parent(Y, X),\ not\, all - anc(J, Y)$$

$$all - anc(J+1, X) \leftarrow all - anc(J, X)$$

$$all - anc(J, X) \leftarrow delta - anc(J, X)$$

Assuming additional facts about parents, the query $\leftarrow all -$ *anc(3, X)* will give all great-grandparents (third-generation ancestors) of Mike. This program is not stratified, but it is XY-stratified, has a unique stable model (see the Nonstratified Deductive Databases section), and allows for efficient computation.

SQL:1999

Many techniques introduced within *DDBs* are finding their way into relational technology. The new SQL standards for relational databases are beginning to adopt many of the powerful features of *DDBs*. The *SQL:1999* standard includes queries involving recursion and hence recursive views (10). The recursion must be linear with at most one invocation of the same recursive item. Negation is stratified by allowing it to be applied only to predicates defined without recursion. The naive algorithm must have a unique fixpoint, and it provides the semantics of the recursion; however, an implementation need not use the naive algorithm.

To illustrate the syntax, we show an example of a recursive query. We assume a relation called *family* with attributes *child* and *parent*. The query asks for all the ancestors of John. We write this query in a way that is more complicated than needed, just for illustration, by creating the relation *ancestor* recursively and then using it to find John's ancestors.

```
With Recursive Ancestor(child,anc) as
(Select child, parent
From Family
Union All
    Select Family.child, Ancestor.anc
    From Family, Ancestor
    Where Family.parent = Ancestor.child)
Select anc
From Ancestor
Where child = 'John';
```

The language also allows for the specification of depth-first or breadth-first traversal. Breadth-first traversal would ensure that all parents are followed by all grandparents, and so on.

Also in SQL:1999, a carryover from SQL-92, is a general class of integrity constraints called *Asserts,* which allow for arbitrary relationships between tables and views to be declared. These constraints exist as separate statements in the database and are not attached to a particular table or view. This extension is powerful enough to express the types of integrity constraints generally associated with *DDBs*.

Linear recursion, in which there is at most one subgoal of any rule that is mutually recursive with the head, is currently a part of the client server of *IBM's DB2* system. They are using the *magic sets* method to perform linear recursion. Indications are that the *ORACLE* database system will support some form of recursion.

Summary of Stratified Deductive Database Implementations

As discussed, the modern era of deductive databases started in 1977 with the workshop "Logic and Data Bases" organized in Toulouse, France, that led to the publication of the book *Logic and Data Bases* edited by Gallaire and Minker (11). As of the writing of this article, no commercial deductive databases are available. Among the prototype systems developed, the only ones remaining are *Aditi* and *LDL++*. There are no current plans to make *LDL++* commercially available. *Aditi* may, in the future, be made commercially available, but it is not yet a commercial product.

Deductive databases have had an influence in commercial relational systems. SQL:1999 adopted an approach to SQL recursion that makes use of stratified negation. Thus, the use of recursive rules and stratified deductive databases can be handled to some extent in relational database systems that follow these rules.

There are two possible reasons why deductive databases have not been made commercially available. The first reason is the prohibitive expense to develop such systems. They are more expensive to implement than were relational databases. The second reason is that relational database systems now incorporate deductive database technology, as discussed above.

As more sophisticated applications are developed that are required for *knowledge base systems* (see section on DDB, DDDB, and EDDB Implementations for Knowledge Base Systems), additional tools will be required to handle them. Some tools required for applications may be able to be added to SQL so that they may be incorporated into extensions of relational database technology. For example, adding a capability to provide cooperative answering may be one such tool (see Datalog Databases section). However, other tools needed will be difficult to incorporate into relational technology. For example, handling inconsistent, incomplete, or disjunctive databases are examples of such tools (see DDB, DDDB, and EDDB Implementations for Knowledge Base Systems section). In the remainder of this article, we discuss developments in extending deductive database technology to be able to handle complicated databases, and we also discuss current prototype systems.

Nonstratified Deductive Databases

The theory of stratified databases was followed by permitting recursion through negation in Formula (1) where the L_1 and M_j are atomic formulas, $n = 1$, $m \geq 0$, $l \geq 0$. In the context of *DDBs*, they are called *normal deductive databases*. Many semantics have been developed for these databases. The most prominent are the *well-founded semantics* of Van Gelder, Ross, and Schlipf and the *stable semantics* of Gelfond and Lifschitz. When the *well-founded semantics* is used, the database is called $Datalog^{\neg}_{norm,wfs}$, and when the stable semantics is used, the database is called $Datalog^{\neg}_{norm,\ stable}$. The *well-founded semantics* leads to a unique three-valued model, whereas the *stable semantics* leads to a (possibly empty) collection of models.

Example 6 [Non-Stratified Database]. *Consider the database given by*:

$r_1 : p(X) \leftarrow not\, q(X)$
$r_2 : q(X) \leftarrow not\ p(X)$
$r_3 : r(a) \leftarrow p(a)$
$r_4 : r(a) \leftarrow q(a)$

Notice that r_1 and r_2 are recursive through negation. Hence, the database is not stratified. According to the well-founded semantics, {*p*(*a*), *q*(*a*), *r*(*a*)} *are assigned* unknown. *However, for the* stable model semantics, *there are two minimal stable models:* {{*p*(*a*), *r*(*a*)}, {*q*(*a*), *r*(*a*)}}. *Hence, one can conclude that r*(*a*) *is* true *and the disjunct, p*(*a*) ∨ *q*(*a*), is also true *in the stable model semantics. The stable model semantics has been renamed the* answer set semantics *and throughout the remainder of this article, we will use that term. Because of the importance of this semantics, we discuss it in some detail below in a more expressive context*.

Extended Deductive Databases

The ability to develop a semantics for databases in which rules have a literal (i.e., an atomic formula or the negation of an atomic formula) in the head and literals with possibly negated-by-default literals in the body of a rule, has significantly expanded the ability to write and understand the semantics of complex applications. Such rules, called *extended clauses,* contain rules in Formula (1) where $n = 1, m \geq 0, l \geq 0$, and the *Ls* and *Ms* are literals. Such databases combine *classical negation* (represented by $\neg$) and *default negation* (represented by *not* immediately preceding a literal), and are called *extended deductive databases*. Combining classical and default negation provides users greater expressive power.

The material on answer set semantics is drawn from Ref. 12. For a comprehensive discussion of *ANS* semantics, see Ref. 13. The *ANS* semantics is important for *Knowledge Base Systems (KBS)* semantics.

By an extended deductive database, Π, is meant a collection of rules of the form (1) where $n = 1$ and the M_i, $1 \leq i \leq m + l$, are literals.

The set of all literals in the language of Π is denoted by *Lit*. The collection of all ground literals formed by the predicate *p* is denoted by *Lit(p)*. The semantics of an extended deductive database assigns to it a collection of its *answer sets*—sets of literals that correspond to beliefs that can be built by a rational reasoner on the basis of Π. A literal $\neg p$ is *true* in an answer set *S* if $\neg p \in S$. We say that *not p* is *true* in *S* if $p \notin S$. We say that Π's answer set to a literal query *q* is *yes* if *q* is *true* in all answer sets of Π, *no* if $\neg q$ is *true* in all answer sets of Π, and *unknown* otherwise.

The *answer set* of Π not containing default negation *not* is the smallest (in the sense of set-theoretic inclusion) subset *S* of *Lit* such that

1. if all the literals in the body of a rule of Π are in *S*, then $L_1 \in S$; and
2. if *S* contains a pair of complementary literals, then $S = Lit$. (That is, the extended deductive database is inconsistent.)

Every deductive database that does not contain default negation has a unique answer set, denoted by $b(\Pi)$. The *answer set* $b(\Pi)$ of an extended deductive database Π that contains default negation without variables, and hence is said to be *ground,* is obtained as follows. Let *S* be a candidate answer set and let Π^S be the program obtained from Π by deleting

1. each rule that has a default negation *not L* in its body with $L \in S$, and
2. all default negations *not L* in the bodies of the remaining rules.

It is clear that Π^S does not contain *not,* so that $b(\Pi^S)$ is already defined. If this answer set coincides with *S,* then we say that *S* is an *answer set* of Π. That is, the answer sets of Π are characterized by the equation $S = b(\Pi^S)$.

As an example, consider the extended deductive database Π_1 that consists of one rule:

$\neg q \leftarrow not\ p.$

The rule intuitively states: "q is *false* if there is no evidence that *p* is *true*." The only answer set of this program is $\neg q$. Indeed, here $S = \{\neg q\}$, and $\Pi^S = \{\neg q \leftarrow\}$. Thus, answers to the queries *p* and *q* are *unknown* and *false*, respectively.

There have been several implementations that incorporate the well-founded and the answer set semantics. These systems can handle large knowledge bases that consist of data facts and rules. In addition, in the following section, we discuss the extension of deductive systems to handle incomplete information and disjunctive information. There have been implementations of such systems. In the DDB, DDDB, and EDDB Implementations for Knowledge Base Systems section, we describe the most important systems that contain the well-founded semantics, the answer set semantics, or the disjunctive semantics.

DISJUNCTIVE DEDUCTIVE DATABASES

The Need for Disjunction

In the databases considered so far, information is definite. However, many applications exist where knowledge of the world is *incomplete*. For example, when a null value appears as an argument of an attribute of a relation, the value of the attribute is unknown. Also, uncertainty in databases may be represented by probabilistic information. Another area of incompleteness occurs when it is unknown which among several facts are *true,* but it is known that one or more are *true*. It is, therefore, necessary to be able to represent and understand the semantics of theories that include incomplete data. The case in which there is disjunctive information is discussed below. A natural extension is to permit disjunctions in the *EDB* and disjunctions in the heads of *IDB* rules. These rules are represented in Formula(1), where $n \geq 1$, $m \geq 0$, and $l \geq 0$, and are called *extended disjunctive rules*. Such databases are called *extended disjunctive deductive databases (EDDDBs),* or $Datalog^{\neg}_{disj,ext}$. Below, we illustrate a knowledge base system that contains disjunctive information, logical negation ($\neg$), and default negation *(not)*.

Example 7 (Knowledge Base (13)). *Consider the database, where p(X,Y) denotes* X is a professor in department Y, *a(X, Y) denotes* individual X has an account on machine Y, *ab(W, Z) denotes* it is abnormal in rule W to be individual Z.

We wish to represent the following information where mike *and* john *are* professors *in the* computer science department*:*

1. *As a rule, professors in the computer science department have* m1 accounts. *This rule is not applicable to Mike, represented by* ab(r4,mike) *(that is, that it is abnormal that in rule r4 we have mike). He may or may not have an account on that machine.*
2. *Every computer science professor has either an* $m1$ or an $m2$ *account, but not both.*

These rules are reflected in the following extended disjunctive database.

r1 $p(mike, cs) \leftarrow$

r2 $p(john, cs) \leftarrow$

r3 $\neg p(X, Y) \leftarrow not\ p(X, Y)$

r4 $a(X, m1) \leftarrow p(X, cs),\ not\, ab(r4, X),\ not \neg a(X, m1)$

r5 $ab(r4, mike) \leftarrow$

r6 $a(X, m1) \vee a(X, m2) \leftarrow p(X, cs), ab(r4, X)$

r7 $\neg a(X, m2) \leftarrow p(X, cs), a(X, m1)$

r8 $\neg a(X, m1) \leftarrow p(X, cs), a(X, m2)$

r9 $a(X, m2) \leftarrow \neg a(X, m1), a(X, cs)$

Rule r3 states that if by default negation p(X, Y) fails, then p(X, Y) is logically false. *The other rules encode the statements listed above. From this formalization, one can deduce that* john *has an* m1 *account, whereas* mike *has either an* m1 *or an* m2 *account, but not both.*

The semantics of *DDDBs* is discussed first, where clauses are given by Formula (1), literals are restricted to atoms, and there is no default negation in the body of a clause. Then the semantics of *EDDDBs,* where there are no restrictions on clauses in Formula (1), is discussed.

Disjunctive Deductive Databases (DDDBs)

The field of *disjunctive deductive databases (DDDBs),* referred to as $Datalog^{\neg}_{disj}$, started in 1982 by Minker who described how to answer both positive and negated queries in such databases. A major difference between the semantics of *DDBs* and *DDDBs* is that *DDBs* usually have a unique minimal model, whereas *DDDBs* generally have multiple minimal models.

To answer positive queries over *DDDBs*, it is sufficient to show that the query is satisfied in every minimal model of the database. Thus, for the *DDDB,* $\{a \vee b\}$, there are two minimal models, {{a}, {b}}. The query a is not satisfied in the model {*b*}, and hence, it cannot be concluded that a is *true*. However, the query $\{a \vee b\}$ is satisfied in both minimal models and hence the answer to the query $\{a \vee b\}$ is *yes*. To answer negated queries, it is not sufficient to use Reiter's *CWA* because, as he noted, from $DB = \{a \vee b\}$, it is not possible to prove a, and it is not possible to prove b. Hence, by the *CWA, not a* and *not b* follow. But, {*a* ∨ *b, not a, not b*} is not consistent. The *Generalized Closed World Assumption (GCWA),* developed by Minker, resolves this problem by specifying that a negated atom is *true* if the atom does not appear in any minimal model of the database, which provides a model theoretic definition of negation. An equivalent proof theoretic definition, also by Minker, is that an atom a is considered *false* if whenever $a \vee C$ is proved *true,* then C can be proven *true,* where C is an arbitrary positive clause.

Answering queries in *DDDBs* has been studied by several individuals. Fernández and Minker developed the concept of a *model tree,* a tree whose nodes consist of atoms. Every branch of the model tree is a model of the database. They show how one can incrementally compute sound and complete answers to queries in *hierarchical DDDBs,* where the database has no recursion. However, one can develop a fixpoint operator over trees to capture the meaning of a *DDDB* that includes recursion. Fernández and Minker compute the model tree of the extensional *DDDB* once. To answer queries, *intensional database* rules may be invoked. However, the models of the extensional disjunctive part of the database do not have to be generated for each query. Their approach to compute answers generalizes to stratified and normal *DDDBs*.

Fernández and Minker also developed a fixpoint characterization of the minimal models of disjunctive and stratified disjunctive deductive databases. They proved that the operator iteratively constructs the perfect models semantics (Przymusinski) of *stratified DDBs*. Given the equivalence between the *perfect model semantics of stratified programs* and *prioritized circumscription* as shown by Przymusinski, their characterization captures the meaning of the corresponding circumscribed theory. They present a bottom-up evaluation algorithm for *stratified DDDBs*. This algorithm uses the *model-tree* data structure to compute answers to queries.

Loveland and his students have developed a top-down approach when the database is *near Horn,* that is, there are few disjunctive statements. They developed a case-based reasoner that uses *Prolog* to perform the reasoning and introduced a relevancy detection algorithm to be used with *SATCHMO,* developed by Manthey and Bry, for automated theorem proving. Their system, termed *SATCHMORE (SATCHMO with RElevancy),* improves on *SATCHMO* by limiting uncontrolled use of forward chaining. There are currently several efforts devoted to implementing disjunctive deductive databases from a bottom-up approach, prominent among these is the system DLV discussed in the next section.

Alternative semantics were developed for nonstratifiable *normal DDDBs* by: Ross (the *strong well-founded semantics);* Baral, Lobo, and Minker (*Generalized Disjunctive Well-Founded Semantics* (*GDWFS*)); Przymusinski (*disjunctive answer set semantics*); Przymusinski (*stationary semantics*); and Brass and Dix (*D-WFS semantics*). Przymusinski described a *semantic framework* for disjunctive logic programs and introduced the *static expansions* of disjunctive programs. The class of static expansions extends both the classes of answer sets, well-founded and stationary models of normal programs, and the class of minimal models of disjunctive programs. Any static expansion of a program P provides the corresponding semantics for P consisting of the set of all sentences logically implied by the expansion. The D-WFS semantics permits a general approach to bottom-up computation in disjunctive programs. The Answer set semantics has been modified to apply to disjunctive as well as extended DDBs. Answer set semantics has become the most used semantics for these types of databases. The semantics encompasses the answer set semantics, and hence the Smodels semantics. We discuss this semantics in the following subsection.

Answer Set Semantics for EDDDBs

A disjunctive deductive database is a collection of rules of the form (1) where the Ls and Ms are literals. When the Ls and Ms are atoms, the program is called a *normal disjunctive program*. When $l = 0$ and the Ls and Ms are atoms, the program is called a *positive disjunctive deductive database*.

An *answer set* of a disjunctive deductive database Π not containing *not* is a smallest (in a sense of set-theoretic inclusion) subset S of *Lit* such that

1. for any rule of the form (1), if $M_1, \ldots, M_m \in S$, then for some i, $0 \leq i \leq n$, $L_i \in S$; and
2. If S contains a pair of complementary literals, then $S = Lit$ (and hence is inconsistent).

The answer sets of a disjunctive deductive database that does not contain *not* is denoted as $\alpha(S)$. A disjunctive deductive database without *not* may have more than one answer set.

A set of literals S is said to be an answer set of a disjunctive deductive database Π if $S \in \alpha(\Pi^S)$, where Π^S is defined in the Extended Deductive Databases section.

Consider the disjunctive deductive database,
$\Pi_0 = p(a) \vee p(b) \leftarrow .$
This deductive database has two answer sets: $\{p(a)\}$ and $\{p(b)\}$.
The disjunctive deductive database,
$\Pi_1 = \Pi_0 \cup \{r(X) \leftarrow not\ p(X)\}$,
has two answer sets: $\{p(a), r(b)\}$ and $\{p(b), r(a)\}$.

Selecting Semantics for EDDBs and EDDDBS

There are a large number of different semantics, in addition to those listed here. A user who wishes to use such a system is faced with the problem of selecting the appropriate semantics for his needs. No guidelines have been developed. However, one way to assess the semantics desired is to consider the complexity of the semantics. Results have been obtained for these semantics by Schlipf and by Eiter and Gottlob.

Ben-Eliahu and Dechter showed that there is an interesting class of disjunctive databases that are tractable. In addition to work on tractable databases, consideration has been given to approximate reasoning where one may give up soundness or completeness of answers. Selman and Kautz developed lower and upper bounds for Horn (Datalog) databases, and Cadoli and del Val developed techniques for approximating and compiling databases.

A second way to determine the semantics to be used is through their properties. Dix proposed criteria that are useful to consider in determining the appropriate semantics to be used. Properties deemed to be useful are: *elimination of tautologies,* where one wants the semantics to remain the same if a tautology is eliminated; *generalized principle of partial evaluation,* where if a rule is replaced by a one-step deduction, the semantics is unchanged; *positive / negative reduction; elimination of nonminimal rules,* where if a subsumed rule is eliminated, the semantics remains the same; *consistency,* where the semantics is not empty for all disjunctive databases; and *independence,* where if a literal l is *true* in a program P and P' is a program whose language is independent of the language of P, then l remains *true* in the program consisting of the union of the two languages.

A semantics may have all the properties that one may desire, and be computationally tractable and yet not provide answers that a user expected. If, for example, the user expected an answer *r(a)* in response to a query *r(X),* and the semantics were, for Example 6, the *well-founded semantics,* the user would receive the answer, *r(a)* is *unknown*. However, if the *answer set semantics* had been used, the answer returned would be *r(a)*. Perhaps the best that can be expected is to provide users with complexity results and criteria by which they may decide which semantics meets the needs of their problems. However, to date, the most important semantics have been the answer set semantics and the well-founded semantics, discussed earlier.

Understanding the semantics of disjunctive theories is related to nonmonotonic reasoning. The field of nonmonotonic reasoning has resulted in several alternative approaches to perform default reasoning. Hence, *DDDBs* may be used to compute answers to queries in such theories. Cadoli and Lenzerini developed complexity results concerning circumscription and closed world reasoning. Przymusinski and Yuan and You describe relationships between autoepistemic circumscription and logic programming. Yuan and You use two different belief constraints to define two semantics the *stable circumscriptive semantics*, and *the well-founded circumscriptive semantics* for autoepistemic theories.

References to work by Fernández and Minker and by Minker and Ruiz may be found in Ref. 2. Work on complexity results appears in Schlipf (15) and in Eiter and Gottlob Refs. (16,17). Relationships between $Datalog^{\neg}_{ext}$ and nonmonotonic theories may be found in Ref. 2. Prototype implementations of extended deductive and extended disjunctive deductive databases are given in the following section.

DDB, DDDB, AND EDDB IMPLEMENTATIONS FOR KNOWLEDGE BASE SYSTEMS

General Considerations

Chen and Warren implemented a top-down approach to answer queries in the well-founded semantics, whereas Leone and Rullo developed a bottom-up method for $Datalog^{\neg}_{norm,wfs}$ databases. Several methods have been developed for computing answers to queries in answer set semantics. Fernández, Lobo, Minker, and Subrahmanian developed a bottom-up approach to compute answers to queries in answer set semantics based on the concept of *model trees*. Bell, Nerode, Ng, and Subrahmanian developed a method based on linear programming.

These notions of default negation have been used as separate ways to interpret and to deduce default information. That is, each application chose one notion of negation and applied it to every piece of data in the domain of the application. Minker and Ruiz defined a more expressive *DDB* that allows several forms of default negation in the same database. Hence, different information in the domain may be treated appropriately. They introduced a new semantics called the *well-founded stable* semantics that characterizes the meaning of *DDBs* that combine well-founded and stable semantics.

Knowledge bases are important for artificial intelligence and expert system developments. A general way to represent knowledge bases is through logic. Work developed for *extended DDBs* concerning semantics and complexity apply directly to knowledge bases. For an example of a knowledge base, see Example 7. *Extended DDBs* permit a wide range of *knowledge bases (KBs)* to be implemented.

Since alternative *extended DDBs* have been implemented, the *KB* expert can focus on writing rules and integrity constraints that characterize the problem, selecting the semantics that meets the needs of the problem, and employing a *DDB* system that uses the required semantics.

Articles on stratified databases by Apt, Blair, and Walker, by Van Gelder, and by Przymusinski may be found in Ref. 18. See Refs. 5 and 6 for a description of computing answers to queries in stratified databases. For an article on the semantics of $Datalog^{\neg}_{wfs}$, see Ref. 19 see Ref. 20 for the answer set semantics; see Ref. 2 for references to work on other semantics for normal extended deductive databases and Schlipf (21) for a comprehensive survey article on complexity results for deductive databases. For results on negation in deductive databases, see the survey article by Shepherdson (22). The development of the semantics and complexity results of extended DDBs that permit a combination of classical negation and multiple default negations in the same DDB are important contributions to database theory. They permit wider classes of applications to be developed.

There have been several implementations of systems for handling extended databases and extended disjunctive databases. There have also been many semantics proposed for these systems. However, of these systems, the most important systems are the *well-founded semantics* (WFS) and the *answer set semantics* (ANS). See Ref. 2 for a discussion of the alternate proposals. There is one major system developed and in use for the WFS, and there are several implementations for the ANS.

Implementation of the Well-Founded Semantics

Warren, Swift, and their associates (23) developed an efficient deductive logic programming system, *XSB,* that computes the well-founded semantics. *XSB* is supported to the extent of answering questions and fixing bugs within the time schedule of the developers. The system extends the full functionality of *Prolog* to the *WFS*. *XSB* forms the core technology of a start-up company, XSB, Inc., whose current focus is application work in data cleaning and mining. In Ref. 24, it is shown how nonmonotonic reasoning may be done within *XSB* and describes mature applications in medical diagnosis, model checking, and parsing. XSB also permits the user to employ Smodels, discussed below. XSB is available on the Internet and is available as open-source. There is no intent by XSB, Inc. to market the program.

Implementation of Answer Set Semantics

Three important implementations of answer set semantics are by Marek and Truszczyński (25), by Niemelä and Simons (26–28), and by Eiter and Leone (29,30). Marek and Truszczyński developed a program, *Default Reasoning System (DeReS),* that implements Reiter's default logic. It computes extensions of default theories. As logic programming with answer set semantics is a special case of Reiter's default logic, *DeReS* also computes the answer sets of logic programs. To test *DeReS,* a system, called *TheoryBase,* was built to generate families of large default theories and logic programs that describe graph problems such as existence of colorings, kernels, and Hamiltonian cycles. No further work is anticipated on the system.

Niemelä and Simons developed a system, *Smodels,* to compute the answer sets of programs in *Datalog* with negation. At present, *Smodels* is considered the most efficient implementation of answer set semantics computation. *Smodels* is based on two important ideas: intelligent grounding of the program, limiting the size of the grounding, and use of the *WFS* computation as a pruning technique. The system is used at many sites throughout the world. New features are continually being added. The system is available for academic use. It is possible to license the system from a company in Finland called Neotide.

Implementation of Disjunctive Deductive Databases

Eiter and Leone developed a system, *DLV (DataLog with Or),* that computes answer sets (in the sense of Gelfond and Lifschitz) for disjunctive deductive databases in the syntax generalizing *Datalog* with negation. As *Smodels, DLV* also uses a very powerful grounding engine and some variants of *WFS* computation as a pruning mechanism. The method used to compute *disjunctive answer sets* is described in Ref. 31. The work is the joint effort between Tech U, Austria and U Calabria, Italy. Many optimization techniques have been added to the system (e.g., magic sets and new heuristics), the system language has been enhanced (e.g., aggregate functions), and new front ends were developed for special applications such as planning.

Definition of a Knowledge Base System

Knowledge bases are important for artificial intelligence and expert system developments. A general way to represent knowledge bases is through logic. All work developed for extended *DDBs* concerning semantics and complexity apply directly to knowledge bases. Baral and Gelfond (14) describe how extended *DDBs* may be used to represent knowledge bases. Many papers devoted to knowledge bases consider them to consist of facts and rules, which is certainly one aspect of a knowledge base, as is the ability to extract proofs. However, integrity constraints supply another aspect of knowledge and differentiate knowledge bases that may have the same rules but different integrity constraints. Since alternative extended deductive databases have been implemented, knowledge base experts can focus on the specification of the rules and integrity constraints and employ the extended deductive databases that have been implemented.

Work on the implementation of semantics related to extended disjunctive deductive databases has been very impressive. These systems can be used for nonmonotonic reasoning. Brewka and Niemela (32) state as follows:

> At the plenary panel session[2], the following major trends were identified in the field: First, serious systems for nonmonotonic reasoning are now available (XSB, SMODELS, DLV). Second, people outside the community are starting to use these systems with encouraging success (for example, in planning). Third, nonmonotonic techniques for reasoning about action are used in highly ambitious long-term projects (for example, the WITAS Project, www.ida.liu.se/ext/witas/eng.html). Fourth, causality is still an important issue; some formal models of causality have surprisingly close connections to standard nonmonotonic techniques. Fifth, the nonmonotonic logics being used most widely are the classical ones: default logic, circumscription, and autoepistemic logic.

APPLICATIONS

There are many applications that cannot be handled by relational database technolgy, but are necessary for advanced knowledge base and artificial intelligence applications (AI). One cannot handle disjunctive information, databases that have default negation that are not stratified, incomplete information, planning for robotics, handling databases with preferences, and other topics. However, all of the above topics can be handled by extensions to databases as described in the previous sections. In this section, we discuss how the following topics can be handled by deductive databases: data integration in which one can combine databases; handling preferences in databases; updating deductive databases; AI planning problems; and handling databases that may be inconsistent. The applications described can be incorporated or implemented on the deductive databases discussed in the previous section. These applications form a representative sample of capabilities that can be implemented with extended deductive database capabilities.

Two specific examples of deductive database applications are briefly discussed here. Abduction is a method of reasoning, which, given a knowledge base and one or more observations, finds possible explanations of the observations in terms of predicates called abducible predicates. The concept of abduction has been used in such applications as law, medicine, diagnosis, and other areas; Refs. 14 and 33. With the vast number of heterogeneous information sources now available, particularly on the world wide web, multiagent systems of information agents have been proposed for solving information retrieval problems, which requires advanced capabilities to address complex tasks, query planning, information merging, and handling incomplete and inconsistent information. For a survey of applications to intelligent information agents see Ref. 34.

Data Integration

Data integration deals with the integration of data from different databases and is a relevant issue when many overlapping databases are in existence. In some cases, various resources exist that are more efficient to access than the actual relations or, in fact, the relations may even be virtual so that all data must be accessed through resources. We review here the approach given in Ref. 35. The basis of this approach is the assumption that the resources are defined by formulas of deductive databases and that integrity constraints can be used, as in SQO, to transform a query from the extensional and intensional predicates to the resources. Grant and Minker show how to handle arbitrary constraints, including the major types of integrity constraints, such as functional and inclusion dependencies. Negation and recursion are also discussed in this framework. We use a simple example to illustrate the basic idea.

Assume that there are three predicates:

$p_1(X, Y, Z), p_2(X, U)$, and $p_3(X, Y)$,

and an integrity constraint:

$p_3(X, Y) \leftarrow p_1(X, Y, Z), Z > 0.$

The resource predicate is defined by the formula

$r(X, Y, Z) \leftarrow p_1(X, Y, Z), p_2(X, U).$

Let the query be:

$p_1(X, Y, Z), p_2(X, U), p_3(X, Y), Z > 1.$

Intuitively one can see from the integrity constraint that p_3 is superfluous in the query, hence is not needed, and therefore the resource predicate can be used to answer the query. Formally, the first step involves reversing the resource rules to define the base predicates, p_1 and p_2 in this case, in terms of the resource predicates. This step is justified by the fact that the resource predicate definition really represents an if-and-only-if definition and is the Clark completion, as mentioned in the Deductive Data-

[2] The plenary panel session was held at the Seventh International Workshop on Nonmonotonic Reasoning as reported in (32).

bases: The Formative Years 1969–1978 section. In this case, the rules are:

$$p_1(X,Y,Z) \leftarrow r(X,Y,Z)$$
$$p_2(X,f(X,Y,Z)) \leftarrow r(X,Y,Z).$$

It is possible then to use resolution theorem proving, starting with the query, the integrity constraint, and these new rules, to obtain a query in terms of r, namely

$$\leftarrow r(X,Y,Z), Z > 1.$$

That is, to answer the original query, a conjunction of three predicates and a select condition, one need only perform a select on the resource predicate.

Handling Preferences

In a standard deductive database, all the clauses are considered to have equal status. But, as was shown, there may be several answer sets for a deductive database. In some cases, one answer set may be preferred over another because there may be preferences among the clauses. Consider the following simple propositional example with two clauses.

r1 : $a \leftarrow not\ b$
r2 : $b \leftarrow not\ a$

There are two answer sets: $\{a\}$ and $\{b\}$. If $r1$ is preferred over $r2$, then the preferred answer set is $\{a\}$.

The general approach to handling preferences has been to use a meta-formalism to obtain preferred answer sets. One way is to generate all answer sets and then select the ones that are preferred. A somewhat different approach is taken in Ref. 36 and is briefly reviewed here.

They start with the original deductive database and using the preferences between clauses transform (compile) them to another deductive database such that the answer sets of the new (tagged) deductive database are exactly the preferred answer sets of the original deductive database. For the simple propositional example with two clauses given above, the new deductive database (actually a simplified version) would be:

$ok(r1) \leftarrow$
$ok(r2) \leftarrow ap(r1)$
$ok(r2) \leftarrow bl(r1)$
$ap(r1) \leftarrow ok(r1),\ not\ b$
$ap(r2) \leftarrow ok(r2),\ not\ a$
$a \leftarrow ap(r1)$
$b \leftarrow ap(r2)$
$bl(r1) \leftarrow b$
$bl(r2) \leftarrow a$

There are three new predicates: ok, ap (for applicable), and bl (for blocked). The first three rules reflect the preference of r1 over r2. The next four rules are obtained from r1 and r2 by adding the ok of the appropriate rules and deducing a (resp. b) in two steps. The last two rules show when a rule is blocked. There is one answer set in this case:

$\{ok(r1),\ ap(r1),\ a,\ bl(r2),\ ok(r2)\}$
whose set of original atoms is $\{a\}$.

This article handles both static rules and dynamic rules, that is, rules that are themselves considered as atoms in rules. The implementation is straightforward and the complexity is not higher than for the original deductive database.

Updates

Although the study of deductive databases started in 1977, as discussed in the Deductive Databases section, for many years it dealt with static databases only. More recently, researchers have tried to incorporate update constructs into deductive databases. We briefly consider here an extension of Datalog, called *DatalogU* (37). This extension has the capability to apply concurrent, disjunctive, and sequential update operations in a direct manner and it has a clear semantics.

We illustrate DatalogU by giving a couple of simple examples. Consider a predicate *employee* with three arguments: name, department, and salary.

To insert a new employee, *joe* into department *5* with salary *45000,* we write *insertemployee(joe,* 5,45000)
To delete all employees from department 7, write
deleteemployee(N, 7, *S)*
Consider now the update that gives every employee in department 3 a 5% raise *deleteemployee(N,* 3, *S*), $S' = S \times 1.05$, *insertemployee(N,* 3, *S'*)
DatalogU allows writing more general rules, such as
$raiseSalary(N,D,P) \leftarrow deleteemployee(N,D,S), S' = S \times (1+P),\ insertemployee(N,D,S')$
that can be used, such as
raiseSalary(N, D, 0.1)
to give everyone a 10% raise.

Another example is the rule for transferring money from one bank account to another. We can use the following rules:

$transfer(BA1,\ BA2,\ Amt) \leftarrow withdraw(BA1,\ Amt),$
$\quad deposit(BA2,\ Amt), BA1 \neq BA2$
$withdraw(BA, Amt) \leftarrow deleteaccount(BA, Bal),$
$\quad insertaccount(BA, Bal'), Bal \geq Amt, Bal' = Bal - Amt$
$deposit(BA, Amt) \leftarrow deleteaccount(BA, Bal),$
$\quad insertaccount(BA, Bal'), Bal' = Bal + Amt$

So now, to transfer $200 from account A0001 to A0002, we write *transfer* (*A*0001, *A*0002, 200).

AI Planning

Planning in AI can be formalized using deductive databases, as shown in Ref. 38. A planning problem can be described in terms of an initial state, a goal state, and a set of possible actions. A successful plan is a sequence of actions that, starting with the initial state and applying the actions in the given sequence, leads to the goal. Each action consists of preconditions before the action can take place as well as the addition and deletion of atoms leading to postconditions that hold after the action has taken place. The following simple example for illustration involves a world of named blocks stacked in columns on a table. Consider the action *pickup (X)* meaning that the robot picks up X. In this case,

$$
\begin{aligned}
&Pre = \{onTable(X), clear(X), handEmpty\}\\
&Post = \{\neg onTable(X),\ \neg handEmpty, holding(X)\}
\end{aligned}
$$

So before the robot can pick up a block, the robot's hand must be empty and the block must be on the table with no block above it. After the robot picks up the block, it is holding it, its hand is not empty, and the block is not on the table.

The idea of the formalization is to write clauses representing postconditions, such as

$$postcond(pickup(X), onTable(X), neg)$$

and use superscripts to indicate the step number in the action, such as in

$$add^J(Cond) \leftarrow\ fired^J(\alpha), postcond(\alpha, Cond, pos)$$

to indicate, for instance, that if an action α is fired at step J, then a particular postcondition is added. A tricky issue is that at each step only one action can be selected among all the firable actions. A nondeterministic choice operator (see also Current Prototype section on LDL++) is used to express this concept:

$$fired^J(\alpha) \leftarrow\ firable^J(\alpha),\ \neg\ firable^J(end), choice^J(\alpha)$$

We have left out many details, but the important issue is that the existence of a solution for a planning problem is equivalent to the existence of a model in the answer set semantics for the planning deductive database and the conversion of the problem to the deductive database can be done in linear time. In fact, each answer set represents a successful plan. These results are also generalized in various ways, including to parallel plans.

The oldest problem in AI planning, the ability of an agent to achieve a specified goal, was defined by McCarthy (39). He devised a logic-based approach to the problem based on the situation calculus that was not entirely satisfactory. One of the problems with the approach was how to handle the *frame problem,* the seeming need for *frame axioms,* to represent changes in the situation calculus. Lifschitz et al. (40) have shown how to solve this problem. They state, "The discovery of the frame problem and the invention of the nonmonotonic formalisms that are capable of solving it may have been the most significant events so far in the history of reasoning about actions." See the paper by Litschitz et al. for their elegant solution to the McCarthy AI planning problem.

Handling Inconsistencies

As explained in The Background section, a database must satisfy its integrity constraints. However, there may be cases where a database becomes inconsistent. For example, a database obtained by integrating existing databases (see Data Integration section) may be inconsistent even though each individual database is consistent. Reference 41 presents a comprehensive approach to dealing with inconsistent databases through giving consistent answers and computing repairs, which is accomplished by transforming the database into extended disjunctive database rules; the answer sets of this database are exactly the repairs of the inconsistent database. We note that the basic definitions for querying and repairing inconsistent databases were introduced in Ref. 47.

We illustrate the technique on a simple example. Let

$$EDB = \{p(a), p(b), q(a), q(c)\} \text{ and } IC = \{q(x) \leftarrow p(x)\}.$$

This database is inconsistent because it contains *p(b)* but not *q(b)*. There are two simple ways of repairing the database: (1) delete *p(b),* (2) insert *q(b)*. However, even though the database is inconsistent, certain queries have the same answers in both repairs. For example, $\leftarrow q(x), not\ p(X)$ has c as its only answer. In this example, the transformation modifies the *IC* to the rule

$$\neg\ p_u(X) \vee q_u(X) \leftarrow p(X), not\, q(X)$$

where p_u and q_u are new "update" predicates. The meaning of this rule is that in case $p(X)$ holds and $q(X)$ does not hold, either delete $p(X)$ or insert $q(X)$. The answer sets of the transformed database are

$M_1 = \{p(a), p(b), q(a), q(c), \neg p_u(p)\}$ and $M_2 = \{p(a), p(b), q(a), q(c), q_u(b)\}$ leading to the two repairs mentioned above.

SUMMARY AND REFERENCES

The article describes how the rule of inference, based upon the Robinson Resolution Principle (developed by J.A. Robinson (42)), started in 1968 with the work of Green and Raphael (43,44), led to a number of systems and culminated in the start of the field of deductive databases in November 1977, with a workshop held in Toulouse, France that resulted in the appearance of a book edited by Gallaire and Minker (11).

The field has progressed rapidly and has led to an understanding of negation, has provided a theoretical framework so that it is well understood what is meant by a query, and an answer to a query. The field of relational databases is encompassed by the work in *DDBs*. As discussed, some concepts introduced in deductive databases have been incorporated into relational technology. As noted, complex knowledge based systems can be implemented using advanced deductive database concepts not contained in relational technology. There are, however, many different kinds of *DDBs* as described in this article. Theoretical results concerning fixpoint theory for *DDBs* may be found in Lloyd (7), while fixpoint theory and theories of negation for disjunctive deductive databases may be found in Lobo, Minker, and Rajasekar (45). Complexity results have not been summarized in this article. The least complex *DDBs* are, in order, *Datalog*, $Datalog^{\neg}_{str}$, $Datalog^{\neg}_{wfs}$, and $Datalog^{\neg}_{stab}$. The first three databases result in unique minimal models. Other databases are more complex and, in addition, there is no current semantics that is uniformly agreed on for $Datalog_{disj}$. However, the answer set semantics discussed in the Extended Deductive Databases section for deductive databases and in the Answer Set Semantics for EDDDBs section for disjunctive deductive databases appears to be the semantics generally favored. As noted in the Selecting Semantics for EDDBs and EDDDBs section, a combination of properties of *DDBs,* developed by Dix and discussed in Ref. 46, (and the complexity of these systems as described in Ref. 15–17), could be used once such systems are developed.

DISCRETE EVENT SYSTEMS: UNTIMED MODELS AND THEIR ANALYSIS

INTRODUCTION

Mathematical system theory is concerned with modeling, analyzing, and controlling *dynamic systems*, that is, systems described by variables that evolve over time. A "system" is an abstract concept to describe an entity that comprises input, state, and output variables. An important class of dynamic systems is that of electromechanical systems. Examples of such dynamic systems abound around us at all scales of human activity including disk drives in computers; heating, ventilation, and air conditioning systems in buildings; powertrains in automobiles; jet engines; power distribution networks, and so on. Their associated variables, such as rotation speed, temperature, torque, and voltage, are continuous in nature, and the laws of electricity and mechanics can be used to obtain a mathematical model of their behavior over time, usually in the form of differential or difference equations.

Another important class of dynamic systems is the class of *discrete event systems*. The distinguishing features of discrete event systems are (*1*) their variables do not evolve according to differential or difference equations, but rather according to the occurrence of asynchronous "events", and (*2*) these variables belong to a discrete (as opposed to continuous) set. The proliferation of technological systems that comprise computers interconnected by networks has led to the development of a mathematical system theory for discrete event systems. A communication protocol between a sender and a receiver in a network is an example of a discrete event system. The "state" of the sender belongs to a discrete set that includes states such as *idle*, *ready-to-send*, *waiting-for-acknowledgment*, and so forth, with similar states for the receiver. The dynamical evolution of the states of the sender and receiver is described by the occurrence of asynchronous events such as *packet-sent*, *packet-received*, *timer-started*, and *timer-expired*. To contrast this kind of behavior with that of a system described by a differential equation, the dynamics are said to be *event-driven* instead of being *time-driven*. Thus, the rules of the protocol lead to a mathematical model of this discrete event system.

Discrete event systems arise in many areas of computer science and engineering, which involve both hardware and software, such as protocols, databases, server systems, and so on. They also are generated in many classes of technological systems that involve automation, such as manufacturing, robotics, transportation, and so forth. The mathematical theory of discrete event systems is multidisciplinary in nature and involves concepts and techniques from computer science theory, dynamic systems, control theory, and operations research. A wide variety of modeling formalisms is used to describe and study the behavior of discrete event systems. Two widely used modeling formalisms for discrete event systems are *automata* and *Petri nets*.

Once a discrete event model of a system has been obtained, it can be used to analyze the behavior of the system in a formal manner. Many analytical questions are often posed in a *verification* context. Namely, along with the model of the system, one is also given a set of *specifications* or *requirements* regarding the desired behavior of the system. Three main categories of specifications are safety, liveness, and diagnosability. *Safety* specifications are concerned with the reachability of illegal states or illegal sequences of events in the behavior of the system. *Liveness* specifications pertain to the ability of the system to complete the tasks it starts. *Diagnosability* specifications arise in partially observed systems and refer to the ability of detecting the occurrence of significant unobservable events based on the observed sequences of events and the model of the system. If the result of the verification phase is that the behavior of the system is unsatisfactory in terms of safety, liveness, or diagnosability, then feedback control can be used to alter its behavior and ensure that all specifications are met. A controller module is adjoined to the system; this module is synthesized in such a way that the behavior of the closed-loop system, that is, the system plus the controller, is guaranteed to meet all specifications. Clearly, controller existence issues are of concern in systems where sensing and actuation limitations restrict the ability of the controller module to observe and affect the behavior of the system.

The remainder of this article will introduce the reader to modeling and analysis of discrete event systems. The discussion will be centered around the automaton modeling formalism.

MODELING AND ANALYSIS USING AUTOMATA

When modeling electromechanical systems in terms of the usual continuous variables of interest, for example, current, voltage, and position, the laws of nature can be used to obtain differential equations that model the behavior of these variables accurately over time. If necessary, techniques such as linearization can be used to obtain a model that is more analytically tractable. When modeling how packets are moved in a digital communications network, or how robots interact with conveyors and automated guided vehicles in moving parts in an automated manufacturing plant, models based on the asynchronous occurrences of a set of discrete events are more appropriate than models based on differential equations.

The first step in modeling a discrete event system is to identify a relevant set of *events* that capture all possible behaviors of the system at the desired level of abstraction. The concept of event is an intuitive one and does not require a formal definition. The level of granularity to consider when defining events depends on the level of abstraction of the verification or control task at hand. Here, one can argue that discrete event modeling is more art than science, in the sense that the knowledge of an expert is needed to

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

choose the right level of abstraction at which to study the system. When modeling the flow of traffic through a signalized intersection, one could define events such as *vehicle arrives*, *vehicle turns left*, *signal changes to red*, and so forth, if the goal is to keep track of how many vehicles are present at each approach. Individual vehicle dynamics, which are based on differential equations, would be too detailed for this kind of analysis.

Events cause state changes in the variables of interest in the system. That is why the dynamics are said to be event driven as opposed to time driven. For instance, the number of customers present in a queueing system will change during an *arrival* event or a *service-starts* event. The variables of interest have values that belong to a discrete set. They could be numerical, (e.g., the number of customers in the queue) or logical (e.g., the state of the server is *idle* or *busy*). The state of the entire system is formed by considering the states of its variables of interest. In the study of a communication protocol between two nodes in a network, the global state would be composed of the states of the sender, channel, and receiver.

Discrete event models of dynamic systems are classified in terms of how they abstract timing information and randomness in the system behavior. Untimed models abstract away precise timing issues by focusing only on the ordering of the events and not on the exact times of their occurrence. Untimed models also abstract away statistical information about the probabilities of the events and consider all possible “sample paths” in the system behavior. Untimed models are often referred to as “logical” models. A large class of logical specifications that involve safety, liveness, and diagnosability can be addressed with untimed models. Timed models enrich untimed models and explicitly include timing information. This information may be provided in a “non-stochastic” manner or in a “stochastic” manner. Event occurrence times can be specified in terms of time intervals for instance, or by means of probability distribution functions. Timed models are necessary to study specifications that involve real time and deadlines. Stochastic models are used for performance analysis under specific statistical assumptions. The process of model refinement from untimed models to [non-]stochastic timed ones is discussed in detail in the textbook by Cassandras and Lafortune (1). The remainder of this article is concerned exclusively with untimed models of discrete event systems.

Languages

Let E be the finite set of events associated with the discrete event system under consideration. This set consists of all events that can possibly be executed by the system. A *string* (or trace) is a finite sequence of events from E. Thus, a string models one possible behavior of the system during its operation. In the case of untimed models of discrete event systems, the exact time of occurrence of the event is abstracted away in the string; only the ordering of the events is retained. The length of a string s, denoted by $|s|$, is a non-negative integer that corresponds to the number of events composing the string, counting multiple occurrences of the same event. The empty string, which is denoted by ε (not to be confused with the generic event $e \in E$), is the string containing no events (i.e., $|\varepsilon| = 0$). The concatenation of two strings s_1 and s_2 is the trace $s_1 s_2$ (i.e., s_1 followed by s_2). Thus, the empty string ε can be interpreted as the identity element for concatenation.

The concept of *language* is central for modeling a discrete event system. An untimed language, or simply language, is a set of strings of events over an event set. The set of all finite strings of elements of E, including the empty string ε, is denoted by E^*; the * operation is called the Kleene closure. For example, if $E = \{a, b, c\}$, then

$$E^* = \{\varepsilon, a, b, c, aa, ab, ac, ba, bb, bc, ca, cb, cc, aaa, \ldots\}$$

If $t_1 t_2 t_3 = s$ with $t_1, t_2, t_3 \in E^*$, then t_1 is called a *prefix* of s, t_2 a substring of s, and t_3 a *suffix* of s. Both ε and s are prefixes of s by definition.

Clearly, a given system with event set E cannot in general execute all possible strings in E^*. The set of all possible behaviors of a discrete event system is therefore modeled by a *subset* of E^* (i.e., by a language). The language associated with a discrete event system is usually infinite, because the system behavior might include repetitions. It is impractical to represent a language by enumerating all its elements. A *discrete event modeling formalism* is a mechanism for representing in a compact manner the language associated with the system. It can be thought of as a data structure as well as an analytical tool.

Automata

The automaton modeling formalism is the most widely used and studied.

Definition – Automaton. A *deterministic automaton*, denoted by G, is a six-tuple

$$G = (X, E, f, \Gamma, x_0, X_m)$$

where X is the set of *states*, which could be infinite; E is the finite set of *events* associated with the transitions in G; $f : X \times E \rightarrow X$ is the *transition function*; $f(x, e) = y$ means that there is a transition labeled by event e from state x to state y (in general, f is a *partial* function on its domain); $\Gamma : X \rightarrow 2^E$ is the *feasible event function*.[1] $\Gamma(x)$ is the set of all events e for which $f(x, e)$ is defined; x_0 is the *initial* state; $X_m \subseteq X$ is the set of *marked states*.

Proper selection of which states to mark is a modeling issue that depends on the problem of interest. By designating certain states as marked, one may for instance be recording that the system, on entering these states, has completed some operation or task.

When $|X|$ is finite and small, it is convenient to represent automata graphically by means of their *state transition diagrams*. The state transition diagram of an automaton is a directed graph in which nodes represent states, and labeled arcs between nodes are used to represent the transition function f: if $f(x, e) = y$, then an arc labeled by “e” is

[1] Given a set A, the notation 2^A means the power set of A (i.e., the set of all subsets of A).

drawn from x to y. Special notation is used to identify the initial state and marked states when drawing a state transition diagram.

Automata are used to represent and manipulate languages. For the sake of convenience, the transition function f of an automaton is extended from domain $X \times E$ to domain $X \times E^*$ in the following recursive manner:[2]

$$\begin{aligned} f(x,\varepsilon) &:= x \\ f(x,se) &:= f(f(x,s),e) \quad \text{for } s \in E^* \text{ and } e \in E \end{aligned}$$

The *language generated* by G is

$$\mathcal{L}(G) := \{s \in E^* : f(x_0, s) \text{ is defined}\}$$

The *language marked* by G is

$$\mathcal{L}_m(G) := \{s \in \mathcal{L}(G) : f(x_0, s) \in X_m\}$$

The language $\mathcal{L}(G)$ represents all directed paths that can be followed along the state transition diagram of G starting at the initial state; the string corresponding to a path is the concatenation of the event labels of the transitions that compose the path. Therefore, a string s is in $\mathcal{L}(G)$ if and only if it corresponds to an admissible path in the state transition diagram, equivalently, if and only if f is defined at (x_0, s). The second language represented by G, $\mathcal{L}_m(G)$, is the subset of $\mathcal{L}(G)$ that consists only of the strings s for which $f(x_0, s) \in X_m$, that is, these strings correspond to paths that end at marked states in the state transition diagram.

The prefix-closure of a language L, which is denoted by $\overline{L}$, is the language that consists of all prefixes of all the strings in L. In general, $L \subseteq \overline{L}$. L is said to be *prefix-closed* if $L = \overline{L}$. Clearly, $\mathcal{L}(G)$ is prefix-closed by definition, because a path is only possible if all its prefixes are also possible. If f is a total function over its domain, then necessarily $\mathcal{L}(G) = E^*$. However, the language marked by G, $\mathcal{L}_m(G)$, is not prefix-closed in general, unless all the reachable states of G are marked. The language marked is also called the language *recognized* by the automaton, and the given automaton is often referred to as a *recognizer* of the given language.

An automaton G thus represents *two* languages: $\mathcal{L}(G)$ and $\mathcal{L}_m(G)$. In the standard definition of automaton in automata theory, the function f is required to be a total function, and the notion of language generated is not meaningful because it is always equal to E^*. Allowing f to be a partial function is a consequence of the fact that a discrete event system may not produce (or execute) all the strings in E^*.

A language is said to be *regular* if it can be marked by a *finite-state* automaton (i.e., by an automaton where X is a finite set). The class of regular languages is denoted by $\mathcal{R}$. It can be shown that $\mathcal{R}$ is a proper subset of 2^{E^*}, which is the class of all languages over event set E. The class $\mathcal{R}$ is very important because it delimits the languages that possess automata representations that require finite memory when stored in a computer. In other words, automata are a practical means of manipulating regular languages in analysis or controller synthesis problems. A textbook on automata and language theory, such as the book by Sipser (2), can be consulted for additional study of the properties of $\mathcal{R}$. However, automata are not a practical means for representing nonregular languages, because they would require infinite memory. The Petri net modeling formalism has proved useful for modeling many classes of nonregular languages. It will not be discussed more in this article. The interested reader is referred to Chapter 4 in Cassandras and Lafortune (1) and to the book by Hrúz and Zhou (3).

Reachability and Blocking

From the definitions of $\mathcal{L}(G)$ and $\mathcal{L}_m(G)$, all states of G that are not *accessible* or *reachable* from x_0 by some string in $\mathcal{L}(G)$ can be deleted without affecting the languages generated and marked by G. When "deleting" a state, all transitions that are *attached* to that state are also deleted. This operation is denoted by $Ac(G)$, where Ac stands for taking the "accessible" part.

In general, from the definitions of G, $\mathcal{L}(G)$, and $\mathcal{L}_m(G)$, the following set inclusions hold:

$$\mathcal{L}_m(G) \subseteq \overline{\mathcal{L}_m(G)} \subseteq \mathcal{L}(G)$$

The first set inclusion occurs because X_m may be a proper subset of X, whereas the second set inclusion is a consequence of the definition of $\mathcal{L}_m(G)$ and the fact that $\mathcal{L}(G)$ is prefix-closed. It is worth examining this second set inclusion in more detail. An automaton G could reach a state x where $\Gamma(x) = \emptyset$ but $x \notin X_m$. This result is called a *deadlock* because no other event can be executed in a state that is not marked. Another issue to consider is when a set of unmarked states in G form a strongly connected component (i.e., these states are reachable from one another) but with *no transition going out of the set*. When the system enters this set of states, its resulting behavior is a *livelock*. Although the system is "live" in the sense that it can always execute an event, it can never complete the task started because no state in the set is marked, and the system cannot leave this set of states.

Automaton G is said to be *blocking* if $\overline{\mathcal{L}_m(G)} \subset \mathcal{L}(G)$ where the set inclusion is proper,[3] and *nonblocking* when $\overline{\mathcal{L}_m(G)} = \mathcal{L}(G)$. Thus, if an automaton is blocking, then deadlock and/or livelock can happen. The notion of marked states and the above definitions for language generated, language marked, and blocking, provide an approach for considering deadlock and livelock that is useful in a wide variety of applications.

Composition of Automata

Discrete event models of complex dynamic systems are built rarely in a monolithic manner. Instead, a modular approach is used where models of individual components are built first, followed by the composition of these models to

[2] The Notation ":=" stands for "equal to by definition."

[3] The notation $\subset$ is for "strictly contained in" and $\subseteq$ is for "contained in or equal to."

obtain the model of the overall system. In the automaton modeling formalism, the synchronization, or coupling, between components is captured by the use of *common events*. Namely, if components G_A and G_B share event c, then event c should only occur if both G_A and G_B execute it. The process of composing individual automata (that model interacting system components) in a manner that captures the synchronization constraints imposed by their common events is formalized by the *parallel composition* operation, which is denoted by $||$.

Consider the two automata $G_1 = (X_1, E_1, f_1, \Gamma_1, x_{01}, X_{m1})$ and $G_2 = (X_2, E_2, f_2, \Gamma_2, x_{02}, X_{m2})$. The *parallel composition* of G_1 and G_2 is the automaton

$$G_1 \,||\, G_2 := Ac(X_1 \times X_2, E_1 \cup E_2,\ f, \Gamma_{1||2}, (x_{01}, x_{02}), X_{m1} \times X_{m2})$$

where

$$f((x_1, x_2), e) := \begin{cases} (\,f_1(x_1, e),\ f_2(x_2, e)) & \text{if } e \in \Gamma_1(x_1) \cap \Gamma_2(x_2) \\ (\,f_1(x_1, e), x_2) & \text{if } e \in \Gamma_1(x_1) \setminus E_2 \\ (x_1,\ f_2(x_2, e)) & \text{if } e \in \Gamma_2(x_2) \setminus E_1 \\ \text{undefined} & \text{otherwise} \end{cases}$$

and thus $\Gamma_{1||2}(x_1, x_2) = [\Gamma_1(x_1) \cap \Gamma_2(x_2)] \cup [\Gamma_1(x_1) \setminus E_2] \cup [\Gamma_2(x_2) \setminus E_1]$.

Associativity is used to extend the definition of parallel composition to more than two automata. The accessible operation is used to capture the fact that only the states reachable from (x_{01}, x_{02}) need to be considered. In the parallel composition, a common event (i.e., an event in $E_1 \cap E_2$) can only be executed if the two automata both execute it simultaneously. Thus, the two automata are “synchronized” on their common events. The “private” events, namely, those in $(E_2 \setminus E_1) \cup (E_1 \setminus E_2)$, are not subject to such a constraint and can be executed whenever possible by an automaton without the participation of the other automaton. Thus, the required synchronization on common events provides a modeling strategy to capture interactions among components in a system.

If $E_1 = E_2$, then the parallel composition of G_1 and G_2 results in their lock-step behavior: They must jointly execute every single event. If $E_1 \cap E_2 = \emptyset$, then no synchronized transitions occur, and $G_1||G_2$ is the *concurrent* behavior of G_1 and G_2. This behavior is often termed the *shuffle* of G_1 and G_2.

Analysis

Once a complete system model has been obtained by parallel composition of a set of automata, the resulting monolithic model, which is denoted by G_{all}, can be used to analyze the properties of the system. *Safety properties* are properties that are concerned with the reachability of certain undesirable states (from the initial state or from some other state) in G_{all}, the presence of certain undesirable strings or substrings in $\mathcal{L}(G_{all})$, or more generally the inclusion of $\mathcal{L}(G_{all})$ in a given language, which is referred to as the “legal” or “admissible” language. When G_{all} is finite state, safety properties can be answered by examination and/or manipulation of its transition structure; such tests are usually of polynomial-time complexity in the size of the state set of G_{all}. *Blocking properties* are properties that are concerned with the presence of deadlock and/or livelock in G_{all}. Observe that $G_1||G_2$ may be blocking even if G_1 and G_2 are each nonblocking. Thus, it is necessary to examine the transition structure of G_{all} to answer blocking properties. Again, this process can be done in polynomial-time complexity in the size of the state set.

It should be noted that the size of the state set of G_{all} may in the worst case grow exponentially in the number of automata that are composed by $||$. This process is known as the “curse of dimensionality” in the study of complex systems composed of many interacting components. The presence of common events can curtail this growth significantly by means of the synchronization constraints that it imposes.

Example. Consider the sequential transmission of packets between two nodes, which are denoted by A and B, in a data network. The transmission channel is noisy, and thus packets can “get lost” (namely, they can be corrupted by errors or dropped if memory buffers are full). One class of protocols that control the transmission between A and B is the class of STOP and WAIT protocols. These protocols operate as follows:

1. A sends packet to B then starts timer;
2.a. A receives acknowledgement (ACK) from B: Go back to 1;
2.b. A times out: A resends packet to B and starts timer. Go back to 2.

A little thought shows that node B needs to know whether a packet received is a new packet or a retransmission of a previous packet by node A, because the transmission delay is not known exactly and ACKs can get lost too. A widely used strategy to address this problem is to add one bit to each packet header, which results in “0-packets” and “1-packets.” This header bit is flipped by node A each time A sends a new packet (as opposed to a retransmission). This protocol is called the *alternating bit protocol* (ABP). It is desired to model a simple version of ABP, for transmission from A to B only, using the automaton modeling formalism. Assume that the channel can only contain one packet at a time (half-duplex case). Based on the above discussion, the following list of nine events is defined for this system. [This modeling strategy is inspired by that in the book by Tanenbaum (4, sections 3.3.3 and 3.5.1).]

- *lost*: contents of channel lost
- *new0*: 0-packet received by B; ACK sent by B to A; 0-packet delivered by node B
- *ack + 1*: ACK received by A; 1-packet sent by A to B
- *new1*: 1-packet received by B; ACK sent by B to A; 1-packet delivered by node B
- *ack + 0*: ACK received by A; 0-packet sent by A to B
- *repeat0*: 0-packet received by B; ACK sent by B to A
- *repeat1*: 1-packet received by B; ACK sent by B to A
- *timeout + 0*: timeout at A; 0-packet retransmitted to B
- *timeout + 1*: timeout at A; 1-packet retransmitted to B

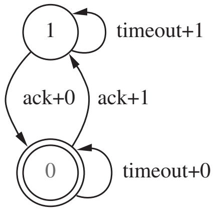

Figure 1. Sender automaton S. The event set is $E_S = \{ack+0, ack+1, timeout+0, timeout+1\}$.

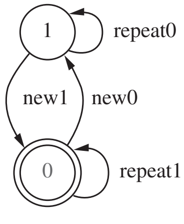

Figure 3. Receiver automaton R.

A packet is "delivered by node B" when B forwards the packet to the application program running at that node.

Three automata are defined as follows: S, the sender automaton, C, the channel automaton, and R, the receiver automaton. They are shown in Figs. 1, 2, and 3, respectively. The software tool DESUMA (5) was used to perform the calculations on automata discussed in this article and to draw the transition diagrams in the figures.[4] The sender has two states: State i models the situation where the sender is attempting to send an i-packet. Similarly, state i of the receiver models the situation where the receiver is expecting an i-packet. The four states of the channel refer to its four possible contents: *EMPTY*, 0- or *1*-packet, and *ACK*. The initial state of the system is chosen to be that where S is sending a 0-packet (state 0 in Fig. 1), C contains a 0-packet (state 0 in Fig. 2), and R is expecting a 0-packet (state 0 in Fig. 3), which is the starting point of the ABP protocol after proper initialization of the communication session between A and B transmission of the first packet. Only the relevant events are included in each automaton. The event set of the sender is $E_S = \{ack + 0, ack + 1, timeout + 0, \quad timeout + 1\}$. The event set of the receiver is $E_R = \{new0, new1, repeat0, repeat1\}$. The event set of the channel is $E_S \cup E_R$ plus the event *lost*. Common events are used to capture the coupling between the sender and the channel and between the receiver and the channel.

The parallel composition $SCR = S||C||R$ is shown in Fig. 4; note that states of SCR are triples formed by the corresponding states of S, C, and R. SCR has 10 reachable states from its initial state (0,0,0), which is less than the 16 possible combinations of states of S, R, and C. Because the only marked states in S, C, and R are their respective initial states, then state (0,0,0) is the only marked state of SCR. Because any state of SCR can eventually reach state (0,0,0), automaton SCR is nonblocking. It can be observed from the transition diagram of SCR that events *new0* and *new1* alternate, and that no *ack+1* events occur between events *new1* and *new0*, and no *ack+0* events occur between events *new0* and *new1*. Thus, it can be concluded that all new packets transmitted by A are eventually delivered by B.

The book by Holzmann (6) may be consulted for further reading on the formal study of communication/computer protocols using discrete-event modeling formalisms such as automata.

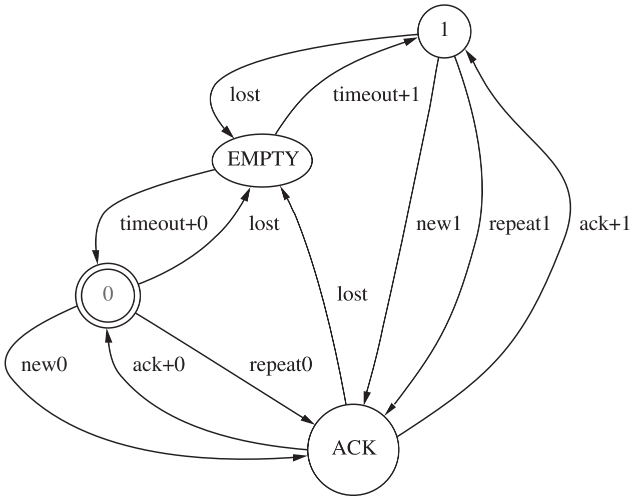

Figure 2. Channel automaton C.

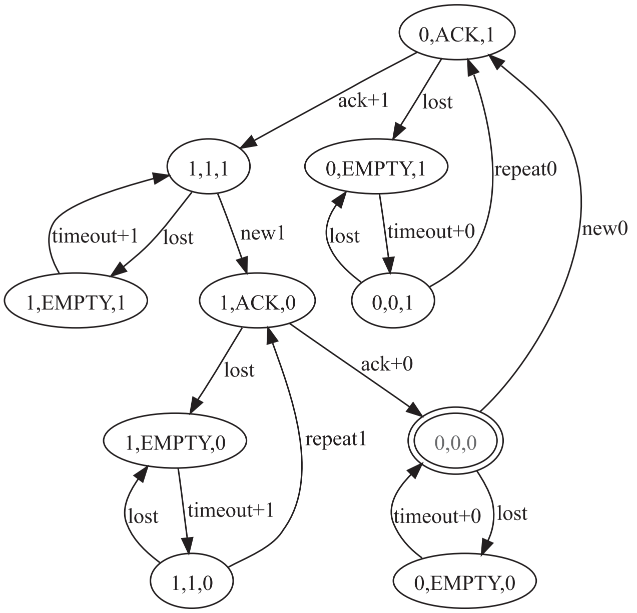

Figure 4. *SCR*: Parallel composition of sender, channel, and receiver.

[4] DESUMA uses the color blue to identify the initial state and draws double circles around marked states. We will indicate in the text the initial state of each automaton.

PARTIALLY OBSERVED SYSTEMS

Automata models of discrete event systems often include descriptive properties for the events, such as observability and controllability, that capture sensing and actuation capabilities. An event is said to be *observable* if it is "seen" by an outside observer of the system behavior. In practice, observable events are those recorded by the sensors attached to the system. Let the set E of events of an automaton G be partitioned into the set of observable events, E_o, and the set of unobservable events, E_{uo}, where $E = E_o \cup E_{uo}$ and $E_o \cap E_{uo} = \emptyset$. From the point of view of the outside observer (whose task may be state estimation, diagnostics, or control), the unobservable transitions of G are not observed; thus, the outside observer may not know the exact state of the system even if it knows the initial state.

To capture the unobservability of events in E_{uo} in the strings of a language, a *projection* operation is introduced. It is denoted by P and it projects strings in E^* to strings in $E_o^* : P : E^* \to E_o^*$ where

$$\begin{aligned} P(\varepsilon) &:= \varepsilon \\ P(e) &:= \begin{cases} e & \text{if } e \in E_o \\ \varepsilon & \text{if } e \in E_{uo} = E \setminus E_o \end{cases} \\ P(se) &:= P(s)P(e) \quad \text{for } s \in E^*, e \in E \end{aligned}$$

(Recall that ε is the symbol for the empty string.) As can be observed from the definition, the projection operation takes a string formed from the event set E and *erases* events in it that are unobservable. The corresponding inverse map $P^{-1} : E_o^* \to 2^{E^*}$ is defined as follows:

$$P^{-1}(t) := \{s \in E^* : P(s) = t\}$$

Given a string of observable events, the inverse projection P^{-1} returns the set of all strings in E^* that project, with P, to the given string. The projection P and its inverse P^{-1} are extended to languages by simply applying them to all the strings in the language. For $L \subseteq E^*$,

$$P(L) := \{t \in E_o^* : (\exists s \in L)\, [P(s) = t]\}$$

and for $L_o \subseteq E_o^*$,

$$P^{-1}(L_o) := \{s \in E^* : (\exists t \in L_o)\, [P(s) = t]\}$$

Observer Automata

Given a language K represented by nonblocking automaton G [i.e., $\mathcal{L}_m(G) = K$ and $\mathcal{L}(G) = \overline{K}$], an automaton representation of language $P(K)$ can be obtained by replacing all occurrences of unobservable events in the transition diagram of G by ε; let us denote the resulting automaton by $P(G)$. The inclusion of ε-transitions makes $P(G)$ a *nondeterministic* automaton. It is desired to obtain a *deterministic* automaton that will represent the language $P(K)$. Such an automaton can be constructed from G by adopting the standard determinization algorithm of automata theory. In the terminology of discrete event systems, the resulting automaton is called the *observer* of G and denoted by $Obs(G)$. The construction of $Obs(G)$ uses the notion of *unobservable reach* of state x, which is the set of states reachable from x by unobservable transitions, including x itself. Formally,

$$UR(x) = \{y \in X : (\exists t \in E_{uo}^*)\, [f(x,t) = y]\}$$

This definition is extended to sets of states $B \subseteq X$ as follows: $UR(B) = \cup_{x \in B} UR(x)$.

Procedure for Building Observer *Obs(G)* of Automaton *G* with Unobservable Events. Let $G = (X, E, f, \Gamma, x_0, X_m)$ be a deterministic automaton and let $E = E_o \cup E_{uo}$.

Then $Obs(G) = (X_{obs}, E_o, f_{obs}, \Gamma_{obs}, x_{0,obs}, X_{m,obs})$ and it is built as follows.

Step 1: Define $x_{0,obs} := UR(x_0)$.
Set $X_{obs} = \{x_{0,obs}\}$.

Step 2: For each $B \in X_{obs}$ and $e \in E_o$, define

$$f_{obs}(B,e) := UR(\{x \in X : (\exists x_e \in B)\, [x = f(x_e, e)]\})$$

whenever $f(x_e, e)$ is defined for some $x_e \in B$. In this case, add the state $f_{obs}(B,e)$ to X_{obs}. If $f(x_e, e)$ is not defined for any $x_e \in B$, then $f_{obs}(B,e)$ is not defined.

Step 3: Repeat Step 2 until the entire *accessible* part of $Obs(G)$ has been constructed.

Step 4: Γ_{obs} is inferred from f_{obs} and $X_{m,obs} := \{B \in X_{obs} : B \cap X_m \neq \emptyset\}$.

By construction, $Obs(G)$ is a deterministic automaton such that $\mathcal{L}(Obs(G)) = P[\mathcal{L}(G)]$ and $\mathcal{L}_m(Obs(G)) = P[\mathcal{L}_m(G)]$. Moreover, let $B(t) \subseteq X$ be the state of $Obs(G)$ that is reached after string $t \in P[\mathcal{L}(G)]$ [i.e., $B(t) = f_{obs}(x_{0,obs}, t)$]. Then $x \in B(t)$ iff X is reachable in G by a string in $P^{-1}(t) \cap \mathcal{L}(G)$. In this sense, state $B(t)$ of $Obs(G)$ is the best possible estimate of the state of G after the observed string of events t.

Observer automata are used to study properties of partially observed discrete event systems. One such property is *diagnosability*, and it is briefly discussed in the next section.

Example. Recall the automaton SCR shown in Fig. 4. Let the set of observable events be $E_o = E_S$, namely, the event set of the sender. The observer automaton of SCR for this set of observable events is given in Fig. 5. The initial state of $Obs(SCR)$ is $\{(0,0,0), (0, EMPTY, 0), (0, ACK, 1), (0, EMPTY, 1)\}$, which is the unobservable reach of state $(0,0,0)$ in Fig. 4.

Diagnoser Automata

When the system model contains unobservable events, one may be interested in determining whether certain unobservable events occurred in the string of events executed by the system. This question is the problem of *event diagnosis*. If these unobservable events of interest model faults of system components, then knowing that one of these events has occurred is very important when monitoring

the performance of the system. The key point here is that as more observations of the system behavior are recorded, uncertainty about prefixes of the string of events executed by the system can be reduced.

Consider for instance automaton SCR of Fig. 4. An observer with knowledge of this model but having only access to the events in E_S at run time would deduce, on the occurrence of *timeout+0* or *timeout+1*, that unobservable event *lost* must have occurred in the string of events executed so far by the system. It is desirable to "automate" this inferencing process using the system model and the string of observable events. The observer $Obs(SCR)$ in Fig. 5 is not sufficient for this purpose; as was discussed earlier, the observer returns the estimate of the state of the system but without accounting for past occurrences of specific unobservable events. Labels can be attached to the states of G in the observer to record execution of specific unobservable events. Assume a single unobservable event denoted by d needs to be diagnosed. Let label N denote that the event has not yet occurred and label Y denote that it has occurred. The label of the initial state x_0 is always N. Once label N has been updated to y to record the occurrence of d, the label will remain Y for all future reachable states. Namely, d causes the label to change from N to Y, after which no additional label change occurs. This label propagation rule can be captured in the form of an automaton. Consider the automaton in Fig. 6. Let us refer to this automaton as the *label automaton* for diagnosing event d and denote it by $A_{label} := (\{N, Y\}, \{d\}, f_{label}, \Gamma_{label}, N, \{N, Y\})$. The state names in A_{label} contain the label information. All the states of A_{label} are marked, and N is the initial state.

An automaton called *diagnoser automaton* and denoted by $Diag(G)$ is built for the purpose of event diagnosis. First, G is composed with A_{label} by parallel composition; note that all states of A_{label} were marked to guarantee that state marking in $G||A_{label}$ is consistent with that in G. Second, the observer of $G||A_{label}$ is constructed for the given set of observable events by applying the construction procedure described earlier. Overall:

$$Diag(G) = Obs(G||A_{label})$$

The parallel composition does not affect the language generated by G but it will result in attaching labels to the states of G as the states of $G||A_{label}$ are of the form $(x, label)$, where $label \in \{N, Y\}$. The label attached to x will depend on the absence (N) or presence (Y) of d in strings that reach x from x_0. State splitting will occur for those states of G that are reachable by strings that contain d and by strings that do not contain d.

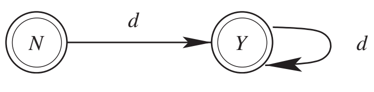

Figure 6. Automaton for building diagnoser.

Example. Recall again the automaton SCR shown in Fig. 4, and let the set of observable events be $E_o = E_S$. Two diagnoser automata are constructed: one for diagnosing unobservable event *lost* the other for diagnosing unobservable event *new0*. The diagnoser for *lost* is shown in Fig. 7; in this case, the label *F1* is used in place of Y[5]. The initial state of this diagnoser is the initial state of the observer in Fig. 5 with label information attached:$\{[(0,0,0), N], [(0, EMPTY, 0), F1], [(0, ACK, 1), N], [(0, EMPTY, 1), F1]$.The diagnoser for *new0* is shown in Fig. 8; in this case, the label *F2* is used in place of Y. Similarly, its initial state is $\{[(0,0,0), N], [(0, EMPTY, 0), N], [(0, ACK, 1), F2], [(0, EMPTY, 1), F2]\}$.

Online (or "on-the-fly") diagnosis of event d is performed by tracking the current diagnoser state in response to the observable events executed by the system G. First, if all states of G in the current state of $Diag(G)$ have label N, then it is certain that event d has not occurred yet. Such a state is called a *negative* state. Second, if all states of G in the current state of $Diag(G)$ have label Y, then it is certain that event d has occurred at

[5] This result is a consequence of the notation employed by the software tool DESUMA.

some point in the past. Such a state is called a *positive* state. If $t \in P[\mathcal{L}(G)]$ has been observed and $f_d(x_{0,d}, t)$ is positive, where $x_{0,d}$ is the initial state of $Diag(G)$ and f_d its transition function, then all strings in $P^{-1}(t) \cap \mathcal{L}(G)$ must contain d. If not, one state of G in $f_d(x_{0,d}, t)$ would have label N as all the strings in $P^{-1}(t) \cap \mathcal{L}(G)$ lead to state $f_d(x_{0,d}, t)$ of $Diag(G)$. Last, if the current state of $Diag(G)$ contains at least one state of G with label N and at least one state of G with label Y, then event d may or may not have occurred in the past. Such a state is called an *uncertain* state. In this case, two strings exist in $\mathcal{L}(G)$, say s_1 and s_2, such that $P(s_1) = P(s_2)$ (hence, they lead to the same state

in $Diag(G)$), where s_1 contains d but s_2 does not. Note that state marking information in $Diag(G)$ is not used in event diagnosis.

Returning to automaton G in Fig. 4 and its diagnoser $Diag(G)$ for event $d = new0$ in Fig. 8, let us consider the two following strings in $\mathcal{L}(G)$: $s_N = (lost\ timeout + 0)^m$ and $s_Y = new0\ (lost\ timeout +\ 0\ repeat0)^m$. String s_Y has the following property: Given any $n \in \mathbb{N}$, m always exists such that the suffix of s_Y after event $d = new0$ has length greater than n. In other words, "s_Y is of arbitrarily long length after d." An examination of the transition diagram of G reveals that the suffix of s_Y after d loops in a cycle of G. Clearly, $P(s_N) = P(s_Y)$. Thus, if s_Y is executed by the system, then it is not possible to diagnose with certainty the occurrence of $d = new0$. After the occurrence of d, $P(s_Y) = P(s_N)$ will cycle in uncertain states in $Diag(G)$. In Fig. 8, a self-loop is caused by event *timeout+0* at state $\{[(0,0,0),N],\ [(0,EMPTY,0),N],\ [(0,ACK,1),F2],\ [(0,EMPTY,1),F2],\ [(0,0,1),F2]\}$. When such strings s_Y and s_N exist, the occurrence of d in s_Y is *not diagnosable*.

To formalize the notion of diagnosability, consider for simplicity languages that are *live*, that is, languages that do not contain terminating strings. A language L is said to be live if whenever $s \in L$, then $e \in E$ exists such that $se \in L$. In terms of automata, an automaton that has no deadlock state generates a live language. Unobservable event d is *not diagnosable* in live language $\mathcal{L}(G)$ if two strings s_N and s_Y exist in $\mathcal{L}(G)$ that satisfy the following conditions: (*1*) s_Y contains d and s_N does not, (*2*) s_Y is of arbitrarily long length after d, and (*3*) $P(s_N) = P(s_Y)$. When no such pair of strings exists, d is said to be *diagnosable* in $\mathcal{L}(G)$.

To avoid situations where G keep executing unobservable events after the occurrence of d, which means that no diagnosis can be performed as the state of $Diag(G)$ never gets updated, it is customary to assume that G has no cycles of unobservable events that are reachable after any occurrence of d. When the property of diagnosability is satisfied, if d occurs, then $Diag(G)$ will necessarily enter a positive state in a bounded number of events after the occurrence of d. To see this, observe that (*1*) G does not have a loop of unobservable events after d (by hypothesis), (*2*) $Diag(G)$ cannot loop in a cycle of uncertain states as this would contradict diagnosability, and (*3*) $Diag(G)$ has a finite set of states. An examination of G in Fig. 4 and its diagnoser $Diag(G)$ for event $d = lost$ in Fig. 7 confirms that event *lost* is indeed diagnosable. The cycle formed by events *ack+0* and *ack+1* in $Diag(G)$ and that involves uncertain states does not lead to the existence of a pair of strings s_Y and s_N violating diagnosability; indeed, no s_Y with the above properties exists, and this cycle will be exited by events *timeout+0* or *timeout+1* should event *lost* occur, taking the diagnoser to positive states.

DISCUSSION

This article has introduced modeling and analysis of discrete event systems represented by finite-state automata. An example from communication protocols was used to illustrate key concepts. The interested reader is encouraged to consult recent textbooks in discrete event systems, such as the books by Cassandras and Lafortune (1), Hrúz and Zhou (3), and Zimmermann (7). More advanced treatments of control of discrete event systems can be found in the notes of Wonham (8) as well as in the book of Iordache and Antsaklis (9). Simulation of stochastic discrete event systems is treated in the book by Law (10).

DISK STORAGE

CONCEPT

Disk storage is a general category of computer storage, in which data are recorded on planar, round, and rotating surfaces (disks, discs, or platters). A disk drive is a peripheral device from which information is collected. Main implementations are hard disks, floppy disks, and optical discs.

Nowadays the term "disk storage" almost exclusively refers to hard disk or magnetic disk, in which a thin spinning disk with magnetic coating is used to hold data. Read/write heads are placed above and/or below the disk so that as the disk spins, each head traverses a circle, called a track, around the disk's upper or lower surface. Since a track can contain more information than we would normally want to manipulate at any one time, each track is divided into arcs called sectors on which information is recorded as a continuous string of bits (1, 2).

The location of tracks and sectors is not a permanent part of a disk's physical structure. Instead, they are marked magnetically through a process called "formatting the disk" (1). This process is usually performed by the disk's manufacturer or an end user, resulting in what are known as formatted disks. In an exemplified Microsoft Windows/MS-DOS formatting operation, some code such as File Allocation Table (FAT) is copied into the boot sector. The boot sector is a special area used by the computer to start the process of booting the computer.

Disk storage is usually managed by a (disk) file system. In the view screen of an application program, a file is a sequence of logic blocks (each block is one or more sectors). A file has a structure that determines how its blocks are organized. The file system also includes software routines used to control access to the storage on a hard disk system. The disk directory knows how big a file is and when it was created. For example, FAT stores the location of the first block for a given filename (Fig. 1) and knows where the other blocks are located.

The physical structure is associated with how a file is actually organized on the storage medium on which it resides. In a Windows environment, FAT is supposed to translate a logic location to a physical location. The FAT contains information about which blocks are assigned to which file. FAT is such an important file on a disk that destroying the FAT makes the disk useless. When a file is written to a hard disk, it is unlikely to have it in a consecutive order. The file (blocks) would be scattered over different sectors. To preserve the proper order, most operating systems maintain a linked list of the blocks on which the file is stored. By means of this list, the operating system can retrieve the sectors in the proper sequence, and therefore, the application software can be written as if the file were stored sequentially, even though the file is actually scattered over various portions of the disk (Fig. 1).

In Unix/Linux environments, indoe (3) is used to preserve a file's order on a disk (Fig. 2). The first 12 of these pointers point to direct blocks; that is, they contain addresses of blocks that contain data of the file. Thus, the data for small (no more than 12 blocks) files do not need a separate index block. The next three pointers point to indirect blocks. The first indirect pointer is the address of a single index block, containing not data, but rather the addresses of blocks that do contain data. This approach could be continued to a second indirect level or third indirect level, depending on the desired maximum file size.

DISK STORAGE HISTORY

In 1956, IBM launched a 305 RAMAC system that consisted of fifty 24-inch diameter disk platters, superseding magnetic cores and magnetic drums. Weighting over a ton and storing 5 MB of data, the 305 RAMAC is the beginning of what we currently call a "disk drive" in which data are stored on magnetic disk platters and accessed by moving disk heads. The random-access, low-density storage of disks also complements the already used sequential-access, high-density storage provided by magnetic tape (4).

Over the past five decades, the disk drive has experienced dramatic development. For example, the recording density has achieved over six orders of magnitude and the performance has been improved over four orders. However, the basic mechanical architecture in disk drive has not been changed too much (4).

The need for large-scale, reliable storage, independent of a particular device, led to the introduction of various disk storage configurations such as redundant array of independent disks (RAID), massive array of idle disks (MAID), network attached storage (NAS), grid-oriented storage (GOS) (5), and storage area network (SAN) that provide efficient, reliable, and remote access to large volumes of data in network and/or grid environments.

DISK STORAGE TECHNIQUES

In disk storage, degradation in performance over time is a serious and common concern. Sometimes, people benchmark their disks when new, and then many months later, they are surprised to find that the disk is getting slower. In fact, the disk most likely has not changed at all, but the second benchmark may have been run on tracks closer to the center of the disk. The tracks on the outside are much longer than the ones on the inside, typically doubling the circumference or more and, therefore containing more data, but the angular velocity of the platters is constant regardless of which track is being read. To counteract the above disk devolution process, an evolutionary disk storage system is constructed.

Modern hard disks employ zoned bit recording (ZBR). Tracks are grouped into zones (6). ZBR stores more sectors

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

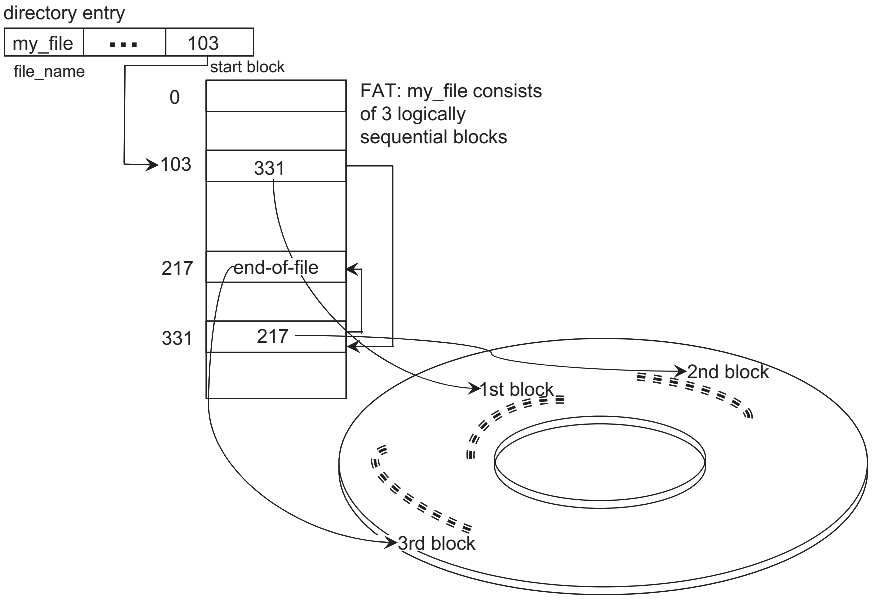

Figure 1. Disk storage replies on a FAT to preserve a file's order in a Microsoft's Windows environment. Each block is one or more sectors.

per track on outer tracks than on inner tracks. The raw data transfer rate of the disk when reading the outside cylinders is much higher than when reading the inside ones.

In the ZBR-based evolutionary disk storage system, the outer 10% of cylinders are grouped into the fast band that absorbs the frequent data, whereas the remaining inner 90% of cylinders, which are grouped into the slow band, contain relatively infrequent data. Object frequency is used to move frequently accessed data to their optimal locations during idle periods, so as not to conflict with system use (7).

The same technique can also be used in a hybrid disk (8). A hybrid hard disk drive was originally concepted by Samsung, which incorporates a flash memory into a magnetic disk. The hybrid disk outplays the above fast band disk at little additional cost on a flash memory.

The combined ultra-high-density benefits of magnetic storage and the low-power and fast read access of NAND technology inspires the construction of redundant arrays of hybrid disks (RAHD; Fig. 3) (9) to offer a possible alternative to today's RAID and/or MAID. Two separable

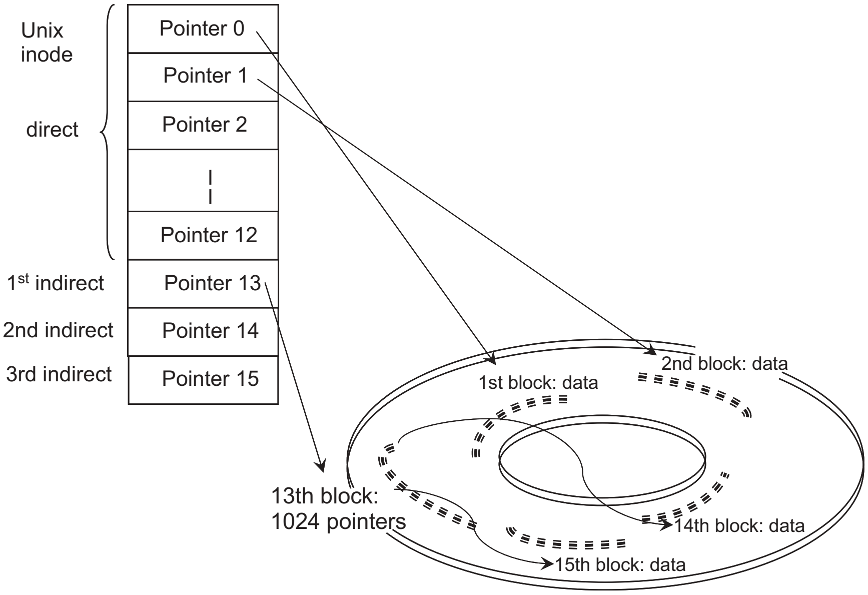

Figure 2. In Unix/Linux environments, indoe is used to preserve a file's order on a disk. The first 12 of these pointers point to direct blocks. The first indirect pointer is the address of a single index block, containing not data, but rather the addresses of blocks that do contain data.

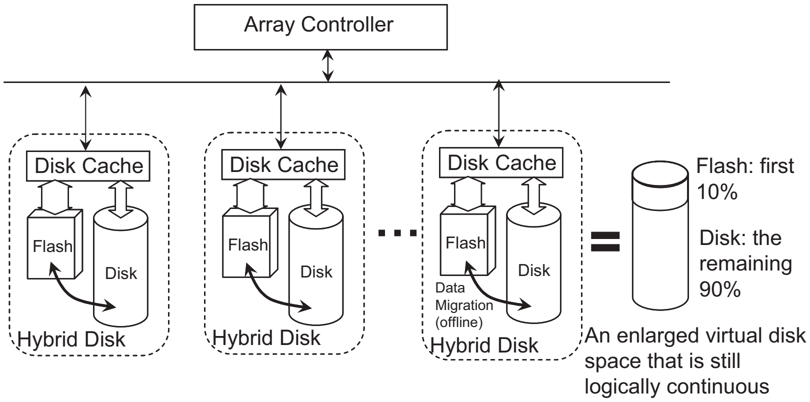

Figure 3. RAHD. Based on the observation that the majority of the disk I/Os are probably going to less than 10% of the total disk space, a flash memory occupies the first 10% of an enlarged disk space that is virtually continuous. Accordingly, the most frequently accessed data blocks are migrated into the flash memory periodically.

working modes have been designed for RAHD arrays: (*1*) high-speed (HS) mode targeting at displaying the full potential speed of hybrid disks; and (*2*) energy-efficient (EE) mode targeting at reducing the energy consumption while maintaining acceptable performance.

In the HS mode, the flash memory always contains frequent data objects. Two schemes have been designed to move the frequent data blocks into the flash memory: (*1*) using the decision tree from data mining to predict the frequencies of data blocks (file attributes of a newly generated file are used to predict its frequency). Blocks with high (predicted) frequency are then written onto the flash memory; (*2*) Tracking the frequencies of data blocks (when the disk is being used) and then migrating the most frequently accessed data blocks into the flash memory during the system idle periods (9). Because of the high skew in common application loads, most requests are likely to be satisfied in the flash memory without bothering the slower disks.

In the EE mode, some “active drives” remain constantly spinning, whereas the remaining “passive drives” are allowed to spin-down after a period of inactivity. A request is directed to the flash in the first instance. If the request is fulfilled by hitting the flash memory, there is no need to awaken the sleeping disk. Otherwise, the request will be forwarded to the disk that is already active or needs to be awakened from sleep (9).

DISK STORAGE APPLICATIONS

Disk storage was originally developed for use with computers. In the twenty-first century, applications for disk storage have expanded beyond computers to include digital video recorders, digital audio players, personal digital assistants, digital cameras, and video game consoles. In 2005, the first mobile phones to include disks were introduced by Samsung and Nokia (10).

Hybrid disks are specially designed for personal and mobile applications, whereas the RAHD can be used more broadly. It is found that a RAHD will provide improvements in performance, power consumption, and scalability. It is a conceptually simple technique for dramatically improving disk storage performance, which is desirable for supercomputers and transaction processing.

E

ENTITY-RELATIONSHIP MODEL

Data modeling is an important phase in the development of a database system. The entity-relationship (ER) model was introduced by Chen (1). This model has been widely used for conceptual data modeling and has become a tool for communication between database designers and end users at the analysis phase of database development. The main constructs of the ER model—entities and relationships and their associated attributes—provide natural modeling concepts of the real world. The ER model has been extended and refined in variuos ways to include additional constructs (2,3) and notations (4).

In this article, we describe the basic concepts in the ER model and some of its extensions. We also discuss how conceptual database design can be carried out using the ER model, the normal form ER diagram, and its properties. Then we present the translation of an ER diagram to the relational database model. Finally, we conclude with several applications of the ER model including view update and schema integration.

BASIC CONCEPTS

The basic concepts in the ER model are entity type and relationship type. An *entity* is an object that exists in our mind and can be distinctly identified. For example, we can have a person entity Ng Hong Kim with IC# 0578936I, or a car entity with licence plate number SBG 3538P. Entities can be classified into different types. An *entity type* contains a set of entities that each satisfy a set of predefined common properties. For example, every person is an instance of the entity type PERSON.

A *relationship* is an association among several entities. For example, we can have a relationship that associates person “Ng Hong Kim” with bank account 50756. A *relationship type* is a set of relationships of the same type that satisfy a set of predefined common properties. Formally, if E1, E2, . . ., En are entity types, then a relationship type R is a subset of the Cartesian product E1 × E2 × . . . × En, that is,

$$\begin{aligned}&\mathrm{R} \subseteq \mathrm{E1} \times \mathrm{E2} \times \ldots \times \mathrm{E}n \qquad \text{or}\\&\mathrm{R} \subseteq \{(\mathrm{e1}, \mathrm{e2}, \ldots, \mathrm{e}n) | \mathrm{ei} \in \mathrm{Ei}, \mathrm{i} = 1, 2, \ldots, n\}\end{aligned}$$

where (e1, e2, . . ., en) is a relationship. For example, we can define the relationship type CUSTACCT to denote the association between customers and the bank accounts that they have, that is,

$$\mathrm{CUSTACCT} \subseteq \mathrm{CUSTOMER} \times \mathrm{ACCT}.$$

The entity types involved in a relationship type are called *participants* of the relationship type. The number of participants in a relationship is called the *degree* of the relationship type. A relationship can be binary, ternary, or even recursive.

An entity type E (or a relationship type R) has attributes that represent the structural (static) properties of E (or R respectively). An *attribute* A is a mapping from E (or R) into a Cartesian Product of n values sets, V1 × V2 × . . . × Vn. If $n \geq 2$, then A is a *composite attribute*. Otherwise, A is a *simple attribute*. For example, Date is a composite attribute with values sets Day, Month, Year. The mapping can be one-to-one (1:1), many-to-one (m:1), one-to-many (1:m), or many-to-many (m:m). If an attribute is a 1:1 or m:1 mapping from E (or R) into the associated value sets, then A is called a *single-valued attribute*, otherwise it is called a *multivalued attribute*.

A minimal set of attributes K of an entity type E that defines a one-to-one mapping from E into the Cartesian product of the associated value sets of K is called a *key* of E. One key of an entity type is designed as the *identifier*. Let K be a set of identifiers of some entity types that participate in a relationship type R. K is called a *key* of the relationship type R if a 1:1 mapping exists from R into the Cartesian product of the associated value sets of K and no proper subset of K has such property. One key of R is designed as the *identifier* of R.

ENTITY-RELATIONSHIP DIAGRAM

The structure (or schema) of a database organized according to the ER approach can be represented graphically using an entity-relationship diagram (ERD). An entity type is represented by the rectangle symbol, whereas a relationship type is represented by the diamond symbol connected by lines to the related entity types. Attributes are denoted by ellipses that are connected by arrowed lines to their owner entity type or relationship type. We use the notation $\leftrightarrow$, $\rightarrow$, $\rightarrow\rightarrow$, $\langle - \rangle\rangle$, to denote that an attribute has a one-to-one (1:1), many-to-one (m:1), many-to-many (m:m), or one-to-many (1:m) mapping, respectively.

Figure 1 shows a simplified ER diagram for a company. The entity type EMP has four attributes: Emp#, Name, Qual, and Child, whereas the entity type PROJ has two attributes, Proj# and Budget. The attributes Emp# and Proj# are the identifiers of the entity types EMP and PROJ, respectively. Hence, they have a mapping of 1:1, as denoted by $\leftrightarrow$. Because each employee has a name and may have many qualifications and each project has a budget, the attributes Name and Budget have a m: 1 mapping, denoted by $\rightarrow$, whereas the attribute Qual has a m:m mapping, denoted by $\rightarrow\rightarrow$. The attribute Child of EMP has a 1:m mapping, which indicates that an employee may have many children but one child can only belong to one employee. The relationship type WORKFOR associates the entity types EMP and PROJ, and it has one attribute Effort. {Emp#, Proj#} is the only key of the relationship type WORKFOR. The cardinalities of EMP and PROJ in WORKFOR are m and m, which indicate that the relationship type WORKFOR between employees and projects is a many-to-many relationship.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

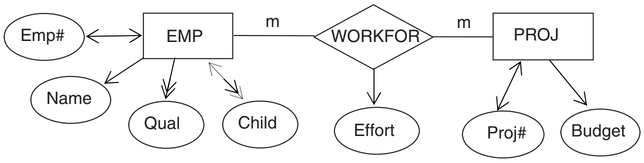

Figure 1. Example ER diagram.

Note that the original ER diagram proposed by Chen (1) does not distinguish between the different mappings for the attributes. As such, one cannot automatically obtain the functional dependencies that involve attributes. The work in Ref. 5 provides a set of heuristics to derive the set of functional dependencies based on the associations among the entity types and their attributes. However, using the arrow notations to specify the mappings for the attributes in the ER diagram as described in Ref. 6, we can directly obtain the functional dependencies as follows:

1. The identifier or 1:1 attributes of an entity type or relationship type functionally determines the single-valued attributes in the entity type or relationship type respectively.
2. The identifier of an entity type or relationship type multidetermines each multivalued attribute in the entity type or relationship type respectively.
3. A 1:m attribute of an entity type or relationship type functionally determines the identifier of the entity type or relationship type.
4. A 1:1 attribute of of an entity type or relationship type functionally determines the identifier of the entity type or relationship type.

For example, in Fig. 1, we can obtain the functional dependencies: Emp# → Name, Emp# →→ Qual, Child → Emp#, Proj# → Budget, {Emp#, Proj#} → Effort.

Figure 2 shows examples of ternary relationship types that involve three participating entity types A, B, and C, as well as their cardinalities. To simplify discussion, we use A, B, and C to denote the identifiers of entity types A, B, and C, respectively. The cardinalities of the participating entity types imply the functional dependencies that hold in the relationship type. Except for the case in which all participating entity types have a cardinality of m (or 1), a participating entity type occurs on the left-hand side of the functional dependency if it has a cardinality of m. Similarly, a participating entity type occurs on the right-hand side of the functional dependency if it has a cardinality of 1. If all the participating entity types have a cardinality of m, as shown in relationship type R1 in Fig. 2(a), then no functional dependency exists in R1. On the other hand, if all the participating entity types have a cardinality of 1, as shown in the relationship type R4 in Fig. 2(d), then the functional dependencies A→ BC, B → AC and C → AB hold in R4. In Fig. 2(b), the functional dependency AB → C in R2, because both A and B have the cardinality m whereas C has the cardinality 1. The functional dependency A → BC holds in R3 [see Fig. 2(c)] because A is the only entity type with the cardinality m.

A relationship type could also have multiple sets of cardinalities for its participating entity types. This finding is illustrated by the relationship type R5 in Fig. 2(e), which has two functional dependencies AB → C and C → A. The first functional dependency AB → C is obtained from the cardinalities m, m, and 1 for A, B, and C, respectively. The second functional dependency C → A is obtained from the cardinalities m, 1 for C and A, respectively. The symbol "/" separates the different sets of cardinalities, whereas the symbol "-" for the participating entity type B in R5 indicates that B is not involved in the second functional dependency. By providing for multiple sets of cardinalities in a relationship type, we can express any number of functional dependencies that involve the participating entity types of the relationship type.

Note that the methods discussed in Refs 5 and 7 cannot express the types of functional dependencies shown in Fig. 2(c–e).

In addition to the specification of key constraints, the ER model also allows *participation constraints* to be specified. The participation constraints of an entity type in a relationship type is denoted by *x:y*, where *x* and *y* denote the minimum and maximum cardinality respectively. These constraints indicate the minimum and maximum number of relationships in which each participating entity can par-

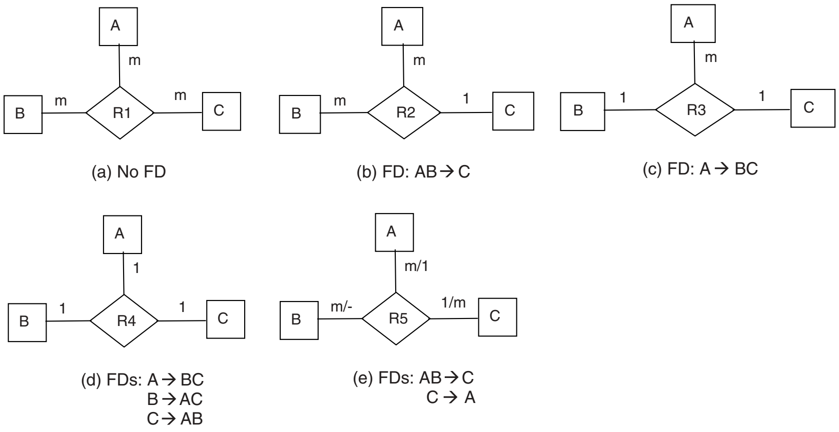

Figure 2. Examples of ternary relationship types.

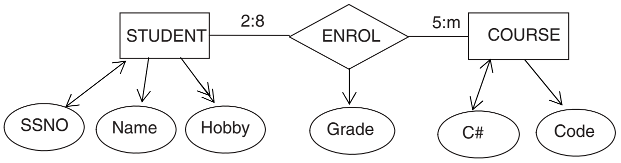

Figure 3. Example to illustrate participation constraints.

ticipate. The values of x and y can be any integer including 0, or m to indicate an unconstrained value. Figure 3 shows the participation constraints of the entity types STUDENT and COURSE in a relationship type ENROL where each student enrolls in a minimum of 2 courses and maximum of 8 courses, and each course should have at least 5 student enrollments with no limit on the class size.

Note that participation constraints cannot be used to express all possible functional dependencies for n-ary relationship types when $n \geq 3$. For example, in Fig. 2(a and b), the participation constraints of all the entity types are either 0:n or 1:n depending on whether the participation is optional or mandatory. Hence, we cannot obtain the functional dependency AB → C for Fig. 2(b) using participation constraints only.

Entity types can be regular or weak. A *weak entity* is one that is existence-dependent on some other entity type, that is, it cannot exist if the other entity does not exist. In Fig. 4(a), the existence of a CHILD entity depends on the existence of an associated EMPLOYEE entity. Thus, if an employee entity is deleted, then its associated child entities are also deleted. The dependent entity type CHILD is a *weak entity type* (represented by a double rectangle), and EMPLOYEE is a *regular entity type*. A relationship type that involves a weak entity type is called *existence-dependency relationship type* (denoted by "EX" together with a relationship type name). Note that an EX relationship type is a one-to-many (1:m) relationship type.

If an entity cannot be identified by the value of its own attributes, but it has to be identified by its relationship with other entities, then such a relationship is called *identifier-dependency relationship type* (denoted by ID). Figure 4(b) shows a typical example of an ID relationship type in which a city can only be uniquely identified together with its country(e.g., the city London can be a city in UK or a city of in the province Ontario in Canada). By definition, an identifier-dependency relationship type is also an existence-dependency relationship type.

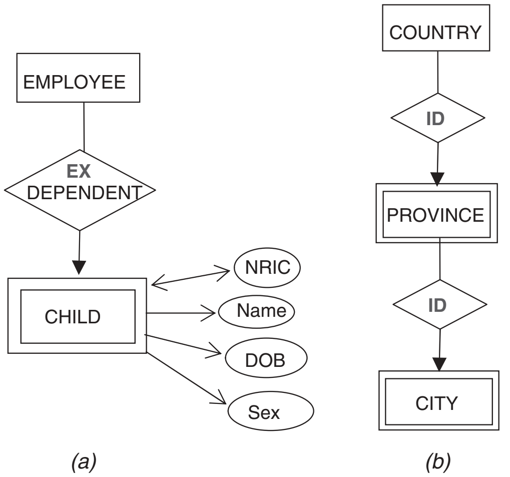

Figure 4. Examples of existence-dependency relationship types and weak entity types.

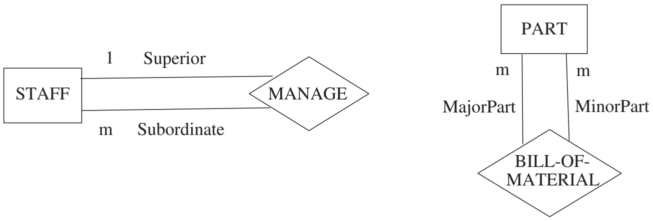

Figure 5. Examples of recursive relationship types.

Relationship types can be *recursive* when they involve an entity type twice. Figure 5 shows the relationship type MANAGE that associates the STAFF entity type twice; one has a *role name* of Superior whereas the other has a role name of Subordinate. Similarly, the relationship type BILL-OF-MATERIAL associates PART entity type twice.

We can also have more than one relationship type between the same set of entity types. Figure 6 shows the two relationship types OWN and LIVE-IN between the entity types PERSON and HOUSE where a person may own many houses but live in one house; a house may be co-owned by several persons and many persons can live in one house.

EXTENDED ER MODEL

The ER model can be extended to include the notions of superclass/subclass relationships between entities as well as specialization and generalization. Set operations such as UNION, INTERSECT, and DECOMPOSE can also be incorporated to link different entity types. We will illustrate these extensions briefly here.

In the real world, entities in an entity type typically can be organized into subgroups that are meaningful and require explicit representation. For instance, in a university database application, the entity type PERSON can be classified even more into STAFF and STUDENT; STAFF can be subclassified into ACAD and ADMIN; STUDENT can be subclassified into UNDERGRAD and GRAD. These entity types can be linked together in an ISA hierarchy as

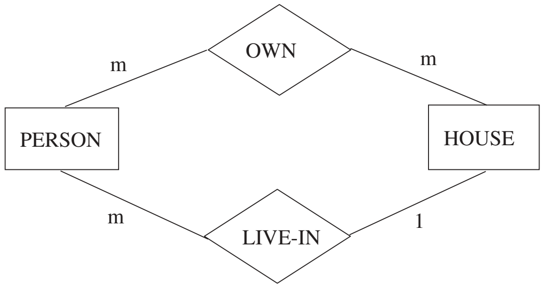

Figure 6. Two relationship types between the same set of entity types.

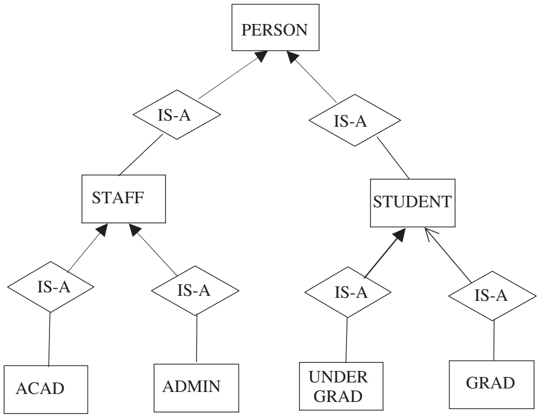

Figure 7. Subtype relationships organized into an ISA hierarchy.

shown in Fig. 7. We call PERSON a superclass of STAFF and STUDENT, whereas STAFF and STUDENT are subclasses of PERSON. The ISA hierarchy is also known as type inheritance. An entity in a subclass represents the same real-world entity in the superclass, and thus it inherits all attributes and relationships of the entity in the superclass in addition to its own specific attributes and relationships.

We can also use set operations to link different entity types together as shown in Fig. 8.

Generalization is the result of taking the union of two or more (lower level) entity types to produce a higher-level entity type. Generalization is the same as UNION, and it is used to emphasize the similarity among lower-level entity types and to hide their differences. *Specialization* is the result of taking a subset of a higher-level entity type to form a lower-level entity type. Specialization is the same as ISA, and its main aim is to highlight the special properties of the lower-level entity types. The attributes of the higher-level entity types are to be inherited by lower-level entity types. Figure 9 shows how an ACCOUNT entity type can be specialized into FIXED-DEP and CHECKING-ACCT entity types. Besides their own specific attributes, that is, FIXED-DEP has InterestRate, StartDate, and MaturityDate, whereas CHECKING-ACCT has OverdraftLimit; these entity types also inherit the attributes Acct#, Name, and Balance from their superclass ACCOUNT. Note that in generalization, every higher-level entity must also be a lower-level entity, whereas specialization does not have this constraint.

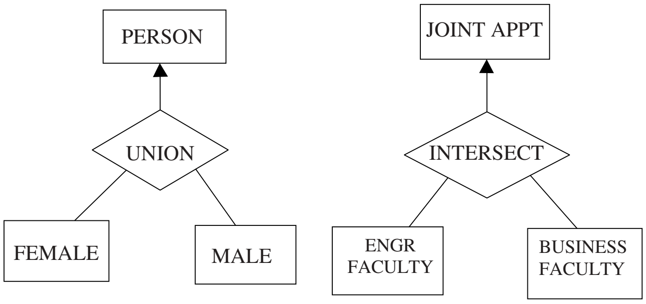

Figure 8. Using set operators to link entity types.

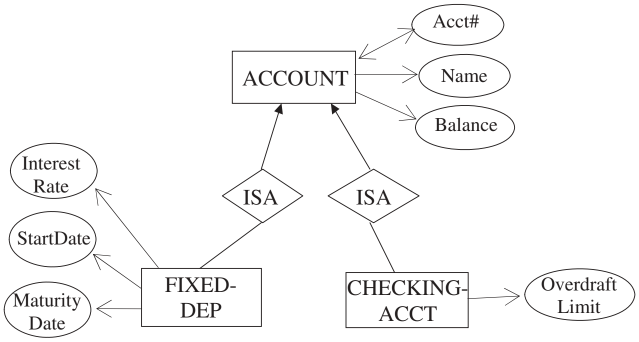

Figure 9. Specialization of ACCOUNT entity type into SAVING-ACCT and CHECKING-ACCT.

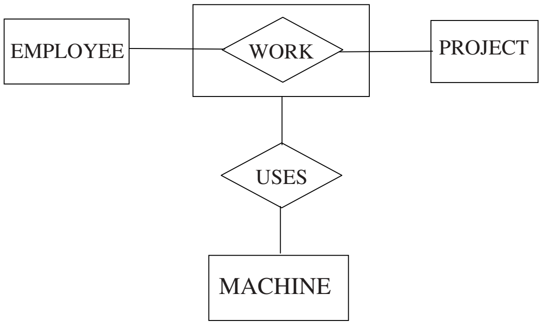

Figure 10. Using aggregations to model relationships among relationships.

Other extensions to the ER model include allowing aggregations and composite constructs to model relationships among relationship types and complex object classes (complex entity types). *Aggregation* is an abstraction through which relationships are treated as higher-level entities. The ER diagram in Fig. 10 treats the relationship type WORK, which is defined between the entity types EMPLOYEE and PROJECT, as a higher-level entity type called WORK. We can then define a many-to-many relationship type between WORK and MACHINE, that is, each work uses many machines and a machine can be used by many works. Note that if the cardinality of a relationship type is not explicitly specified, then by default, it is many-to-many.

We can also use a construct called COMPOSITE to construct complex objects (complex entities) from some other simple and/or complex objects (see Fig. 11). The

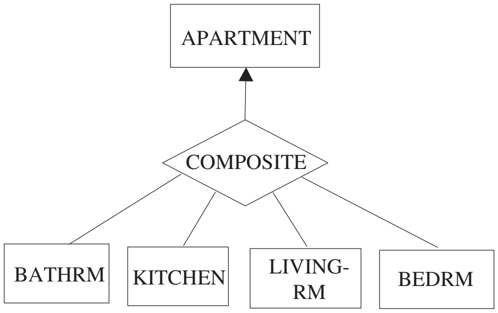

Figure 11. Using the composite construct to model complex objects.

complex object and its component objects are not necessarily type (or object) compatible.

CONCEPTUAL DATABASE DESIGN USING ER MODEL

Using the ER approach for database design has three advantages. First, it is database management system independent. Second, the designer can concentrate on “information requirements” and not on “storage or access efficiency”. Third, the ER diagram is easy to understand by users and database designers. Five main steps to database design exist using the ER approach.

Step 1. Identify the entity types and the attributes that clearly belong to them.

Step 2. Identify the relationship types and their participating entity types as well as the attributes that clearly belong to the relationship types.

Step 3. Identify the remaining attributes, keys, and identifiers of each entity type and relationship type and obtain an ER diagram.

Step 4. Convert the ER diagram to a normal form ER diagram (NF-ER).

Step 5. Translate the NF-ER diagram to a relational database schema (or other data models such as object-oriented data model).

We will cover the first three steps in this section and discuss Steps 4 and 5 separately in the subsequent two sections.

To accomplish steps 1 to 3 properly, the database designer not only has to interview users but also must study the system specification documents that are written in some natural language, such as English. The work in Ref. 8 presented guidelines/rules for translating English sentences into ER diagrams. We list some guidelines below.

R1. A common noun (such as student and employee) in English corresponds to an entity type in an ER diagram.

Note that proper nouns such as John, Singapore, and New York City are entities, not entity type.

R2. A transitive verb in English corresponds to a relationship type in an ER diagram. Note that a transitive verb must have an object.

For example, a person may own one or more cars and a car is owned by only one person. The cardinalities of PERSON and CAR in the OWNS relationship type are 1 and m, respectively, and the participation of PERSON in the OWNS relationship type is optional as some people may not own any car [see Fig. 12(a)].

R3. An adjective in English corresponds to an attribute of an entity type in an ER diagram.

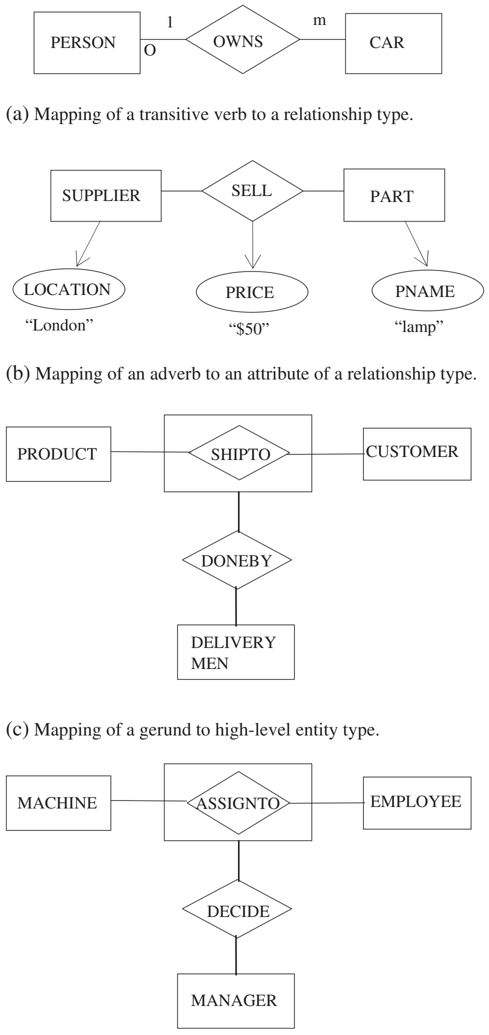
R4. An adverb in English corresponds to an attribute of a relationship type in an ER diagram.

For example, the ER diagram in Fig. 12(b) models a London supplier sells a part with part name lamp for $50.

R5. A gerund in English corresponds to a high-level entity type (or aggregation) converted from a relationship type in an ER diagram. A gerund is a noun in the form of the present participle of a verb.

For example, “shopping” in the sentence “I like shopping.” Figure 12(c) shows the ER diagram that models the situation in which products are shipped to customers, and the shipping is done by delivery men.

R6. A clause in English is a high-level entity type abstracted from a group of interconnected low-level entity and/or relationship types in an ER diagram. A clause is a group of words that contains a subject and a verb, but it is usually only part of a sentence.



(a) Mapping of a transitive verb to a relationship type.

(b) Mapping of an adverb to an attribute of a relationship type.

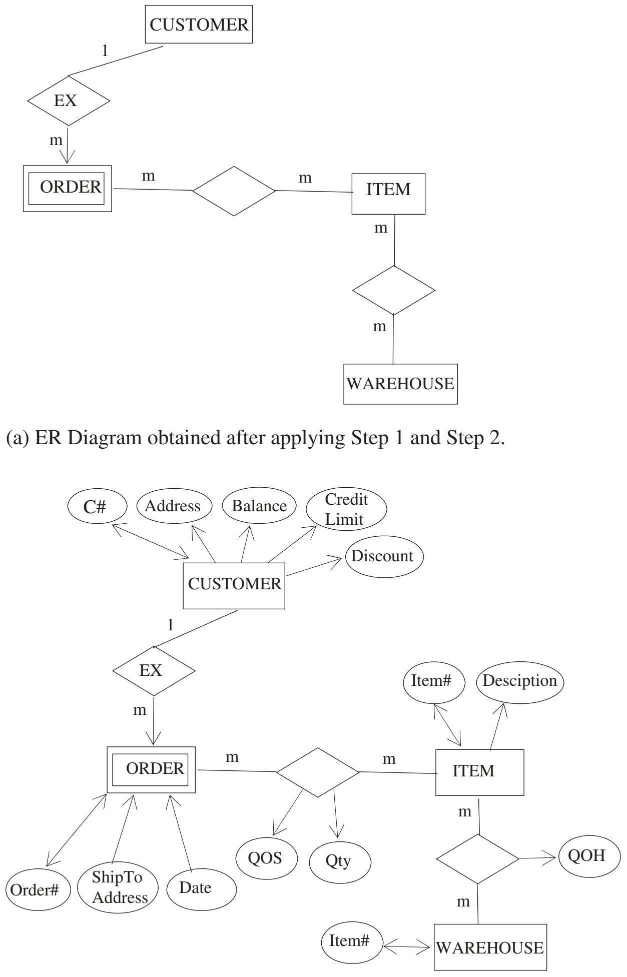
(c) Mapping of a gerund to high-level entity type.

(d) Mapping of a clause to high-level entity type

Figure 12. Examples to illustrate the translation of english sentences into ER diagrams.

For example, Fig. 12(d) models the case in which managers decide which machine is assigned to which employee.

Example 1. We will now work through a case study to illustrate how an ERD can be obtained. Suppose we need to design a database for an order-entry system. The database will capture the following information about customers, items, and orders. For each customer, we record the customer number (unique), valid "ship to" address (several per customer), balance, credit limit, and discount. For each order, we have a header that contains customer number, "ship to" address, date of order, and detail lines (several per order), each giving the item number and quantity ordered. For each item, we record the item number (unique), warehouses, quantity on hand at each warehouse, and item description. For internal processing reasons, a quantity outstanding value is associated with each detail line of each order. Figure 13(a) shows the ERD after performing Step 1 and Step 2. After Step 3, we will obtain the ERD as shown in Fig. 13(b).



(a) ER Diagram obtained after applying Step 1 and Step 2.

(b) ER Diagram obtained after applying Step 3 by adding attributes.

Figure 13. Example to illustrate conceptual database design using the ER diagram.

TRANSLATION OF (NORMAL FORM) ER DIAGRAM TO RELATIONAL MODEL

After obtaining the conceptual design in ER diagram, we can now map it to the relational model. The resulting relational schema may not be in normal form and we can use the normalization theory in relational model to derive a third normal form relational schema. Alternatively, we can first convert the ER diagram to a normal form (6) before mapping it to the relational model, and the relational schema obtained is guaranteed to be in normal form. In this section, we will discuss the steps to translate an ER diagram to the relational schema. The algorithm to obtain a normal form ER diagram will be presented in the next section.

Step 1. Assign role names to certain arcs in a cycle in the ER diagram to conform to the universal relation assumption. Here, a cycle in an ER diagram is defined as a cycle in the corresponding graph of the ER diagram in which all entity types and relationship types are nodes in the graph and arcs that connect entity types and relationship types are edges in the graph, except for cycles formed only by ISA, UNION, INTERSECT, and DECOMPOSE special relationships.

Step 2. Assign identifiers for entity types involved in special relationship such as ISA, UNION, INTERSECT, and DECOMPOSE.

Step 3. Generate relations for each entity type.

a) All the m:1 and 1:1 attributes of an entity type E form a relation. The keys and identifier of E are the keys and primary key of the generated relation.
b) Each m:n attribute and the identifier of E form an all key relation.
c) Each 1:m attribute and the identifier of E form a relation with the 1:m attribute as its key.

Note that all composite attributes are replaced by their components in the generated relations.

Step 4. Generate relations for each regular relationship type R.

a) All the identifiers of the entity types participating in R and all the m:1 and 1:1 attributes of R form a relation. Keys and 1:1 attributes of R are keys of the generated relation, and the identifier of R is the primary key of the generated relation.

   Furthermore, if A → B is a full functional dependency in the generated relation and A is not a key of R, then we record A → B as a constraint of the relation generated.
b) Each m:m attribute of R and the identifier of R form an all key relation.
c) Each 1:m attribute of R and the identifier of R form a relation with the 1:m attribute as the key of the relation.

Example 2. We will use the ER diagram in Fig. 14 to illustrate the translation process. The role names AX, AY,

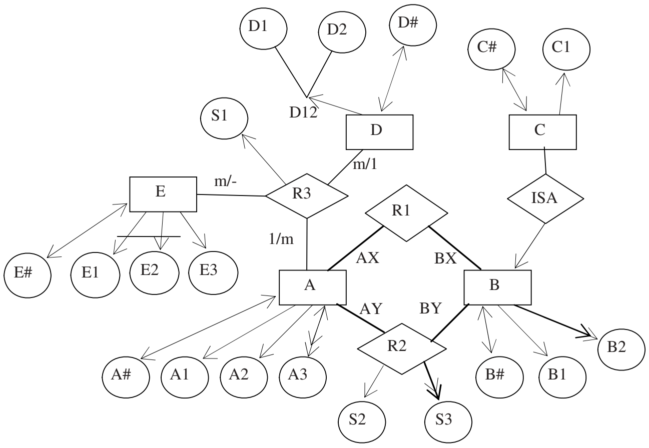


Figure 14. Example to illustrate translation of ER diagram to relations.

BX, and BY are assigned by Step 1. Note that the relationship type R3 has two functional dependencies, namely {E#, D#} → A#, and A# → D#, we will have {E#, D#} and {A#, E#} as the keys of R3, and we designate {E#, D#} as the identifier of R3. The relations generated are as follows:

For entity type A, AE1 A#, A1, A2) and AE3(A3, A#).

For entity type B, BE1(B#, B1) and BE2(B#,B2).

For entity type C, CE1(C#, C1).

Note that C# is generated and we have the constraint C# ISA B# of BE1, that is, CE1[C#] ⊆ BE1[B#].

For entity type D, DE1(D#, D1, D2).

Note that D12 is replaced by D1 and D2.

For entity type E, EE1(E#, E1, E2, E3) where E# is primary key.

For relationship type R1, R1R1(AX, BX).

Note that AX and BX are generated, and we have the constraints AX ISA A# and BX ISA B#.

For relationship type R2, R2R1(AY, BY, S2) and R2R2(AY, BY, S3).

Again, AY and BY are generated and we have the constraints AY ISA A# and BY ISA B#.

For relationship type R3, R3R1(A#, E#, D#, S1).

{D#, E#} is the primary key and we have the constraint A# → D#. Note that R3R1 is in 3NF but not in BCNF. Furthermore no relation is generated for the ISA relationship. Instead, it is translated to C# ISA B#.

Similarly, the ER diagram in Fig. 15 can be translated to the following relations.

Entity relations: Employee (E#, Name, Salary)
Employee_Hobby (E#, Hobby)
Employee_skill (E#, Skill) Project (P#, Pname, Budget)
Relationship relation: Emp_Proj (E#, P#, Progress)

NORMAL FORM ER DIAGRAM

The work in Ref. 6 introduced the notion of a normal form ER diagram. The objectives for defining a normal form for (ERD) are threefold. First, it aims to capture and preserve all the semantics of the real world of a database that can be expressed in terms of functional, multivalued, and join dependencies, by representing them explicitly in the ERD. Second, it ensures that all the relationship types represented in the ERD are nonredundant. Finally, the normal form ERD ensures that all the relations translated from the ERD are in good normal form: either in 3NF or 5NF.

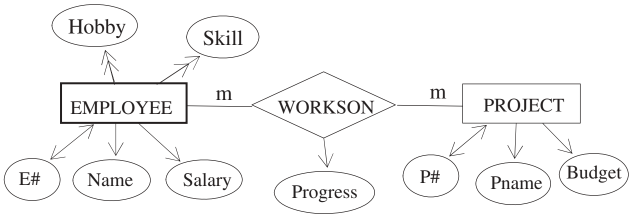

Figure 15. Example ER diagram.

A normal form ERD may consist of composite attributes, multivalued attributes, weak entity types and special relationships such as existence dependent, identifier dependent, ISA, UNION, INTERSECT, and DECOMPOSE relationships. The main steps for deriving a normal form ERD are as follows:

1. Define the set of basic dependencies of an entity type
2. Define the entity normal form (E-NF)
3. Define the set of basic dependencies of a relationship type
4. Define the relationship normal form (R-NF)
5. Define the set of basic dependencies of an ERD
6. Define the normal form ERD (ER-NF)
7. Convert an ERD to a normal form ERD

Definition 1. The set of *basic dependencies of entity type* E with identifier K, denoted by BD(E), is defined as:

(i) For each m:1 attribute A of E, we have K → A ∈ BD(E)
(ii) For each 1:m multivalued attribute A of E, we have A → K ∈ BD(E)
(iii) For each 1:m or m:n multivalued attribute A of E, we have K→→ A ∈ BD(E)
(iv) For each key K1 of E, K1 ≠ K, K → K1 ∈ BD(E) and K1 → K ∈ BD(E)
(v) No other FDs or MVDs are in BD(E).

Definition 2. An entity type E is in E-NF if and only if all the given FDs and MVDs which only involve the attributes of E, can be derived from BD(E).

Informally, BD(E) is the set of functional dependencies and multivalued dependencies involving only the attributes of E, which are explicitly represented in the ERD.

Consider the ERDs in Fig. 16. The entity type EMPLOYEE in Fig. 16(a) has the set of basic dependencies BD(EMPLOYEE) = {E# → SSNO, Name, Gender; SSNO →

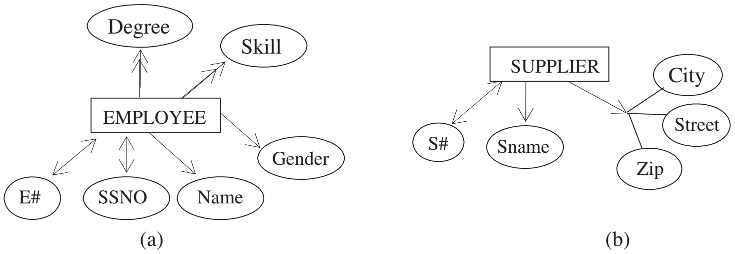

Figure 16. ER diagrams to illustrate basic dependencies in entity types.

E#; E# →→ Skill; E# →→ Degree}. Furthermore, EMPLOYEE is in E-NF. In contrast, the entity type SUPPLIER in Fig. 16(b) is not in E-NF. It is because we have BD(SUPPLIER) = {S# → Sname, S# → {City, Street, Zip}}. However, the two known functional dependencies {City, Street} → Zip, and Zip → City cannot be derived from BD(SUPPLIER).

Definition 3. Let R be a relationship type with identifier K, and $\mathcal{F}$ be the associated set of FDs that only involve the identifiers of the set of entity types participating in R. The set of basic dependencies of R, BD(R) is defined as:

(i) For each 1:1 attribute A of R, we have $K \rightarrow A \in BD(R)$ and $A \rightarrow K \in BD(R)$

(ii) For each m:1 single valued attribute A of R, we have $K \rightarrow A \in BD(R)$

(iii) For each 1:m multivalued attribute A of R, we have $A \rightarrow K \in BD(R)$

(iv) For each 1:m or m:m multivalued attribute A of R, we have $K \rightarrow\rightarrow A \in BD(R)$

(v) Let $A \rightarrow B$ be a full functional dependency in $\mathcal{F}$ such that A is a set of identifiers of entity types participating in R, and B is the identifier of some entity type participating in R. If A is a key of R or B is part of key of R, then we have $A \rightarrow B \in BD(R)$

(vi) No other FDs or MVDs are in BD(R).

In other words, BD(R) is the set of functional dependencies and multivalued dependencies involving only the identifiers of the participating entity types of R and attributes of R that are explicitly represented in the ERD.

Definition 4. An relationship type R of an ERD is in R-NF if and only if all the given FDs and MVDs that only involve the attributes of R and the identifiers of the entity types participating in R are implied by BD(R).

Consider the ERDs in Figure 17. ABD is the identifier of relationship type R1 in Fig. 17(a). BD(R1) = ABD → EG, G → ABD, ABD →→ F, ABD → C} and R1 is in R-NF.

Suppose we have $C \rightarrow D \in \mathcal{F}$, then C → D is also in BD(R1) by definition and hence R1 is still in R-NF. In Fig. 17(b), we have BD(R2) = {AB → CD} and $C \rightarrow D \notin BD(R2)^+$. Hence, R2 is not in R-NF.

Definition 5. The set of basic dependencies of an ERD D, denoted by BD(D), is defined as the union of the sets of basic dependencies of all the entity types of D and the sets of basic dependencies of all relationship types of D.

Definition 6. An ERD D is in normal form (ER-NF) if is satisfies the following conditions:

(1) All attribute names are distinct and of different semantics.

(2) Every entity type in the ERD is in E-NF.

(3) Every relationship type in the ERD is in R-NF.

(4) All given relationships and dependencies are implied by BD(D).

(5) No relationship type (including its attributes) can be derived from other relationship types by using join and projection.

Note that condition 1 in Definition 6 is required in order to conform to the universal relation assumption; condition 2 ensures that all relations generated for all entity types are in 5NF; condition 4 ensures that ERD has captured all relationship types and dependencies of the given database; conditions 3 and 5 ensure that all relations generated for all regular relationship types are either in 3NF or in 5NF, and no relation exists in BCNF but not in 4NF or 5NF, that is, no

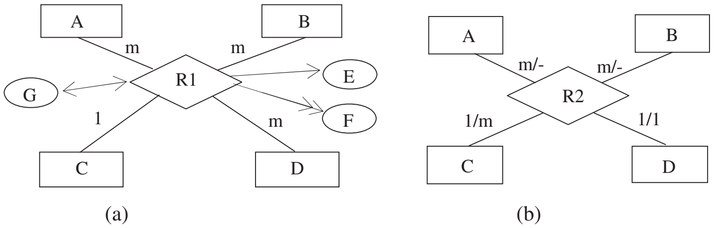

Figure 17. ER Diagram to illustrate basic dependencies in relationship types.

relationship type (together with its attributes) can be derived from other relationship types using join and projection operations.

We have the following important property.

Theorem. The relations generated for each of entity type of a NF-ER diagram are in 5NF. The relations generated for each of the relationship type of a NF-ER diagram are either in 3NF or 5NF.

Based on the above definitions, we can now convert an ERD to a normal form ERD as follows.

Step 1. Ensure that all attribute names are unique and of different semantics to conform to the Universal Relation Assumption.

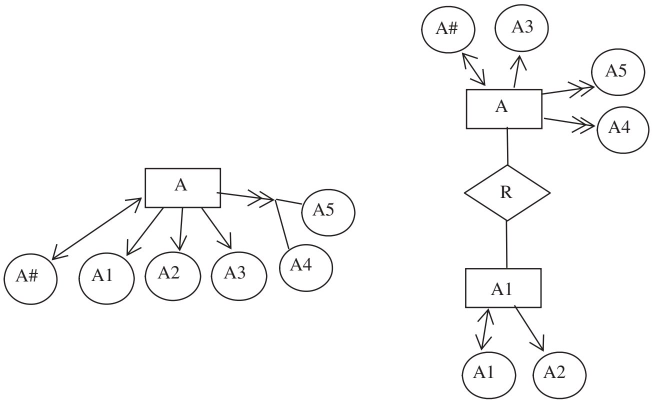
Step 2. Convert any non E-NF entity type to E-NF. Remove all undesirable FDs and/or MVDs by introducing new entity types and relationship types.

Step 3. Convert any non–R-NF relationship type to R-NF. Remove all undesirable FDs, MVDs, and/or JDs by introducing new entity types and relationship types or by splitting the relationship type into smaller ones.

Step 4. Remove relationship types that have no associated attributes and are equal to the join and/or projection of other relationship types as they can be derived.

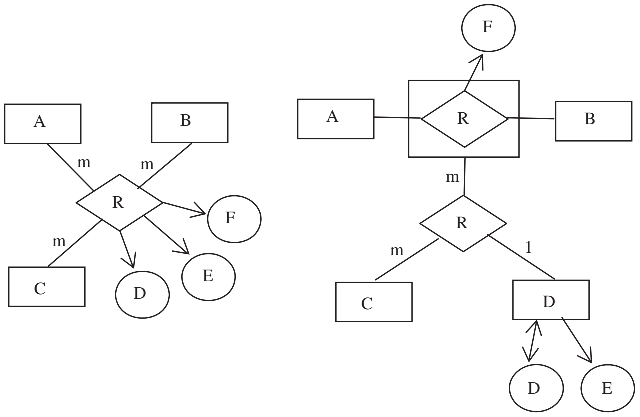
We will now give two examples on how to convert an ERD that is not in NF-ERD to one that is in NF-ERD. Details of the conversion process can be found in Ref. 6.

Example 3. Consider the ERD in Fig. 18(a). If the entity type A has additional dependencies A1 → A2 and A# →→ A4, then A is not in E-NF. To make A into entity normal form because A1 → A2 ∉ $BD(A)^+$, we convert the attribute A1 into an entity type with identifier A1 and a single-valued attribute A2, and create a binary relationship type R between A and A1. Furthermore, because A# →→ A4 ∉ $BD(A)^+$, we split the multivalued composite attribute into two multivalued attributes A4 and A5. The resulting ERD is shown in Fig. 18(b). Note that the two dependencies A1 → A2 and A# →→ A4 are now explicitly represented in Fig. 18(b). The entity types A and A1 are in E-NF.



(a) A is not in E-NF (b) A is now in E-NF

Figure 18. ER diagram to illustrate entity normal form.



(a) R is not in E-NF (b) ERD is now in NF-ERD

Figure 19. Example to illustrate normal form ERD.

Example 4. Next, let us examine the ERD in Fig. 19(a). If the relationship type R has additional dependencies AB → F and D → E, then R is not in R-NF. Because D → E ∉ $BD(R)^+$, we convert D into an entity type with identifier D and attribute E, and connect the entity type D with the relationship type R. Because AB → F ∉ $BD(R)^+$, we create a new binary relationship type R1 between A and B with single-valued attribute F. We make R1 as a high-level entity type (aggregation) and redefine the relationship type R as a relationship type that associates this high-level entity type R1 and entity types C and D. The resulting ERD shown in Fig. 19(b) is a NF-ERD.

CONCLUSION

In this chapter, we have reviewed the basic concepts of the ER model as well as some commonly used extensions. The semantics captured in the ER model provides for the intuitive modeling of real-world concepts. We have discussed how the conceptual design of a database can be carried out using the ER model and the translation to the relational database. We have also shown the properties of a normal-form ERD and how it can be obtained.

Besides conceptual database design, the semantics in the ER model also play an important role in view updates (9) and schema integration (10,11). Views are external schemas. They increase the flexibility of a database by allowing multiple users to observe the data in different ways. Views also provide logical independence by allowing some changes to be made to the conceptual schema without affecting the application programs. For a view to be useful, users must be able to apply retrieval and update operations to it. These update operations on the view are allowed only if they can be translated into the corresponding update operations on the conceptual schema instances.

Reference 12 describes how one can automatically generate the external-to-conceptual mapping and the conceptual-to-internal mapping of an ER based database management system. Using this mapping, retrievals from a view can always be mapped into equivalent retrievals from the conceptual schema. A mapping is also required to translate view updates into the corresponding updates on the conceptual schema. However, such a mapping does not always exist, and even when it does exist, it may not be unique. We can model views using ER diagrams and use the semantics captured to help resolve any ambiguity when translating view updates. Ling and Lee (8) develop a theory within the framework of the ER approach that characterizes the conditions under which mappings exist from view updates into conceptual schema updates. Concepts such as virtual updates and three types of insertions are introduced.

Schema integration is essential to define a global schema that describes all the data in existing databases participating in a distributed or federated database management system. Lee and Ling (10) describe how the semantics in the ER model can facilitate schema integration. For example, the ER model can easily help in the resolution of structural conflicts, that is, when related real world concepts are modeled using different constructs in different schemas. An attribute in one schema can be transformed into an equivalent entity type in another schema without any loss of semantics or functional dependencies which approaches based on the relational model have not considered. Furthermore, from the ER model, we can conclude that an entity type in one schema cannot be equivalent to (or modeled as) a relationship set in another schema, that is, this type of conflict inherently does not exist.

The ER model captures semantics that are essential for view update translation and meaningful schema integration. Many semantics cannot be captured by the relational model, and therefore, view update translation and schema integration using the relational model is limited.

MULTIAGENT SYSTEMS

INTRODUCTION

A multiagent system (MAS) is a system composed of several computing entities called "agents." Being a sub-discipline of distributed artificial intelligence (DAI), multiagent systems research represents a new paradigm for conceptualizing, designing, and implementing large-scale and complex systems that require spatially, functionally, or temporally distributed processing (1–3).

Agents in a MAS typically have distributed resource, expertise, intelligence, and processing capabilities, and they need to work collaboratively to solve complex problems that are beyond the capabilities of any individuals. MAS research covers a very broad areas, including multiagent learning, distributed resource planning, coordination, and interagent communications, to mention only a few (1,4,5), and many studies have insights drawn from other disciplines, such as game theories, communications research, and statistical approaches. In addition to the wide applications in industries (e.g., Network-Centric Warfare, air-traffic control, and trading agents), multiagent systems have also been used in simulating, training, and supporting collaborative activities in human teams.

Different perspectives exist on multiagent systems research. From the AI perspective, people may focus on fundamental issues such as coordination algorithms, agent architectures, and reasoning engines. From the engineering perspective, people may concern system building methodologies, property verifications, and agent-oriented programming. Detailed reviews of MAS from several distinct perspectives have been provided in Sycara (3), Stone and Veloso (2), Bond and Gasser (6), O'Hare and Jennings (7), and Huhns and Singh (8). The objective of this article is to briefly present a view of MAS from the perspective of multiagent teamwork. The remainder is organized as follows. The next section introduces the concept of shared mental models that underpin team-based agent systems. Then some generic multiagent architectures in the literature are described, and the issue of interagent coordination is discussed. Communication and helping behaviors are reviewed, and a summary is given in the last section.

SHARED MENTAL MODELS

The notion of shared mental models (SMMs) is a hypothetical construct that has been put forward to explain certain coordinated behaviors of human teams (6,9). An SMM produces a mutual situation awareness, which is the key for supporting many interactions within a team that lead to its effectiveness and efficiency (10). The scope of shared mental models is very broad, which may involve shared ontology (11), common knowledge and/or beliefs (12), joint goals/intentions (13), shared team structures (5), common recipes (14), shared plans (15), and so on.

A shared ontology provides the common vocabulary for a group of agents to communicate directly. Without a shared ontology, agents can communicate only through a "broker" who provides translations between different ontologies. Because of its importance, ontology is covered in KQML (Knowledge Query and Manipulation Language), and many efforts such as DARPA Agent Markup Language (DAML) have been aimed to facilitate sharing ontology on the semantic web (11).

Agents in a MAS typically have a collection of overlapped knowledge/beliefs that serve as a common basis for the agents to understand and respond to each other's behaviors. Such common knowledge/beliefs may be the description of domain tasks (up to certain levels of detail), the communication protocols to be used, the social laws or social normatives to follow, and so on.

Some MASs also allow individual agents to have a partial picture of the organizational structure (5), which may include information regarding membership of a group, sub-group relations, predetermined group leader, roles each member can play, capability requirements on each role, and so forth. Having a well-defined structure does not imply that the structure is static. A system can still have flexibility in changing its structure through dynamically assigning responsibility to the agents in the system. Having a shared team structure enables an agent to develop a higher level abstraction about the capabilities, expertise, and responsibilities of other agents. It is important for an agent to initiate helping behaviors proactively.

Having a shared objective (goal) is a key characteristic of agent teams (13,16–18), a kind of tightly coupled MASs. A common goal can serve as a cohesive force that binds team members together (16). To distinguish team behavior from coordinated individual behavior (individuals' goal happen to be the same), a notion of joint mental attitude (i.e., joint intention) is introduced based on the concept of joint persistent goal (13). A joint intention can be viewed as a shared commitment to perform a collective action to achieve a shared goal. The joint intentions theory requires a team of agents with a joint intention to not only each try to do its part in achieving the shared goal but also commit to informing others when an individual agent detects that the goal has been accomplished, becomes impossible to achieve, or becomes irrelevant. Thus, having a joint intention not only means all the team members have established the same goal, but also it means that they have committed to maintaining the consistency about the dynamic status of the shared goal. The joint intentions theory is important because it not only offers a framework for studying numerous teamwork issues, but also it provides a foundation for implementing multiagent systems (4).

Joint intentions prescribe how agents should behave when certain things go wrong; it thus indicates that robust multiagent systems can be implemented to work in a dynamic environment if agents can monitor joint intentions and rationally react to changes in the environment.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Jennings pointed out that this is desirable but not sufficient (14). He proposed the joint responsibility model with the explicit representation of cooperation using common recipes. A common recipe provides a context for the performance of actions in much the same way as the joint goal guides the objectives of the individuals (14). Mainly focusing on handling unexpected failures, the joint responsibility model refines Cohen and Levesque's work (16,19) on joint intentions and explicitly captures different causes of recipe failures. In particular, it clearly specifies the conditions under which an agent involved in a team activity should reconsider its commitments (three related to joint goal commitment: goal has been attained, goal will never be attained, or goal motivation no longer present; four related to common recipe commitment: desired outcome is available, or recipe becomes invalid, untenable, or violated). The model furthermore describes how the agent should behave both locally and with respect to its fellow team members if any such situations develop. It should drop the commitment and must endeavor to inform all other team members so that futile activities can be stopped at the earliest possible opportunity.

Although Jennings gave a simple distributed planning protocol for forming teams and for achieving agreement on the details (i.e., timing constraints, and actual performers) of common recipe (14), Grosz and Kraus prescribed a more general process for collaboratively evolving partial shared plans into complete shared plans (15,20). A shared plan is characterized in a mental-state view as a particular collection of beliefs and intentions. An agent is said to have a shared plan with others if and only if the agent works toward establishing and maintaining those required mental attitudes, and it believes that the other agents do so likewise. The common recipes in the SharedPlan theory and in the joint responsibility model have different meanings. In the joint responsibility model, each team member will have the same picture of the common recipe being adopted. Whereas in the SharedPlan theory, even though the common recipe is complete from the external, different team members may have different partial views of the common recipe being considered. In pursuing their common goals, it is the shared plans that ensure team members cooperate smoothly rather than prohibit each other's behavior, which may occur otherwise because of the partial views of common recipes.

Jennings admitted that an agent must track the ongoing cooperative activity to fulfill its social roles (14). However, it is insufficient to allow agents to monitor simply the viability of their commitment through continuously monitoring the relevant events that may occur within the system, as is implemented in GRATE*. The monitoring of teamwork progress is also important for agents to gain awareness of the current context so that they can (*1*) better anticipate others' needs (e.g., relevant information needs) and avoid performing irrelevant actions (e.g., communicating irrelevant information), and (*2*) dynamically adapt the team process to external changes. For example, the already executed part of a team process may never be re-invoked again; thus, the associated information-needs become no longer active. A team process may include decision points, each of which can specify several potential ways to proceed based on the current situation. Each team member needs to track the team's choices at these points because they may affect significantly their information-needs in the future. The CAST (5) system implements a richer notion of shared mental models that covers the dynamic status of team processes. Each member of a CAST agent team can monitor dynamically the progress of team activities that are represented internally as Petri nets.

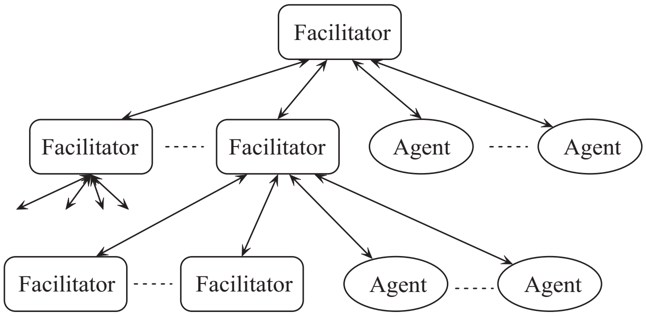

Figure 1. Facilitator-based architecture.

MULTIAGENT ARCHITECTURES

We here focus on multiagent architectures only. Individual agent architectures such as reactive architectures and BDI-style architectures (21), are beyond the scope.

Multiagent architectures can be classified into two categories: facilitator-based architectures and layered architectures. Figures 1 and 2 illustrate a generic facilitator-based architecture and a generic layered architecture, respectively.

In a facilitator-based architecture, facilitator agents play an important role in linking individual agents. Typically, a facilitator maintains knowledge that records the capabilities of a collection of agents or subfacilitators and uses that knowledge to establish connections between service requesters and providers. As well as providing a general notion of transparent delegation, facilitators also offer a mechanism for organizing an agent society in a hierarchical way. OAA (Open Agent Architecture) (22) is a representative of facilitator-based architectures. OAA adopts a blackboard-based framework that allows individual agents to communicate by means of goals posted on blackboard controlled by facilitator agents. Basically, when

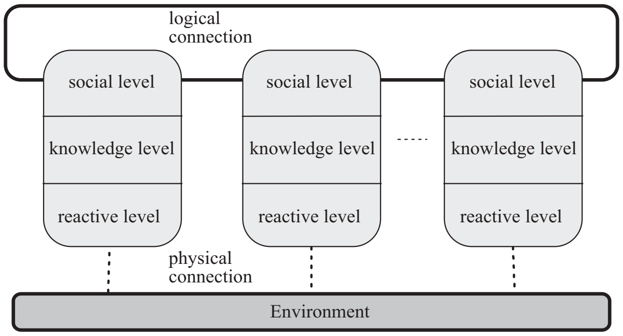

Figure 2. Layered architecture.

a local facilitator agent determines that none of its subordinate agents can achieve the goal posted on its blackboard, it propagates the goal to a higher level blackboard controlled by a higher level facilitator, who in turn can propagate the goal to its superior facilitator if none of its subsidiary blackboards can handle the goal.

Most existing multiagent systems have a layered architecture that can be divided into three levels (see Fig. 2): reactive level, knowledge level, and social level (3). Agent behavior at the reactive level responds to external changes perceived directly from the environment. Deliberative (or reflective) behaviors are often covered at the knowledge level, where an agent achieves situation awareness by translating the external input into internal representations and may project into the future (refer to the Endsley's PCP model of situation awareness in Ref. 23). Social or collaborative behaviors are reflected at the social level, where an agent identifies collaboration needs, adjusts self behavior, and exchanges information to coordinate joint behaviors.

The representatives with such an architecture include TEAMCORE (24), RETSINA (25), JACK (26), and CAST (5).

TEAMCORE is an extension of STEAM (a Shell for TEAMwork) (4), which takes the perspective of team-oriented programming. STEAM is a hybrid teamwork model built on top of the SOAR architecture (27). STEAM borrows insights from both the joint intentions theory and the SharedPlans formalism. It uses joint intentions as a building block to hierarchically build up the mental attitude of individual team members and to ensure that team members pursue a common solution path. STEAM exhibits two valuable features: selective communication and a way of dealing with teamwork failures. In STEAM, communication is driven by commitments embodied in the joint intentions theory as well as by explicit declaration of information-dependency relationships among actions. To make a decision on communication, STEAM agents take into consideration the communication costs, benefits, and the likelihood that some relevant information may be mutually believed already. To handle failures, STEAM uses role-monitoring constraints (AND, OR, dependency) to specify the relationship of a team operator and an individual's or subteam's contributions to it. When an agent is unable to complete actions in its role and the embedding team operator is still achievable, the remaining agents will invoke a repair plan accordingly.

TEAMCORE realized a wrapper agent by combining the domain-independent team expertise initially encoded in STEAM and the domain-specific knowledge at the team level. Hence, a TEAMCORE wrapper agent is a purely social agent that only has core teamwork capabilities. This team-readiness layer hides the details of the coordination behavior, low-level tasking, and replanning (24). To map TEAMCORE to Fig. 2, the TEAMCORE wrapper agent lies at the social level, whereas domain agents implemented using SOAR encompass functionalities required by the knowledge and reactive levels.

RETSINA multiagent infrastructure (25) (RETSINA-MAS) is extended from the RETSINA individual agent architecture (28). A RETSINA agent has four components: Communicator, HTN Planner, Enabled Action Scheduler, and Execution Monitor. RETSINA-MAS agents interact with each other via capability-based and team-oriented coordination as follows. Initially all agents have a commonly agreed partial plan for fulfilling a team task (goal). Each agent then matches his/her capabilities to the requirements of the overall team goal within the constraints of his/her authority and other social parameters. This process will produce a set of candidate roles for the agent, who can select some and communicate to teammates as proposals for his/her role in the team plan. Once the team members have reached a consensus that all plan requirements are covered by the role proposals without any conflicts, they can commit to executing the team plan. The team-oriented coordination implemented in RETSINA-MAS lies at the social level, whereas the RETSINA architecture covers reactive and deliberative behaviors.

JACK Teams (26) is an extension to JACK Intelligent Agents that provides a team-oriented modeling framework. JACK agents are BDI-style agents each with beliefs, desires, and intentions. A JACK team is an individual reasoning entity that is characterized by the roles it performs and the roles it requires others to perform. To form a team is to set up the declared role obligation structure by identifying particular subteams capable of performing the roles to be filled. JACK Teams has constructs particularly for specifying team-oriented behaviors. For instance, *Teamdata* is a concept that allows propagation of beliefs from teams to subteams and vice versa. Statements *@team_achieve* and *@parallel* are used in JACK for handling team goals. An *@parallel* allows several branches of activity in a team plan to progress in parallel. An *@parallel* statement can specify success condition, termination condition, how termination is notified, and whether to monitor and control the parallel execution. JACK Teams can also be viewed as a team wrapper that provides programmable team-level intelligence.

CAST (Collaborative Agents for Simulating Teamwork) (5) is a team-oriented agent architecture that supports teamwork using a shared mental model among teammates. The structure of the team (roles, agents, subteams, etc.) as well as team processes (plans to achieve various team tasks) are described explicitly in a declarative language called MALLET (29). Statements in MALLET are translated into PrT nets (specialized Petri-Nets), which use predicate evaluation at decision points. CAST supports predicate evaluation using a knowledge base with a Java-based backward-chaining reasoning engine called JARE. The main distinguishing feature of CAST is proactive team behavior enabled by the fact that agents within a CAST architecture share the same declarative specification of team structure and team process. Therefore, every agent can reason about what other teammates are working on, what the preconditions of the teammate's actions are, whether the teammate can observe the information required to evaluate a precondition, and hence what information might be potentially useful to the teammate. As such, agents can figure out what information to deliver proactively to teammates and can use a decision-theoretic cost/benefit analysis of the proactive information delivery before actually communicating. Compared with the architectures mentioned above, the layered behavior in CAST is flexible: It depends more on the input language than on the architecture. Both individual reactive behaviors and planned team activities can be encoded in MALLET, whereas the CAST kernel dynamically determines the appropriate actions based on the current situation awareness and on the anticipation of teammates' collaboration needs.

COORDINATION

Agents in MAS possess different expertise and capabilities. A key issue to a multiagent system is how it can maintain global coherence among distributed agents without explicit global control (13). This process requires agent coordination.

Distributed agents need to coordinate with one another when they pursue a joint goal, but the achievement of the goal is beyond the capability, knowledge, or capacity of any individuals. Team tasks in multiagent systems can be classified into three categories: atomic team actions, coordinated tasks, and planned team activities.

Atomic team actions refer to those atomic actions that cannot be done by a single agent and must involve at least two agents to do it. For instance, lifting a heavy object is a team operator. Before doing a team operator, the associated preconditions should be satisfied by all agents involved, and the agents should synchronize when performing the action. The team-oriented programming paradigm (hereafter TOP) (30) and CAST support atomic team operators. In CAST, the number of agents required by a team operator can be specified as constraints using the keyword *num*. For example, the following MALLET code specifies a team operator called *co_fire* that requires at least three agents firing at a given coordinate simultaneously:

```
(toper co_fire (?x ?y) (num ge 3)...).
```

By coordinated tasks, we refer to those short-term (compared with long-term) activities involving multiple agents. Executing a coordinated task often requires the involved agents to establish joint and individual commitments to the task or subtasks, to monitor the execution of the task, to broadcast task failures or task irrelevance whenever they occur, and to replan doing the task if necessary. A coordinated task is composed typically of a collection of temporally or functionally related subtasks, the assigned doers of which have to synchronize their activities at the right time and be ready to backup others proactively. STEAM (4) uses role-constraints (a role is an abstract specification of a set of activities in service of a team's overall activity) to specify the relationship between subtasks of a coordinated task. An AND-combination is used when the success of the task as a whole depends on the success of all subtasks; An OR-combination is used when any one subtask can bring success to the whole task; and role-dependency can be used when the execution of one subtask depends on another. Complex joint team activities can be specified by using these role-constraints combinatively and hierarchically. Similarly, in CAST (5), the Joint-Do construct provides a means for describing multiple synchronous processes to be performed by the identified agents or teams in accordance with the specified share type. A share type is either AND, OR, or XOR. For an AND share type, all specified subprocesses must be executed. For an XOR, exactly one subprocess must be executed, and for an OR, one or more subprocesses must be executed. A Joint-Do statement is not executed until all involved team members have reached this point in their plans. Furthermore, the statement after a Joint-Do statement in the team process does not begin until all involved team members have completed their part of the Joint-Do.

Planned team activities refer to common recipes that govern the collaboration behaviors of teammates in solving complex problems. A planned team activity is a long-term process that often involves team formation, points of synchronization, task allocation, execution constraints, and temporal ordering of embedded subactivities. GRATE (14) has a recipe language, where trigger conditions and structure of suboperations can be specified for a recipe. STEAM (4) uses the notion of team operator to prescribe the decomposition of task structures. RETSINA-MAS (25) also uses the concept of shared plans to coordinate individual behaviors, but it lacks an explicit team plan encoding language. Instead of providing a higher level planning encoding language, JACK Teams (26) tried to extend a traditional programming language (i.e., Java) with special statements for programming team activities. In JACK, team-oriented behaviors are specified in terms of roles using a construct called *teamplan*. TOP (30) uses *social structures* to govern team formation, and it is assumed that each agent participating in the execution of a joint plan knows the details of the whole plan.

In MALLET, plans are decomposable higher level actions, which are built on lower level actions or atomic operators hierarchically. A plan specifies which agents (variables), under what preconditions, can achieve which effects by following which processes, and optionally under which conditions the execution of the plan can be terminated. The process component of a plan plays an essential role in supporting coordination among team members. A process can be specified using constructs such as sequential (SEQ), parallel (PAR), iterative (WHILE, FOREACH, FORALL), conditional (IF), and choice (CHOICE).

MALLET has a powerful mechanism for dynamically binding agents with tasks. The *AgentBind* construct introduces flexibility to a teamwork process in the sense that agent selection can be performed dynamically based on the evaluation of certain teamwork constraints (e.g., finding an agent with specific capabilities). For example,

```
(AgentBind (?f)
  (constraints (playsRole ?f fighter)
  (closestToFire ?f ?fireid)))
```

states that the agent variable ?f needs to be instantiated with an agent who can play the role of fighter and is the closest to the fire ?fireid (?fireid already has a value from the preceding context). The selected agent is then responsible for performing later steps (operators, subplans, or processes) associated with ?f. An agent-bind statement becomes eligible for execution at the point when progress of the embedding plan has reached it, as opposed to being executed when the plan is entered. The scope for the binding to an agent variable extends to either the end of the plan in which the variable appears or the beginning of the next agent-bind statement that binds the same variable, whichever comes first. AgentBind statements can be anywhere in a plan as long as agent variables are instantiated before they are used. External semantics can be associated with the constraints described in an AgentBind statement. For instance, a collection of constraints can be ordered increasingly in terms of their priorities. The priority of a constraint represents its degree of importance compared with others. In case not all constraints can be satisfied, the constraints with the least priority will be relaxed first.

Agents also need to coordinate when to make choices on the next course of actions. The *Choice* construct in MALLET can be used to specify explicit choice points in a complex team process. For example, suppose a fire-fighting team is assigned to extinguish a fire caused by an explosion at a chemical plant. After collecting enough information (e.g., nearby chemicals or dangerous facilities), the team needs to decide how to put out the fire. They have to select a suitable plan among several options. The *Choice* construct is composed of a list of branches, each of which invokes a plan (a course of actions) and is associated with preference conditions and priority information. The preference conditions of a branch describe the situation in which the branch is preferred to others. If the preference conditions of more than one branch are satisfied, the one with the highest priority is chosen. In implementation (31), some specific agents can be designated as decision makers at the team level to simplify the coordination process. For instance, at a choice point, each agent can check whether it is the designated decision maker. If it is, the agent evaluates the preference conditions of the potential alternatives based on the information available currently. If no branch exists whose preference condition can be satisfied, the agent simply waits and reevaluates when more information becomes available. If more than one selectable branch exists, the agent can choose one randomly from those branches with the highest priority. The agent then informs others of the chosen branch before performing it. For those agents who are not the designated decision maker, they have to wait until they are informed of the choice from the decision maker. However, while waiting, they still could help in delivering information proactively to the decision maker to make better decisions.

COMMUNICATION

Communication is essential to an effective functional team. For instance, communication plays an important role in dynamic team formation, in implementing team-oriented agent architectures, and more theoretically, in the forming, evolving, and terminating of both joint intentions (16) and SharedPlans (15). Interagent communications can be classified into two categories: reactive communications and proactive communications.

Reactive communications (i.e., ask/reply) are used prevalently in existing distributed systems. Although the ask/reply approach is useful and necessary in many cases, it exposes several limitations. First, an information consumer may not realize certain information it has is already out of date. If this agent needs to verify the validity of every piece of information before they are used (e.g., for decision-making), the team can be overwhelmed easily by the amount of communications entailed by these verification messages. Second, an agent may not realize it needs certain information because of its limited knowledge (e.g., distributed expertise). For instance, a piece of information may be obtained only through a chain of inferences (e.g., being fused according to certain domain-related rules). If the agent does not have all the knowledge needed to make such a chain of inferences, it will not be able to know it needs the information, not to mention request for it.

Proactive information delivery means “providing relevant information without being asked.” As far as the above-mentioned issues are concerned, proactive information delivery by the information source agents offers an alternative, and it shifts the burden of updating information from the information consumer to the information provider, who has direct knowledge about the changes of information. Proactive information delivery also allows teammates to assist the agent who cannot realize it needs certain information because of its limited knowledge.

In fact, to overcome the above-mentioned limitations of “ask,” many human teams incorporate proactive information delivery in their planning. In particular, psychological studies about human teamwork have shown that members of an effective team can often anticipate the needs of other teammates and choose to assist them proactively based on a shared mental model (32).

Interagent communication has been studied extensively (38). For instance, many researchers have been studying agent communication languages (ACLs), by which agents in distributed computing environments can share information. KQML (34) and FIPA’s ACL (35) are two attempts toward a standardized ACL. A complete ACL often covers various categories of communicative acts, such as assertives, directives, commissives, permissives, prohibitives, declaratives, and expressives. Some reseachers even argued for the inclusion of proactives (i.e., proactive performatives) (36).

The mental-state semantics of ACL is one of the most developed areas in agent communication, where most efforts are based on Cohen and Levesque’s work (19). For instance, the semantics of FIPA’s performatives are given in terms of *Attempt*, which is defined within Cohen and Levesque’s framework (35). The semantics of proactive performatives are also treated as attempts but within an extended SharedPlans framework (36).

To understand fully the ties between the semantics of communicative acts and the patterns of these acts, conversation policies or protocols have been studied heavily in the ACL field (33). More recently, social agency is emphasized as a complement to mental agency because communication is inherently public (37), which requires the social construction of communication to be treated as a first-class notion rather than as a derivative of the mentalist concepts. For instance, in Ref. 37, speech acts are defined as social commitments, which are obligations relativized to both the beneficiary agent and the whole team as the social context.

Implemented systems often apply the joint intentions theory (13) in deriving interagent communications. The joint intentions theory requires that all agents involved in a joint persistent goal (JPG) take it as an obligation to inform other agents regarding the achievement or impossibility of the goal. Communication in STEAM (4) is driven by commitments embodied in the joint intentions theory. STEAM also integrated decision-theoretic communication selectivity: Agents deliberate on communication necessities vis-à-vis incoherency, considering communication costs and benefits as well as the likelihood that some relevant information may be mutually believed already.

GRATE*(14), which was built on top of the joint responsibility model, relies even more on communications. As we mentioned, the joint responsibility model clearly specifies the conditions under which an agent involved in a team activity should reconsider its commitments. For instance, as well as communications for dropping a joint intention, an agent should also endeavor to inform all other team members whenever it detects that either one of the following happens to the common recipe on which the group are working: The desired outcome is available already, the recipe becomes invalid, the recipe becomes untenable, or the recipe is violated.

The strong requirement on communication among teammates by the joint intentions theory is necessary to model coherent teamwork, but in a real case, it is too strong to achieve effective teamwork; enforced communication is not necessary and even impossible in time-stress domains. Rather than forcing agents to communicate, CAST (5) allows agents to anticipate others' information needs, which depending on the actual situations, may or may not result in communicative actions. The proactive information delivery behavior is realized in the DIARG (Dynamic Inter-Agent Rule Generator) algorithm. Communication needs are inferred dynamically through reasoning about the current progress of the shared team process. The following criteria are adopted in Ref. 38. First, a team process may include choice (decision) points, each of which can specify several branches (potential ways) to achieving the goal associated with the choice point. Intuitively, those information needs that emerge from the branches should not be activated until a specific branch is selected. Second, a team or an agent may dynamically select goals to pursue. The information needed to pursue one goal may be very different from those needed in another. Third, the already executed part of a team process may never be reinvoked again; thus, the associated information needs become no longer "active." DIARG is designed to generate interagent communication based on the identified information needs and on the speaker's model of others mental models. For instance, an agent will not send a piece of information if the possibility of the information being observed by the potential receiver is high enough. A decision-theoretic approach is also employed in CAST to evaluate the benefits and cost of communications.

HELPING BEHAVIORS

Pearce and Amato (39) have developed an empirically-derived taxonomy of helping behaviors. The model has a threefold structure of helping: (*1*) doing what one can (*direct help*) versus giving what one has (*indirect help*), (*2*) spontaneous help (informal) versus planned help (formal), and (*3*) serious versus nonserious help. These three dimensions correspond to the type of help offered, the social setting where help is offered, and the degree of need of the recipient.

Helping behavior in MASs can be defined as helping other team members perform their roles under conditions of poor workload distributions or asymmetric resource allocations or as helping team members when they encounter unexpected obstacles. As indicated by the above taxonomy, helping behaviors can come in many different forms, such as emergency aids and philanthropic acts. However, *planned direct help* and *spontaneous indirect help* are the two predominant forms of helping behaviors in MASs. For example, agents for an operational cell in simulated battlefields often have contingency plans in responding to environmental uncertainties. Collaborative agents also tend to deliver relevant information only to information consumers by first filtering irrelevant information away.

Helping behaviors can also be classified as *reactive* helping and *proactive* helping. Much helping that occurs in MASs is reactive: in response to specific requests for help. For instance, in the RoboRescue domain, fire fighters ask police agents to clear a blocked area when detecting such a place. A fire-fighting team asks another one for help when the fire is getting out-of-control.

Proactive helping refers to the helping that is not initiated by requests from recipients but by the anticipation of others' needs from shared mental models—even if those needs are not expressed directly (40). Proactive helping often occurs in highly effective human teams. For instance, providing assistance to others who need it has been identified as a key characteristic of human teamwork (41).

The joint intentions theory and the SharedPlans theory are two widely accepted formalisms for modeling teamwork; each has been applied successfully in guiding the design and the implementation of multiagent systems, such as GRATE*(14), STEAM (4), and CAST (5). Both theories allow agents to derive helping behaviors. In particular, the joint intentions theory implies that an agent will intend to help if it is mutually known that one team member requires the assistance of the agent (13).

Grosz and Kraus even proposed axioms for deriving helpful behaviors (15,20). For instance, axiom A5 and A6 in (15) state that an agent will form a potential intention to do ALL the actions it thinks might be helpful. whereas Axiom 2 in Ref. 20 states that if an agent intends that a property *p* hold and some alternative actions exist the agent can take that would lead to *p* holding, then the agent must be in one of three potential states: (*1*) The agent holds a potential intention to do some of these actions, (*2*) the agent holds an intention to do some of these actions; or (*3*) the agent has reconciled all possible actions it could take and has determined they each conflict in some way with other intentions. These two treatments are actually consistent; they characterize "intending-that" from two perspectives. The former shows how potential intentions are triggered from intentions. The latter reflects the process of means-ends reasoning: An agent first adopts a potential intention, then reconciles the potential intention with existing intentions—either adopts it as an actual intention or drops it and considers other options, and then it abandons—if all potential intentions serving the same ends have been tried but none can be reconciled into actual intentions. For instance, suppose an agent A has an intention to make the property p true. A will adopt a potential intention to do action α if the performance of α will enable another agent B to perform some action β, which would directly make p true. Ask/reply is an instance of using this axiom. Enabling other's physical actions also falls into this category. For example, a logistics person supplies ammunition to a fighter in a joint mission.

However, the axioms in the SharedPlans theory are still not rich enough to cover helping behaviors involving three or more parties. Such behaviors occur predominantly in large hierarchical teams with subteams. For instance, as a team scales up in size, the team is often organized into subteams, each of which may be divided even more into smaller subteams, and so on. In such cases, team knowledge might be distributed among several subteams. Hence, agents in one subteam might not be able to anticipate the information needs of agents in other subteams because they may not share the resources for doing so, such as the subteam process, the plans, and the task assignments. To enable information sharing among subteams, some agents in a subteam are often designated as the point of contacts with other subteams. For example, an agent who simultaneously participates in the activities of two subteams can be designated as the broker agent of the two subteams. These broker agents play a key role in informing agents outside the subteam about the information needs of agents in the subteam. Such helping behaviors involving more than two parties can be accounted for by the axiom given in Ref. 42, which establishes a basis for third-party communicative acts.

SUMMARY

Multiagent systems offer a new way of analyzing, designing, and implementing large-scale, complex systems, and they have been applied in an increasing range of software applications. Here, we discussed the concept of shared mental models, multiagent architectures, coordination, communications, and helping behaviors, which are critical in developing team-based multiagent systems. This article certainly is not an exhaustive summary of MAS research; it simply covers a limited view of the MAS research from teamwork perspective. Readers are encouraged to refer to the key conferences in MAS area (such as AAMAS, KIMAS, IAT), which have been attracting a growing number of researchers to present, demonstrate, and share their systems and ideas.

OBJECT-ORIENTED DATABASES

Traditional database management systems (DBMSs), which are based on the relational data model, are adequate for business and administrative applications and are characterized by data with a very simple structure and by the concurrent execution of several not-so-complex queries and transactions. The rapid technologic evolution raised, since the early 1980s, new application requirements for which the relational model demonstrated as inadequate. The relational model, indeed, is not suitable to handle data typical of complex applications, such as design and manufacturing systems, scientific and medical databases, geographical information systems, and multimedia databases. Those applications have requirements and characteristics different from those typical of traditional database applications for business and administration. They are characterized by highly structured data, long transactions, data types for storing images and texts, and nonstandard, application-specific operations. To meet the requirements imposed by those applications, new data models and DBMSs have been investigated, which allow the representation of complex data and the integrated specification of domain-specific operations.

Getting a closer look at the large variety of applications DBMSs are mainly used by, we can distinguish different types of applications, with each characterized by different requirements toward data handling. The most relevant application types include *business applications*, which are characterized by large amounts of data, with a simple structure, on which more or less complex queries and updates are executed, which must be accessed concurrently by several applications and require functionalities for data management, like access control; *complex navigational applications*, such as CAD and telecommunications, that need to manipulate data whose structures and relationships are complex and to efficiently traverse such relationships; *multimedia applications*, requiring storage and retrieval of images, texts and spatial data, in addition to data representable in tables, that require the definition of application-specific operations, and the integration of data and operations from different domains. Relational DBMSs handle and manipulate simple data; they support a query language (SQL) well suited to model most business applications, and they offer good performance, multiuser support, access control, and reliability. They have demonstrated extremely successfully for the first kind of applications, but they have strong limitations with respect to the others.

The object-oriented approach, which was becoming powerful in the programming language and software engineering areas in the early 1980s, seemed a natural candidate, because it provides the required flexibility not being constrained by the data types and query languages available in traditional database systems and specifies both the structures of complex objects and the operations to manipulate these structures. The basic principle of the object-oriented approach in programming is indeed to consider the program consisting of independent objects, grouped in classes, communicating among each other through messages. Classes have an interface, which specifies the operations that can be invoked on objects belonging to the class, and an implementation, which specifies the code implementing the operations in the class interface. The encapsulation of class implementation allows for hiding data representation and operation implementation. Inheritance allows a class to be defined starting from the definitions of existing classes, called superclasses. An object can use operations defined in its base class as well as in its superclasses. Inheritance is thus a powerful mechanism for code reuse. Polymorphism (overloading) allows for defining operations with the same name for different object types; together with overriding and late binding, this functionality allows an operation to behave differently on objects of different classes. The great popularity of the object-oriented approach in software development is mainly caused by the increased productivity: The development time is reduced because of specification and implementation reuse; the maintenance cost is reduced as well because of the locality of modifications. Another advantage of object orientation is represented by the uniqueness of the paradigm: All phases of the software lifecycle (analysis, design, programming, etc.) rely on the same model, and thus, the transition from one phase to another is smooth and natural. Moreover, the object-oriented paradigm represents a fundamental shift with respect to how the software is produced: The software is no longer organized according to the computer execution model (in a procedural way); rather, it is organized according to the human way of thinking. Objects encapsulate operations together with the data these operations modify, which thus provides a *data-oriented* approach to program development. Finally, the object-oriented paradigm, because of encapsulation, is well suited for heterogeneous system integration, which is required in many applications.

In an object-oriented programming language, objects exist only during program execution. In a database, by contrast, objects can be created that *persist* and can be shared by several programs. Thus, *object databases* must store persistent objects in secondary memory and must support object sharing among different applications. This process requires the integration of the object-oriented paradigm with typical DBMS mechanisms, such as indexing mechanisms, concurrency control, and transaction management mechanisms. The efforts toward this integration led to the definition and development of object-oriented database management systems (OODBMSs) (1–4) and, later on, of object relational database management systems (5–7). Object-oriented databases are based on an object data model, which is completely different from the traditional relational model of data, whereas object relational databases rely on extensions of the relational data

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

model with the most distinguishing features of the object paradigm. Thanks to their "evolutive" nature with respect to relational DBMSs, object relational systems are succeeding in the marketplace and the data model of the SQL standard has been an object relational data model since SQL: 1999 (7).

OODBMSs have been proposed as an alternative technology to relational DBMSs. They mainly result from the introduction of typical DBMS functionality in an object-oriented programming environment (8). OODBMSs allow for directly representing complex objects and efficiently supporting navigational applications. Because the underlying data model is an object model, they allow you to *"store your data in the same format you want to use your data"* (9), and thus, they overcome the *impedance mismatch* between the programming language and the DBMS (10). Research in the area of object-oriented databases has been characterized by a strong experimental work and the development of several prototype systems, whereas only later theoretical foundations have been investigated and standards have been developed. The ODMG (Object Data Management Group) standard for OODBMSs was indeed first proposed in 1993, several years later than the first OODBMSs were on the market. Moreover, because OODBMSs mainly originated from object-oriented programming languages, systems originating from different languages rely on different data models. Even nowadays, despite the advent of Java, that *de facto* standardized the object model in programming, sensible differences persit among different systems, even those participating in the ODMG consortium. This lack of an initial common reference model and the low degree of standardization, together with the limited support for powerful declarative, high-level query languages, and functionalities not comparable with those of relational DBMSs for what concerned data security, concurrency control, and recovery, are among the main reasons because OODBMSs could not impose themselves in the marketplace.

Object relational DBMSs, by contrast, which were born as an extension of the relational technology with the characteristics of the object model, needed to support a wider range of applications. They are motivated by the need to provide relational DBMS functionalities in "traditional" data handling while extending the data model so that complex data can be handled. The choice is to introduce the distinguishing features of the object paradigm in the relational model without changing the reference model. As relational DBMSs, indeed, object relational DBMSs handle rows of tables, provide a declarative query language (SQL), and inherit the strength of relational systems in terms of efficiency and reliability in data management.

In this article, we discuss the application of the object-oriented paradigm to the database context, with a focus on data model and query language aspects. We first introduce the main notions of object-oriented data models and query languages, and then present the ODMG standard. Existing OODBMSs are then surveyed briefly, and object-relational databases are introduced. We conclude by mentioning some issues in object databases that are not dealt with in the article.

OBJECT-ORIENTED DATA MODELS

In this section, we introduce the main concepts of object-oriented data models, namely, objects, classes, and inheritance. In the next section, we will present the data model of the ODMG standard.

Objects

An object-oriented database is a collection of objects. In object-oriented systems, each real-world entity is represented by an object. Each object has an identity, a state, and a behavior. The identity is different from the identity of any other object and is immutable during the object lifetime; the state consists of the values of the object attributes; the behavior is specified by the methods that act on the object state, which is invoked by the corresponding operations.

Many OODBMs actually do not require each entity to be represented as an object; rather, they distinguish between objects and values. The differences between values and objects are as follows (11)

- Values are universally known abstractions, and they have the same meaning for each user; objects, by contrast, correspond to abstractions whose meaning is specified in the context of the application.
- Values are *built-in* in the system and do not need to be defined; objects, by contrast, must be introduced in the system through a definition.
- The information represented by a value is the value itself, whereas the meaningful information represented by an object is given by the relationships it has with other objects and values; values are therefore used to describe other entities, whereas objects are the entities being described.

Thus, values are elements of built-in domains, whereas objects are elements of uninterpreted domains. Typical examples of values are integers, reals, and strings. Each object is assigned an immutable identifier, whereas a value has no identifier; rather it is identified by itself.

Object Identity. Each object is identified uniquely by an object identifier (OID), which provides it with an identity independent from its value. The OID is unique within the system, and it is immutable; that is, it does not depend on the state of the object. Object identifiers are usually not visible and accessible directly by the database users; rather they are used internally by the system to identify objects and to support object references through object attribute values. Objects can thus be interconnected and can share components. The semantics of *object sharing* is illustrated in Fig. 1. The figure shows two objects that, in case (b), share a component, whereas in case (a), they do not share any object and simply have the same value for the attribute `date`. Although in case (a) a change in the publication date of `Article[i]` from `March 1997` to `April 1997` does not affect the publication date of `Article[j]`, in case (b), the change is also reflected on `Article[j]`.

The notion of object identifier is different from the notion of *key* used in the relational model to identify uniquely each

Figure 1. Object-sharing semantics.

tuple in a relation. A key is defined as the value of one or more attributes, and it can be modified, whereas an OID is independent from the value of an object state. Specifically, two different objects have different OIDs even when all their attributes have the same values. Moreover, a key is unique with respect to a relation, whereas an OID is unique within the entire database. The use of OIDs, as an identification mechanism, has several advantages with respect to the use of keys. First, because OIDs are implemented by the system, the application programmer does not have to select the appropriate keys for the various sets of objects. Moreover, because OIDs are implemented at a low level by the system, better performance is achieved. A disadvantage in the use of OIDs with respect to keys could be the fact that no semantic meaning is associated with them. Note, however, that very often in relational systems, for efficiency reasons, users adopt semantically meaningless codes as keys, especially when foreign keys need to be used.

The notion of object identity introduces at least two different notions of object equality:

- **Equality by identity:** Two objects are *identical* if they are the same object, that is, if they have the same identifier.
- **Equality by value:** Two objects are *equal* if the values for their attributes are *equal* recursively.

Obviously, two identical objects are also equal, whereas the converse does not hold. Some object-oriented data models also provide a third kind of equality, which is known as *shallow value equality* by which two objects are equal, although not being identical, if they share all attributes.

Object State. In an object-oriented database, the value associated with an object (that is, its state) is a complex value that can be built starting from other objects and values, using some type constructors. Complex (or structured) values are obtained by applying those constructors to simpler objects and values. Examples of primitive values are integers, characters, strings, booleans, and reals. The minimal set of constructors that a system should provide include sets, lists, and tuples. In particular, sets are crucial because they are a natural way to represent real-world collections and multivalued attributes; the tuple constructor is important because it provides a natural way to represent the properties of an entity; lists and arrays are similar to sets, but they impose an order on the elements of the collection and are needed in many scientific applications. Those constructors can be nested arbitrarily. A complex value can contain as components (references to) objects.

Many OODBMSs, moreover, support storage and retrieval of nonstructured values of large size, such as character strings or bit strings. Those values are passed as they are, that is, without being interpreted, to the application program for the interpretation. Those values, which are known as **BLOBs** *(binary large objects)*, are big-sized values like image *bitmaps* or long text strings. Those values are not structured in that the DBMS does not know their structure; rather the application using them knows how to interpret them. For example, the application may contain some functions to display an image or to search for some keywords in a text.

Object Behavior. Objects in an object-oriented database are manipulated through methods. A method definition consists of two components: a *signature* and an *implementation*. The *signature* specifies the method name, the names and types of method arguments, and the type of result, for methods returning a result value. Thus, the signature is a specification of the operation implemented by the method. Some OODBMSs do not require the specification of argument types; however, this specification is required in systems performing static-type checking. The method implementation consists of a set of instructions expressed in a programming language. Various OODBMSs exploited different languages. For instance, ORION exploited Lisp; GemStone a Smalltalk extension, namely OPAL; and O_2 a C extension, namely CO_2; other systems, among which are ObjectStore, POET, and Ode, exploited C++ or Java.

The use of a *general-purpose*, computationally complete programming language to code methods allows the whole application to be expressed in terms of objects. Thus no need exists, which is typical of relational DBMSs, to embed the query language (e.g., SQL) in a programming language.

Encapsulation. In a relational DBMS, queries and application programs that act on relations are expressed in an imperative language incorporating statements of the data manipulation language (DML), and they are stored in a traditional file system rather than in the database. In such an approach, therefore, a sharp distinction is made between programs and data and between query language and programming language. In an object-oriented database, data and operations manipulating them are *encapsulated* in a single structure: the object. Data and operations are thus designed together, and they are both stored in the same system.

This notion of encapsulation in programming languages derives from the concept of abstract data type. In this view, an object consists of an interface and an implementation. The interface is the specification of the operations that can be executed on the object, and it is the only part of the object that can be observed from outside. Implementation, by contrast, contains data, that is, the representation or state of the object, and methods specifying the implementation of each operation. This principle, in the database context, is reflected in that an object contains both programs and data, with a variation: In the database context, it is not clear whether the structure that defines the type of object is part of the interface. In the programming language context, the data structure is part of the implementation and, thus, not visible. For example, in a programming language, the data `type list` should be independent from the fact that lists are implemented as arrays or as dynamic structures; thus, this information is hidden correctly. By contrast, in the database context, the knowledge of an object attributes, and references made through them to other objects, is often useful.

Some OODBMSs, like ORION, allow us to read and write the object attribute values, which thus violates encapsulation. The reason is to simplify the development of applications that simply access and modify object attributes. Obviously, those applications are very common in the database context. Strict encapsulation would require writing many trivial methods. Other systems, like O_2, allow for specifying which methods and attributes are visible in the object interface and thus can be invoked from outside the object. Those attributes and methods are called *public*, whereas those that cannot be observed from outside the object are called *private*. Finally, some other systems, including GemStone, force strict encapsulation.

Classes

Instantiation is the mechanism that offers the possibility of exploiting the same definition to generate objects with the same structure and behavior. Object-oriented languages provide the notion of class as a basis for instantiation. In this respect, a class acts as a *template*, by specifying a structure, that is, the set of instance attributes, which is a set of methods that define the instance interface (method signatures) and implement the instance behavior (method implementations). Given a class, the *new* operation generates objects answering to all messages defined for the class. Obviously, the attribute values must be stored separately for each object; however, no need exists to replicate method definitions, which are associated with the class.

However, some class features cannot be observed as attributes of its instances, such as the number of class instances present in each moment in the database or the average value of an attribute. An example of an operation that is invoked on classes rather than on objects is the *new* operation for creating new instances. Some object-oriented data models, like those of GemStone and ORION, allow the definition of attributes and methods that characterize the class as an object, which are, thus, not inherited by the class instances.

Aggregation Hierarchy and Relationships. In almost all object-oriented data models, each attribute has a *domain*, that specifies the class of possible objects that can be assigned as values to the attribute. If an attribute of a class C has a class C' as domain, each C instance takes as value for the attribute an instance of C' or of a subclass of its. Moreover, an **aggregation** relationship is established between the two classes. An aggregation relationship between the class C and the class C' specifies that C is defined in terms of C'. Because C' can be in turn defined in terms of other classes, the set of classes in the schema is organized into an *aggregation hierarchy*. Actually, it is not a hierarchy in a strict sense, because class definitions can be recursive.

An important concept that exists in many semantic models and in models for the conceptual design of databases (12) is the *relationship*. A relationship is a link between entities in applications. A relationship between a person and his employer (*) is one example; another (classic) example is the relationship among a product, a customer, and a supplier (**), which indicates that a given product is supplied to a given customer by a given supplier. Associations are characterized by a *degree*, which indicates the number of entities that participate in the relationship, and by some *cardinality constraints*, which indicate the minimum and maximum number of relationships in which an entity can participate. For example, relationship (*) has degree 2; that is, it is binary, and its cardinality constraints are (0,1) for person and (1,n) for employer. This example reflects the fact that a person can have at most one employer, whereas an employer can have more than one employee. Referring to a maximum cardinality constraint, relationships are partitioned in one-to-one, one-to-many, and many-to-many relationships. Finally, relationships can have their own attributes; for example, relationship (**) can have attributes `quantity` and `unit price`, which indicate, respectively, the quantity of the product supplied and the unit price quoted. In most object-oriented data models, relationships are represented through object references. This approach, however, imposes a directionality on the relationship. Some models, by contrast, allow the specification of binary relationships, without, however, proper attributes.

Extent and Persistence Mechanisms. Besides being a *template* for defining objects, in some systems, the class also denotes the collection of its instances; that is, the class has also the notion of **extent**. The extent of a class is the collection of all instances generated from this class. This aspect is important because the class is the basis on which queries are formulated: Queries are meaningful only when they are applied to object collections. In systems in which classes do not have the extensional function, the extent of each class must be maintained by the applications through the use of constructors such as the set constructor. Different sets can contain instances of the same class. Queries are thus formulated against such sets and not against classes. The automatic association of an extent with each class (like in the ORION system) has the advantage of simplifying the management of classes and their instances. By contrast, systems (like O_2 and GemStone) in which classes define only specification and implementation of objects and queries are issued against *collections* managed by the applications, which provide a greater flexibility at the price of an increased complexity in managing class extents.

An important issue concerns the *persistence* of class instances, that is, the modalities by which objects are made persistent (that is, inserted in the database) and are deleted eventually (that is, removed from the database). In relational databases, explicit statements (like INSERT and DELETE in SQL) are provided to insert and delete data from the database. In object-oriented databases, two different approaches can be adopted with respect to object persistence:

- Persistence is an implicit property of all class instances; the creation (through the *new* operation) of an instance also has the effect of inserting the instance in the database; thus, the creation of an instance automatically implies its persistence. This approach usually is adopted in systems in which classes also have an extensional function. Some systems provide two different *new* operations: one for creating persistent objects of a class and the other one for creating temporary objects of that class.
- Persistence is an orthogonal properties of objects; the creation of an instance does not have the effect of inserting the instance in the database. Rather, if an instance has to survive the program that created it, it must be made persistent, for example, by assigning it a name or by inserting it into a persistent collection of objects. This approach usually is adopted in systems in which classes do not have the extensional function.

With respect to object *deletion*, two different approaches are possible:

- The system provides an explicit delete operation. The possibility of explicitly deleting objects poses the problem of referential integrity; if an object is deleted and other objects refer to it, references are not any longer valid (such references are called as *dangling references).* The explicit deletion approach was adopted by the ORION and Iris systems.
- The system does not provide an explicit delete operation. A persistent object is deleted only if all references to it have been removed (a periodic *garbage collection* is performed). This approach, which was adopted by the GemStone and O_2 systems, ensures referential integrity.

Migration. Because objects represent real-world entities, they must be able to reflect the evolution in time of those entities. A typical example is that of a person who is first of all a student, then an employee, and then a retired employee. This situation can be modeled only if an object can become an instance of a class different from the one from which it has been created. This evolution, known as object *migration*, allows an object to modify its features, that is, attributes and operations, by retaining its identity. Object migration among classes introduces, however, semantic integrity problems. If the value for an attribute A of an object O is another object O', an instance of the class domain of A, and O' changes class, if the new class of O' is no more compatible with the class domain of A, the migration of O' will result in O containing an illegal value for A. For this reason, migration currently is not supported in most existing systems.

Inheritance

Inheritance allows a class, called a *subclass*, to be defined starting from the definition of another class, called a *superclass*. The subclass inherits attributes and methods of its superclass; a subclass may in addition have some specific, noninherited features. Inheritance is a powerful reuse mechanism. By using such a mechanism, when defining two classes their common properties, if any, can be identified and factorized in a common superclass. The definitions of the two classes will, by contrast, specify only the distinguishing specific properties of these classes. This approach not only reduces the amount of code to be written, but it also has the advantage of giving a more precise, concise, and rich description of the world being represented.

Some systems allow a class to have several direct superclasses; in this case, we talk of *multiple inheritance*. Other systems impose the restriction to a single superclass; in this case, we talk of *single inheritance*. The possibility of defining a class starting from several superclasses simplifies the task of the class definition. However, conflicts may develop. Such conflicts may be solved by imposing an ordering on superclasses or through an explicit qualification mechanism.

In different computer science areas and in various object-oriented languages, different inheritance notions exist. In the knowledge representation context, for instance, inheritance has a different meaning from the one it has in object-oriented programming languages. In the former context, a subclass defines a *specialization* with respect to features and behaviors of the superclass, whereas in the latter, the emphasis is on attribute and method reuse. Different inheritance hierarchies can then be distinguished: *subtype hierarchy*, which focuses on consistency among type specifications; *classification hierarchy*, which expresses inclusion relationships among object collections; and *implementation hierarchy*, which allows code sharing among classes. Each hierarchy refers to different properties of the type/class system; those hierarchies, however, generally are merged into a single inheritance mechanism.

Overriding, Overloading, and Late Binding. The notion of *overloading* is related to the notion of inheritance. In many cases, it is very useful to adopt the same name for different operations, and this possibility is extremely useful in the object-oriented context. Consider as an example (9) a **display** operation receiving as input an object and displaying it. Depending on the object type, different display mechanisms are exploited: If the object is a figure, it should appear on the screen; if the object is a person, its data should be printed in some way; if the object is a graph, a graphical representation of it should be produced. In an application developed in a conventional system, three different operations `display_graph`, `display_person`, and `display_figure` would be defined. This process requires the programmer to be aware of all possible object types and all associated display operations and to use them properly.

In an object-oriented system, by contrast, the **display** operation can be defined in a more general class in the class hierarchy. Thus, the operation has a single name and can be used indifferently on various objects. The operation implementation is *redefined* for each class; this redefinition is known as *overriding*. As a result, a single name denotes different programs, and the system takes care of selecting the appropriate one at each time during execution. The resulting code is simpler and easier to maintain, because the introduction of a new class does not require modification of the applications. At any moment, objects of other classes, for example, information on some products, can be added to the application and can be displayed by simply defining a class, for example, `product`, to provide a proper (re)definition of the `display` operation. The application code would not require any modification.

To support this functionality, however, the system can no longer bind operation names to corresponding code at compile time; rather, it must perform such binding at run time: This late translation is known as *late binding*. Thus, the notion of *overriding* refers to the possibility for a class of redefining attributes and methods it inherits from its superclasses; thus, the inheritance mechanism allows for specializing a class through additions and substitutions. Overriding implies *overloading*, because an operation shared along an inheritance hierarchy can have different implementations in the classes belonging to this hierarchy; therefore, the same operation name denotes different implementations.

An Example

Figure 2 illustrates an example of object-oriented database schema. In the figure, each node represents a class. Each node contains names and domains of the attributes of the class it represents. For the sake of simplicity, we have included in the figure neither operations nor class features. Moreover, only attributes and no relationships have been included in classes. Nodes are connected by two different kinds of arcs. The node representing a class C can be linked to the node representing class C' through:

1. A thin arc, which denotes that C' is the domain of an attribute A of C (aggregation hierarchy).
2. A bold arc, which denotes that C' is superclass of C (inheritance hierarchy).

QUERY LANGUAGES

Query languages are an important functionality of any DBMS. A query language allows users to retrieve data by simply specifying some conditions on the content of those data. In relational DBMSs, query languages are the only

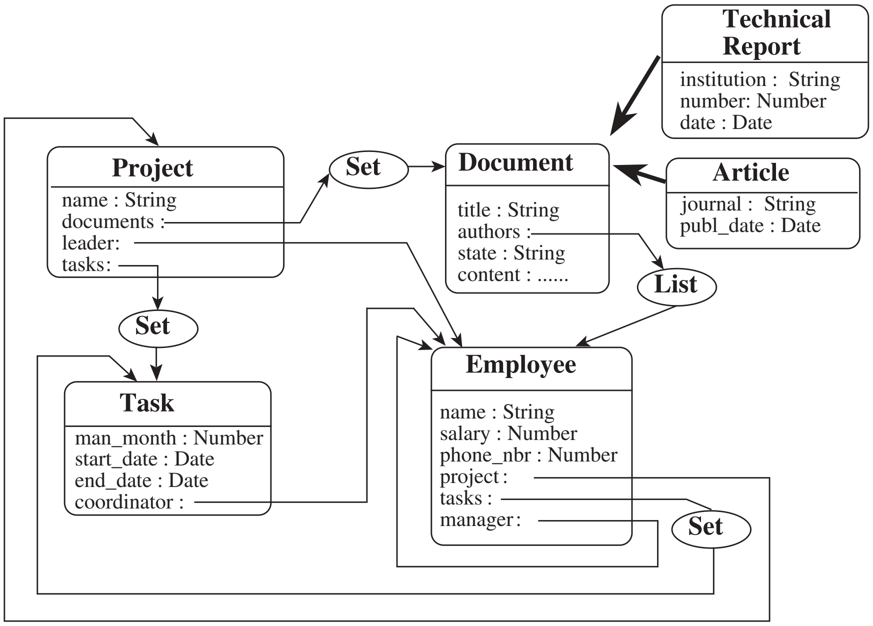

Figure 2. An example of object-oriented database schema.

way to access data, whereas OODBMSs usually provide two different modalities to access data. The first one is called *navigational* and is based on object identifiers and on the aggregation hierarchies into which objects are organized. Given a certain OID, the system can access directly and efficiently the object referred by it and can navigate through objects referred by the components of this object. The second access modality is called *associative*, and it is based on SQL-like query languages. These two different access modalities are used in a complementary way: A query is evaluated to select a set of objects that are then accessed and manipulated by applications through the navigational mechanism. Navigational access is crucial in many applications, such as graph traversal. Such type of access is inefficient in relational systems because it requires the execution of a large number of join operations. Associative access, by contrast, has the advantage of supporting the expression of declarative queries, which reduces thus application development time. Relational DBMSs are successful mostly because of their declarative query languages.

A first feature of object-oriented query languages is the possibility they offer of imposing conditions on nested attributes of an object aggregation hierarchy, through *path expressions*, which allows for expressing joins to retrieve the values of the attributes of an object components. In object-oriented query languages, therefore, two different kinds of join can be distinguished: *implicit join*, which derives from the hierarchical structure of objects, and *explicit join*, which, as in relational query languages, explicitly compares two objects. Other important aspects are related to inheritance hierarchies and methods. First, a query can be issued against a class or against a class and all its subclasses. Most existing languages support both of these possibilities. Methods can be used as *derived attributes* or as *predicate methods*. A method used as a derived attribute is similar to an attribute; however, whereas the attribute stores a value, the method computes a value starting from data values stored in the database. A predicate method is similar, but it returns the Boolean constants *true* or *false*. A predicate method evaluates some conditions on objects and can thus be part of the Boolean expressions that determine which objects satisfy the query.

Moreover, object-oriented query languages often provides constructs for expressing recursive queries, although recursion is not a peculiar feature of the object-oriented paradigm and it has been proposed already for the relational data model. It is, however, important that some kind of recursion can be expressed, because objects relevant for many applications are modeled naturally through recursion. The equality notion also influences query semantics. The adopted equality notion determines the semantics and the execution strategy of operations like union, difference, intersection, and duplicate elimination. Finally, note that *external names* that some object-oriented data models allow for associating with objects provides some semantically meaningful handlers that can be used in queries.

A relevant issue for object-oriented query languages is related to the language *closure*. One of the most remarkable characteristics of relational query languages is that the results of a query are in turn relations. Queries can then be composed; that is, the result of a query can be used as an operand in another query. Ensuring the closure property in an object-oriented query language is by contrast more difficult: The result of a query often is a set of objects, whose class does not exist in the database schema and that is defined by the query. The definition of a new class "on-the-fly" as a result of a query poses many difficulties, including where to position the new class in the inheritance hierarchy and which methods should be defined for such class. Moreover, the issue of generating OIDs for the new objects, which are the results of the query and instances of the new class, must be addressed.

To ensure the closure property, an approach is to impose restrictions on the projections that can be executed on classes. A common restriction is that either all the object attributes are returned by the query or only a single attribute is returned. Moreover, no explicit joins are allowed. In this way the result of a query is always a set of already existing objects, which are instances of an already existing class; the class can be a primitive class (such as the class of integers, string, and so forth) or a user-defined class. If one wants to support more general queries with arbitrary projections and explicit joins, a first approach to ensure closure is to consider the results of a query as instances of a general class, accepting all objects and whose methods only allow for printing or displaying objects. This solution, however, does not allow objects to be reused for other manipulations and, therefore, limits the nesting of queries, which is the main motivation for ensuring the closure property. Another possible approach is to consider the result of a query as a collection of objects, instances of a new class, which is generated by the execution of the query. The class implicitly defined by the query has no methods; however, methods for reading and writing attributes are supposed to be available, as system methods. The result of a query is thus similar to a set of tuples. An alternative solution (11) is, finally, that of including relations in the data model and of defining the result of a query as a relation.

THE ODMG STANDARD

ODMG is an OODBMS standard, which consists of a data model and a language, whose first version was proposed in 1993 by a consortium of major companies producing OODBMSs (covering about 90% of the market). This consortium included as voting members Object Design, Objectivity, O_2 Technology, and Versant Technology and as nonvoting members HP, Servio Logics, Itasca, and Texas Instruments. The ODMG standard consists of the following components:

- A data model (ODMG Object Model)
- A data definition language (ODL)
- A query language (OQL)
- Interfaces for the object-oriented programming languages C++ Java, and Smalltalk and data manipulation languages for those languages

The ODMG Java binding is the basis on which the *Java Data Objects* specification (13) has been developed, which provides the reference data model for persistent Java applications. In this section, we briefly introduce the main features of the ODMG 3.0 standard data model and of its query language OQL (14).

Data Definition in ODMG

ODMG supports both the notion of object and the notion of value (literal in the ODMG terminology). Literals can belong to atomic types like long, short, float, double, Boolean, char, and string; to types obtained through the set, bag, list, and array constructors; to enumeration types (enum); and to the structured types date, interval, time, and timestamp.

A schema in the ODMG data model consists of a set of object types related by inheritance relationships. The model provides two different constructs to define the external specification of an object type. An *interface* definition only defines the abstract behavior of an object type, whereas a *class* definition defines the abstract state and behavior of an object type. The main difference between class and interface types is that classes are types that are instantiable directly, whereas interfaces are types that cannot be instantiated directly. Moreover, an *extent* and one or more *keys* can be associated optionally with a class declaration. The extent of a type is the set of all instances of the class.

Objects have a state and a behavior. The object state consists of a certain number of properties, which can be either *attributes* or *relationships*. An attribute is related to a class, whereas a relationship is defined between two classes. The ODMG model only supports binary relationships, that is, relationships between two classes. One-to-one, one-to-many, and many-to-many relationships are supported. A relationship is defined implicitly through the specification of a pair of *traversal paths*, which enable applications to use the logical connection between objects participating in the relationship. Traversal paths are declared in pairs, one for each traversal direction of the binary relationship. The inverse clause of the traversal path definition specifies that two traversal paths refer to the same relationship. The DBMS is responsible for ensuring value consistency and referential integrity for relationships, which means that, for example, if an object participating in a relationship is deleted, any traversal path leading to it is also deleted.

Like several object models, the ODMG object model includes inheritance-based type–subtype relationships. More precisely, ODMG supports two inheritance relationships: the *ISA* relationship and the *EXTENDS* relationships. Subtyping through the ISA relationship pertains to the inheritance of behavior only; thus, interfaces may inherit from other interfaces and classes may also inherit from interfaces. Subtyping through the EXTENDS relationship pertains to the inheritance of both state and behavior; thus, this relationship relates only to classes. Multiple inheritance is allowed for the ISA, whereas it is not allowed for the EXTENDS relationship.

The ODMG class definition statement has the following format:

```
class ClassName[:SuperInterface List]
[EXTENDS SuperClass]
[(extent Extent Name[key[s] Attribute List])]
{ Attribute List
  Relationship List
  Method List }
```

In the above statement:

- The : clause specifies the interfaces by which the class inherits through *ISA*.
- The EXTENDS clause specifies the superclass by which the class inherits through *EXTENDS*.
- The extent clause specifies that the extent of the class must be handled by the OODBMS.
- The key [s] clause, which can appear only if the extent clause is present, specifies a list of attributes for which two different objects belonging to the extent cannot have the same values.
- Each attribute in the list is specified as

```
attribute Domain Name;
```

- Each relationship in the list is specified as

```
relationship Domain Name
  inverse Class:: Inverse Name
```

where *Domain* can be either *Class*, in the case of unary relationships, or a collection of *Class* elements, and *Inverse Name* is the name of the inverse traversal path.

- Each method in the list is specified as

```
Type Name(Parameter List) [ raises Exception
List]
```

where *Parameter List* is a list of parameters specified as

```
in | out | inout Parameter Name
```

and the raises clause allows for specifying the exceptions that the method execution can introduce.

The following ODL definition defines the following classes: Employee, Document, Article, Project, and Task of the database schema of Fig. 2, in which some relationships between projects and employees (rather than the leader attribute of class Project), and between employees and tasks (rather than the tasks attribute of class Employee), have been introduced. The main difference in representing a link between objects as a relationship rather than as a reference (that is, attribute value) is in the nondirectionality of the relationship. If, however, only one direction of the link is interesting, the link can be represented as an attribute.

```
class Employee (extent Employees key name)
{ attribute string name;
attribute unsigned short salary;
attribute unsigned short phone_nbr[ 4] ;
attribute Employee manager;
attribute Project project;
relationship Project leads
   inverse Project::leader;
```

```
  relationship Set<Task> tasks
     inverse Task:participants;
}

class Document (extent Documents key title)
{ attribute string title;
  attribute List<Employee> authors;
  attribute string state;
  attribute string content;
}

class Article EXTENDS Document (extent Articles)
{ attribute string journal;
  attribute date publ_date;
}

class Project (extent Projects key name)
{ attribute string name;
  attribute Set<Document> documents;
  attribute Set<Task> tasks;
  relationship Employee leader
    inverse Employee::leads;
}

class Task (extent Tasks)
{ attribute unsigned short man_month;
  attribute date start_date;
  attribute date end_date;
  attribute Employee coordinator;
  relationship Set<Employee> participants
    inverse Employee::tasks;
}
```

Data Manipulation in ODMG

ODMG does not support a single DML; rather, three different DMLs are provided, which are related to C++, Java, and Smalltalk, respectively. These OMLs are based on different persistence policies, which correspond to different object-handling approaches in the languages. For example, C++ OML supports an explicit delete operation (`delete_object`), whereas Java and Smalltalk OMLs do not support explicit delete operations; rather, they are based on a garbage collection mechanism.

ODMG, by contrast, supports an SQL-like query language (OQL), which is based on queries of the `select from where` form that has been influenced strongly by the O_2 query language (15). The query returning all tasks with a manpower greater than 20 months, whose coordinator earns more than $20,000, is expressed in OQL as follows:

```
select t
from Tasks t
where t.man_month > 20 and
  t.coordinator.salary > 20000
```

OQL is a functional language in which operators can be composed freely as a consequence of the fact that query results have a type that belongs to the ODMG type system. Thus, queries can be nested. As a stand-alone language, OQL allows for querying objects denotable through their names. A name can denote an object of any type (atomic, collection, structure, literal). The query result is an object whose type is inferred from the operators in the query expression. The result of the query "retrieve the starting date of tasks with a man power greater than 20 months," which is expressed in OQL as

```
select distinct t.start_date
from Tasks t
where t.man_month > 20
```

is a literal of type `Set < date >`.

The result of the query "retrieve the starting and ending dates of tasks with a man power greater than 20 months," which is expressed in OQL as

```
select distinct struct(sd: t.start_date,
  ed: t.end_date)
from Tasks t
where t.man_month > 20
```

is a literal of type `Set < struct(sd : date, ed : date) >`.

A query can return structured objects having objects as components, as it can combine attributes of different objects. Consider as an example the following queries. The query "retrieve the starting date and the coordinator of tasks with a man power greater than 20 months," which is expressed in OQL as

```
select distinct struct(st: t.start_date,
  c: coordinator)
from Tasks t
where t.man_month > 20
```

produces as a result a literal with type `Set < struct(st : date, c : Employee) >`. The query "retrieve the starting date, the names of the coordinator and of participants of tasks with a man power greater than 20 months," which is expressed in OQL as

```
select distinct struct(sd: t.start_date,
  cn: coordinator.name,
  pn: (select p.name
    from t.participants p))
from Tasks t
where t.man_month > 20
```

produces as a result a literal with type `Set < struct(st : date, cn : string, pn : bag < string >) >`.

OQL is a very rich query language. In particular it allows for expressing, in addition to path expressions and projections on arbitrary sets of attributes, which are illustrated by the above examples, explicit joins and queries containing method invocations. The query "retrieve the technical reports having the same title of an article", is expressed in OQL as

```
select tr
from Technical_Reports tr, Articles a
where tr.title = a title
```

The query “retrieve the name and the bonus of employees having a salary greater than 20000 and a bonus greater than 5000” is expressed in OQL as

```
select distinct struct(n: e.name, b: e.bonus)
from Employees e
where e.salary > 20000 and e.bonus > 5000
```

OQL finally supports the aggregate functions `min`, `max`, `count`, `sum`, and `avg`. As an example, the query “retrieve the maximum salary of coordinators of tasks of the CAD project” can be expressed in OQL as

```
select max(select t.coordinator.salary
  from p.tasks t)
from Projects p
where p.name = ' CAD'
```

OBJECT-ORIENTED DBMSs

As we have discussed, the area of object-oriented databases has been characterized by the development of several systems in the early stages, followed only later by the development of a standard. Table 1 compares some of the most influential systems along several of dimensions. In the comparison, we distinguish systems in which classes have an extensional function, that is, in which with a class the set of its instances is associated automatically, from those in which object collections are defined and handled by the application. We point out, moreover, the adopted persistence mechanism, which distinguishes among systems in which all objects are created automatically as persistent, systems in which persistence is ensured by linking an object to a persistence root (usually an external name), and systems supporting two different creation operations, one for creating temporary objects and the other one for creating persistent objects. The different policies with respect to encapsulation are also shown, which distinguishes among systems forcing strict encapsulation, systems supporting direct accesses to attribute values, and systems distinguishing between private and public features. Finally, the O_2 system allows the specification of exceptional instances, that is, of objects that can have additional features and/or redefine (under certain compatibility restrictions) features of the class of which they are instances.

Most OODBMSs in Table 1, although they deeply influenced the existing OODBMSs and the ODMG standard, are no more available in the marketplace. Table 2 lists most popular commercial and open-source OODBMSs available in 2007 (www.odbms.org). Although most of their producers are ODMG members, the system still exhibits different levels of ODMG compliance.

OBJECT RELATIONAL DATABASES

As discussed at the beginning of this article, object relational databases rely on extensions of the relational data model with the most distinguishing features of the object paradigm. One of the first object relational DBMS is UniSQL (24), and nowadays object relational systems include, among others, DB2 (25,26), Oracle (27), Microsoft SQL Server (28), Illustra/Informix (29), and Sybase (30). All of these systems extend a relational DBMS with object-oriented modeling features. In all those DBMSs, the type system has been extended in some way and the possibility has been introduced of defining methods to model user-defined operations on types. The SQL standard, since its SQL:1999 version (7), has been based on an object-relational data model. In what follows, we discuss briefly the most relevant type system extensions according to the most recent version of the SQL standard, namely, SQL:2003 (31).

Table 1. Comparison among data models of most influential OODBMSs

	Gem-Stone	Iris	O2	Orion	Object-Store	Ode	ODMG
Reference	(16)	(17)	(18), (19)	(20), (21)	(22)	(23)	(14)
Class extent	NO	YES	NO	YES	NO	YES	YES[a]
Persistence	R	A	R	A	R	2op	A[b]
Explicit deletion	NO	YES	NO	YES	YES	YES	YES[b]
Direct access to attributes	NO	YES	P	YES	P	P	YES
Domain specification for attributes	O	M	M	M	M	M	M
Class attributes and methods	YES	NO	NO	YES	NO	NO	NO
Relationships	NO	YES	NO	NO	YES	NO	YES
Composite objects	NO	NO	NO	YES	NO	NO	NO
Referential integrity	YES	NO	YES	NO	YES[c]	NO	YES[c]
Multiple inheritance	NO	YES	YES	YES	YES	YES	YES
Migration	L	YES	NO	NO	NO	NO	NO
Exceptional instances	NO	NO	YES	NO	NO	NO	NO

R = root persistence, A = automatic, 2op = two different *new* operations.
P = only for public attributes.
O = optional, M = mandatory.
L = in limited form.
[a] For those classes in which definition of an extent clause is specified.
[b] In C++ OML, created objects are automatically persistent and explicit deletion is supported; in Smalltalk OML, persistence is by root and no explicit delete operation exists.
[c] Referential integrity is ensured for relationships but not for attributes.

Primitive Type Extensions

Most DBMSs support predefined types like integers, floating points, strings, and dates. Object relational DBMSs support the definition of new primitive types starting from predefined primitive types and the definition of user-defined operations for these new primitive types. Operations on predefined types are inherited by the user-defined type, unless they are redefined explicitly. Consider as an example a `yen` type, which corresponds to the Japanese currency. In a relational DBMS, this type is represented as a numeric type with a certain scale and precision, for example `DECIMAL(8,2)`. The predefined operations of the DECIMAL type can be used on values of this type, but no other operations are available. Thus, any additional semantics, for instance, as to convert yens to dollars, must be handled by the application, as the display in an appropriate format of values of that type. In an object relational DBMS, by contrast, a type `yen` can be defined as follows:

```
CREATE TYPE yen AS Decimal(8,2);
```

and the proper functions can be associated with it.

Complex Types

A complex, or structured, type includes one or more attributes. This notion corresponds to the notion of struct of the C language or to the notion of record of the Pascal language. Complex types are called *structured types* in SQL:2003 (31). As an example, consider the type `t_Address`, defined as follows:

```
CREATE TYPE t_Address AS (street VARCHAR(50),
                          number INTEGER,
                          city CHAR(20),
                          country CHAR(2),
                          zip INTEGER),
```

Relations can contain attributes whose type is a complex type, as shown by the following example:

```
CREATE TABLE Employees(name CHAR(20),
                       emp# INTEGER,
                       curriculum CLOB,
                        salary INTEGER,
                        address t_Address);
```

This relation can be defined as equivalently :

```
CREATE TYPE t_Employee AS (name CHAR(20),
                      emp# INTEGER,

             curriculum CLOB,
             salary INTEGER,
             address t_Address);
            CREATE TABLE Employees OF t_Employee;
```

Note that for what concerns the structure of the tuples in the relation, the above declarations are equivalent to the following one, which makes use of an anonymous *row type* for specifying the structure of addresses:

```
CREATE TABLE Employees (name CHAR(20),
                             emp# INTEGER,
                             curriculum CLOB,
                             salary INTEGER,
        address ROW (street VARCHAR(50),
                        number INTEGER,
                        city CHAR(20),
                        country CHAR(2),
                        zip INTEGER));
```

Components of attributes, whose domain is a complex type, are accessed by means of the nested *dot notation*. For example, the zipcode of the address of an employee is accessed as `Employees.address.zip`.

Methods. Methods can be defined on simple and complex types, as part of the type definition. Each method has a signature and an implementation that can be specified in SQL/PSM (31) or in different programming languages. The method body can refer to the instance on which the method is invoked through the `SELF` keyword.

The definition of the type `t_Employee` can, for example, be extended with the definition of some methods as follows:

```
CREATE TYPE t_Employee (...)
INSTANCE METHOD double_salary()
   RETURNS BOOLEAN;
INSTANCE METHOD yearly_salary()
   RETURNS INTEGER;
INSTANCE METHOD add_telephone(n CHAR(15))
   RETURNS BOOLEAN;
```

With each complex type, a *constructor* method, which is denoted by `NEW` and the name of the type, is associated. This method creates an instance of the type, given its attribute values. As an example, the invocation

```
 NEW t_address('via pisa', 36, 'genova',
'italy', 16146)
```

returns a new instance of the `t_address` type.

For each attribute `A` in a complex type, an *accessor* method `A`, returning the attribute value, and a *mutator* method A, taking as input a value *v* and setting the attribute value to *v*, are associated implicitly with the type.

Referring to type `t_Employee` and to relation `Employees` above, the statement:

```
SELECT address.city()
FROM Employees;
```

contains an invocation of the accessor method for attribute `city`. Because the method has no parameters, the brackets can be omitted (i.e., `address.city`). By contrast, the statement:

```
UPDATE Employees
SET address = address.city('genova')
WHERE empl# = 777;
```

contains an invocation of the mutator method for attribute `city`.

Collection Types

Object relational DBMSs support constructors for grouping several instances of a given type, which thus models *collections* of type instances. Specifically, SQL:2003 supports `ARRAY` and `MULTISET` collections. Referring to the `Employees` relation above, suppose we want to add a `tel_nbrs` attribute as a collection of telephone numbers (strings). An attribute declared as

```
tel_nbrs CHAR(15) ARRAY[3]
```

allows for representing a maximum of three telephone numbers, ordered by importance. By contrast, an attribute declared as

```
tel_nbrs CHAR(15) MULTISET
```

allows for representing an unlimited number of telephone numbers, without specifying an order among them. Note that duplicates are allowed because the collection is a multiset.

Elements of the collections are denoted by indexes in case of arrays (for example, `tel_nbrs[2]` accesses the second number in the array), whereas multisets can be converted to relations through the `UNNEST` function and then they can be iterated over through an SQL query as any other relation. The following SQL statement:

```
SELECT e.name, T.N
FROM Employees e, UNNEST(e.tel_nbrs) T(N)
WHERE e.emp# = 777;
```

returns the employee name and the set of its telephone numbers. In the previous statement, `T` is the name of a virtual table and `N` is the name of its single column.

Reference Types

As we have seen, a structured type can be used in the definition of types and tables. Its instances are complex values. Structured types can be used as well for defining objects, as tuples with an associated identifier. These tuples are contained in *typed tables*, which are characterized by an additional identifier field, which is specified as `REF IS`. Note that the uniqueness of identifiers is not ensured across relations. The `Employees` relation above can be specified as a typed table as follows (provided the definition of type `t_Employee`:

```
CREATE TABLE Employees OF t_Employee
   (REF IS idE);
```

The values for the `idE` additional field are system-generated.

Reference types allow a column to refer a tuple contained in a typed table through its identifier. Thus, those types allow a tuple in a relation to refer to a tuple in another relation. The reference type for a type `T` is the type of the identifier of instances of `T` and is denoted by `REF(T)`. Given the following declaration and the above declarations of the `Employees` relation:

```
CREATE TYPE t_Department (name CHAR(10),
                dept# INTEGER,
                chair REF(t_Employee),
                dependents REF(t_Employee)
                MULTISET);
CREATE TABLE Departments
OF t_Department
(REF IS idD);
```

the values of the `chair` and `dependents` attributes are identifiers of instances of type `t_Employee`. This definition, however, does not provide information about the relation containing the instances of the type (SQL:2003 calls these *unconstrained* references). To ensure referential integrity, a `SCOPE` clause, which requires the reference to belong to the extent associated with a typed table, can be used. With the following declaration of the `Departments` relation:

```
CREATE TABLE Departments OF t_Department
(REF IS idD,
chair WITH OPTIONS SCOPE Employees,
dependents WITH OPTIONS SCOPE Employees);
```

for each tuple in the `Departments` relation, the `chair` column is guaranteed to refer to a tuple of the `Employees` relation (corresponding to the department chair) and the values in the multiset in the `dependent` column are guaranteed to refer to tuples of the `Employees` relation.

To manipulate reference-type instances, SQL provides the dereferencing function `DEREF`, returning the tuple referenced by a reference, and the reference function `->`, returning the value of a specific attribute of the tuple referenced by a reference. The attributes of a referred instance can be accessed by means of the dot notation. For example, referring to the example above, the name of a department chair can be denoted either as `Departments.chair->name` or `Departments.DEREF(chair).name`.

Inheritance

Inheritance specifies subtype/supertype relationships among types. Subtypes inherit attributes and methods of their supertypes. Object relational DBMSs allow for specifying inheritance links both among types and among relations. The following declarations specify types `t_ Student` and `t_Teacher` as subtypes of the `t_Person` type:

```
 CREATE TYPE t_Person AS (name      CHAR(20),
                          ssn       INTEGER,
                          b_date    DATE,
                          address   t_Address);
CREATE TYPE t_Teacher UNDER t_Person AS
                         (salary  DECIMAL(8,2),
                          dept     REF t_Department,
                         teaches  REF(t_Course) MULTISET);
CREATE TYPE t_Student UNDER t_Person AS
                       (avg_grade  FLOAT,
                       attends    REF(t_Course) MULTISET);
```

The following declarations, by contrast, specify inheritance relationships among relations:

```
 CREATE TABLE Persons OF t_Person;
 CREATE TABLE Teachers OF t_Teacher
 UNDER Persons;
 CREATE TABLE Students OF t_Student
 UNDER Persons;
```

At the data level, those two declarations imply that instances of Teachers and Students relations are also instances of the Persons relation (inheritance among relations) and that instances of those relations have `name`, `ssn`, `b_date`, and `address` as attributes (inheritance among types). The following query:

```
 SELECT name, address
 FROM Teachers
 WHERE salary > 2000
```

can thus be expressed.

Inheritance among types also implies method inheritance and method overloading. Overriding and late binding are supported.

LOBs

Object relational DBMSs, finally, provide LOB types to support the storage of multimedia objects, such as documents, images, and audio messages. LOBs are stored semantically as a column of the relation. Physically, however, they are stored outside the relations, typically in an external file. Usually, for efficiency reasons, those external files are not manipulated under transactional control (or, at least, logging is disabled). LOBs can be either CLOBs (characters) or BLOBs (binaries). Ad hoc indexing mechanisms are exploited to handle LOBs efficiently.

CONCLUDING REMARKS

In this article, we have focused on the modeling aspects and query and data manipulation languages of OODBMs and object relational DBMSs. The effective support of object-oriented data models and languages requires revisiting and possibly extending techniques and data structures used in DBMS architectures. In this section, we briefly discuss some of those architectural issues and point out relevant references. We mention moreover some relevant issues in OODBMSs not dealt with in the article.

An important aspect is related to the indexing techniques used to speed up query executions. Three object-oriented concepts have an impact on the evaluation of object-oriented queries as well as on the indexing support required: the inheritance hierarchy, the aggregation hierarchy, and the methods. For what concerns inheritance, a query on a class C has two possible interpretations. In a *single-class query*, objects are retrieved from only the queried class C itself, whereas in a *class-hierarchy query*, objects are retrieved from all the classes in the inheritance hierarchy rooted at C. To facilitate the evaluation of such types of queries, a *class-hierarchy index* needs to support efficient retrieval of objects from a single class as well as from all the classes in the class hierarchy. A class-hierarchy index is characterized by two parameters: the hierarchy of classes to be indexed and the index attribute of the indexed hierarchy.

Two approaches to class-hierarchy indexing exist: The *class-dimension-based approach*(32,33) partitions the data space primarily on the class of an object, and the *attribute-dimension-based approach*(32) partitions the data space primarily on the indexed attribute of an object. Although the class-dimension-based approach supports single-class queries efficiently, it is not effective for class-hierarchy queries because of the need to traverse multiple single-class indexes. On the other hand, the attribute-dimension-based approach generally provides efficient support for class-hierarchy queries on the root class (i.e., retrieving objects of all indexed classes), but it is inefficient for single-class queries or class-hierarchy queries on a subhierarchy of the indexed class hierarchy, as it may need to access many irrelevant leaf nodes of the single index structure. To support both types of queries efficiently, the index must support both ways of data partitioning (34). However, this is not a simple or direct application of multi-dimensional indexes, because totally ordering of classes is not possible and, hence, partitioning along the class dimension is problematic.

A second important issue in indexing techniques is related to aggregation hierarchies and to navigational accesses along these hierarchies. Navigational access is based on traversing object references; a typical example is represented by graph traversal. Navigations from one object in a class to objects in other classes in a class aggregation hierarchy are essentially expensive pointer-chasing operations. To support navigations efficiently, indexing structures that enable fast path instantiation have been developed, including the the multi-index technique, the nested index, the path index, and the join hierarchy index. In practice, many of these structures are based on precomputing traversals along aggregation hierarchies. The major problem of many of such indexing techniques is related to update operations that may require access to several objects to determine the index entries that need updating. To reduce update overhead and yet maintain the efficiency of path indexing structures, paths can be broken into subpaths that are then indexed separately (35,36). The proper splitting and allocation is highly dependent on the query and update patterns and frequencies. Therefore, adequate index allocation tools should be developed to support the optimal index allocation.

Finally, a last issue to discuss is related to the use of user-defined methods into queries. The execution of a query involving a method may require the execution of such method for a large number of instances. Because a method can be a general program, the query execution costs may become prohibitive. Possible solutions are based on method precomputation; such approaches, however, make object updates rather expensive. We refer the reader to Ref. 37, for an extensive discussion on indexing techniques for OODBMSs.

Another important issue, which is related to performance, is query optimization. Because most object-oriented queries only require implicit joins through aggregation hierarchies, the efficient support of such a join is important. Therefore, proposed query execution strategies have focused on efficient traversal of aggregation hierarchies. Because aggregation hierarchies can be represented as graphs, and a query can be observed as a visit of a portion of such a graph, traversal strategies can be formalized as strategies for visiting nodes in a graph. The main methods proposed for such visits include forward traversal, reverse traversal, and mixed traversal. They differ with respect to the order according to which the nodes involved in a given query are visited. A second dimension in query processing strategies concerns how instances from the visited class are retrieved. The two main strategies are the nested-loop and the sort-domain. Each of those strategies can be combined with each node traversal strategy, which results in a wide spectrum of strategies. We refer the reader to Ref. 1 for an extensive discussion on query execution strategies and related cost models.

Other relevant issues that we do not discuss here, but are dealt with in Ref. 1, include access control mechanisms, versioning models, schema evolutions, benchmarks, concurrency control, and transaction management mechanisms. Another aspect concerns integrity constraint and trigger support (38).

A final topic we would like to mention is related to the modeling and the management of *spatiotemporal* and *moving* objects. A large percentage of data managed in a variety of different application domains has spatiotemporal characteristics. For what concerns the spatial characteristics of data, for instance, an object may have a geographical location. Specifically, geographic objects, such as a land parcel, a car, and a person, do have a location. The location of a geographic object is a spatial attribute value, whose data type can be, for instance, a polygon or a point. Moreover, attribute values of geographic objects may be space dependent, which is different from spatial attribute values. For instance, the soil type of a land parcel applies to the entire spatial extent (i.e., the location of the land parcel) and it is not a "normal" attribute of a land parcel, but it is inherited from the underlying geographical space via the object location. This means that the attribute can be modeled as a function from the spatial domain. For what concerns the temporal characteristics of objects, both the time when some property holds *(valid time)* and the time when something is believed in/recorded as current in the database *(transaction time)* can be of interest. Several kinds of applications can be devised in which both spatial and temporal aspects of objects are important, among which at least three different types can be distinguished: *cadastral applications*, in which the spatial aspects are modeled primarily as regions and points and changes occur discretely across time; *transportation applications*, in which the spatial aspects are modeled primarily as linear features, graphs, and polylines and changes occur discretely across time; and *environmental applications*, or "location-based services," characterized by continuously changing spatial aspects. Several proposals that provide an integrated approach for the management of spatial and temporal information have been presented in the recent past (39,40). A growing interest has been devised also in the area of moving and geometric objects, mainly involving abstract modeling. Recently, spatiotemporal extensions of SQL:1999 and the ODMG model also have been proposed (41–43).

PROCESS-AWARE INFORMATION SYSTEMS: DESIGN, ENACTMENT, AND ANALYSIS

INTRODUCTION

Information technology has changed business processes within and between enterprises. More and more work processes are being conducted under the supervision of information systems that are driven by process models. Examples are workflow management systems such as FileNet P8, Staffware, WebSphere, FLOWer, and YAWL and enterprise resource planning (ERP) systems such as SAP and Oracle. Moreover, many domain-specific systems have components driven by (process) models. It is hard to imagine enterprise information systems that are unaware of the processes taking place. Although the topic of business process management using information technology has been addressed by consultants and software developers in depth, more fundamental approaches toward such *process-aware information systems* (PAISs) have been rare (1). Only since the 1990s have researchers started to work on the foundations of PAISs.

The goal of this article is to (a) provide an overview of PAISs and put these systems in a historical context, (b) to show their relevance and potential to improve business processes, dramatically, and (c) to discuss some more advanced topics to provide insights in current challenges and possible inhibitors. Before going into more detail, we first provide some definitions and give an overview of the different types of PAISs.

PAISs play an important role in *business process management* (BPM). Many definitions of BPM exist. Here we will use the following definition: "Business process management (BPM) is a field of knowledge that combines knowledge from information technology and knowledge from management sciences and applies this to operational business processes." BPM can be viewed as an extension of *workflow management* (WFM), which primarily focuses on the automation of business processes.

Figure 1 shows the relation among PAISs, BPM, and WFM. Note that the term "PAIS" refers to software, whereas the terms "BPM" and "WFM" refer to fields of knowledge in which PAISs can be used. Workflow management systems (WFMSs) can be seen as a particular kind of PAISs where the emphasis is on process automation rather than on redesign and analysis. A definition of WFMS could be "a generic software system that is driven by explicit process designs to enact and manage operational business processes." Clearly, a WFMS should be process-aware and generic in the sense that it is possible to modify the processes it supports. Note that the process designs automated by a WFMS are often graphical and that the focus is on structured processes that need to handle many cases.

Although a WFMS can be seen as a prototypical example of a PAIS, not all PAISs can be classified as pure WFMSs. As shown in Fig. 1, WFMSs are considered to be a subclass of all PAISs. Many examples of systems are process-aware, but they do not provide a generic approach to the modeling and enactment of operational business processes. For example, there may be systems where processes are hard-coded and cannot be modified. For example, many processes supported by an ERP system (e.g., SAP R/3) are hard-coded in software and can only be modified through explicit configuration parameters; that is, the set of possible variation points is predefined, and no notion of a process model can be modified freely. Many organizations have developed software to support processes without using a WFMS; for example, many banks, hospitals, electronic shops, insurance companies, and municipalities have created custom-made software to support processes. These systems are process-aware but are developed without using a WFMS. Another difference between PAISs and WFMSs is the fact that process automation is just one aspect of BPM. Process analysis and diagnosing existing processes clearly extend the scope beyond pure process automation.

Figure 1 also shows some more terms that are relevant in this context (BPR, SOA, BAM, etc.). Business process redesign (BPR) is concerned with finding better process designs. BPR efforts can be supported and enabled by PAISs. Business activity monitoring (BAM) uses information about running processes extracted from PAISs. Process mining techniques can be used to analyze this information and to come up with ideas to improve processes. Recently, the so-called *service-oriented architecture* (SOA) has been proposed as a platform for realizing PAISs. SOA is an architectural style whose goal is to achieve loose coupling among interacting parties. A service is a unit of work done by a service provider to achieve desired end results for a service consumer. Both provider and consumer are roles played by different pieces of software. The provider and consumer may reside in the same organization but also within different organizations. By using the SOA, it becomes easier to compose and maintain PAISs, because application functionality can be wrapped into servers that are invoked using a BPEL engine. The Business Process Execution Language (BPEL) (2) is the de facto standard for process execution in a SOA environment. In BPEL one can specify processes and enact them using the process engines of systems such as IBM's WebSphere or Oracle BPEL.

BPEL is a textual XML-based language, and its constructs are close to programming (2). People talk about "programming in the large" illustrating that it is not easy for nonprogrammers to model processes using BPEL. Therefore, languages such as BPMN (Business Process Modeling Notation) (3) have been proposed. Note that many modeling tools support languages similar to BPMN (e.g., ARIS and Protos). Figure 1 shows that the emphasis of execution languages like BPEL is on enactment, whereas languages like BPMN, EPCs, and Protos focus more on (re)design. Note that BPMN is not executable and has no formal semantics. However, in many cases, it is possible to generate some BPEL template code (3,4).

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

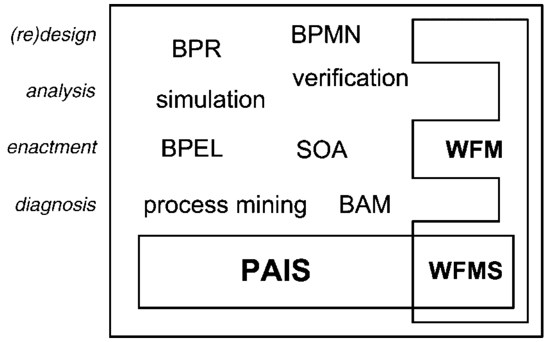

Figure 1. Relating PAISs to other approaches and tools in BPM.

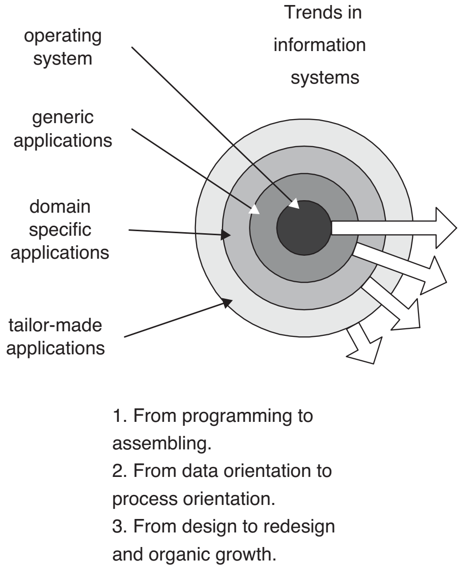
A PAIS requires the modeling of different perspectives (e.g., control flow, information, and organization/ resources). This article will mention the different perspectives, but it will focus primarily on the control-flow perspective. Moreover, we use a particular technique to model this perspective: Petri nets (5).

In the remainder of this article, we will first put BPM and related PAIS technology in their historical context (see the next Section 2). Then, we discuss models for process design. As PAIS are typically driven by explicit models, it is important to use the right techniques. Therefore, we discuss techniques for the analysis of process models. We will argue that it is vital to have techniques to assert the correctness of workflow designs. Based on this argument, we focus on systems for process enactment (i.e., systems that actually make the "work flow" based on a model of the processes and organizations involved). Finally, we focus on two more advanced topics: process flexibility and process mining.

BUSINESS PROCESS MANAGEMENT FROM A HISTORICAL PERSPECTIVE

To show the relevance of PAISs, it is interesting to put them in a historical perspective (6). Consider Fig. 2, which shows some ongoing trends in information systems. This figure shows that today's information systems consist of several layers. The center is formed by the operating system (i.e., the software that makes the hardware work). The second layer consists of generic applications that can be used in a wide range of enterprises. Moreover, these applications are typically used within multiple departments within the same enterprise. Examples of such generic applications are a database management system, a text editor, and a spreadsheet program. The third layer consists of domain-specific applications. These applications are only used within specific types of enterprises and departments. Examples are decision support systems for vehicle routing, call center software, and human resource management software. The fourth layer consists of tailor-made applications. These applications are developed for specific organizations.

In the 1960s, the second and third layer were missing. Information systems were built on top of a small operating system with limited functionality. As no generic nor domain-specific software was available, these systems mainly consisted of tailor-made applications. Since then, the second and third layer have developed and the ongoing trend is that the four circles are increasing in size (i.e., they are moving to the outside while absorbing new functionality). Today's operating systems offer much more functionality. Database management systems that reside in the second layer offer functionality that used to be in tailor-made applications. As a result of this trend, the emphasis has shifted from programming to assembling of complex software systems. The challenge no longer is the coding of individual modules but the orchestrating and gluing together of pieces of software from each of the four layers.



Trends in information systems
operating system
generic applications
domain specific applications
tailor-made applications
1. From programming to assembling.
2. From data orientation to process orientation.
3. From design to redesign and organic growth.

Figure 2. Trends relevant for business process management.

Another trend is the shift from data to processes. The 1970s and 1980s were dominated by data-driven approaches. The focus of information technology was on storing and retrieving information, and as a result, data modeling was the starting point for building an information system. The modeling of business processes was often neglected, and processes had to adapt to information technology. Management trends such as business process reengineering illustrate the increased emphasis on processes. As a result, system engineers are resorting to a more process-driven approach.

The last trend we would like to mention is the shift from carefully planned designs to redesign and organic growth. Because of to the omnipresence of the Internet and its standards, information systems change on the fly. Few systems are built from scratch. In most cases, existing applications are partly used in the new system. As a result, software development is much more dynamic.

The trends shown in Fig. 2 provide a historical context for PAISs. PAISs are either separate applications residing in the second layer or are integrated components in the domain-specific applications (i.e., the third layer). Notable examples of PAISs residing in the second layer are WFMSs (7–9) such as Staffware, FileNet P8, and COSA, and case handling systems such as FLOWer. Middleware platforms such as IBM's WebSphere provide a workflow engine (typically based on BPEL (2). Moreover, many open-source WFMSs exist (cf. ActiveBPEL, Enhydra-Shark, jBPM, and YAWL). Note that leading ERP systems populating the third layer also offer a workflow management module. The workflow engines of SAP, Baan, PeopleSoft, Oracle, and JD Edwards can be considered integrated PAISs. The idea to isolate the management of business processes in a separate component is consistent with the three trends identified. PAISs can be used to avoid hard-coding the work processes into tailor-made applications and thus support the shift from programming to assembling. Moreover, process orientation, redesign, and organic growth are supported. For example, today's workflow management systems can be used to integrate existing applications and to support process change by merely changing the workflow diagram. Given these observations, we hope to have demonstrated the practical relevance of PAISs. In the remainder of this article, we will focus more on the scientific importance of these systems. Moreover, for clarity, we will often restrict the discussion to clear-cut business process management systems such as WFMSs.

An interesting starting point from a scientific perspective is the early work on office information systems. In the 1970s, people like Skip Ellis (10), Anatol Holt (11), and Michael Zisman (12) already worked on so-called office information systems, which were driven by explicit process models. It is interesting to see that the three pioneers in this area independently used Petri net variants to model office procedures. During the 1970s and 1980s, there was great optimism about the applicability of office information systems. Unfortunately, few applications succeeded. As a result of these experiences, both the application of this technology and the research almost stopped for a decade. Consequently, hardly any advances were made in the 1980s. In the 1990s, there again was a huge interest in these systems. The number of WFMSs developed in the past decade and the many papers on workflow technology illustrate the revival of office information systems. Today WFMSs are readily available. However, their application is still limited to specific industries such as banking and insurance. As indicated by Skip Ellis, it is important to learn from these ups and downs. The failures in the 1980s can be explained by both technical and conceptual problems. In the 1980s, networks were slow or not present at all, there were no suitable graphical interfaces, and proper development software was missing. However, more fundamental problems also existed: A unified way of modeling processes was missing, and the systems were too rigid to be used by people in the workplace. Most of the technical problems have been resolved by now. However, the more conceptual problems remain. Good standards for business process modeling are still missing, and even today's WFMSs are too rigid.

One of the great challenges of PAISs is to offer both support and flexibility. Today's systems typically are too rigid, thus, forcing people to work around the system. One of the problems is that software developers and computer scientists are typically inspired by processes inside a computer system rather than by processes outside a computer. As a result, these engineers think in terms of control systems rather than in terms of support systems, which explains why few of the existing WFMSs allow for the so-called implicit choice (i.e., a choice resolved by the environment rather than by the system).

To summarize we would like to state that, although the relevance of PAISs is undisputed, many fundamental problems remain to be solved. In the remainder of this article, we will try to shed light on some of these problems.

MODELS FOR PROCESS DESIGN

PAISs are driven by models of processes and organizations (1). By changing these models, the behavior of the system adapts to its environment and changing requirements. These models cover different perspectives. Figure 3 shows some of the perspectives relevant for PAISs (9). The process perspective describes the control flow (i.e., the ordering of tasks). The information perspective describes the data that are used. The resource perspective describes the structure of the organization and identifies resources, roles, and groups. The task perspective describes the content of individual steps in the processes. Each perspective is relevant. However, the process perspective is dominant for the type of systems addressed in this article.

Many techniques have been proposed to model the process perspective. Some of these techniques are informal in the sense that the diagrams used have no formally defined semantics. These models are typically very intuitive, and the interpretation shifts depending on the modeler, application domain, and characteristics of the business processes at hand. Examples of informal techniques are ISAC, DFD, SADT, and IDEF. These techniques may serve well for discussing work processes. However, they are inadequate for directly driving information systems because they are incomplete and subject to multiple interpretations. Therefore, more precise ways of modeling are required.

Figure 4 shows an example of an order handling process modeled in terms of a so-called workflow net (13). Workflow nets are based on the classic Petri net model invented by Carl Adam Petri in the early 1960s (5). The squares are

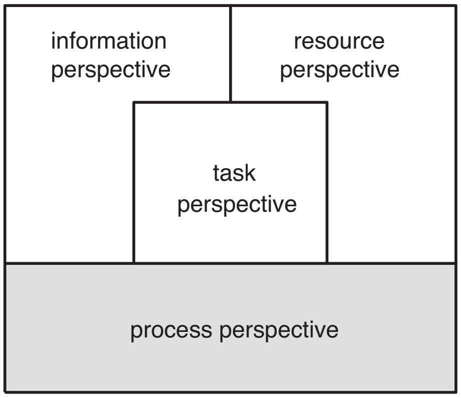


Figure 3. Perspectives of models driving PAISs.

the active parts of the model and correspond to tasks. The circles are the passive parts of the model and are used to represent states. In the classic Petri net, the squares are named transitions and the circles places. A workflow net models the lifecycle of one case. Examples of cases are insurance claims, tax declarations, and traffic violations. Cases are represented by tokens, and in this case, the token in *start* corresponds to an order. Task *register* is a so-called AND-split and is enabled in the state shown. The arrow indicates that this task requires human intervention. If a person executes this task, the token is removed from place *start* and two tokens are produced: one for *c1* and one for *c2*. Then, in parallel, two tasks are enabled: *check_availability* and *send_bill*. Depending on the eagerness of the workers executing these two tasks, either *check_available* or *send_bill* is executed first. Suppose *check_availability* is executed first. If the ordered goods are available, they can be shipped by executing task *ship_goods*. If they are not available, either a replenishment order is issued or not. Note that *check_availability* is an OR-split and produces one token for *c3*, *c4*, or *c5*. Suppose that not all ordered goods are available but that the appropriate replenishment orders were already issued. A token is produced for *c3*, and task *update* becomes enabled. Suppose that at this point in time task *send_bill* is executed, resulting in the state with a token in *c3* and *c6*. The token in *c6* is input for two tasks. However, only one of these tasks can be executed, and in this state, only *receive_payment* is enabled. Task *receive_payment* can be executed the moment the payment is received. Task *reminder* is an AND-join/AND-split and is blocked until the bill is sent and the goods have been shipped. Note that the reminder is sent after a specified period as indicated by the clock symbol. However, it is only possible to send a remainder if the goods have been actually shipped. Assume that in the state with a token in *c3* and *c6,* task *update* is executed. This task does not require human involvement and is triggered by a message of the warehouse indicating that relevant goods have arrived. Again *check_availability* is enabled. Suppose that this task is executed and that the result is positive. In the resulting state, *ship_goods* can be executed. Now there is a token in *c6* and *c7*, thus enabling task *reminder*. Executing task *reminder* again enables the task *send_bill*. A new copy of the bill is sent with the appropriate text. It is possible to send several reminders by alternating *reminder* and *send_bill*. However, let us assume that after the first loop, the customer pays resulting in a state with a token in *c7* and *c8*. In this state, the AND-join *archive* is enabled and executing this task results in the final state with a token in *end*.

This very simple workflow net shows some of the routing constructs relevant for business process modeling. Sequential, parallel, conditional, and iterative routing are present in this model. There also are more advanced constructs such as the choice between *receive_payment* and *reminder*, which is a so-called *implicit choice* (14) because it is not resolved by the system but by the environment of the system. The moment the bill is sent, it is undetermined whether *receive_payment* or *reminder* will be the next step in the process. Another advanced construct is the fact that task *reminder* is blocked until the goods have been shipped. The latter construct is a so-called *milestone* (14). The reason that we point out both constructs is that many systems have problems supporting these fundamental process patterns (14).

Workflow nets have clear semantics. The fact that one can play the so-called "token game" using a minimal set of rules shows the fact that these models are executable. None of the informal informal techniques mentioned before (i.e., ISAC, DFD, SADT, and IDEF) have formal semantics. Besides these informal techniques, many formal techniques also exist. Examples are the many variants of process algebra and statecharts. The reason we prefer to use a variant of Petri nets is threefold (13):

- Petri nets are graphical and yet precise.
- Petri nets offer an abundance of analysis techniques.
- Petri nets treat states as first-class citizens.

The latter point deserves some more explanation. Many techniques for business process modeling focus exclusively on the active parts of the process (i.e., the tasks), which is very strange because in many administrative processes, the actual processing time is measured in minutes and the flow time is measured in days. This process for measuring means that most of the time cases are in between two subsequent tasks. Therefore, it is vital to model these states explicitly.

At the beginning of this section, we mentioned that there are informal techniques (without formal semantics) and rigorous formal methods such as Petri nets. Over the last two decades, many semiformal methods have been proposed (i.e., in between the two extreme classes mentioned earlier). These methods are informal, however, because the models that need to be transformed into executable code for more rigorous interpretations are added afterward. The UML (Unified Modeling Language) (15) in an example of such a language. It has become the de facto standard for software development. UML has four diagrams for process modeling. UML supports variants of statecharts, and its activity diagrams are inspired by Petri nets (i.e., a token-based semantics is used). Many notations exist that are at the same level as UML activity diagrams. BPMN (3) diagrams and event-driven process chains (EPCs) (16) are examples of such languages. Many researchers are trying to provide solid semantics for UML, EPCs, BPMN, BPEL, and so on. For subsets of these languages, there are formalizations in terms of Petri nets and transition systems. These formalizations typically reveal ambiguous constructs in the corresponding language.

Note that the goal of this article is not to advocate Petri nets as an end-user modeling language. UML, EPCs, and BPMN provide useful constructs that support the workflow designer. However, Petri nets serve as an important foundation for PAIS technology. Without such foundations it is impossible to reason about semantics, correctness, completeness, and so on. A nice illustration is the OR-join in EPC and BPMN models that have semantics leading to paradoxes such as the "vicious circle" (16). Moreover, a solid foundation can be used for analysis as will be shown next.

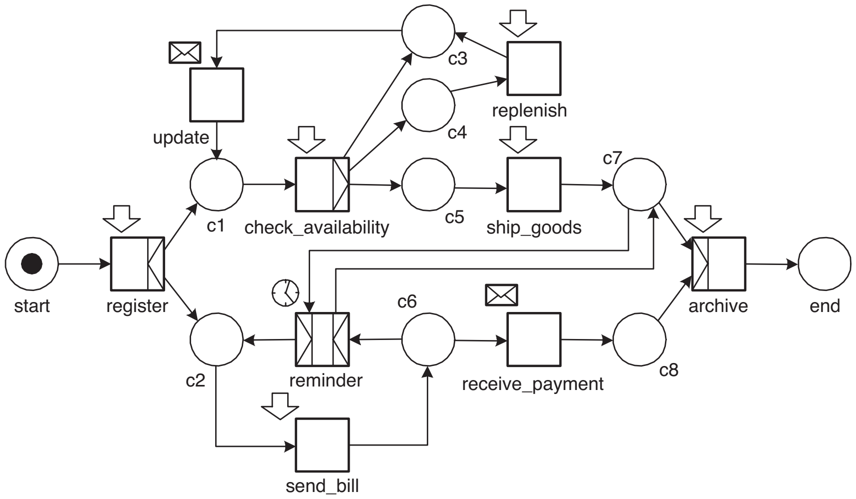

Figure 4. A WF net modeling the handling of orders. The top part models the logistical part of the process, whereas the bottom part models the financial part.

TECHNIQUES FOR PROCESS ANALYSIS

Many PAISs allow organizations to change their processes by merely changing the models. The models are typically graphical and can be changed ability to change easily. This provides more flexibility than conventional information systems. However, by reducing the threshold for change, errors are introduced more easily. Therefore, it is important to develop suitable analysis techniques. However, it is not sufficient to just develop these techniques. It is as least as important to look at methods and tools to make them applicable in a practical context.

Traditionally, most techniques used for the analysis of business processes originate from operations research. All students taking courses in operations management will learn to apply techniques such as simulation, queuing theory, and Markovian analysis. The focus mainly is on *performance analysis,* and less attention is paid to the correctness of models. *Verification* and *validation* are often neglected. As a result, systems fail by not providing the right support or even break down. Verification is needed to check whether the resulting system is free of logical errors. Many process designs suffer from deadlocks and livelocks that could have been detected using verification techniques. Validation is needed to check whether the system actually behaves as expected. Note that validation is context dependent, whereas verification is not. A system that deadlocks is not correct in any situation. Therefore, verifying whether a system exhibits deadlocks is context independent. Validation is context dependent and can only be done with knowledge of the intended business process.

To illustrate the relevance of validation and verification and to demonstrate some of the techniques available, we return to the workflow net shown in Fig. 4. This workflow process allows for the situation where a replenishment is issued before any payment is received. Suppose that we want to change the design such that replenishments are delayed until receiving payment. An obvious way to model this change is to connect task *receive_payment* with *replenish* using an additional place *c9* as shown in Fig. 5. Although this extension seems to be correct at first glance, the resulting workflow net exhibits several errors. The workflow will deadlock if a second replenishment is needed and something is left behind in the process if no replenishments

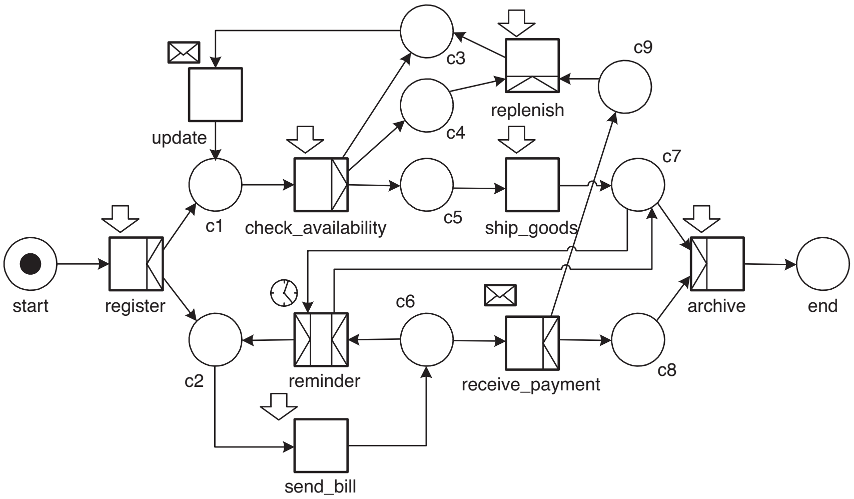

Figure 5. An incorrect WF net. Place *c9* has been added to model that a replenishment order can only be placed if the customer has paid. However, because of this addition, the process can deadlock and a token is left behind in the process if no replenishments are needed.

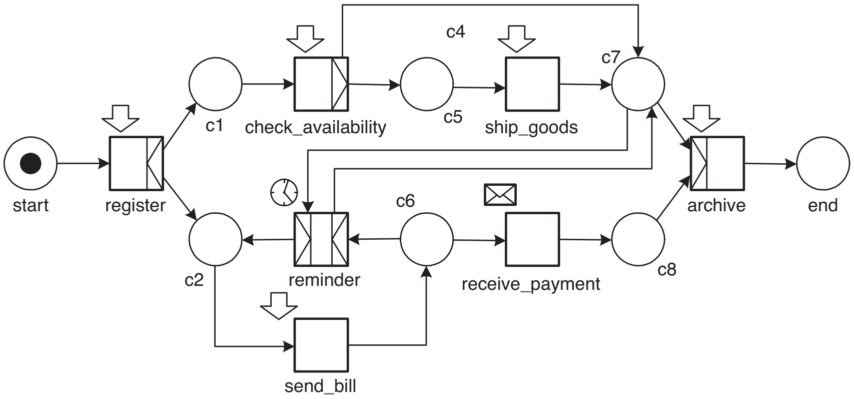

Figure 6. A sound but incorrect WF net. The shipping of goods is no longer guaranteed.

are needed. These logical errors can be detected without any knowledge of the order handling process. For verification, application-independent notions of correctness are needed. One of these notions is the so-called *soundness property*(13). A workflow net is sound if an only if the workflow contains no dead parts (i.e., tasks that can never be executed), from any reachable state it is always possible to terminate, and the moment the workflow terminates all places except the sink place are empty. Note that soundness rules out logical errors such as deadlocks and livelocks. The notion of soundness is applicable to any workflow language. An interesting observation is that soundness corresponds to liveness and boundedness of the short-circuited net (13). The latter properties have been studied extensively (17). As a result, powerful analysis techniques and tools can be applied to verify the correctness of a workflow design. Practical experience shows that many errors can be detected by verifying the soundness property. Moreover, Petri net theory can also be applied to guide the designer toward the error.

Soundness does not guarantee that the workflow net behaves as intended. Consider, for example, the workflow net shown in Fig. 6. Compared with the original model, the shipment of goods is skipped if some goods are not available. Again this idea may seem like a good one at first glance. However, customers are expected to pay even if the goods are never delivered. In other words, task *receive_payment* needs to be executed although task *ship_goods* may never be executed. The latter error can only be detected using knowledge about the context. Based on this context, one may decide whether this is acceptable. Few analysis techniques exist to support this kind of validation automatically. The only means of validation offered by today's WFMSs is gaming and simulation.

An interesting technique to support validation is inheritance of dynamic behavior. Inheritance can be used as a technique to compare processes. Inheritance relates subclasses with superclasses (18). A workflow net is a subclass of a superclass workflow net if certain dynamic properties are preserved. A subclass typically contains more tasks. If by hiding and/or blocking tasks in the subclass one obtains the superclass, the subclass inherits the dynamics of the superclass.[1] The superclass can be used to specify the minimal properties the workflow design should satisfy. By merely checking whether the actual design is a subclass of the superclass, one can validate the essential properties. Consider, for example, Fig. 7. This workflow net describes the minimal requirements the order handling process should satisfy. The tasks *register*, *ship_goods*, *receive_payment*, and *archive* are mandatory. Tasks *ship_goods* and *receive_payment* may be executed in parallel but should be preceded by *register* and followed by *archive*. The original order handling process shown in Fig. 4 is a subclass of this superclass. Therefore, the minimal requirements are satisfied. However, the order handling process shown in Fig. 6 is not a subclass. The fact that task *ship_goods* can be skipped demonstrates that not all properties are preserved.

Inheritance of dynamic behavior is a very powerful concept that has many applications. Inheritance-preserving transformation rules and transfer rules offer support at design time and at run time (19). Subclass–superclass relationships also can be used to enforce correct processes in an e-commerce setting. If business partners only execute subclass processes of some common contract process, then the overall workflow will be executed as agreed. It should be noted that workflows crossing the borders of organizations are particularly challenging from a verification and validation point of view. Errors resulting from miscommunication between business partners are highly disruptive and costly. Therefore, it is important to develop techniques and tools for the verification and validation of these processes. For example, in the context of SOA-based processes (e.g., BPEL processes), the so-called open WF nets (OWF-nets) (20,21) are used to study notions such as controllability and accordance.

Few mature tools aiming at the verification of workflow processes exist. Woflan (22) is one of the notable exceptions. Figure 8 shows a screenshot of Woflan. Woflan combines state-of-the-art scientific results with practical applications (22). Woflan can interface with WFMSs such as Staffware, Websphere, Oracle BPEL, COSA, and YAWL. It can also interface with BPR tools such as Protos and process mining tools such as ProM (23). Workflow processes

[1] We have identified four notions of inheritance. In this article, we only refer to life-cycle inheritance.

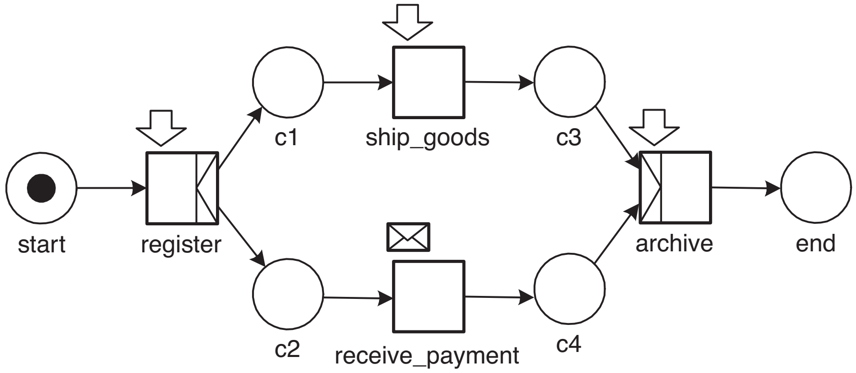

Figure 7. A superclass WF net.

designed using any of these tools can be verified for correctness. It turns out that the challenge is not to decide whether the design is sound. The real challenge is to provide diagnostic information that guides the designer to the error. Woflan also supports the inheritance notions mentioned before. Given two workflow designs, Woflan can decide whether one is a subclass of the other. Tools such as Woflan illustrate the benefits of a more fundamental approach. Recently, several tools have been developed for the analysis of BPEL processes. The Tools4BPEL toolset consisting of Fiona, LoLa, and BPEL2oWFN is an example of a state-of-the-art BPEL analyzer (21).

To conclude this section, we would like to refer to a study reported in Ref. 24. This study shows that of the 604 process models in the SAP R/3 Reference Model, 20% contain errors that can easily be discovered using verification. Since the middle of the 1990s, the SAP R/3 Reference Model has been available in different versions to support the implementation and configuration of the SAP system. The reference model is not only included in the SAP system, but also it is shipped with the business process modeling tools ARIS of IDS Scheer or NetProcess of IntelliCorp. The reference model covers several modeling perspectives such as data and organization structure, but the main emphasis is on 604 nontrivial business processes represented as EPCs. More than 20% of these EPCs contain errors stemming from incorrect combinations of connector elements such as deadlocks and livelocks. A deadlock describes a situation in a process model where a customer order remains waiting for an activity to complete that can never be executed. A simple pattern leading to a deadlock is an XOR split is joined with an AND. A livelock is an infinite loop (i.e., it is impossible to move beyond a certain point and terminate). The many errors in the SAP R/3 Reference Model illustrate the need for rigorous analysis techniques.

SYSTEMS FOR PROCESS ENACTMENT

Progress in computer hardware has been incredible. In 1964 Gordon Moore predicted that the number of elements on a produced chip would double every 18 months.[2] Up until now, Moore's law still applies. Information technology has also resulted in a spectacular growth of the information being gathered. The commonly used term "information overload" illustrates this growth. Already in 2003, it is estimated that for each individual (i.e., child, man, and woman), 800 megabytes of data are gathered each year (25). The Internet and the World Wide Web have made an abundance of information available at low costs. However, despite the apparent progress in computer hardware and information processing, many information systems leave much to be desired. One problem is that process logic is mixed with application logic. As a result, it is difficult to change a system and people need to "work around the system" rather than getting adequate support. To improve flexibility and reliability, process logic should be separated from application logic. These observations justify the use of solid models and analysis techniques, as discussed before.

Thus far, the focus of this article has been on the design and analysis of work processes. Now it is time to focus on the systems to enact these work processes. Fig. 9 shows the typical architecture of a business process management system. The designer uses the design tools to create models describing the processes and the structure of the organization. The manager uses management tools to monitor the flow of work and act if necessary. The worker interacts with the enactment service. The enactment service can offer work to workers, and workers can search, select, and per-

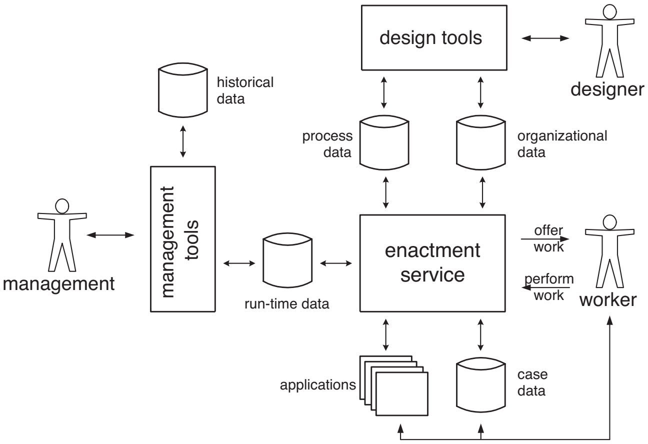

Figure 9. The architecture of a PAIS.

form work. To support the execution of tasks, the enactment service may launch various kinds of applications. Note that the enactment service is the core of the system deciding on "what," "how," "when," and "by whom." Clearly, the enactment service is driven by models of the processes and the organizations. By merely changing these models, the system evolves and adapts, which is the ultimate promise of PAISs.

However, PAIS systems are not the "silver bullet" that solves all problems (i.e., "there is no such thing as a free lunch"), and rigorous modeling is needed to capture processes adequately. Moreover, existing WFMSs still have problems supporting flexibility.

Today's WFMSs have an architecture consistent with Fig. 9. Consider, for example, the screenshots of Staffware shown in Fig. 10. Staffware is one of the leading WFMSs. The top window shows the design tool of Staffware while defining a simple workflow process. Work is offered through so-called work queues. One worker can have multiple work queues, and one work queue can be shared among multiple workers. The window in the middle shows the set of available work queues (left) and the content of one of these work queues (right). The bottom window shows an audit trail of a case. The three windows show only some of the capabilities offered by contemporary workflow management systems. It is fairly straightforward to map these windows onto the architecture. In other processes-aware information systems such as, for example, enterprise resource planning systems, one will find the architecture shown in Fig. 9 embedded in a larger architecture.

The architecture shown in Fig. 9 assumes a centralized enactment service. Inside a single organization such an assumption may be realistic. However, in a cross-organizational setting, this is not the case. Fortunately, most vendors now support the SOA, mentioned earlier. In a SOA, tasks are subcontracted to other parties (i.e., what is one task for the service consumer may be a complex process for a service consumer). The Web services stack using standards such as WSDL and BPEL facilitates the development of cross-organizational workflows.

Despite the acceptance of PAISs, the current generation of products leaves much to be desired. To illustrate,

Figure 10. The Graphical Workflow Definer, Work Queue, and Audit Trail of Staffware.

we focus on the current generation of WFMSs. We will use Fig. 9 to identify five problems.

First of all, there is a lack of good standards for workflow management. There is, for example, not a good standard for exchanging process models. Existing formats have no clearly defined semantics and fail to capture many routing constructs. Current standards for workflow management are incomplete, inconsistent, at the wrong abstraction level, and mainly driven by the commercial interests of workflow vendors. The Workflow Management Coalition (WfMC) has been trying to standardize workflow processes since the early 1990s. This effort resulted in the Workflow Process Definition Language (WPDL) and the XML Process Definition Language (XPDL). Only a few vendors actively supported these standards. The standards had no clearly defined semantics and encouraged vendors to make product-specific extensions. The BPEL (2) emerged later and is currently the de facto standard for process execution in a SOA environment. However, this language also has no clearly defined semantics and is at a technical level (26). BPEL has the look and feel of a programming language rather than a high-level modeling language.

Second, the expressive power (i.e., the ability to represent complex work processes) of the current generation of WFMSs is insufficient. Several evaluations revealed that the classic WFMSs support less than half of the desirable workflow patterns (14). As an example, consider the workflow process shown in Fig. 4. Few systems can handle the implicit choice and milestone construct identified before. Fortunately, modern systems (e.g., based on BPEL) support more patterns.

A third problem is the lack of understanding of how people actually work. Work processes are more than the ordering of tasks. Work is embedded in a social context. A better understanding of this context is needed to make systems socially aware as well. Modeling processes as if people are "machines" is a too limited view of reality. It is vital to empower workers and to provide more flexibility.

The fourth problem is the limited support for workflow analysis. As indicated before, there are powerful techniques for workflow analysis. However, few systems embed advanced analysis techniques. Besides model-based verification, validation, and performance analysis, new types of analysis are possible. The combination of historical and run-time data, on the one hand, and workflow designs, on the other, offers breathtaking possibilities. Historical data can be used to obtain stochastic data about routing and timing. Using run-time data to reconstruct the current state in a simulation model allows for *on-the-fly simulation*. Simulation based on the current state, historical data, and a good model offers high-quality information about potential problems in the near future. Historical data can also be used for *process mining*. The goal of workflow mining is to derive process models from transaction logs.

Finally, many technical problems remain. Some of these problems can be resolved using Internet-based technology and standards. However, many problems related to the integration of components and long-lived transactions remain unsolved. Since the early 1990s (8) many database researchers have been focusing on transactional aspects of workflows. Note that an instance of a workflow can be viewed as a long running transaction [e.g., some cases (such as a mortgage or insurance) may run dozens of years] (27).

In the remainder, we would like to focus on two particular challenges: *process flexibility* and *process mining*.

CHALLENGE: FLEXIBILITY

Adaptability has become one of the major research topics in the area of workflow management (28). Today's WFMSs and many other PAISs have problems supporting flexibility. As a result, these systems are not used to support dynamically changing business processes or the processes are supported in a rigid manner (i.e., changes are not allowed or handled outside of the system). These problems have been described and addressed extensively in the literature (29–36). Nevertheless, many problems related to flexibility remain unsolved.

In this section, we provide a taxonomy of flexibility because it is probably the biggest challenge today's PAISs are facing. To clarify things, we focus on WFMSs rather than on the broader class of PAISs.

To start, let us identify the different *phases* of a process (instance) in the context of a WFMS:

- *Design time*. At design time, a generic process model is created. This model cannot be enacted because it is not connected to some organizational setting.
- *Configuration time*. At configuration time, a generic model is made more specific and connected to some organizational context that allows it to be instantiated.
- *Instantiation time*. At instantiation time, a process instance is created to handle a particular case (e.g., a customer order or travel request).
- *Run time*. At run time, the process instance is executed according to the configured model. The different activities are being enacted as specified.
- *Auditing time*. At auditing time, the process instance has completed; however, its audit trail is still available and can be inspected and analyzed.

Flexibility plays a role in most phases. At design time, some modeling decisions can be postponed to run time. At run time, one can decide to deviate from the model, and at instantiation time, one can change the process model used for the particular instance. When it comes to flexibility, we identify three *flexibility mechanisms*:

- *Defer, i.e., decide to decide later*. This flexibility mechanism deliberately leaves freedom to maneuver at a later phase. Examples are the use of a declarative process modeling language that allows for the "under specification" of processes and the use of late binding (i.e., the process model has a "hole" that needs to be filled in a later phase).
- *Change, i.e., decide to change model*. Most researchers have addressed flexibility issues by allowing for change. Decisions made at an earlier phase may be revisited. For example, for premium customers, the process may be adapted in an ad hoc manner. The change may refer to the model for a single instance (adhoc change) or to all future cases (evolutionary change). In both cases, a change can create inconsistencies. For evolutionary change, cases may also need to be migrated.
- *Deviate, i.e., decide to ignore model*. The third mechanism is to deviate from the model (e.g., tasks are skipped even if the model does not allow for this to happen). In many environments, it is desirable that people are in control (i.e., the system can only suggest activities but not force them to happen).

Figure 11 relates the two dimensions just mentioned. Based on the different phases and the three mechanisms, different types of flexibility are classified. Note that we did not mention any examples of flexibility at auditing time. After the process instance completes, it is not possible to defer, change, or violate things, because this would imply fraud. Figure 11 can be used to characterize the support for flexibility of a concrete WFMS. Unfortunately, today's systems support only a few forms of flexibility, thus limiting the applicability of PAISs.

It is impossible to provide a complete overview of the work done on flexibility in workflows. The reader is referred to Ref. 28 for another taxonomy. Many authors have focused on the problems related to change (31–34) (cf. the cell "change at run time" in Fig. 11). The problem of changing a process while instances are running was first

	defer (decide to decide later)	change (decide to change model)	deviate (decide to ignore model)
design time	e.g., defer to run-time by using late binding or declarative modeling	N/A	N/A
configuration time	e.g., defer configuration decisions	e.g., remodel parts of the process at configuration time	e.g., violate a configuration constraint
instantiation time	e.g., defer the selection of parameters or process fragments	e.g., modify model for a particular customer	N/A
run time	N/A	e.g., change model for running instance or migrate instance to new model	e.g., skip or redo a task while this is not specified
auditing time	N/A	N/A	N/A

Figure 11. Classification of the different types of flexibility based on the phase and mechanism.

mentioned in Ref. 31. In the context of ADEPT (32,34), many problems have been addressed. See Ref. 34 for an excellent overview of problems related to dynamic change (the cell "change at run time" in Fig. 11). Other authors approach the problem by avoiding change, for example, either by using a more declarative language (33) or by late binding (30,35,36) (also referred to as worklets, pockets of flexibility, or process fragments). These approaches fit into the column "defer" in Fig. 11. Another interesting approach is provided by the system FLOWer of Pallas Athena. This system uses the so-called "case handling" concept to provide more flexibility (29). Most of the ideas of case handling relate to the "defer" and "deviate" columns in Fig. 11.

CHALLENGE: PROCESS MINING

Process mining has emerged as a way to analyze systems and their actual use based on the event logs they produce (37,38). Process mining always starts with *event logs*. Events logs may originate from all kinds of PAISs. Examples are classic WFMSs, ERP systems (e.g., SAP), case handling systems (e.g., FLOWer), PDM systems (e.g., Windchill), CRM systems (e.g., Microsoft Dynamics CRM), middleware (e.g., IBM's WebSphere), hospital information systems (e.g., Chipsoft), and so on. These systems provide very detailed information about the activities that have been executed.

The goal of process mining is to extract information (e.g., process models) from these logs (i.e., process mining describes a family of *a posteriori* analysis techniques exploiting the information recorded in the event logs). Typically, these approaches assume that it is possible to record events sequentially such that each event refers to an activity (i.e., a well-defined step in the process) and is related to a particular case (i.e., a process instance). Furthermore, some mining techniques use additional information such as the performer or originator of the event (i.e., the person/resource executing or initiating the activity), the timestamp of the event, or data elements recorded with the event (e.g., the size of an order).

Process mining addresses the problem that most "process/system owners" have limited information about what is actually happening. In practice, there is often a significant gap between what is prescribed or supposed to happen and what *actually* happens. Only a concise assessment of reality, which process mining strives to deliver, can help in verifying process models and ultimately be used in system or process redesign efforts.

The idea of process mining is to discover, monitor, and improve real processes (i.e., not assumed processes) by extracting knowledge from event logs. We consider three basic types of process mining (Fig. 12):

- *Discovery*: No a priori model exists (i.e., based on an event log, some model is constructed). For example, using the α-algorithm (37), a process model can be discovered based on low-level events.
- *Conformance*: An a priori model exists. This model is used to check whether reality conforms to the model. For example, a process model may indicate that purchase orders of more than one million Euro require two checks. Another example is the checking of the

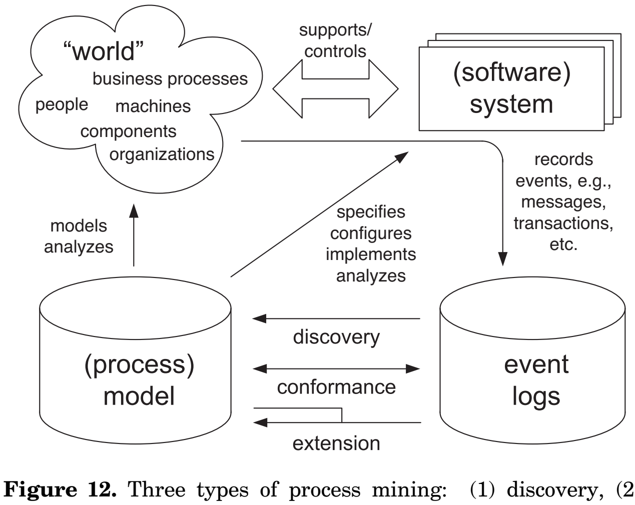

Figure 12. Three types of process mining: (1) discovery, (2) conformance, and (3) extension.

four-eyes principle. Conformance checking may be used to detect deviations, to locate and explain these deviations, and to measure the severity of these deviations.

- *Extension*: An a priori model exists. This model is extended with a new aspect or perspective (i.e., the goal is not to check conformance but to enrich the model with the data in the event log). An example is the extension of a process model with performance data (i.e. some a priori process model is used on which bottlenecks are projected).

Traditionally, process mining has been focusing on *discovery* (i.e., deriving information about the original process model, the organizational context, and execution properties from enactment logs). An example of a technique addressing the control flow perspective is the α-algorithm, which constructs a Petri net model (17) describing the behavior observed in the event log. However, process mining is not limited to process models (i.e., control flow) and recent process mining techniques are more and more focusing on other perspectives (e.g., the organizational perspective or the data perspective). For example, there are approaches to extract social networks from event logs and analyze them using social network analysis. This allows organizations to monitor how people, groups, or software/system components are working together.

Conformance checking compares an a priori model with the observed behavior as recorded in the log. In Ref. 39, it is shown how a process model (e.g., a Petri net) can be evaluated in the context of a log using metrics such as "fitness" (Is the observed behavior possible according to the model?) and "appropriateness" (Is the model "typical" for the observed behavior?). However, it is also possible to check conformance based on organizational models, predefined business rules, temporal formulas, quality of service (QoS) definitions, and so on.

There are different ways to *extend* a given process model with additional perspectives based on event logs (e.g., decision mining, performance analysis, and user profiling). Decision mining, also referred to as decision point analysis, aims at the detection of data dependencies that affect the routing of a case. Starting from a process model, one can analyze how data attributes influence the choices made in the process based on past process executions. Classic data mining techniques such as decision trees can be leveraged for this purpose. Similarly, the process model can be extended with timing information (e.g., bottleneck analysis).

At this point in time there are mature tools such as the ProM framework (23), featuring an extensive set of analysis techniques that can be applied to real-life logs while supporting the whole spectrum depicted in Fig. 12.

Although flexibility requirements may form an inhibitor for the application of PAISs, process mining techniques may in fact increase the value of a PAIS. The structured analysis of the event logs of PAISs provides an added value over information systems that are not aware of the processes these support.

Process mining is strongly related to classic data mining approaches (40). However, the focus is not on data but on process-related information (e.g., the ordering of activities). Process mining is also related to monitoring and business intelligence (41).

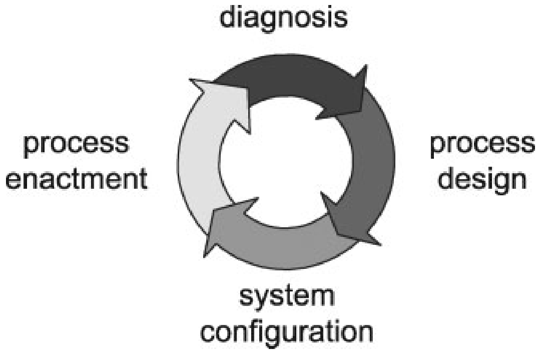

Figure 13. PAIS lifecycle.

CONCLUSION

Process-aware information systems (PAISs) follow a characteristic *lifecycle*. Figure 13 shows the four phases of such a lifecycle (7). In the *design phase*, the processes are (re)designed. In the *configuration phase*, designs are implemented by configuring a PAIS (e.g., a WFMS). After configuration, the *enactment phase* starts where the operational business processes are executed using the system configured. In the *diagnosis phase*, the operational processes are analyzed to identify problems and to find things that can be improved. The focus of traditional workflow management (systems) is on the lower half of the lifecycle. As a result, there is little support for the diagnosis phase. Moreover, support in the design phase is limited to providing a graphical editor while analysis and real design support are missing.

In this article, we showed that PAISs support operational business processes by combining advances in information technology with recent insights from management science. We started by reviewing the history of such systems and then focused on process design. From the many diagramming techniques available, we chose one particular technique (Petri nets) to show the basics. We also emphasized the relevance of process analysis, for example, by pointing out that 20% of the more than 600 process models in the SAP reference model are flawed (24). We also discussed the systems that enact such process designs (e.g., the workflow engines embedded in various systems) and concluded by elaborating on two challenges: flexibility and process mining. More flexibility is needed to widen the scope of PAISs. Today's systems tend to restrict people in their actions, even if this is not desired. Process mining is concerned with extracting knowledge from event logs. This is relatively easy in the context of PAISs and offers many opportunities to improve the performance of the underlying business processes. Moreover, process mining is an essential factor in closing the PAIS lifecycle shown in Fig. 13.

REAL TIME DATABASE SYSTEMS

INTRODUCTION

A real-time database system (RTDBS) is a database system providing all the features of a traditional database system such as data independence and concurrency control, while also enforcing real-time constraints that applications may have (1). Like a traditional database system, a RTDBS functions as a repository of data, provides efficient storage, and performs retrieval and manipulation of information. However, as a part of a real-time system, tasks have time constraints; therefore, an RTDBS has the added requirement of ensuring some degree of confidence in meeting the system's timing requirements (2). A real-time database is a database in which transactions have deadlines or timing constraints (3). Real-time databases are commonly used in real-time computing applications that require timely access to data. And, usually, the definition of timeliness is not quantified; for some applications, it is milliseconds, and for others, it is minutes (4).

Traditional database systems differ from an RTDBS in many aspects. Most importantly, RTDBSs have a different performance goal, correctness criteria, and assumptions about the applications. Unlike a traditional database system, an RTDBS may be evaluated based on how often transactions miss they deadlines, the average lateness or tardiness of late transactions, the cost incurred in transactions missing their deadlines, data external consistency, and data temporal consistency.

For example, a stock market changes very rapidly and is dynamic. The graphs of the different markets appear to be very unstable, and yet, a database has to keep track of the current values for all of the markets of the stock exchange.

Numerous real-word applications contain time-constrained access to data as well as access to data that has temporal validity (5). Consider, for example, a telephone switching system, network management, navigation systems, stock trading, and command and control systems. Moreover, consider the following tasks within these environments: looking up the "800 directory," obstacle detection and avoidance, radar tracking, and recognition of objects. All of these tasks entail gathering data from the environment, processing information in the context of information obtained in the past, and contributing a timely response. Another characteristic of these examples is that they entail processing both temporal data, which lose their validity after certain time intervals, as well as historical data.

Traditional databases, hereafter referred to as databases, deal with persistent data. Transactions access these data while preserving their consistency. The goal of transaction and query processing approaches chosen in databases is to get a good throughput or response time. In contrast, real-time systems can also deal with temporal data, i.e., data that becomes outdated after a certain time. Because of the temporal character of the data and the response-time requirements forced by the environment, tasks in real-time systems have time constraints, e.g., periods or deadlines. The important difference is that the goal of real-time systems is to meet the time constraints of the tasks.

One of the most important points to remember here is that real time does not just mean fast (4). Furthermore, real time does not mean timing constraints that are in nanoseconds or microseconds. Real time means the need to manage *explicit* time constraints in a predictable fashion, that is, to use time-cognizant methods to deal with deadlines or periodicity constraints associated with tasks. Databases are useful in real-time applications because they combine several features that facilitate (*1*) the description of data, (*2*) the maintenance of correctness and integrity of the data, (*3*) efficient access to the data, and (*4*) the correct executions of query and transaction execution despite concurrency and failures (6).

Previous work on real-time databases in general has been based on simulation. However, several prototypes of general-purpose, real-time databases has been introduced. One of the first real-time database implementations was the disk-based transaction processing testbed, RT-CARAT (7). Some of the early prototype projects are the REACH (Real-time Active and Heterogeneous) mediator system project (8) and the STRIP (Stanford Real-time Information Processor) project (9).

Kim and Son (10) have presented a StarBase real-time database architecture. This architecture has been developed over a real-time microkernel operating system, and it is based on relational model. Wolfe et al. (11) have implemented a prototype of the object-oriented, real-time database architecture RTSORAC. Their architecture is based on open OODB architecture with real-time extensions. The database is implemented over a thread-based POSIX-compliant operating system. Additionally, the DeeDS project at the University of Skövde (12) and the BeeHive project at the University of Virginia (13) are examples of more recent RTDBS prototype projects.

Another object-oriented architecture is presented by Cha et al. (14). Their M2RTSS-architecture is a main-memory database system. It provides classes that implement the core functionality of storage manager, real-time transaction scheduling, and recovery. Real-Time Object-Oriented Database Architecture for Intelligent Networks (RODAIN) (15) is an architecture for a real-time, object-oriented, and fault-tolerant database management system. The RODAIN prototype system is a main-memory database, which uses priority- and criticality-based scheduling and optimistic concurrency control.

At the same time, commercial "real-time" database system products have started to appear on the marked, such as Eaglespeed-RTDB (16), Clustra (17), Timesten (18), Empress (19), eXtremeDB (20), and SolidDB (21). Although these products may not be considered true RTDBS from the viewpoint of many researchers in the RTDB community

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

since most of them only have very limited real-time features, they represent a significant step forward in the success of RTDB. Most of these products use main-memory database techniques to achieve a better real-time performance. Additionally, some of them include features for real-time transaction management.

Several research angles emerge from real-time databases: real-time concurrency control (e.g., Refs. 22–24), buffer management (e.g., Refs. 25), disk scheduling (e.g., Refs. 26 and 27), system failure and recovery (e.g., Refs. 28 and 29), overload management (e.g., Refs. 30–32), sensor data (e.g., Ref. 32, 33), security (e.g., Refs. 34–36), and distributed real-time database systems (e.g., Refs. 37–44).

While developing RTDB systems that provide the required timeliness of the data and transactions, several issues must be considered. Below is a list of some of the issues that have been the subject of research in this field (45).

- *Data, transactions, and system characteristics:* An RTDB must maintain not only the logical consistency of the data and transactions, but it must also maintain transaction timing properties as well as the temporal consistency of the data. These issues will be presented in more detail in the next section.

- *Scheduling and transaction processing:* Scheduling and transaction processing issues that consider data and transaction features have been a major part of the research that has been performed in the field of RTDB. These issues will be discussed in more detail in the third section.

- *Managing I/O and buffers:* Although the scheduling of CPU and data resources have been studied extensively, study of other resources like disk I/O and buffers has begun only recently (25, 45). Work presented in Refs. 46–48, 27, 49, and 26 has shown that transaction priorities must be considered in the buffer management and disk I/O.

- *Concurrency control*: Concurrency control has been one of the main research areas in RTDBSs. This issue will be discussed in the fourth section.

- *Distribution*: Many applications that require RTDB are not located on a single computer. Instead, they are distributed and may require that real-time data be distributed as well. Issues involved with distributing data include deadline assignment (41, 44, 33, 50), distributed database architectures (12), distributed resource management (51) data replication (43), replication consistency (52) distributed transaction processing (53, 54, 40, 38), and distributed - concurrency control (55, 51).

- *Quality of service and quality of data:* Maintaining logical consistency of the database and the temporal consistency of the data is hard (56). Therefore, there must be a trade-off made to decide which is more important (57, 58).

REAL-TIME DATABASE MODEL

A real-time system consists of a *controlling system* and a *controlled system* (3). The controlled system is the environment with which the computer and its software interacts. The controlling system interacts with its environment based on the data read from various sensors, e.g., distance and speed sensors. It is essential that the state of the environment is consistent with the actual state of the environment to a high degree of accuracy. Otherwise, the actions of the controlling systems may be disastrous. Hence, timely monitoring of the environment as well as timely processing of the information from the environment is necessary. In many cases, the read data are processed to derive new data (59).

This section discusses the characteristics of data and the characteristics of transactions in real-time database systems.

Data and Consistency

In addition to the timing constraints that originate from the need to continuously track the environment, the timing correctness requirements in a real-time database system also surface because of the need to make data available to the controlling system for its decision-making activities (60). The need to maintain consistency between the actual state of the environment and the state as reflected by the contents of the database leads to the notion of *temporal consistency*. Temporal consistency has two components (61):

- *Absolute consistency:* Data are only valid between absolute points in time. This is due to the need to keep the database consistent with the environment.

- *Relative consistency:* Different data items that are used to derive new data must be temporally consistent with each other. This requires that a set of data items used to derive a new data item form a *relative consistency set R*.

Data Item d is *temporally consistent* if and only if d is absolutely consistent and relatively consistent (3). Every data item in the real-time database consists of the current state of the object (i.e., current value stored in that data item) and two timestamps. These timestamps represent the time when this data item was last accessed by the committed transaction. These timestamps are used in the concurrency control method to ensure that the transaction reads only from committed transactions and writes after the latest committed write. Formally,

Definition 2.1. *A data item in the real-time database is denoted by d: (value, RTS, WTS, avi), where* d_{value} *denotes the current state of d;* d_{RTS} *denotes when the last committed* *transaction has read the current state of d;* d_{WTS} *denotes when the last committed transaction has written d, i.e., when the observation relating to d was made; and* d_{avi} *denotes d's absolute validity interval, i.e., the length of the time interval following* R_{WTS} *during which d is considered to have absolute validity.*

A set of data items used to derive a new data item form a relative consistency set R. Each such set R is associated with a *relative validity interval*. Assume that $d \in R$. d has a correct state if and only if (3):

1. d_{value} is logically consistent, i.e., satisfies all integrity constraints.
2. d is temporally consistent:

   - Data item $d \in R$ is absolutely consistent if and only if $(current\_time - d_{observationtime}) \leq \mathrm{d}_{absolutevalidityinterval}$.
   - Data items are relatively consistent if and only if $\forall d' \in R |d'_{timestamp} - d'_{timestamp}| \leq R_{relativevalidityinterval}$.

In this section we do not consider temporal data or temporal constraints. A good book on temporal databases can be found in Ref. 62. A discussion on integration of temporal and real-time database systems can be found from (63). Finally, temporal consistency maintenance is discussed in Refs. 64 and 65.

Transactions in Real-Time Database System

In this section, transactions are characterized along three dimensions: the manner in which data is used by transactions, the nature of time constraints, and the significance of executing a transaction by its deadline, or more precisely, the consequence of missing specified time constraints (66).

To reason about transactions and about the correctness of the management algorithms, it is necessary to define the concept formally. For the simplicity of the exposition, it is assumed that each transaction reads and writes a data item at most once. From now on, the abbreviations r, w, a, and c are used for the read, write, abort, and commit operations, respectively.

Definition 2.2. *A transaction* T_i *is partial order with an ordering relation* $\prec_i$*, where (67):*

1. $T_i \subseteq \{r_i[x], w_i[x] | x \textit{ is a data item}\} \cup \{a_i, c_i\}$;
2. $a_i \in T_i$ *if and only if* $c_i \notin T_i$;
3. *if* t *is* c_i *or* a_i*, for any other operation* $p \in T_i$, $p \prec_i t$; *and*
4. *if* $r_i[x]$, $w_i[x] \in T_i$, *then*
   either $r_i[x] \prec_i w_i[x]$ *or* $w_i[x] \prec_i r_i[x]$.

Informally, (*1*) a transaction is a subset of read, write, and abort or commit operations. (2) If the transaction executes an abort operation, then the transaction is not executing a commit operation. (3) If a certain operation t is abort or commit, then the ordering relation defines that for all other operations precede operation t in the execution of the transaction. (4) If both read and write operation are executed to the same data item, then the ordering relation defines the order between these operations.

A *real-time transaction* is a transaction with additional real-time attributes. We have added additional attributes for a *real-time transaction*. These attributes are used by the real-time scheduling algorithm and concurrency control method. Additional attributes are as follows (2):

- Timing constraints—For example, the deadline is a timing constraint associated with the transaction.
- Criticalness—It measures how critical it is that a transaction meets its timing constraints. Different transactions have different criticalness. Furthermore, criticalness is a different concept from deadline because a transaction may have a very tight deadline, but missing it may not cause great harm to the system.
- Value function—The value function is related to a transaction's criticalness. It measures how valuable it is to complete the transaction at some point in time after the transaction arrives.
- Resource requirements—Indicates the number of I/O operations to be executed, expected CPU usage, and so on.
- Expected execution time—Generally very hard to predict but can be based on an estimate or experimentally measured value of worst-case execution time.
- Data requirements—Read sets and write sets of transactions.
- Periodicity—If a transaction is periodic, what its period is.
- Time of occurrence of events—At which point in time a transaction issues a read or write request.
- Other semantics—Transaction type (read-only, write-only, etc.).

Based on the values of the above attributes, the availability of the information, and other semantics of the transactions, a real-time transaction can be characterized as follows (68):

- Implication of missing deadline: *hard, critical*, or *soft (firm)* real time.
- Arrival pattern: *periodic, sporadic*, or *aperiodic*.
- Data access pattern: predefined (*read-only, write-only*, or *update*) or *random*.
- Data requirement: *known* or *unknown*.
- Runtime requirement, i.e., pure processor or data access time: *known* or *unknown*.
- Accessed data type: *continuous, discrete*, or both.

The real-time database system applies all three types of transactions discussed in the database literature (69):

- *Write-only transactions* obtain the state of the environment and write into the database.
- *Update transactions* derive a new data item and store it in the database.
- *Read-only transactions* read data from the database and transmit that data or derived actions based on that data to the controlling system.

The above classification can be used to tailor the appropriate concurrency control methods (2). Some transaction-time constraints come from temporal consistency requirements, and some come from requirements imposed on system reaction time. The former typically take the form of periodicity requirements. Transactions can also be distinguished based on the effect of missing a transaction's deadline.

Transaction processing and concurrency control in a real-time database system should be based on priority and the criticalness of the transactions (70). Traditional methods for transaction processing and concurrency control used in a real-time environment would cause some unwanted behavior. Below the four typified problems are characterized and priority is used to denote either scheduling priority or criticality of the transaction:

- *wasted restart:* A wasted restart occurs if a higher priority transaction aborts a lower priority transaction, and later, the higher priority transaction is discarded when it misses its deadline.
- *wasted wait:* A wasted wait occurs if a lower priority transaction waits for the commit of a higher priority transaction, and later, the higher priority transaction is discarded when it misses its deadline.
- *wasted execution:* A wasted execution occurs when a lower priority transaction in the validation phase is restarted due to a conflicting higher priority transaction that has not finished yet.
- *unnecessary restart:* An unnecessary restart occurs when a transaction in the validation phase is restarted even when history would be serializable.

Traditional two-phase locking methods suffer from the problem of wasted restart and wasted wait. Optimistic methods suffer the problems of wasted execution and unnecessary restart (71).

TRANSACTION PROCESSING IN THE REAL-TIME DATABASE SYSTEM

This section presents several characteristics of transaction and query processing. Transactions and queries have time constraints attached to them, and there are different effects of not satisfying those constraints (3). A key issue in transaction processing is *predictability* (72). If a real-time transaction misses its deadline, it can have catastrophic consequences. Therefore, it is necessary to able to *predict* that such transactions will complete before their deadlines. This prediction will be possible only if the worst-case execution time of a transaction and the data and resource needs of the transaction is known.

In a database system, several sources of unpredictability exist (3):

- Dependence of the transaction's execution sequence on data values.
- Data and resource conflicts.
- Dynamic paging and I/O.
- Transactions abort and the resulting rollbacks and restarts.
- Communication delays and site failures on distributed databases.

Because a transaction's execution path can depend on the values of the data items it accessed, it may not be possible to predict the worst-case execution time of the transaction. Similarly, it is better to avoid using unbounded loops and recursive or dynamically created data structures in real-time transactions. Dynamic paging and I/O unpredictability can be solved by using main memory databases (73). Additionally, I/O unpredictability can be decreased using deadlines and priority-driven I/O controllers (e.g. 48, 46).

Transaction rollbacks also reduce predictability. Therefore, it is advisable to allow a transaction to write only to its own memory area and after the transaction is guaranteed to commit write the transaction's changes to the database (71).

Scheduling Real-Time Transactions

A *transaction scheduling policy* defines how priorities are assigned to individual transactions (66). The goal of transaction scheduling is that as many transactions as possible will meet their deadlines. Numerous transaction scheduling policies are denned in the literature. Only a few examples are quoted here.

Transactions in a real-time database can often be expressed as *tasks* in a realtime system (66). Scheduling involves the allocation of resources and time to tasks in such a way that certain performance requirements are met. A typical real-time system consists of several tasks, which must be executed concurrently. Each task has a *value*, which is gained to the system if a computation finishes in a specific time. Each task also has a *deadline*, which indicates a time limit, when a result of the computing becomes useless.

In this section, the terms *hard, soft*, and *firm* are used to categorize the transactions (66). This categorization tells the *value* imparted to the system when a transaction meets its deadline. In systems that use priority-driven scheduling algorithms, value and deadline are used to derive the priority (74, 75).

A characteristic of most real-time scheduling algorithms is the use of priority based scheduling (66). Here transactions are assigned "priorities" which are implicit or explicit functions of their deadlines or *criticality* or both. The criticality of a transaction is an indication of its level of importance. However, these two requirements sometimes conflict with each other. That is, transactions with very short deadlines might not be very critical, and vice versa (76). Therefore, the criticality of the transactions is used in place of the deadline in choosing the appropriate value to priority. This avoids the dilemma of priority scheduling, yet integrates criticality and deadline so that not only the more critical transactions meet their deadlines. The overall goal is to maximize the net worth of the executed transactions to the system.

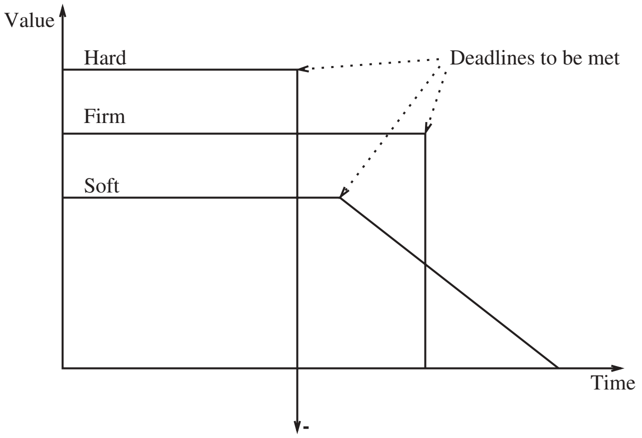

Figure 1. The deadline types.

Whereas arbitrary types of value functions can be associated with transactions (77–79), the following simple functions occur more often (see also Fig. 1):

- *Hard* deadline transactions are those that may result in a catastrophe if the deadline is missed. One can say that a large negative *value* is imparted to the system if a hard deadline is missed. These are typically safety-critical activities, such as those that respond to life or environment-threatening emergency situations (80, 81).
- *Soft* deadline transactions have some value even after their deadlines. Typically, the value drops to zero at a certain point past the deadline (82, 54).
- *Firm* deadline transactions impart no value to the system once their dead lines expire; i.e., the value drops to zero at the deadline (30, 78).

Scheduling Paradigms

Several scheduling paradigms emerge, depending on (*1*) whether a system performs a schedulability analysis; (*2*) if it does, whether it is done statically or dynamically; and (*3*) whether the result of the analysis itself produces a schedule or plan according to which tasks are dispatched at run time. Based on this, the following classes of algorithms can be identified (83):

- Static table-driven approaches: These perform a static schedulability analysis, and the resulting schedule is used at run time to decide when a task must begin execution.
- Static priority-driven preemptive approaches: These perform a static schedu lability analysis, but unlike the previous approach, no explicit schedule is constructed. At run time, tasks are executed using a highest priority first policy.
- Dynamic planning-based approaches: The feasibility is checked at run time; i.e., a dynamically arriving task is accepted for execution only if it is found feasible.
- Dynamic best effort approaches: The system tries to do its best to meet deadlines.

In the *earliest deadline first* (EDF) (80) policy, the transaction with the earliest deadline has the highest priority. Other transactions will receive their priorities in descending deadline order. In the *least slack first* (LSF) (66) policy, the transaction with the shortest slack time is executed first. The slack time is an estimate of how long the execution of a transaction can be delayed and still meet its deadline. In the *highest value* (HV) (74) policy, transaction priorities are assigned according to the transaction value attribute. A survey of transaction scheduling policies can be found in Ref. 66.

Priority Inversion

In a real-time database environment, resource control may interfere with CPU scheduling (84). When blocking is used to resolve a resource allocation such as in 2PL (85), a *priority inversion* (73) event can occur if a higher priority transaction gets blocked by a lower priority transaction.

Figure 2 illustrates an execution sequence, where a priority inversion occurs. A task T_3 executes and reserves a resource. A higher priority task T_1 preempts task T_3 and tries to allocate a resource reserved by task T_3. Then, task T_2 becomes eligible and blocks T_3. Because T_3 cannot be executed, the resource remains reserved suppressing T_1. Thus, T_1 misses its deadline due to the resource conflict.

In Ref. 86, a *priority inheritance* approach was proposed to address this problem. The basic idea of priority inheritance protocols is that when a task blocks one or more higher priority tasks, the lower priority transaction inherits the highest priority among conflicting transactions.

Figure 3 illustrates how a priority inversion problem presented in Fig. 2 can be solved with the priority inheritance protocol. Again, task T_3 executes and reserves a resource, and a higher priority task T_1 tries to allocate the same resource. In the priority inheritance protocol, task T_3 inherits the priority of T_1 and executes. Thus, task T_2 cannot preempt task T_3. When T_3 releases the resource, the priority of T_3 returns to the original level. Now T_1 can acquire the resource and complete before its deadline.

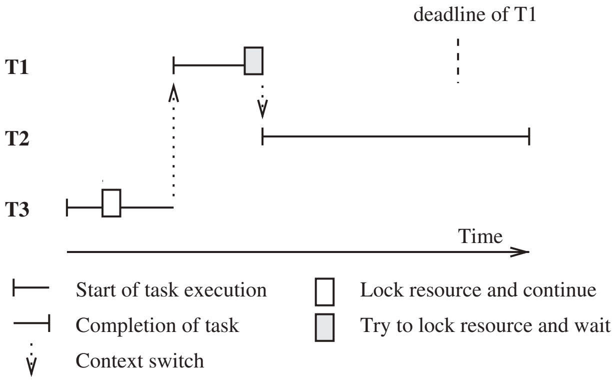

Figure 2. Priority inversion example.

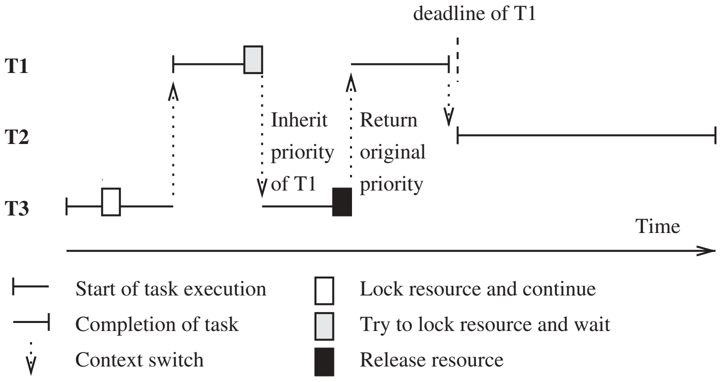

Figure 3. Priority inheritance example.

CONCURRENCY CONTROL IN REAL-TIME DATABASES

A Real-Time Database System (RTDBS) processes transactions with timing constraints such as deadlines (3). Its primary performance criterion is timeliness, not average response time or throughput. The scheduling of transactions is driven by priority order. Given these challenges, considerable research has recently been devoted to designing concurrency control methods for RTDBSs and to evaluating their performance (7, 73, 87, 88, 89, 90). Most of these methods are based on one of the two basic concurrency control mechanisms: *locking* (85) or *optimistic concurrency control* (OCC) (91).

In real-time database systems, transactions are scheduled according to their timing constraints. Task scheduler assigns a priority for a task based on its timing constraints or criticality or both (3). Therefore, higher priority transactions are executed before lower priority transactions. This is true only if a high-priority transaction has some database operation ready for execution. If no operation from a higher priority transaction is ready for execution, then an operation from a lower priority transaction is allowed to execute its database operation. Therefore, the operation of the higher priority transaction may conflict with the already executed operation of the lower priority transaction. In non-preemptive methods, a higher priority transaction must wait for the release of the resource. This is the priority inversion problem presented earlier. Therefore, data conflicts in concurrency control should also be based on transaction priorities or criticalness or both. Hence, numerous traditional concurrency control methods have been extended to the real-time database systems.

There are many ways in which the schedulers can be classified (67). One obvious classification criterion is the mode of database distribution. Some schedulers that have been proposed require a fully replicated database, whereas others can operate on partially replicated or partitioned databases. The schedulers can also be classified according to network topology. The most common classification criterion, however, is the synchronization primitive, i.e., those methods that are based on mutually exclusive access to shared data and those that attempt to order the execution of the transactions according to a set of rules (92). There are two possible views: the pessimistic view that many transactions will conflict with each other, or the optimistic view that not too many transactions will conflict with each other. Pessimistic methods synchronize the concurrent execution of transactions early in their execution, and optimistic methods delay the synchronization of transactions until their terminations (93). Therefore, the basic classification is as follows:

- Pessimistic Methods
  - Timestamp Ordering Methods (94, 95)
  - Serialization Graph Testing (67)
  - Locking Methods (19, 39, 40, 96–98)
- Optimistic Methods
  - Backward Validation Methods (99)
  - Forward Validation Methods (90, 100–103)
  - Serialization Graph Testing (67, 94, 104)
  - Hybrid Methods (105)
- Hybrid Methods (88, 89, 106–108)

In the locking-based methods, the synchronization of transactions is acquired by using physical or logical locks on some portion or granule of the database. The timestamp ordering method involves organizing the execution order of transactions so that they maintain mutual and internal consistency. This ordering is maintained by assigning timestamps to both the transactions and the data that are stored in the database (92).

The state of a conventional non-versioning database represents the state of a system at a single moment of time. Although the contents of the database change as new information is added, these changes are viewed as modification to the state. The current contents of the database may be viewed as a snapshot of the system. Additionally, conventional DBSs provide no guarantee of transaction completion times.

In the following sections, recent related work on locking and optimistic methods for real-time databases are presented.

Locking Methods in Real-Time Databases

In this section, we present some well-known pessimistic concurrency control methods. Most of these methods are based on 2PL.

2PL High Priority. In the 2PL-HP (2PL High Priority) concurrency control method (73, 109, 97), conflicts are resolved in favor of the higher priority transactions. If the priority of the lock requester is higher than the priority of the lock holder, the lock holder is aborted, rolled back, and restarted. The lock is granted to this requester, and the requester can continue its execution. If the priority of the lock requester is lower than that of the lock holder, the requesting transaction blocks to wait for the lock holder to finish and release its locks. High Priority concurrency control may lead to the cascading blocking problem, a deadlock situation, and priority inversion.

2PL Wait Promote. In 2PL-WP (2PL Wait Promote) (84, 97), the analysis of the concurrency control method is developed from Ref. 73. The mechanism presented uses shared and exclusive locks. Shared locks permit multiple concurrent readers. A new definition is made—the priority of a data object, which is defined to be the highest priority of all the transactions holding a lock on the data object. If the data object is not locked, its priority is undefined.

A transaction can join in the read group of an object if and only if its priority is higher than the maximum priority of all transactions in the write group of an object. Thus, conflicts originate from the incompatibility of locking modes as usual. Particular attention is given to conflicts that lead to priority inversions. A priority inversion occurs when a transaction of high priority requests and blocks for an object that has lesser priority. This means that all the lock holders have less priority than the requesting transaction. This same method is also called 2PL-PI (2PL Priority Inheritance) (97).

2PL Conditional Priority Inheritance. Sometimes high priority may be too strict a policy. If the lock holding transaction T_h can finish in the time that the lock requesting transaction T_r can afford to wait, that is within the slack time of T_r, and let T_h proceed to execution and T_r wait for the completion of T_h. This policy is called 2PL-CR (2PL Conditional Restart) or 2PL-CPI (2PL Conditional Priority Inheritance) (97).

Priority Ceiling Protocol (55, 86). The focus is to minimize the duration of blocking to at most one lower priority task and to prevent the formation of deadlocks. A real-time database can often be decomposed into sets of database objects that can be modeled as atomic data sets. For example, two radar stations track an aircraft representing the local view in data objects O_1 and O_2. These objects might include, e.g., the current location, velocity, and so on. Each of these objects forms an atomic data set, because the consistency constraints can be checked and validated locally. The notion of atomic data sets is especially useful for tracking multiple targets.

A simple locking method for elementary transactions is the two-phase locking method; a transaction cannot release any lock on any atomic data set unless it has obtained all the locks on that atomic data set. Once it has released its locks, it cannot obtain new locks on the same atomic data set; however, it can obtain new locks on different data sets. The theory of modular concurrency control permits an elementary transaction to hold locks across atomic data sets. It increases the duration of locking and decreases preemptibility. In this study, transactions do not hold locks across atomic data sets.

Priority Ceiling Protocol minimizes the duration of blocking to at most one elementary lower priority task and prevents the formation of deadlocks (55, 86). The idea is that when a new higher priority transaction preempts a running transaction, its priority must exceed the priorities of all preempted transactions, taking the priority inheritance protocol into consideration. If this condition cannot be met, the new transaction is suspended and the blocking transaction inherits the priority of the highest transaction it blocks.

The priority ceiling of a data object is the priority of the highest priority transaction that may lock this object (55, 86). A new transaction can preempt a lock-holding transaction if and only if its priority is higher than the priority ceilings of all the data objects locked by the lock-holding transaction. If this condition is not satisfied, the new transaction will wait and the lock-holding transaction inherits the priority of the highest transaction that it blocks. The lock-holder continues its execution, and when it releases the locks, its original priority is resumed. All blocked transactions are awakened, and the one with the highest priority will start its execution.

The fact that the priority of the new lock-requesting transaction must be higher than the priority ceiling of all the data objects that it accesses prevents the formation of a potential deadlock. The fact that the lock-requesting transaction is blocked only at most the execution time of one lower priority transaction guarantees, the formation of blocking chains is not possible (55, 86).

Read/Write Priority Ceiling. The Priority Ceiling Protocol is further advanced in Ref. 96, where the Read/Write Priority Ceiling Protocol is introduced. It contains two basic ideas. The first idea is the notion of priority inheritance. The second idea is a total priority ordering of active transactions. A transaction is said to be active if it has started but not completed its execution. Thus, a transaction can execute or wait caused by a preemption in the middle of its execution. Total priority ordering requires that each active transaction execute at a higher priority level than the active lower priority transaction, taking priority inheritance and read/write semantics into consideration.

OPTIMISTIC METHODS IN REAL-TIME DATABASES

Optimistic Concurrency Control (OCC) (99, 91), is based on the assumption that conflict is rare, and that it is more efficient to allow transactions to proceed without delays. When a transaction desires to commit, a check is performed to determine whether a conflict has occurred. Therefore, there are three phases to an optimistic concurrency control method:

- *Read phase:* The transaction reads the values of all data items it needs from the database and stores them in local variables. Concurrency control scheduler stores identity of these data items to a read set. However, writes are applied only to local copies of the data items kept in the transaction workspace. Concurrency control scheduler stores identity of all written data items to a write set.
- *Validation phase:* The validation phase ensures that all the committed transactions have executed in a serializable fashion. For a read-only transaction, this consists of checking that the data values read are still the current values for the corresponding data items. For a transaction that has writes, the validation consists of determining whether the current transaction has executed in a serializable way.
- *Write phase:* This follows the successful validation phase for transactions, including write operations. During the write phase, all changes made by the transaction are permanently stored into the database.

In the following discussion, we introduce some well-known optimistic methods for realtime database systems.

Broadcast Commit. For RTDBSs, a variant of the classic concurrency control method is needed. In Broadcast Commit, OPT-BC (87), when a transaction commits, it notifies other running transactions that conflict with it. These transactions are restarted immediately. There is no need to check a conflict with committed transactions since the committing transaction would have been restarted in the event of a conflict. Therefore, a validating transaction is always guaranteed to commit. The broadcast commit method detects the conflicts earlier than the conventional concurrency control mechanism, resulting in earlier restarts, which increases the possibility of meeting the transaction deadlines (87).

The main reason for the good performance of locking in a conventional DBMS is that the blocking-based conflict resolution policy results in conservation of resources, whereas the optimistic method with its restart-based conflict resolution policy wastes more resources (87). But in an RTDBS environment, where conflict resolution is based on transaction priorities, the OPT-BC policy effectively prevents the execution of a lower priority transaction that conflicts with a higher priority transaction, thus decreasing the possibility of further conflicts and the waste of resources is reduced. Conversely, 2PL-HP loses some of the basic 2PL blocking factor because of the partially restart-based nature of the High Priority scheme.

The delayed conflict resolution of optimistic methods aids in making better decisions since more information about the conflicting transactions is available at this stage (87). Compared with 2PL-HP, a transaction could be restarted by, or wait for, another transaction that is later discarded. Such restarts or waits are useless and cause performance degradation. OPT-BC guarantees the commit, and thus the completion of, each transaction that reaches the validation stage. Only validating transactions can cause the restart of other transactions; thus, all restarts generated by the OPT-BC method are useful.

First of all, OPT-BC has a bias against long transactions (i.e., long transactions are more likely to be aborted if there are conflicts), like in the conventional optimistic methods (87). Second, as the priority information is not used in the conflict resolution, a committing lower priority transaction can restart a higher priority transaction very close to its validation stage, which will cause missing the deadline of the restarted higher priority transaction (100).

Opt-Sacrifice. In the OPT-SACRIFICE (100) method, when a transaction reaches its validation phase, it checks for conflicts with other concurrently running transactions. If conflicts are detected and at least one of the conflicting transactions has a higher priority, then the validating transaction is restarted, i.e., sacrificed in favor of the higher priority transaction. Although this method prefers high-priority transactions, it has two potential problems. First, if a higher priority transaction causes a lower priority transaction to be restarted, but fails in meeting its deadline, the restart was useless. This degrades the performance. Second, if priority fluctuations are allowed, there may be the mutual restarts problem between a pair of transactions (i.e., both transactions are aborted). These two drawbacks are analogous to those in the 2PL-HP method (100).

Opt-Wait and Wait-X. When a transaction reaches its validation phase, it checks whether any of the concurrently running other transactions have a higher priority. In the OPT-WAIT (100) case, the validating transaction is made to wait, giving the higher priority transactions a chance to make their deadlines first. While a transaction is waiting, it is possible that it will be restarted because of the commit of one of the higher priority transactions. Note that the waiting transaction does not necessarily have to be restarted. Under the broadcast commit scheme, a validating transaction is said to conflict with another transaction, if the intersection of the write set of the validating transaction and the read set of the conflicting transaction is not empty. This result does not imply that the intersection of the write set of the conflicting transaction and the read set of the validating transaction is not empty either (100).

The WAIT-50 (100) method is an extension of the OPT-WAIT—it contains the priority wait mechanism from the OPT-WAIT method and a wait control mechanism. This mechanism monitors transaction conflict states and dynamically decides when and for how long a lower priority transaction should be made to wait for the higher priority transactions. In WAIT-50, a simple 50% rule is used—a validating transaction is made to wait while half or more of its conflict set is composed of transactions with higher priority. The aim of the wait control mechanism is to detect when the beneficial effects of waiting are outweighed by its drawbacks (100).

We can view OPT-BC, OPT-WAIT, and WAIT-50 as being special cases of a general WAIT-X method, where X is the cutoff percentage of the conflict set composed of higher priority transactions. For these methods X takes the values infinite, 0, and 50, respectively.

Validation Methods

The validation phase ensures that all the committed transactions have executed in a serializable fashion (91). Most validation methods use the following principles to ensure serializability. If a transaction Ti is before transaction T_j in the serialization graph (i.e., $T_i \prec T_j$), the following two conditions must be satisfied (71):

1. No overwriting. The writes of T_i should not overwrite the writes of T_j.
2. No read dependency. The writes of T_j should not affect the read phase of T_i.

Generally, condition 1 is automatically ensured in most optimistic methods because I/O operations in the write phase are required to be done sequentially in the critical section (71). Thus, most validation schemes consider only condition 2. During the write phase, all changes made by the transaction are permanently installed into the database. To design an efficient real-time optimistic concurrency control method, three issues have to be considered (71):

1. which validation scheme should be used to detect conflicts between transactions;
2. how to minimize the number of transaction restarts; and
3. how to select a transaction or transactions to restart when a nonserializable execution is detected.

In *Backward Validation* (99), the validating transaction is checked for conflicts against (recently) committed transactions. Conflicts are detected by comparing the read set of the validating transaction and the write sets of the committed transactions. If the validating transaction has a data conflict with any committed transactions, it will be restarted. The classic optimistic method in Ref. 91 is based on this validation process.

In *Forward Validation* (99), the validating transaction is checked for conflicts against other active transactions. Data conflicts are detected by comparing the write set of the validating transaction and the read set of the active transactions. If an active transaction has read an object that has been concurrently written by the validating transaction, the values of the object used by the transactions are not consistent. Such a data conflict can be resolved by restarting either the validating transaction or the conflicting transactions in the read phase. Optimistic methods based on this validation process are studied in Ref. 99. Most of the proposed optimistic methods are based on Forward Validation.

Forward Validation is preferable for the real-time database systems because Forward Validation provides flexibility for conflict resolution (99). Either the validating transaction or the conflicting active transactions may be chosen to restart. In addition to this flexibility, Forward Validation has the advantage of early detection and resolution of data conflicts. In recent years, the use of optimistic methods for concurrency control in real-time databases has received more and more attention. Different real-time optimistic methods have been proposed.

Forward Validation (OCC-FV) (99) is based on the assumption that the serialization order of transactions is determined by the arriving order of the transactions at the validation phase. Thus, the validating transaction, if not restarted, always precedes concurrently running active transactions in the serialization order. A validation process based on this assumption can cause restarts that are not necessary to ensure data consistency. These restarts should be avoided.

The major performance problem with optimistic concurrency control methods is the late restart (71). Sometimes the validation process using the read sets and write sets erroneously concludes that a nonserializable execution has occurred, even though it has not done so in actual execution (106) (see Example 1). Therefore, one important mechanism to improve the performance of an optimistic concurrency control method is to reduce the number of restarted transactions.

Example 1. *Consider the following transactions T_1, T_2 and history H_1:*

$$T_1\text{: } r_1[x]c_1$$
$$T_2\text{: } w_2[x]c_2$$
$$H_1\text{: } r_1[x]w_2[x]c_2$$

Based on the OCC-FV method (99), T_1 has to be restarted. However, this is not necessary, because when T_1 is allowed to commit such as:

$$H_2 : r_1[x]w_2[x]c_2c_1,$$

then the schedule of H_2 is equivalent to the serialization order $T_1 \rightarrow T_2$ as the actual write of T_2 is performed after its validation and after the read of T_1. There is no cycle in their serialization graph and H_2 is serializable.

One way to reduce the number of transaction restarts is to adjust dynamically the serialization order of the conflicting transactions (71). Such methods are called *dynamic adjustment of the serialization order* (71). When data conflicts between the validating transaction and active transactions are detected in the validation phase, there is no need to restart conflicting active transactions immediately. Instead, a serialization order of these transactions can be dynamically defined.

Definition 4.1. *Suppose there is a validating transaction T_v and a set of active transactions $T_j (j = 1, 2, \ldots, n)$. Three possible types of data conflicts can cause a serialization order between T_v and T_j* (71,110,106):

1. *$RS(T_v) \cap WS(T_j) \neq \varnothing$ (read–write conflict)*
   A read–write conflict between T_v and T_j can be resolved by adjusting the serialization order between T_v and T_j as $T_v \rightarrow T_j$ so that the read of T_v cannot be affected by T_j's write. This type of serialization adjustment is called forward ordering or forward adjustment.

2. $WS(T_v) \cap RS(T_j) \neq \varnothing$ *(write–read conflict)*
A write–read conflict between T_v and T_j can be resolved by adjusting the serialization order between T_v and T_j as $T_j \rightarrow T_v$. It means that the read phase of T_j is placed before the write of T_v. This type of serialization adjustment is called backward ordering or backward adjustment.
3. $WS(T_v) \cap WS(T_j) \neq \varnothing$ *(write–write conflict)*
A write–write conflict between T_v and T_j can be resolved by adjusting the serialization order between T_v and T_j as $T_v \rightarrow T_j$ such that the write of T_v cannot overwrite T_j's write (forward ordering).

OCC-TI. The OCC-TI (71,111) method resolves conflicts using the timestamp intervals of the transactions. Every transaction must be executed within a specific time slot. When an access conflict occurs, it is resolved using the read and write sets of the transaction together with the allocated time slot. Time slots are adjusted when a transaction commits.

OCC-DA. OCC-DA (90) is based on the Forward Validation scheme (99). The number of transaction restarts is reduced by using dynamic adjustment of the serialization order. This is supported with the use of a dynamic timestamp assignment scheme. Conflict checking is performed at the validation phase of a transaction. No adjustment of the timestamps is necessary in case of data conflicts in the read phase. In OCC-DA, the serialization order of committed transactions may be different from their commit order.

OCC-DATI. Optimistic Concurrency Control with Dynamic Adjustment using Timestamp Intervals (OCC-DATI) (112). OCC-DATI is based on forward validation. The number of transaction restarts is reduced by dynamic adjustment of the serialization order that is supported by similar timestamp intervals as in OCC-TI. Unlike the OCC-TI method, all checking is performed at the validation phase of each transaction. There is no need to check for conflicts while a transaction is still in its read phase. As the conflict resolution between the transactions in OCC-DATI is delayed until a transaction is near completion, there will be more information available for making the choice in resolving the conflict. OCC-DATI also has a new final timestamp selection method compared with OCC-TI.

SUMMARY

The field of real-time database research has evolved greatly over the relatively short time of its existence. The future of RTDB research is dependent of continues progress of this evolution. Research on this field should continue to pursue state-of-the-art applications and to apply both existing techniques to them as well as develop new ones when needed.

RELATIONAL DATABASES

To manage a large amount of persistent data with computers requires storing and retrieving these data in files. However, it was found in the early 1960s that files are not sufficient for the design and use of more and more sophisticated applications. As a consequence, database systems have become a very important tool for many applications over the past 30 years. Database management systems (DBMSs) aim to provide users with an efficient tool for good modeling and for easy and efficient manipulation of data. It is important to note that concurrency control, data confidentiality, and recovery from failure also are important services that a DBMS should offer. The very first DBMSs, known as hierarchical and then as network systems, were based on a hierarchical and then network-like conceptual data organization, which actually reflects the physical organization of the underlying files. Thus, these systems do not distinguish clearly between the physical and the conceptual levels of data organization. Therefore, these systems, although efficient, have some important drawbacks, among which we mention data redundancies (which should be avoided) and a procedural way of data manipulation, which is considered not easy enough to use.

The relational model, proposed by Codd in 1970 (1), avoids the drawbacks mentioned above by distinguishing explicitly between the physical and the conceptual levels of data organization. This basic property of the relational model is a consequence of the fact that, in this model, users see the data as tables and do not have to be aware of how these tables are stored physically. The tables of a relational database are accessed and manipulated as a whole, contrary to languages based on hierarchical or network models, according to which data are manipulated on a record-by-record basis. As a consequence, data manipulation languages for relational databases are set-oriented, and so, they fall into the category of declarative languages, in which there is no need of control structures, such as conditional or iterative statements. On the other hand, because relations are a well-known mathematical concept, the relational model stimulated a lot of theoretical research, which led to successful implementations. As an example of a relational database, Fig. 1 shows the two tables, called EMP and DEPT, of a sample database for a business application.

The main results obtained so far are summarized as follows:

1. The expressional power of relational data manipulation languages is almost that of first-order logic without function symbols. Moreover, relational languages have large capabilities of optimization. This point is of particular importance, because it guarantees that data are efficiently retrieved, independently of the way the query is issued by the user.
2. Integrity constraints, whose role is to account for properties of data, are considered within the model. The most important and familiar are the functional dependencies. Research on this topic led to theoretical criteria for what is meant by a “good” conceptual data organization for a given application.
3. A theory of concurrency control and transaction management has been proposed to account for the dynamic aspects of data manipulation with integrity constraints. Research in this area led to actual methods and algorithms that guarantee that, in the presence of multiple updates in a multiuser environment, the modified database still satisfies the integrity constraints imposed on it.

These fundamental aspects led to actual relational systems that rapidly acquired their position in the software market and still continue to do so today. Relational DBMSs are currently the key piece of software in most business applications running on various types of computers, ranging from mainframe systems to personal computers (PCs). Among the relational systems available on the marketplace, we mention DB2 (IBM), INGRES (developed at the University of California, Berkeley), ORACLE (Oracle Corp.), and SQLServer (Microsoft Corp.), all of which implement the relational model of databases together with tools for developing applications.

In the remainder of this article, we focus on the theory of the relational model and on basic aspects of dependency theory. Then, we deal with problems related to updates and transaction management, and we briefly describe the structure of relational systems and the associated reference language called SQL. We conclude with a brief discussion on several extensions of the relational model.

THEORETICAL BACKGROUND OF RELATIONAL DATABASES

The theory of the relational model of databases is based on relations. Although relations are well known in mathematics, their use in the field of databases requires definitions that slightly differ from those used in mathematics. Based on these definitions, basic operations on relations constitute the relational algebra, which is related closely to first-order logic. Indeed, relational algebra has the same expressional power as a first-order logic language, called relational calculus, and this relationship constitutes the basis of the definition of actual data manipulation

languages, among which the language called SQL is now the reference.

Basic Definitions and Notations

The formal definition of relational databases starts with a finite set, called the *universe*, whose elements are called *attributes*. If U denotes a universe, each attribute A of U is associated with a nonempty and possibly infinite set of values (or constants), called the *domain of* A and denoted by *dom*(A). Every nonempty subset of U is called a *relation scheme* and is denoted by the juxtaposition of its elements. For example, in the database of Fig. 1, the universe U contains the attributes *empno, ename, sal, deptno, dname*, and *mgr* standing, respectively, for numbers of employees, names of employees, salaries of employees, numbers of departments, names of departments and numbers of managers. Moreover, we consider here that *empno*, *deptno*, and *mgr* have the same domain, namely the set of all positive integers, whereas the domain of the attributes *ename* and *dname* is the set of strings of alphabetic characters of length at most 10.

Given a relation scheme R′, a *tuple t over* R is a mapping from R to the union of the domains of the attributes in R, so that, for every attribute A in R, *t*(A) is an element of *dom*(A). Moreover, if R′ is a nonempty subset of R the *restriction of t to* R, being the restriction of a mapping, is also a tuple, denoted by *t*.R′. As a notational convenience, tuples are denoted by the juxtaposition of their values, assuming that the order in which values are written corresponds to the order in which attributes in R are considered.

Given a universe U and a relation scheme R, a *relation over* R is a *finite* set of tuples over R, and a *database over* U is a set of relations over relations schemes obtained from U.

Relational Algebra

From a theoretical point of view, querying a database consists of computing a relation (which in practice is displayed as the answer to the query) based on the relations in the database. The relation to be computed can be expressed in two different languages: relational algebra, which explicitly manipulates relations, and relational calculus, which is based on first-order logic. Roughly speaking, relational calculus is the *declarative* counterpart of relational algebra, which is observed as a *procedural* language.

The six fundamental operations of the relational algebra are union, difference, projection, selection, join, and renaming (note that replacing the join operation by the Cartesian product is another popular choice discussed in Refs. (2) and (3)). The formal definitions of these operations are as follows: Let *r* and *s* be two relations over relation schemes R and S, respectively. Then

1. *Union*. If R = S, then $r \cup s$ is a relation defined over R, such that $r \cup s = \{t | t \in r \text{ or } t \in s\}$. Otherwise $r \cup s$ is undefined.
2. *Difference*. If R = S, then $r - s$ is a relation defined over R, such that $r - s = \{t | t \in r \text{ and } t \notin s\}$. Otherwise $r - s$ is undefined.
3. *Projection*. Let Y be a relation scheme. If $\mathrm{Y} \subseteq \mathrm{R}$, then $\pi_{\mathrm{Y}}(r)$ is a relation defined over Y, such that $\pi_{\mathrm{Y}}(r) = \{t | \exists u \in r \text{ such that } u.\mathrm{Y} = t\}$. Otherwise $\pi_{\mathrm{Y}}(r)$ is undefined.
4. *Selection* of *r* with respect to a condition *C*: $\sigma_c(r)$ is a relation defined over R, such that $\sigma_c(r) = \{t | t \in r \text{ and } t \text{ satisfies } C\}$. Selection conditions are either atomic conditions or conditions obtained by combination of atomic conditions, using the logical connectives $\vee$ (or), $\wedge$ (and), or $\neg$ (not). An atomic condition is an expression of the form $\mathrm{A}\Theta\mathrm{A}'$ or $\mathrm{A}\Theta a$ where A and A′ are attributes in R whose domains are "compatible" [i.e., it makes sense to compare a value in *dom*(A) with a value in *dom*(A′)], *a* is a constant in *dom*(A), and Θis an operator of comparison, such as $<$, $>$, $\leq$, $\geq$, or $=$.
5. *Join*. $r \bowtie s$ is a relation defined over $R \cup S$, such that $r \bowtie s = \{t | t.\mathrm{R} \in r \text{ and } t.\mathrm{S} \in s\}$.
6. *Renaming*. If A is an attribute in R and B is an attribute not in R, such that *dom*(A) = *dom*(B), then $\rho_{\mathrm{B} \leftarrow \mathrm{A}}(r)$ is a relation defined over $(\mathrm{R} - \{\mathrm{A}\}) \cup \{\mathrm{B}\}$ whose tuples are the same as those in *r*.

For example, in the database of Fig. 1, the following expression computes the numbers and names of all departments having an employee whose salary is less than \$10,000:

$$\mathrm{E} : \pi_{\mathrm{deptno\ dname}}[\sigma_{\mathrm{sal} < 10{,}000}(\mathrm{EMP} \bowtie \mathrm{DEPT})]$$

Figure 2 shows the steps for evaluating this expression against the database of Fig. 1. As an example of using renaming, the following expression computes the numbers of employees working in at least two different departments:

$$\mathrm{E}_1 : \pi_{\mathrm{empno}}[\sigma_{\mathrm{deptno} \neq \mathrm{dnumber}}(\mathrm{EMP}) \bowtie \rho_{\mathrm{dnumber} \leftarrow \mathrm{deptno}} [\pi_{\mathrm{deptno\ empno}}(\mathrm{EMP})]]$$

The operations introduced previously enjoy properties, such as commutativity, associativity, and distributivity (see Ref. (3) for full details). The properties of the relational operators allow for syntactic transformations according to which the same result is obtained, but through a more efficient computation. For instance, instead of evaluating

Figure 2. The intermediate relations in the computation of expression **E** applied to the database D of Fig. 1. (a) The computation of the join, (b) the computation of the selection, and (c) the computation of the projection.

the previous expression **E**, it is more efficient to consider the following expression:

$$\text{E}' : \pi_{\text{deptno dname}}[\sigma_{\text{sal} < 10{,}000}(\text{EMP}) \bowtie \pi_{\text{deptno dname}}(\text{DEPT})]$$

Indeed, the intermediate relations computed for this expression are "smaller" than those of Fig. 2 in the number of rows and the number of columns.

Such a transformation is known as query optimization. To optimize an expression of the relational algebra, the expression is represented as a tree in which the internal nodes are labeled by operators and the leaves are labeled by the names of the relations of the database. Optimizing an expression consists of applying properties of relational operators to transform the associated tree into another tree for which the evaluation is more efficient. For instance, one of the most frequent transformations consists of pushing down selections in the tree to reduce the number of rows of intermediate relations. We refer to Ref. (2) for a complete discussion of query optimization techniques. Although efficient in practice, query optimization techniques are not optimal, because, as Kanellakis notices in Ref. (4), the problem of deciding whether two expressions of the relational algebra always yield the same result is impossible to solve.

Relational Calculus

The existence of different ways to express a given query in the relational algebra stresses the fact that it can be seen as a procedural language. Fortunately, relational algebra has a declarative counterpart, namely the relational calculus. This result comes from the observation that, if r is a relation defined over a relation scheme R containing n distinct attributes, then membership of a given tuple t in r is equivalently expressed by first-order formalism if we regard r as an n-ary predicate, and t as an n-ary vector of constants, and if we state that the atomic formula $r(t)$ is true. More formally, the correspondence between relational algebra and calculus is as follows: Given a database $D = \{r_1, r_2, \ldots, r_n\}$ over a universe U and with schema $\{R_1, R_2, \ldots, R_n\}$, we consider a first-order alphabet with the usual connectives $(\wedge, \vee, \neg)$ and quantifiers $(\exists, \forall)$ where

1. the set of constant symbols is the union of all domains of the attributes in U;
2. the set of predicate symbols is $\{r_1, r_2, \ldots, r_n\}$, where each r_i is a predicate symbol whose arity is the cardinality of R_i; and
3. the variable symbols may range over tuples, in which case, the language is called *tuple* calculus, or over domain elements, in which case, the language is called *domain* calculus.

One should notice that no function symbols are considered in relational calculus. Based on such an alphabet, formulas of interest are built up as usual in logic, but with some syntactic restrictions explained later. Now we recall that without loss of generality, a well-formed formula has the form $\psi = (Q_1)(Q_2)\ldots(Q_k)[\varphi(x_1, x_2, \ldots, x_k, y_1, y_2, \ldots, y_1)]$, where $x_1, x_2, \ldots, x_k, y_1, y_2, \ldots, y_1$ are the only variable symbols occurring in φ, where (Q_i) stands for $(\exists x_i)$ or $(\forall x_i)$, and where φ is a quantifier-free formula built up from connectives and atomic formulas (atomic formulas have the form $r(t_1, t_2, \ldots, t_n)$, where r is an n-ary predicate symbol and t_j is either a variable or a constant symbol). Moreover, in the formula ψ, the variables x_i are bound (or quantified) and the variables y_j are free (or not quantified). See Ref. (5) for full details on this topic.

In the formalism of tuple calculus, the relational expression **E** is written as

$$\begin{aligned}\{z \mid (\exists x)(\exists y)(\text{EMP}(x) \;&\wedge\; \text{DEPT}(y) \wedge y.deptno = z.deptno\\ &\wedge\; y.dname = z.dname\\ &\wedge\; x.deptno = y.deptno \wedge x.sal\\ &\quad < 10{,}000)\}\end{aligned}$$

One should note that, in this formula, variables stand for tuples, whose components are denoted as restrictions in the relational algebra. Considering domain calculus, the previous formula is written as follows:

$$\{(z_1,z_2)|(\exists x_1)(\exists x_2)(\exists x_3)(\exists x_4)(\exists y_1)(\exists y_2)(\exists y_3)\\ (\mathbf{EMP}(x_1,x_2,x_3,x_4)\wedge \mathbf{DEPT}(y_1,y_2,y_3)\wedge z_1\\ = y_1 \wedge z_2 = y_2 \wedge x_4 = y_1 \wedge x_1 < \mathbf{10,000})\}$$

The satisfaction of a formula ψ in a database D is defined in a standard way, as in first-order logic. In the context of databases, however, some well-formed formulas must be discarded because relations are assumed to be finite and, thus, so must be the set of tuples satisfying a given formula in a database. For instance, the domain calculus formula $(\exists x)[\neg r(x,y)]$ must be discarded, because in any database, the set of constants a satisfying the formula $\neg r(r_0,a)$ for some appropriate x_0 may be infinite (remember that domains may be infinite). The notion of safeness is based on what is called the domain of a formula ψ, denoted by DOM(ψ). DOM(ψ) is defined as the set of all constant symbols occurring in ψ, together with all constant symbols of tuples in relations occurring in ψ as predicate symbols. Hence, DOM(ψ) is a finite set of constants and ψ is called *safe* if all tuples satisfying it in D contain only constants of DOM(ψ). To illustrate the notion of safeness, again consider the formula $\psi = (\exists x)[\neg r(x,y)]$. Here DOM(ψ) = {α|α occurs in a tuple of *r*}, and so, ψ may be satisfied in D by values β not in DOM(ψ). Therefore, ψ is a nonsafe formula. On the other hand, the formula $\psi' = (\exists x)[\neg r(x,y) \wedge s(x,y)]$ is safe, because every β satisfying ψ′ in D occurs in DOM(ψ′).

It is important to note that tuple and domain calculus are equivalent languages that have resulted in the emergence of actual languages for relational systems. A formal proof of the equivalence between relational calculus and relational algebra was given by Codd in Ref. (6).

DATA DEPENDENCIES

The theory of data dependencies has been motivated by problems of particular practical importance, because in all applications, data stored in a database must be restricted so as to satisfy some required properties or constraints. For instance, in the database of Fig. 1, two such properties could be (*1*) two departments with distinct names cannot have the same number and (*2*) a department has only one manager, so that the relation DEPT cannot contain two distinct tuples with the same *deptno* value. Investigations on constraints in databases have been carried out in the context of the relational model to provide sound methods for the design of database schemas. The impact of constraints on schema design is exemplified through properties (*1*) and (*2*). Indeed, assume that the database consists of only one relation defined over the full universe. Then clearly, information about a given department is stored as many times as the number of its employees, which is redundant. This problem has been solved by the introducing normal forms in the case of particular dependencies called functional dependencies. On the other hand, another problem that arises in the context of our example is the following: Assuming that a database D satisfies the constraints (*1*) and (*2*), does D satisfy other constraints? Clearly, this problem, called the implication problem, has to be solved to make sure that all constraints are considered at the design phase just mentioned. Again, the implication problem has been solved in the context of functional dependencies. In what follows, we focus on functional dependencies, and then, we outline other kinds of dependencies that have also been the subject of research.

The Theory of Functional Dependencies

Let *r* be a relation over a relation scheme R, and let X and Y be two subschemes of R. The functional dependency from X to Y, denoted by X → Y, is satisfied by *r* if, for all tuples *t* and *t*′ in *r*, the following holds: $t.\mathrm{X} = t'.\mathrm{X} \Rightarrow t.\mathrm{Y} = t'.\mathrm{Y}$. Then, given a set F of functional dependencies and a dependency X → Y, F implies X → Y if every relation satisfying the dependencies in F also satisfies the dependency X → Y. For instance, for R = ABC and F = {A → B, AB → C}, F implies A → C. However, this definition of the implication of functional dependencies is not effective from a computational point of view. An axiomatization of this problem, proposed in Ref. (7), consists of the following rules, where X, Y, and Z are relation schemes:

1. $\mathrm{Y} \subseteq \mathrm{X} \Rightarrow \mathrm{X} \rightarrow \mathrm{Y}$
2. $\mathrm{X} \rightarrow \mathrm{Y} \Rightarrow \mathrm{XZ} \rightarrow \mathrm{YZ}$
3. $\mathrm{X} \rightarrow \mathrm{Y}, \mathrm{Y} \rightarrow \mathrm{Z} \Rightarrow \mathrm{X} \rightarrow \mathrm{Z}$

A derivation using these axioms is defined as follows: F derives X → Y if either X → Y is in F or X → Y can be generated from F using repeatedly the axioms above. Then, the soundness and completeness of these axioms is expressed as follows: F implies X → Y if and only if F derives X → Y, thus providing an effective way for solving the implication problem in this case.

An important aspect of functional dependencies is that they allow for the definition of normal forms that characterize suitable database schemas. Normal forms are based on the notion of key defined as follows: If R is a relation scheme with functional dependencies F, then K is a key of (R, F) if K is a minimal relation scheme with respect to set inclusion such that F implies (or derives) K → R. Four normal forms can be defined, among which we mention here only three of them:

1. The first normal form (1NF) stipulates that attributes are atomic in the relational model, which is implicit in the definitions of relational databases but restricts the range of applications that can be taken easily into account. It explains, in particular, the emergence of object-oriented models of databases.
2. The third normal form (3NF) stipulates that attributes participating in no keys depend fully and exclusively on keys. The formal definition is as follows: (R, F) is in 3NF if, for every derived dependency X → A from F, such that A is an attribute not in X and appearing in no keys of (R, F), X contains a key of (R, F).

3. The Boyce–Codd normal form (BCNF) is defined as the previous form, except that the attribute A may now appear in a key of (R, F). Thus, the formal definition is the following: (R, F) is in BCNF if, for every derived dependency X → A from F, such that A is an attribute not in X, X contains a key of (R, F).

It turns out that every scheme (R, F) in BCNF is in 3NF, whereas the contrary is false in general. Moreover, 3NF and BCNF characterize those schemes recognized as suitable in practice. If a scheme (R, F) is neither 3NF nor BCNF, then it is always possible to decompose (R, F) into subschemes that are at least 3NF. More precisely, by schema decomposition, we mean the replacement of (R, F) by schemes (R_1, F_1), (R_2, F_2), …, (R_k, F_k), where

1. each R_i is a subset of R and R in the union of the R_is;
2. each F_i is the set of all dependencies X → Y derivable from F, such that $XY \subseteq R_i$; and
3. each (R_i, F_i) is in 3NF or in BCNF.

Furthermore, this replacement must ensure that data and dependencies are preserved in the following sense:

1. Data preservation: starting with a relation r that satisfies F, the relations r_i are the projections of r over R_i, and their join must be equal to r.
2. Dependency preservation: the set F and the union of the sets F_i must derive exactly the same functional dependencies.

In the context of functional dependencies, data preservation is characterized as follows, in the case where k = 2: The decomposition of (R, F) into (R_1, F_1), (R_2, F_2) preserves the data if F derives at least one of the two functional dependencies $R_1 \cap R_2 \rightarrow R_1$ or $R_1 \cap R_2 \rightarrow R_2$. If k is greater than 2, then the previous result can be generalized using properties of the join operator. Unfortunately, no such easy-to-check property is known for dependency preservation. What has to be done in practice is to make sure that every dependency of F can be derived from the union of the F_is.

It has been shown that it is always possible to decompose a scheme (U, F) so that data and dependencies are preserved and the schemes (R_i, F_i) are all at least in 3NF. But it should be noticed that BCNF is not guaranteed when decomposing a relation scheme. Two kinds of algorithms have been implemented for schema decomposition: the synthesis algorithms (which generate the schemes based on a canonical form of the dependencies of F) and the decomposition algorithms (which repeatedly split the universe U into two subschemes). Synthesis algorithms ensure data and dependency preservation together with schemes in 3NF (at least), whereas decomposition algorithms ensure data preservation together with schemes in BCNF, but at the cost of a possible loss of dependencies.

More on Data Dependencies

Dependencies other than functional dependencies have been widely studied in the past. In particular, multivalued dependencies and their interaction with functional dependencies have motivated much research. The intuitive idea behind multivalued dependencies is that, in a relation over R, a value over X is associated with a set of values over Y, and is independent of the values over R − XY. An example of multivalued dependencies is the following: assume that we have R = {*empno*, *childname*, *car*}, to store the names of the children and the cars of employees. Clearly, every *empno* value is associated with a fixed set of names (of children), independent of the associated *car* values. Multivalued dependencies and functional dependencies have been axiomatized soundly and completely, which has led to an additional normal form, called the fourth normal form, and defined similarly to BCNF.

Other dependencies of practical interest which have been studied are inclusion dependencies. For example, in the database of Fig. 1, stating that every manager must be an employee is expressed by the following inclusion dependency: $\pi_{mgr}(DEPT) \subseteq \pi_{empo}(EMP)$. In general, an inclusion dependency is an expression of the form $\pi_X(r) \subseteq \pi_Y(s)$ where r and s are relations of the database and where X and Y are relation schemes, such that the projections and the inclusion are defined. Although it has been shown that the implication problem for inclusion dependencies in the presence of functional dependencies is not decidable (see Ref. (2)), a restricted case of practical significance is decidable in polynomial time: The restriction is roughly that the relations in inclusion dependencies are all unary.

DATABASE UPDATES

Although updates are an important issue in databases, this area has received less attention from the research community than the topics just addressed. Roughly speaking, updates are basic insert, delete, or modify operations defined on relations seen as *physical* structures, and no theoretical background similar to that discussed for queries is available for updates. As a consequence, no declarative way of considering updates has been proposed so far, although there is much effort in this direction. Actually, current relational systems handle sophisticated updates procedurally, based on the notion of *transactions*, which are programs containing update statements. An important point is that, to maintain data consistency, these programs must be considered as units, in the sense that either all or none of their statements are executed. For instance, if a failure occurs during the execution of a transaction, all updates performed before the failure must be undone before rerunning the whole program. In what follows, we first discuss the relation between updates and data dependencies, and then, we give a short introduction to transaction execution.

Updates and Data Dependencies

There are two main ways to maintain the database consistent with respect to constraints in the presence of updates: (*1*) reject all updates contradicting a constraint and (*2*) take appropriate actions to restore consistency with respect to constraints. To illustrate these two ways of treating updates, let us consider again the database of Fig. 1 and let us assume that the relation DEPT must satisfy the functional dependency *deptno* → *dname mgr*. According to (*1*) previous, the insertion in DEPT of the tuple 1 *toy* 456 is rejected, whereas it is accepted according to (*2*) previous, if, in addition, the tuple 1 *sales* 234 is removed from DEPT. Actually, it turns out that (*1*) gives priority to “old” knowledge over “new” knowledge, whereas (2) does the opposite. Clearly, updating a database according to (*1*) or (*2*) depends on the application. In practice, policy (*1*) is implemented as such for keys and policy (*2*) is specified by transactions.

Before we come to problems related to transaction execution, we would like to mention that an important issue related to policy (*2*) is that of *active rules*. This concept is considered the declarative counterpart of transactions, and thus, is meant as an efficient tool to specify how the database should react to updates, or, more generally, to events.

Active rules are rules of the form: ***on*** ⟨event⟩ ***if*** ⟨condition⟩ ***then*** ⟨action⟩, and provide a declarative formalism for ensuring that data dependencies remain satisfied in the presence of updates. For example, if we consider the database of Fig. 1 and the inclusion dependency $\pi_{\mathrm{mgr}}(\mathrm{DEPT}) \subseteq \pi_{\mathrm{empno}}(\mathrm{EMP})$, the insertion of a new department respects this constraint if we consider the following active rule:

$$\begin{array}{l}\textbf{on}\ \mathrm{insert(n, d, m)\ into\ DEPT}\\ \textit{if}\ \mathrm{m} \notin \pi_{\mathrm{empno}}(\mathrm{EMP})\\ \textbf{then}\ \mathrm{call\ insert\_EMP(m, d)}\end{array}$$

where insert_EMP is an interactive program asking for a name and a salary for the new manager, so that the corresponding tuple can be inserted in the relation EMP.

Another important feature of active rules is their ability to express *dynamic* dependencies. The particularity of dynamic dependencies is that they refer to more than one database state (as opposed to static dependencies that refer to only one database state). A typical dynamic dependency, in the context of the database of Fig. 1, is to state that salaries must never decrease, which corresponds to the following active rule:

$$\begin{array}{l}\textbf{on}\ \mathrm{update\_sal}(ne, new\text{-}sal)\mathrm{in\ EMP}\\ \textit{if}\ new\text{-}sal > \pi_{\mathrm{sal}}(\sigma_{\mathrm{empno=ne}}(\mathrm{EMP}))\\ \textbf{then}\ \mathrm{set}\ sal = new\text{-}sal\ \mathrm{where}\ empno = ne\end{array}$$

where update_sal is the update meant to assign the salary of the employee number *ne* to the value *new-sal* and where the set instruction actually performs the modification.

Although active rules are an elegant and powerful way to specify various dynamic aspects of databases, they raise important questions concerning their execution. Indeed, as the execution of an active rule fires other active rules in its action, the main problem is to decide how these rules are fired. Three main execution modes have been proposed so far in the literature: the immediate mode, the deferred mode, and the concurrent mode. According to the immediate mode, the rule is fired as soon as its event occurs while the condition is true. According to the deferred mode, the actions are executed only after the last event occurs and the last condition is evaluated. In the concurrent mode, no policy of action execution is considered, but a separate process is spawned for each action and is executed concurrently with other processes. It turns out that executing the same active rules according to each of these modes generally gives different results and the choice of one mode over the others depends heavily on the application.

Transaction Management

Contrary to what has been discussed before, the problem of transaction management concerns the physical level of DBMSs and not the conceptual level. Although transaction execution is independent of the conceptual model of databases being used (relational or not), this research area has been investigated in the context of relational databases. The problem is that, in a multiuser environment, several transactions may have to access the same data simultaneously, and then, in this case the execution of these transactions may leave the database inconsistent, whereas each transaction executed alone leaves the database in a consistent state (an example of such a situation will be given shortly). Additionally, modifications of data performed by transactions must survive possible hardware or software failures.

To cope with these difficulties, the following two problems have to be considered: (*1*) the concurrency control problem (that is, how to provide synchronization mechanisms which allow for efficient and correct access of multiple transactions in a shared database) and (*2*) the recovery problem (that is, how to provide mechanisms that react to failures in an automated way). To achieve these goals, the most prominent computational model for transactions is known as the *read-write* model, which considers transactions as sequences of read and write operations operating on the tuples of the database. The operation read(t) indicates that t is retrieved from the secondary memory and entered in the main memory, whereas the operation write(t) does the opposite: The current value of t in the main memory is saved in the secondary memory, and thus survives execution of the transaction. Moreover, two additional operations are considered, modeling, respectively, successful or failed executions: the *commit* operation (which indicates that changes in data must be preserved), and the *abort* operation (which indicates that changes in data performed by the transaction must be undone, so that the aborted transaction is simply ignored). For example, call t the first tuple of the relation EMP of Fig. 1, and assume that two transactions T_1 and T_2 increase John’s salary of 500 and 1,000, respectively. In the read-write model, both T_1 and T_2 have the form: read(t); write(t'); commit, where $t'.sal = t.sal + 500$ for T_1 and where $t'.sal = t.sal + 1{,}000$ for T_2.

Based on these operations, the criterion for correctness of transaction execution is known as *serializability* of schedules. A schedule is a sequence of interleaved operations originating from various transactions, and a schedule built up from transactions $T_1, T_2, \ldots, T_k$ is said to be serializable if its execution leaves the database in the same state as the sequential execution of transactions T_i’s, in some order would do. In the previous example, let us consider the following schedule:

$$\mathrm{read}_1(t); \mathrm{read}_2(t); \mathrm{write}_1(t_1); \mathrm{commit}_1; \mathrm{write}_2(t_2); \mathrm{commit}_2$$

where the subscripts correspond to the transaction where the instructions occur. This schedule is not serializable, because its execution corresponds neither to T_1 followed by T_2 nor to T_2 followed by T_1. Indeed, transactions T_1 and T_2 both read the initial value of t and the effects of T_1 on tuple t are lost, as T_2 commits its changes after T_1.

To characterize serializable schedules, one can design execution protocols. Here again many techniques have been introduced, and we focus on the most frequent of them in actual systems, known as the *two-phase locking protocol*. The system associates every read or write operation on the same object to a lock, respectively, a read-lock or a write-lock, and once a lock is granted for a transaction, other transactions cannot access the corresponding object. Additionally, no lock can be granted to a transaction that has already released a lock. It is easy to see that, in the previous example, such a protocol prevents the execution of the schedule we considered, because T_2 cannot read t unless T_1 has released its write-lock.

Although efficient and easy to implement, this protocol has its shortcomings. For example, it is not free of deadlocks, that is, the execution may never terminate because two transactions are waiting for the same locks at the same time. For instance, transaction T_1 may ask for a lock on object o_1, currently owned by transaction T_2 which in turn asks for a lock on object o_2, currently owned by transaction T_1. In such a situation, the only way to restart execution is to abort one of the two transactions. Detecting deadlocks is performed by the detection of cycles in a graph whose nodes are the transactions in the schedule and in which an edge from transaction T to transaction T′ means that T is waiting for a lock owned by T′.

RELATIONAL DATABASE SYSTEMS AND SQL

In this section, we describe the general architecture of relational DBMSs, and we give an overview of the language SQL which has become a reference for relational systems.

The Architecture of Relational Systems

According to a proposal by the ANSI/SPARC normalization group in 1975, every database system is structured in three main levels:

1. the *internal (or physical) level* which is concerned with the actual storage of data and by the management of transactions;
2. the *conceptual level* which allows describing a given application in terms of the DBMSs used, that is, in terms of relations in the case of a relational DBMSs; and
3. the *external level* which is in charge of taking user's requirements into account.

Based on this three-level general architecture, all relational DBMSs are structured according to the same general schema that is seen as two interfaces, the external interface and the storage interface.

The external interface, which is in charge of the communication between user's programs and the database, contains five main modules: (*1*) precompilers allowing for the use of SQL statements in programs written in procedural languages such as COBOL, C, PASCAL, or JAVA, (*2*) an interactive interface for a real-time use of databases, (*3*) an analyzer which is in charge of the treatment of SQL statements issued either from a user's program or directly by a user via the interactive interface, (*4*) an optimizer based on the techniques discussed previously, and (*5*) a catalog, where information about users and about all databases that can be used, is stored. It is important to note that this catalog, which is a basic component for the management of databases, is itself organized as a relational database, usually called the metadatabase, or data dictionary.

The storage interface, which is in charge of the communications between database and the file management system, also contains five main modules: (*1*) a journal, where all transactions on the database are stored so that the system restarts safely in case of failures, (*2*) the transaction manager which generally works under the two-phase locking protocol discussed previously, (*3*) the index manager (indexes are created to speed up the access to data), (*4*) the space disk manager which is charge of defining the actual location of data on disks, and (*5*) the buffer manager which is in charge of transferring data between the main memory and the disk. The efficiency of this last module is crucial in practice because accesses on disks are very long operations that must be optimized. It is important to note that this general architecture is the basis for organizing relational system that also integrate network and distributed aspects in a client-server configuration or distributed database systems.

An Overview of SQL

Many languages have been proposed to implement relational calculus. For instance, the language QBE (Query By Example) is based on domain calculus, whereas the language QUEL (implemented in the system INGRES) is based on tuple calculus. These languages are described in Ref. (2). We focus here on language SQL which is now implemented in all relational systems.

SQL is based on domain calculus but also refers to the tuple calculus in some of its aspects. The basic structure of an SQL query expression is the following:

```
SELECT ⟨list of attributes⟩
FROM ⟨list of relations⟩
WHERE ⟨condition⟩
```

which roughly corresponds to a relational expression containing projections, selections, and joins. For example, in the database of Fig. 1, the query **E** is expressed in SQL as follows:

```
SELECT EMP.deptno, dname
FROM EMP, DEPT
WHERE sal < 10,000 AND EMP.deptno =
   DEPT.deptno
```

We draw attention to the fact that the condition part reflects not only the selection condition from **E**, but also that, to join tuples from the relations EMP and DEPT, their deptno values must be equal. This last equality must be explicit in SQL, whereas, in the relational algebra, it is a consequence of the definition of the join operator. We also note that terms such as EMP.deptno or DEPT.deptno can be seen as terms from tuple calculus, whereas terms such as deptno or dname, refer to domain calculus. In general, prefixing an attribute name by the corresponding relation name is required if this attribute occurs in more than one relation in the FROM part of the query.

The algebraic renaming operator is implemented in SQL, but concerns relations, rather than attributes as in relational algebra. For example, the algebraic expression $\mathbf{E}_1$ (which computes the number of employees working in at least two distinct departments) is written in SQL as follows:

```
SELECT EMP.empno
FROM EMP,EMP EMPLOYEES
WHERE EMP.deptno != EMPLOYEES.deptno AND
EMP.empno = EMPLOYEES.empno
```

Set theoretic operators union, intersection, and difference are expressed as such in SQL, by the keywords UNION, INTERSECT, and MINUS (or EXCEPT), respectively. Thus, every expression of relational algebra can be written as a SQL statement, and this basic result is known as the *completeness* of the language SQL. An important point in this respect is that SQL expresses more queries than relational algebra as a consequence of introducing functions (whereas function symbols are not considered in relational calculus) and "grouping" instructions in SQL. First, because relations are restricted to the first normal form, it is impossible to consider structured attributes, such as dates or strings. SQL overcomes this problem by providing usual functions for manipulating dates or strings, and additionally, arithmetic functions for counting or for computing minimum, maximum, average, and sum are available in SQL. Moreover, SQL offers the possibility of grouping tuples of relations, through the GROUP BY instruction. As an example of these features, the numbers of departments together with the associated numbers of employees are obtained in the database of Fig. 1 with the following SQL query (in which no WHERE statement occurs, because no selection has to be performed):

```
SELECT deptno, COUNT(empno)
FROM EMP
GROUP BY deptno
```

On the other hand, a database system must incorporate many other basic features concerning the physical storage of tuples, constraints, updates, transactions, and confidentiality. In SQL, relations are created with the CREATE TABLE instruction, where the name of the relation together with the names and types of the attributes are specified. It is important to note that this instruction allows specifying constraints and information about the physical storage of the tuples. Moreover, other physical aspects are taken into account in SQL by creating indexes or clusters to speed up data retrieval.

Update instructions in SQL are either insertion, deletion, or modification instructions in which WHERE statements are incorporated to specify which tuples are affected by the update. For example, in the database of Fig. 1, increasing the salaries of 10% of all employees working in department number 1 is achieved as follows:

```
UPDATE EMP
SET sal = sal * 1.1
WHERE deptno = 1
```

Transactions are managed in SQL by the two-phase locking protocol, using different kinds of locks, allowing only read data or allowing read and write data. Moreover, activeness in databases is taken into account in SQL through the notion of *triggers*, which are executed according to the immediate mode.

Data confidentiality is another very important issue, closely related to data security, but has received very little attention at the theoretical level. Nevertheless, this problem is addressed in SQL in two different ways: (*1*) by restricting the access to data to specified users and (*2*) by allowing users to query only the part of the database they have permission to query. Restricting access to data by other users is achieved through the GRANT instruction, that is specified by the owner either on a relation or on attributes of a relation. A GRANT instruction may concern queries and/or updates, so that, for example, a user is allowed to query for salaries of employees, while forbidding the user to modify them. On the other hand, a different way to ensure data confidentiality consists in defining derived relations called *views*. For instance, to prevent users from seeing the salaries of employees, one can define a view from the relation EMP of Fig. 1 defined as the projection of this relation over attributes *empno*, *ename*, and *deptno*. A view is a query, whose SQL code is stored in the metadatabase, but whose result is not stored in the database. The concept of views is a very efficient tool for data confidentiality, thanks to the high expressional power of queries in SQL. However, the difficulty with views is that they are not updatable, except in very restricted cases. Indeed, because views are derived relations, updates on views must be translated into updates on the relations of the database, and this translation, when it exists, is generally not unique. This problem, known as the nondeterminism of view updating, is the subject of many research efforts, but has not yet been satisfactorily solved.

We conclude by mentioning that relational systems are successful in providing powerful database systems for many applications, essentially for business applications. However, these systems are not adapted to many new applications, such as geographical information systems or knowledge-based management because of two kinds of limitations on the relational model:

1. Relations are flat structures which prevent easily managing data requiring sophisticated structures. This remark led to the emergence of object-oriented database systems that are currently the subject of important research efforts, most of them originating from concepts of object-oriented languages, and also from concepts of relational databases. As

another research direction in this area, we mention the emergence of object-relational data models that extend the relational model by providing a richer type system including object orientation, and that add constructs to relational languages (such as SQL) to deal with the added data types. An introductory discussion on object-oriented databases and object-relational data models is given in Ref. (8), whereas a complete and formal description of these models can be found in Refs. (2) and (9).

2. Relational algebra does not allow for recursivity (see Ref. (3)), and thus, queries, such as the computation of the transitive closure of a graph cannot be expressed. This remark has stimulated research in the field of deductive databases, a topic closely related to logic programming but which also integrates techniques and concepts from relational databases. The basic concepts of deductive databases and their connections with relational databases are presented in Refs. (2) and (9) and studied in full detail in Ref. (10).

We finally mention several new and important fields of investigation that have emerged during the last decade. These fields are *data mining, data warehousing*, and *semistructured data*. Indeed, extracting abstracted information from many huge and heterogeneous databases is now a crucial issue in practice. As a consequence, many research efforts are still currently devoted to the study of efficient tools for knowledge discovery in databases (KDD or data mining), as well as for data integration in a data warehouse. It is important to note that these new fields rely heavily on the concept of relational databases, because the relational model is the basic database model under consideration. Data mining and data warehousing are briefly discussed in Ref. (8) and are introduced in more details in Refs. (2) and (11). On the other hand, the Web is causing a revolution in how we represent, retrieve, and process information. In this respect, the language XML is recognized as the reference for data exchange on the Web, and the field of semistructured data aims to study how XML documents can be managed. Here again, relational database theory is the basic reference for the storage and the manipulation of XML documents. An in-depth and up-to-date look at this new topic can be found in Ref. (12).

We note that the latest versions of DBMSs now available on the marketplace propose valuable and efficient tools for dealing with data mining, data warehousing, and semistructured data.

SPATIAL DATABASES

INTRODUCTION

Spatial database management systems (1–6) aim at the effective and efficient management of data related to

- space in the physical world (geography, urban planning, astronomy, human anatomy, fluid flow, or an electromagnetic field),
- biometrics (fingerprints, palm measurements, and facial patterns),
- engineering design (very large-scale integrated circuits, layout of a building, or the molecular structure of a pharmaceutical drug), and
- conceptual information space (virtual reality environments and multidimensional decision-support systems).

A spatial database management system (SDBMS) can be characterized as follows:

- A SDBMS is a software module that can work with an underlying database management system, for example, an object-relational database management system or object-oriented database management system.
- SDBMSs support multiple spatial data models, commensurate spatial abstract data types (ADTs), and a query language from which these ADTs are callable.
- SDBMSs support spatial indexing, efficient algorithms for spatial operations, and domain-specific rules for query optimization.

Spatial database research has been an active area for several decades. The results of this research are being used several areas. To cite a few examples, the filter-and-refine technique used in spatial query processing has been applied to subsequence mining; multidimensional-index structures such as R-tree and Quad-tree used in accessing spatial data are applied in the field of computer graphics and image processing; and space-filling curves used in spatial query processing and data storage are applied in dimension-reduction problems. The field of spatial databases can be defined by its accomplishments; current research is aimed at improving its functionality, extensibility, and performance. The impetus for improving functionality comes from the needs of existing applications such as geographic information systems (GIS), location-based services (LBS) (7), sensor networks (8), ecology and environmental management (9), public safety, transportation (10), earth science, epidemiology (11), crime analysis (12), and climatology.

Commercial examples of spatial database management include ESRI's ArcGIS Geodatabase (13), Oracle Spatial (14), IBM's DB2 Spatial Extender and Spatial Datablade, and future systems such as Microsoft's SQL Server 2008 (code-named Katmai) (15). Spatial databases have played a major role in the commercial industry such as Google Earth (16) and Microsoft's Virtual Earth (17). Research prototype examples of spatial database management systems include spatial datablades with PostGIS (18), MySQL's Spatial Extensions (19), Sky Server (20), and spatial extensions. The functionalities provided by these systems include a set of spatial data types such as a points, line segments and polygons, and a set of spatial operations such as inside, intersection, and distance. The spatial types and operations may be made a part of a query language such as SQL, which allows spatial querying when combined with an object-relational database management system (21,22). The performance enhancement provided by these systems includes a multidimensional spatial index and algorithms for spatial database modeling such as OGC (23) and 3-D topological modeling; spatial query processing including point, regional, range, and nearest-neighbor queries; and spatial data methods that use a variety of indexes such as quad trees and grid cells.

Related Work and Our Contributions

Published work related to spatial databases can be classified broadly as follows:

- Textbooks (3,4,6,24), which explain in detail various topics in spatial databases such as logical data models for spatial data, algorithms for spatial operations, and spatial data access methods. Recent textbooks (6,25) deal with research trends in spatial databases such as spatio–temporal databases and moving objects databases.
- Reference books (26,27), which are useful for studying areas related to spatial databases, for example, multidimensional data structures and geographic information systems (GIS).
- Journals and conference proceedings (28–37), which are a source of in-depth technical knowledge of specific problem areas in spatial databases.
- Research surveys (1,38,39), which summarize key accomplishments and identify research needs in various areas of spatial databases at that time.

Spatial database research has continued to advance greatly since the last survey papers in this area were published (1,38,39). Our contribution in this chapter is to summarize the most recent accomplishments in spatial database research, a number of which were identified as research needs in earlier surveys. For instance, bulk loading techniques and spatial join strategies are rereferenced here as well as other advances in spatial data mining and conceptual modeling of spatial data. In addition, this chapter provides an extensive updated list of research needs in

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

such areas as management of 3-D spatial data, visibility queries, and many others. The bibliography section at the end of this chapter contains a list of over 100 references, updated with the latest achievements in spatial databases.

Scope and Outline

The goal of this chapter is to provide the reader with a broad introduction to spatial database systems. Spatial databases are discussed in the context of object-relational databases (21,22,40), which provide extensibility to many components of traditional databases to support the spatial domain. Three major areas that receive attention in the database context—conceptual, logical, and physical data models—are discussed (see Table 1). In addition, applications of spatial data for spatial data mining are also explored.

Emerging needs for spatial database systems include the handling of 3-D spatial data, spatial data with temporal dimension, and effective visualization of spatial data. The emergence of hardware technology such as storage area networks and the availability of multicore processors are two additional fields likely to have an impact on spatial databases. Such topics of research interest are introduced at the end of each section. References are provided for more exploration. Because of the size constraints of this chapter, several other overlapping research needs such as spatio–temporal databases and uncertainty are not included in this chapter.

The rest of this chapter is organized as follows: Fundamental concepts helpful to understand spatial databases are presented. Spatial database modeling is described at the conceptual and logical levels; techniques for spatial query processing are discussed; file organizations and index data structures are presented; and spatial data mining patterns and techniques are explored.

MATHEMATICAL FRAMEWORK

Accomplishments

Spatial data are relatively more complex compared with traditional business data. Specific features of spatial data include: (1) rich data types (e.g., extended spatial objects), (2) implicit spatial relationships among the variables, (3) observations that are not independent, and (4) spatial autocorrelation among the features.

Spatial data can be considered to have two types of attributes: nonspatial attributes and spatial attributes. nonspatial attributes are used to characterize nonspatial features of objects, such as name, population, and unemployment rate for a city. Spatial attributes are used to define the spatial location and extent of spatial objects (41). The spatial attributes of a spatial object most often include information related to spatial locations, for example, longitude, latitude, elevation, and shape. Relationships among nonspatial objects are explicit in data inputs, e.g., arithmetic relation, ordering, instance of, subclass of, and membership of. In contrast, relationships among spatial objects are often implicit, such as overlap, intersect, and behind.

Space is a framework to formalize specific relationships among a set of objects. Depending on the relationships of interest, different models of space such as set-based space, topological space, Euclidean space, metric space, and network space can be used (6). Set-based space uses the basic notion of elements, element-equality, sets, and membership to formalize the set relationships such as set-equality, subset, union, cardinality, relation, function, and convexity. Relational and object-relational databases use this model of space.

Topological space uses the basic notion of a neighborhood and points to formalize the extended object relations such as boundary, interior, open, closed, within, connected, and overlaps, which are invariant under elastic deformation. Combinatorial topological space formalizes relationships such as Euler's formula (number of faces + number of vertices − number of edges = 2 for planar configuration). Network space is a form of topological space in which the connectivity property among nodes formalizes graph properties such as connectivity, isomorphism, shortest-path, and planarity.

Euclidean coordinatized space uses the notion of a coordinate system to transform spatial properties and relationships to properties of tuples of real numbers. Metric spaces formalize the distance relationships using positive symmetric functions that obey the triangle inequality. Many multidimensional applications use Euclidean coordinatized space with metrics such as distance.

Research Needs

Many spatial applications manipulate continuous spaces of different scales and with different levels of discretization. A sequence of operations on discretized data can lead to growing errors similar to the ones introduced by finite-precision arithmetic on numbers. Preliminary results (1) are available on the use of discrete basis and bounding errors with peg-board semantics. Another related problem concerns interpolation to estimate the continuous field from a discretization. Negative spatial autocorrelation makes interpolation error-prone. More work is needed on a framework to formalize the discretization process and its associated errors, and on interpolation.

SPATIAL-DATABASE CONCEPTUAL MODELING

Accomplishments

Entity relationship (ER) diagrams are commonly used in designing the conceptual model of a database. Many extensions (42) have been proposed to extend ER to make the conceptual modeling of spatial applications easier and more intuitive. One such extension is the use of pictograms (43). A pictogram is a graphical icon that can represent a spatial entity or a spatial relationship between spatial entities. The idea is to provide constructs to capture the semantics of spatial applications and at the same time to keep the graphical representation simple. Figure 2 provides different types of pictograms for spatial entities and relationships. In the following text we define pictograms to represent spatial entities and relationships and their grammar in graphical form.

Pictogram: A pictogram is a representation of the object inserted inside of a box. These iconic representations are used to extend ER diagrams and are inserted at appropriate places inside the entity boxes. An entity pictogram can be of a basic shape or a user-defined shape.

Shape: Shape is the basic graphical element of a pictogram that represents the geometric types in the spatial data model. It can be a basic shape, a multishape, a derived shape, or an alternate shape. Most objects have simple (basic) shapes [Fig. 1 (b)].

Basic Shape: In a vector model, the basic elements are point, line, and polygon. In a forestry example, the user may want to represent a facility as a point (0-D), a river or road network as lines (1-D), and forest areas as polygons (2-D) [Fig. 1(d)].

Multishape: To deal with objects that cannot be represented by the basic shapes, we can use a set of aggregate shapes. Cardinality is used to quantify multishapes. For example, a river network that is represented as a line pictogram scale will have cardinality 0 [Fig. 1(b) and (e)].

Derived shape: If the shape of an object is derived from the shapes of other objects, its pictogram is italicized. For example, we can derive a forest boundary (polygon) from its “forest-type” boundaries (polygon), or a country boundary from the constituent-state boundaries [Fig. 1(c) and (g)].

Alternate shape: Alternate shapes can be used for the same object depending on certain conditions; for example, objects of size less than x units are represented as points, whereas those greater than x units are represented as polygons. Alternate shapes are represented as a concatenation of possible pictograms. Similarly, multiple shapes are needed to represent objects at different scales; for example, at higher scales lakes may be represented as points and at lower scales as polygons [Fig. 1(d) and (h)].

Any possible shape: A combination of shapes is represented by a wild card * symbol inside a box, which implies that any geometry is possible (Fig. 1(e)).

User-defined shape: Apart from the basic shapes of point, line, and polygon, user-defined shapes are possible. User-defined shapes are represented by an exclamation symbol (!) inside a box [Fig. 1(a)].

Relationship pictograms: Relationship pictograms are used to model the relationship between entities. For example, *part_of* is used to model the relationship between a route and a network, or it can be used to model the partition of a forest into forest stands [Fig. 1(c)].

The popularity of object-oriented languages such as C++ and Java has encouraged the growth of object-oriented database systems (OODBMS). The motivation behind this growth in OODBMS is that the direct mapping of the conceptual database schema into an object-oriented language leads to a reduction of impedance mismatch encountered when a model on one level is converted into a model on another level.

UML is one of the standards for conceptual-level modeling for object-oriented software design. It may also be applied to an OODBMS to capture the design of the system conceptually. A UML design consists of the following building blocks:

Class: A class is the encapsulation of all objects that share common properties in the context of the application. It is the equivalent of the entity in the ER model. The class diagrams in a UML design can be further extended by adding pictograms. In a forestry example, classes can be forest, facility, forest stand, and so forth.

Attributes: Attributes characterize the objects of the class. The difference between an attribute ER and a UML model design is that no notion of a key attribute exists in UML, in an object-oriented system, each object has an implicit system-generated unique identification. In UML, attributes also have a scope that restricts the attribute's access by other classes. Three levels of scope exist, and each has a special symbol: + Public: This symbol allows the attribute to be accessed and manipulated from any class. - Private: Only the class that owns the attribute is allowed to access the attribute. # Protected: Other than the class that owns the attribute, classes derived from the class that owns can access the attibute.

Methods: Methods are functions and a part of class definition. They are responsible for modifying the behavior or state of the class. The state of the class is embodied in the current values of the attributes. In object-oriented design, attributes should only be accessed through methods.

Relationships: Relationships relate one class to another or to itself. This concept is similar to the concept of relationship in the ER model. Three important categories of relationships are as follows:

- *Aggregation*: This category is a specific construct to capture the part–whole relationship. For instance, a group of forest–stand classes may be aggregated into a forest class.
- *Generalization*: This category describes a relationship in which a child class can be generalized to a parent class. For example, classes such as point, line, and polygon can be generalized to a geometry class.
- *Association*: This category shows how objects of different classes are related. An association is binary if it connects two classes or ternary if it connects three classes. An example of a binary association is *supplieswater to* between the classes river and facility.

Figures 2 and 3 provide an example for modeling a *State-Park* using ER and UML with pictograms, respectively.

Research Needs

Conceptual modeling for spatio–temporal and moving-object data needs to be researched. Pictograms as introduced in this section may be extended to handle such data.

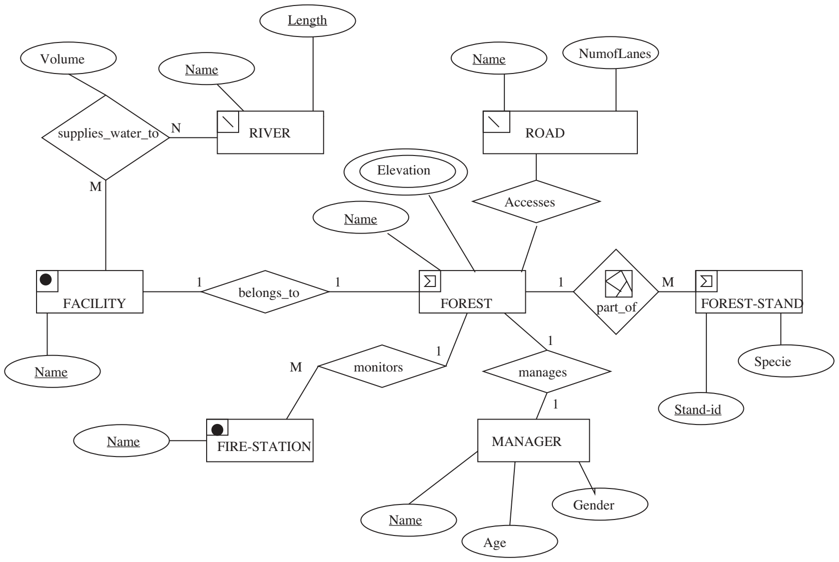

Figure 2. Example ER diagram with pictograms.

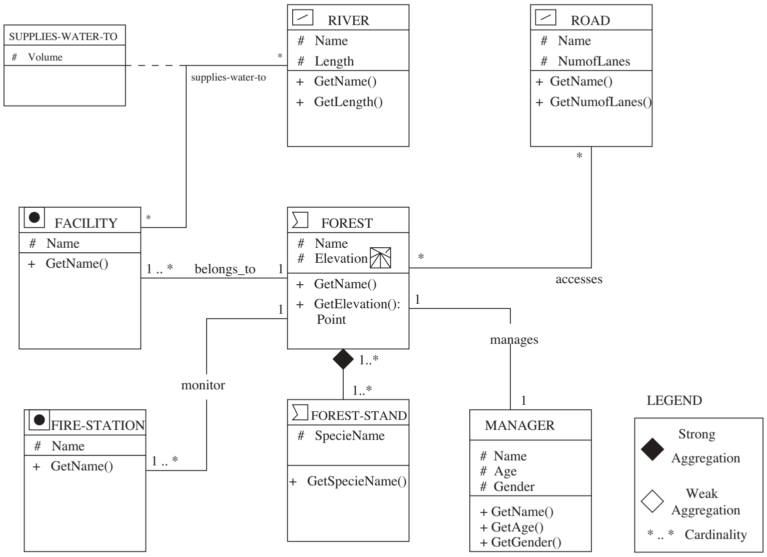

Figure 3. Example UML class diagram with pictograms.

Models used in the spatial representation of data can be extended to conside the time dimension. For instance, the nine-intersection matrix used to represent topology can be differentiated to consider the change in topology over a period of time. Similarly, other spatial properties such as position, orientation, and shape can be differentiated to consider effects over time such as motion, rotation, and deformation of a spatial object. Similarly, series of points can be accumulated to represent time-varying spatial data and properties.

Another area of research is the use of ontology for knowledge management. An ontology defines a common vocabulary that allows knowledge to be shared and reused across different applications. Ontologies provide a shared and common understanding of some domain that can be communicated across people and computers.

Geospatial ontology (44) is specific to the geospatial domain. Research in geospatial ontology is needed to provide interoperability between geospatial data and software. Developing geospatial ontologies is one of the long-term research challenges for the University Consortium for Geographic Information Systems (UCGIS) (37). Research in this area is also being carried out by companies such as CYC for geospatial ontology.

Geospatial ontology can be extended to include the temporal dimension. The ontology of time has been researched in the domain of artificial intelligence as situation calculus. OWL-Time (45) is an ontology developed to represent time.

Semantic web (46) is widely known as an efficient way to represent data on the Web. The wealth of geographic information currently available on the Web has prompted research in the area of GeoSpatial Semantic Web (47,48). In this context, it becomes necessary to create representations of the geographic information resources. This necessity must lead to a framework for information retrieval based on the semantics of spatial ontologies. Developing the geospatial ontology that is required in a geo-spatial semantic web is challenging because the defining properties of geographic entities are very closely related to space (i.e., multidimensional space). In addition, each entity may have several subentities resulting in a complex object (48). One popular data model used in representing semantic web is the resource description framework (RDF) (49).

RDF is being extended (GeoRDF) (50) to include spatial dimensions and hence to provide the necessary support for geographica data on the web.

SPATIAL DATA MODELS AND QUERY LANGUAGES

Accomplishments

Data Models. A spatial data model provides the data abstraction necessary to hide the details of data storage. The two commonly used models are the field-based model and the object-based model. Whereas the field-based model adopts a functional viewpoint, the object-based model treats the information space as a collection of discrete, identifiable, spatially referenced entities. Based on the type of data model used, the spatial operations may change. Table 2 lists the operations specific to the field-based and object-based models. In the context of object-relational databases, a spatial data model is implemented using a set of spatial data types and operations. Over the last two decades, an enormous amount of work has been done in the design and development of spatial abstract data types and their embedding in a query language. Serious efforts are being made to arrive at a consensus on standards through the OGC (51).

OGC proposed the general feature model (51) where features are considered to occur at two levels, namely, feature instances and feature types. A geographic feature is represented as a discrete phenomenon characterized by its geographic and temporal coordinates at the instance

Table 2. Data model and operations

Data Model	Operator Group	Operation
Vector Object	Set-Oriented	equals, is a member of, is empty, is a subset of, is disjoint from, intersection, union, difference, cardinality
	Topological	boundary, interior, closure, meets, overlaps, is inside, covers, connected, components, extremes, is within
	metric	distance, bearing/angle, length, area, perimeter
	Direction	east, north, left, above, between
	Network	successors, ancestors, connected, shortest-path
	Dynamic	translate, rotate, scale, shear, split, merge
Raster Field	Local	point-wise sums, differences, maximumms, means, etc.
	Focal	slop, aspect, weighted average of neighborhood
	Zonal	sum or mean or maximum of field values in each zone

level, and the instances with common characteristics are grouped into classes called feature types. Direction is another important feature used in spatial applications. A direction feature can be modeled as a spatial object (52). Research has also been done to efficiently compute the cardinal direction relations between regions that are composed of sets of spatial objects (53).

Query Languages. When it comes to database sytems, spatial database researchers prefer object-based models because the data types provided by object-based database systems can be extended to spatial data types by creating abstract data types (ADT). OGC provides a framework for object-based models. Figure 4 shows the OpenGIS approach to modeling geographic features. This framework provides conceptual schemas to define abstract feature types and provides facilities to develop application schemas that can capture data about feature instances. Geographic phenomena fall into two broad categories, discrete and continuous. Discrete phenomena are objects that have well-defined boundaries or spatial extent, for example, buildings and streams. Continuous phenomena vary over space and have no specific extent (e.g., temperature and elevation). A continuous phenomenon is described in terms of its value at a specific position in space (and possibly time). OGC represents discrete phenomena (also called vector data) by a set of one or more geometric primitives (points, curves, surfaces, or solids). A continuous phenomenon is represented through a set of values, each associated with one of the elements in an array of points. OGC uses the term “coverage” to refer to any data representation that assigns values directly to spatial position. A coverage is a function from a spatio–temporal domain to an attribute domain. OGC provides standardized representations for spatial characteristics through geometry and topology. Geometry provides the means for the quantitative description of the spatial characteristics including dimension, position, size, shape, and orientation. Topology deals with the characteristics of geometric figures that remain invariant if the space is deformed elastically and continuously. Figure 5 shows the hierarchy of geometry data types. Objects under primitive (e.g., points and curves) will be open (i.e., they will not contain their boundary points), and the objects under complex (e.g., disjoint objects) will be closed.

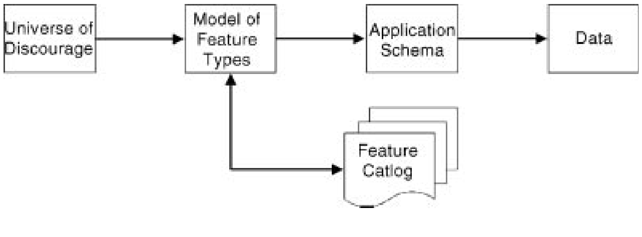

Figure 4. Modeling geographic information [source: (51)].

In addition to defining the spatial data types, OGC also defines spatial operations. Table 3 lists basic operations operative on all spatial data types. The topological operations are based on the ubiquitous nine-intersection model. Using the OGC specification, common spatial queries can be posed intuitively in SQL. For example, the query *Find all lakes which have an area greater than 20 sq. km. and are within 50 km. from the campgrounds* can be posed as shown in Table 4 and Fig. 6. Other GIS and LBS example queries are provided in Table 5. The OGC specification is confined to topological and metric operations on vector data types. Also, several spatio–temporal query languages have been studied that are trigger-based for relational-oriented models (54), moving objects (55), future temporal languages (56), and constraint-based query languages (57).

For spatial networks, commonly used spatial data types include objects such as node, edge, and graph. They may be constructed as an ADT in a database system. Query languages based on relational algebra are unable to express certain important graph queries without making certain assumptions about the graphs. For example, the transitive closure of a graph may not be determined using relational algebra. In the SQL3, a recursion operation RECURSIVE has been proposed to handle the transitive closure operation.

Research Needs

Map Algebra. Map Algebra (58) is a framework for raster analysis that has now evolved to become a preeminent language for dealing with field-based models. Multiple operations can be performed that take multiple data layers that are overlayed upon each other to create a new layer. Some common groups of operations include local, focal, and zonal. However, research is needed to account for the generalization of temporal or higher dimensional data sets (e.g., 3-D data).

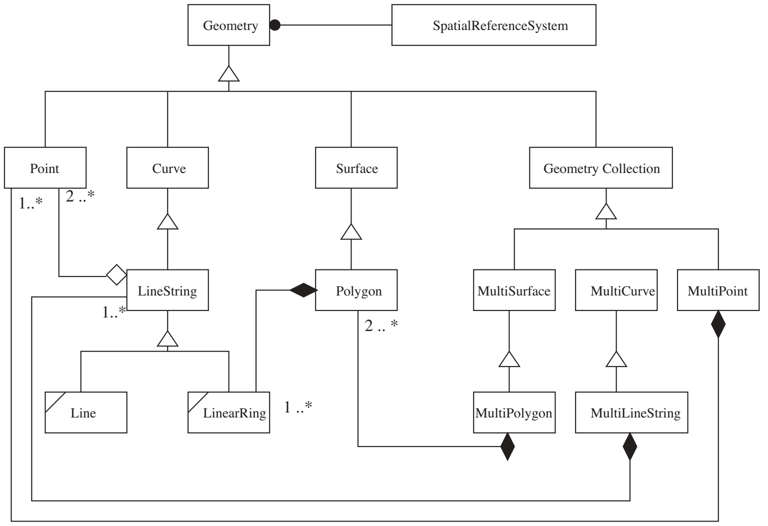

Figure 5. Hierarchy of data types.

Modeling 3-D Data. The representation of volumetric data is another field to be researched. Geographic attributes such as clouds, emissions, vegetation, and so forth. are best described as point fields on volumetric bounds. Sensor data from sensor technologies such as LADAR (Laser Detection and Ranging), 3-D SAR (Synthtic Arperture Radar), and EM collect data volumetrically. Because volumetric data is huge, current convention is to translate the data into lower-dimensional representations such as B-reps, Point clouds, NURBS, and so on. This action results in loss of intrinsic 3-D information. Efforts (59) have been made to develop 3-D data models that emphasize the

Table 3. A sample of operations listed in the OGC standard for SQL

	Basic Functions
SpatialReference()	Returns the underlying coordinate system of the geometry
Envelope()	Returns the minimum orthogonal bounding rectangle of the geometry
Export ()	Returns the geometry in a different representation
IsEmpty()	Returns true if the geometry is an empty set.
IsSimple()	Returns true if the geometry is simple (no self-intersection)
Boundary ()	Returns the boundary of the geometry
	Topological/ Set Operators
Equal	Returns true if the interior and boundary of the two geometries are spatially equal
Disjoint	Returns true if the boundaries and interior do not intersect.
Intersect	Returns true if the interiors of the geometries intersect
Touch	Returns true if the boundaries intersect but the interiors do not.
Cross	Returns true if the interior of the geometries intersect but the boundaries do not
Within	Returns true if the interior of the given geometry does not intersect with the exterior of another geometry.
Contains	Tests if the given geometry contains another given geometry
Overlap	Returns true if the interiors of two geometries have non-empty intersection
	Spatial Analysis
Distance	Returns the shortest distance between two geometries
Buffer	Returns a geometry that consists of all points whose distance from the given geometry is less than or equal to the specified distance
ConvexHull	Returns the smallest convex set enclosing the geometry
Intersection	Returns the geometric intersection of two geometries
Union	Returns the geometric union of two geometries
Difference	Returns the portion of a geometry which does not intersect with another given geometry
SymmDiff	Returns the portions of two geometries which do not intersect with each other

Table 4. SQL query with spatial operators

```
SELECT L.name
FROM Lake L, Facilities Fa
WHERE Area(L.Geometry) > 20 AND
Fa.name = ’campground’ AND
Distance(Fa.Geometry, L.Geometry) < 50
```

significance of the volumetric shapes of physical world objects. This topological 3-D data model relies on Poincare algebra. The internal structure is based on a network of simplexes, and the internal data structure used is a tetrahedronized irregular network (TIN) (59,60), which is the three-dimensional variant of the well-known triangulated irregular network (TIN).

Modeling Spatial Temporal Networks. Graphs have been used extensively to represent spatial networks. Considering the time-dependence of the network parameters and their topology, it has become critically important to incorporate the temporal nature of these networks into their models to make them more accurate and effective. For example, in a transportation network, the travel times on road segments are often dependent on the time of the day, and there can be intervals when certain road segments are not available for service. In such, time-dependent networks modeling the time variance becomes very important. Time-expanded graphs (61) and time-aggregated graphs (62) have been used to model time-varying spatial networks. In the time-expanded representation, a copy of the entire network is maintained for every time instant, whereas the time-aggregated graphs maintain a time series of attributes, associated to every node and edge.

Network modeling can be extended to consider 3-D spatial data. Standard road network features do not represent 3-D structure and material properties. For instance, while modeling a road tunnel, we might want to represent its overpass clearance as a spatial property. Such properties will help take spatial constraints into account while selecting routes.

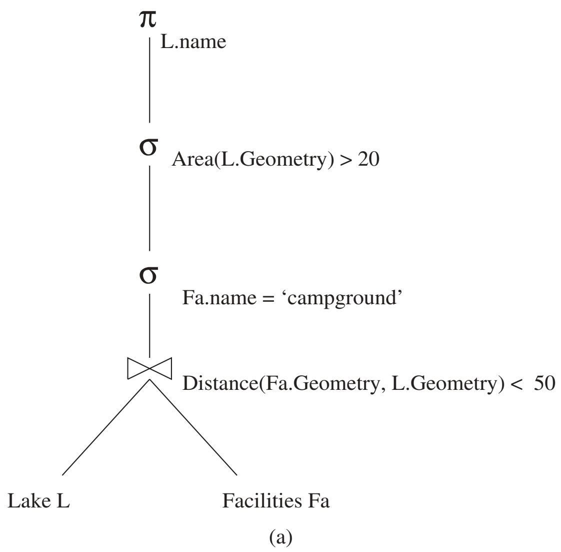

Figure 6. SQL query tree.

Modeling Moving Objects. A moving object database is considered to be a spatio–temporal database in which the spatial objects may change their position and extent over a period of time. To cite a few examples, the movement of taxi cabs, the path of a hurricane over a period of time, and the geographic profiling of serial criminals are a few examples in which a moving-objects database may be considered. Referances 25 and 63 have provided a data model to support the design of such databases.

Markup Languages. The goals of markup languages, such as geography markup language (GML) (64), are to provide a standard for modeling language and data exchange formats for geographic data. GML is an XML-based markup language to represent geographic entities and the relationships between them. Entities associated with geospatial data such as geometry, coordinate systems, attributes, and

Table 5. Typical spatial queries from GIS and LBS

GIS Queries	
Grouping	Recode all land with silty soil to silt-loadm soil
Isolate	Select all land owned by Steve Steiner
Classify	If the population density is less than 100 people / sq. mi., land is acceptable
Scale	Change all measurement’s’ to the metric system
Rank	If the road is an Interstate, assign it code 1; if the road is a state or US highway, assign it code 2; otherwise assign it code 3
Evaluate	If the road code is 1, then assign it Interstate; if the road code is 2, then assign it Main Artery; if the road code is 3, assign it Local Road
Rescale	Apply a function to the population density
Attribute Join	Join the Forest layer with the layer containing forest-cover codes
Zonal	Produce a new map showing state populations given county population
Registration	Align two layers to a common grid reference
Spatial Join	Overlay the land-use and vegetation layers to produce a new layer
LBS Queries	
Nearest Neighbor	List the nearest gas stations
Directions	Display directions from a source to a destation (e.g. Google Maps, Map Quest)
Local Search	Search for restaurants in the neighborhood (e.g. Microsoft Live Local, Google Local)

so forth, can be represented in a standard way using GML. Several computational challenges exist with GML, such as spatial query processing and indexing (65). CityGML (66) is a subclass of GML useful for representing 3-D urban objects, such as buildings, bridges, tunnels, and so on. CityGML allows modeling of spatial data at different levels of detail regarding both geometry and thematic differentiation. It can be used to model 2.5-D data (e.g., digital terrain model), and 3-D data (walkable architecture model). Keyhole markup language (KML) (67) is another XML-based markup language popular with commercial spatial software from Google. Based on a structure similar to GML, KML allows representation of points, polygons, 3-D objects, attributes, and so forth.

SPATIAL QUERY PROCESSING

Accomplishments

The efficient processing of spatial queries requires both efficient representation and efficient algorithms. Common representations of spatial data in an object model include spaghetti, the node-arc-node (NAA) model, the doubly connected-edge-list (DCEL), and boundary representation, some of which are shown in Fig. 7 using entity-relationship diagrams. The NAA model differentiates between the topological concepts (node, arc, and areas) and the embedding space (points, lines, and areas). The spaghetti-ring and DCEL focus on the topological concepts. The representation of the field data model includes a regular tessellation (triangular, square, and hexagonal grid) and triangular irregular networks (TIN).

Query processing in spatial databases differs from that of relational databases because of the following three major issues:

- Unlike relational databases, spatial databases have no fixed set of operators that serve as building blocks for query evaluation.
- Spatial databases deal with extremely large volumes of complex objects. These objects have spatial extensions and cannot be naturally sorted in a one-dimensional array.
- Computationally expensive algorithms are required to test for spatial predicates, and the assumption that I/O costs dominate processing costs in the CPU is no longer valid.

In this section, we describe the processing techniques for evaluating queries on spatial databases and discuss open problems in spatial query processing and query optimization.

Spatial Query Operations. Spatial query operations can be classified into four groups (68).

- **Update Operations:** These include standard database operations such as modify, create, and delete.
- **Spatial Selection:** These can be of two types:
  - **Point Query:** Given a query point, find all spatial objects that contain it. An example is the following query, “Find all river flood-plains which contain the SHRINE.”
  - **Regional Query:** Given a query polygon, find all spatial objects that intersect the query polygon. When the query polygon is a rectangle, this query is called a window query. These queries are sometimes also referred to as range queries. An example query could be “Identify the names of all forest stands that intersect a given window.”
  - **Spatial Join:** Like the join operator in relational databases, the spatial join is one of the more important operators. When two tables are joined on a spatial attribute, the join is called a spatial join. A variant of the spatial join and an important operator in GIS is the *map overlay.* This operation combines two sets of spatial objects to form new ones. The “boundaries” of a set of these new objects are determined by the nonspatial attributes assigned by the overlay operation. For example, if the operation assigns the same value of the nonspatial attribute

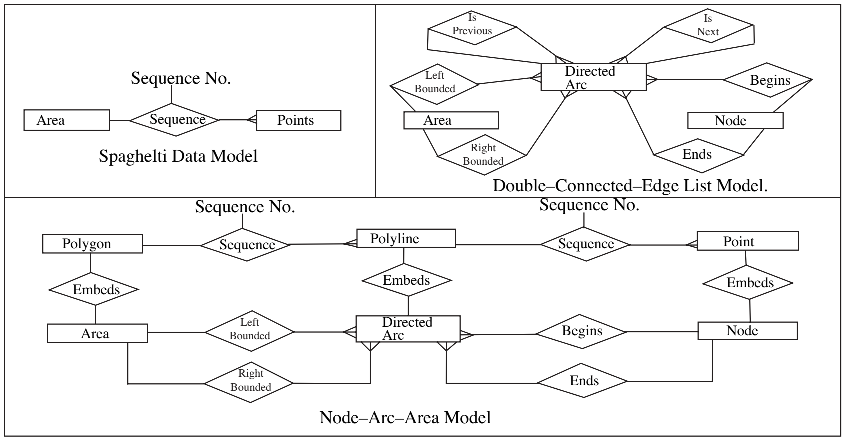

Figure 7. Entity relationship diagrams for common representations of spatial data.

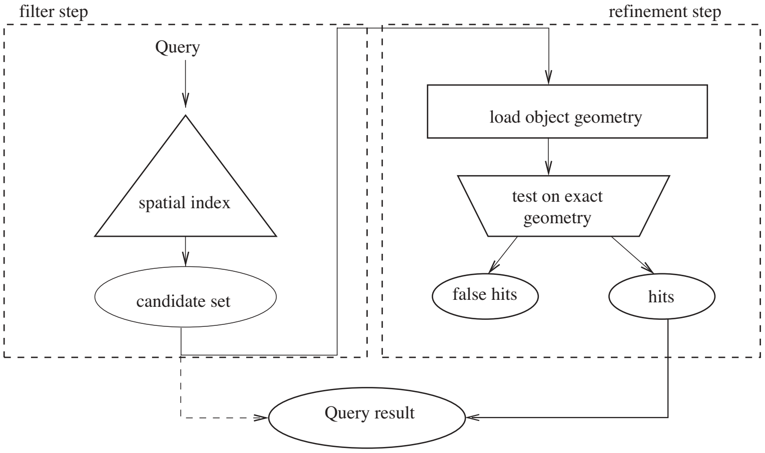

Figure 8. Two-step processing.

to two neighboring objects, then the objects are "merged." Some examples of spatial join predicates are *intersect, contains, is_enclosed_by, distance, northwest, adjacent, meets,* and *overlap*. A query example of a spatial join is "Find all forest-stands and river flood-plains which overlap."

– **Spatial Aggregate:** An example of a spatial aggregate is "Find the river closest to a campground." Spatial aggregates are usually variants of the *Nearest Neighbor* (69–71) search problem: Given a query object, find the object having minimum distance from the query object. A *Reverse Nearest Neighbor* (RNN) (72–76) query is another example of a spatial aggregate. Given a query object, a RNN query finds objects for which the query object is the nearest neighbor. Applications of RNN include army strategic planning where a medical unit, *A*, in the battlefield is always in search of a wounded soldier for whom *A* is the nearest medical unit.

Visibility Queries. Visibility has been widely studied in computer graphics. Visibility may be defined as the parts of objects and the environment that are visible from a point in space. A visibility query can be thought of as a query that returns the objects and part of the environment visible at the querying point. For example, within a city, if the coverage area of a wireless antenna is considered to be the visible area, then the union of coverage areas of all the antennas in the city will provide an idea about the area that is not covered. Such information may be used to place a new antenna strategically at an optimal location. In a visibility query, if the point in space moves, then the area of visibility changes. Such a query may be called a continuous visibility query. For example, security for the president's motorcade involves cordoning off the buildings that have route visibility. In such a case, the visibility query may be thought of as a query that returns the buildings visible at different points on the route.

Visual Queryings. Many spatial applications present results visually, in the form of maps that consist of graphic images, 3-D displays, and animations. These applications allow users to query the visual representation by pointing to the visual representation using pointing devices such as a mouse or a pen. Such graphical interfaces are needed to query spatial data without the need by users to write any SQL statements. In recent years, map services, such as Google Earth and Microsoft Earth, have become very popular. more work is needed to explore the impact of querying by pointing and visual presentation of results on database performance.

Two-Step Query Processing of Spatial Operations. Because spatial query processing involves complex data types, a lake boundary might need a thousand vertices for exact representation. Spatial operations typically follow a two-step algorithm *(filter* and *refinement)* as shown in Fig. 8 to process complex spatial objects efficiently (77). Approximate geometry, such as the minimal orthogonal bounding rectangle of an extended spatial object, is first used to filter out many irrelevant objects quickly. Exact geometry then is used for the remaining spatial objects to complete the processing.

- **Filter step:** In this step, the spatial objects are represented by simpler approximations like the minimum bounding rectangle (MBR). For example, consider the following point query, "Find all rivers whose flood-plains overlap the SHRINE." In SQL this query will be:

```
SELECT   river. name
FROM     river
WHERE    overlap  (river.  flood-plain,  :
SHRINE)
```

  If we approximate the flood-plains of all rivers with MBRs, then it is less expensive to determine whether the point is in a MBR than to check whether a point is in an irregular polygon, that is, in the exact shape of the flood-plain. The answer from this approximate test is a superset of the real answer set. This superset is sometimes called the candidate set. Even the spatial predicate may be replaced by an approximation to simplify a query optimizer. For example, touch (river.flood-plain, :SHRINE) may be replaced by overlap(MBR(river.flood-plain, :SHRINE), and MBR(:SHRINE)) in the filter step. Many spatial operators, for example, inside, north-of, and buffer, can be approximated using the overlap relationship among corresponding MBRs. Such a transformation guarantees that no tuple from the final answer using exact geometry is eliminated in the filter step.

- **Refinement step:** Here, the exact geometry of each element from the candidate set and the exact spatial predicate is examined. This examination usually requires the use of a CPU-intensive algorithm. This step may sometimes be processed outside the spatial database in an application program such as GIS, using the candidate set produced by the spatial database in the filter step.

Techniques for Spatial Operations. This section presents several common operations between spatial objects: selection, spatial join, aggregates, and bulk loading.

Selection Operation. Similar to traditional database systems, the selection operation can be performed on indexed or non indexed spatial data. The difference is in the technique used to evaluate the predicate and the type of index. As discussed in the previous section, a two-step approach, where the geometry of a spatial object is approximated by a rectangle, is commonly used to evaluate a predicate. Popular indexing techniques for spatial data are R-tree, and space-filling curves. An R-tree is a height-balanced tree that is a natural extension of a B-tree for k-dimensions. It allows a point search to be processed in *O(log n)* time. Hash filling curves provide one-to-one continuous mappings that map points of multidimensional space into one-dimensional space. This mapping allows the user to impose order on higher-dimensional spaces. Common examples of space-filling curves are row-order Peano, Z-order, and Hilbert curves. Once the data has been ordered by a space-filling curve, a B-tree index can be imposed on the ordered entries to enhance the search. Point search operations can be performed in *O(log n)* time.

Spatial Join Operation. Conceptually, a join is defined as a cross product followed by a selection condition. In practice, this viewpoint can be very expensive because it involves materializing the cross product before applying the selection criterion. This finding is especially true for spatial databases. Many ingenious algorithms have been proposed to preempt the need to perform the cross product. The two-step query-processing technique described in the previous section is the most commonly used. With such methods, the spatial join operation can be reduced to a rectangle–rectangle intersection, the cost of which is relatively modest compared with the I/O cost of retrieving pages from secondary memory for processing.

A number of strategies have been proposed for processing spatial joins. Interested readers are encouraged to refer to Refs. 78 through 82.

Aggregate Operation: Nearest Neighbor, Reverse Nearest Neighbor. Nearest Neighbor queries are common in many applications. For example, a person driving on the road may want to find the nearest gas station from his current location. Various algorithms exist for nearest neighbor queries (69–71,83,84). Techniques based on Voronoi diagrams, Quad-tree indexing, and Kd-trees have been discussed in Ref. 27.

Reverse Nearest Neighbor queries were introduced in Ref. 72 in the context of decision support systems. For example, a RNN query can be used to find a set of customers who can be influenced by the opening of a new store-outlet location.

Bulk Loading. Bulk operations affect potentially a large set of tuples, unlike other database operations, such as insert into a relation, which affects possibly one tuple at a time. Bulk loading refers to the creation of an index from scratch on a potentially large set of data. Bulk loading has its advantages because the properties of the data set may be known in advance. These properties may be used to design efficiently the space-partitioning index structures commonly used for spatial data. An evaluation of generic bulk loading techniques is provided in Ref. 85.

Parallel GIS. A high-performance geographic information system (HPGIS) is a central component of many interactive applications like real-time terrain visualization, situation assessment, and spatial decision-making. The geographic information system (GIS) often contains large amounts of geometric and feature data (e.g., location, elevation, and soil type) represented as large sets of points, chains of line segments, and polygons. This data is often accessed via range queries. The existing sequential methods for supporting GIS operations do not meet the real-time requirements imposed by many interactive applications.

Hence, parallelization of GIS is essential for meeting the high performance requirements of several realtime applications. A GIS operation can be parallelized either by function partitioning (86–88) or by data partitioning (89–97). Function-partitioning uses specialized data structures (e.g., distributed data structures) and algorithms that may be different from their sequential counterparts. Data partitioning techniques divide the data among different processors and independently execute the sequential algorithm on each processor. Data partitioning in turn is achieved by declustering (98,99) the spatial data. If the static declustering methods fail to distribute the load equally among different processors, the load balance may be improved by redistributing parts of the data to idle processors using dynamic load-balancing (DLB) techniques.

Research Needs

This section presents the research needs for spatial query processing and query optimization.

Query Processing. Many open research areas exist at the logical level of query processing, including query-cost modeling and queries related to fields and networks. Cost

Table 6. Difficult spatial queries from GIS

Voronoize	Classify households as to which supermarket they are closest to
Network	Find the shortest path from the warehouse to all delivery stops
Timedependentnetwork	Find the shortest path where the road network is dynamic
Allocation	Where is the best place to build a new restaurant
Transformation	Triangulate a layer based on elevation
BulkLoad	Load a spatial data file into the database
Raster ↔ Vector	Convert between raster and vector representations
Visibility	Find all points of objects and environment visible from a point
EvacuationRoute	Find evacuation routes based on capacity and availability constraints
PredictLocation	Predict the location of a mobile person based on personal route patterns

models are used to rank and select the promising processing strategies, given a spatial query and a spatial data set. However, traditional cost models may not be accurate in estimating the cost of strategies for spatial operations, because of the distance metric and the semantic gap between relational operators and spatial operation. Comparison of the execution costs of such strategies required that new cost models be developed to estimate the selectivity of spatial search and join operations. Preliminary work in the context of the R-tree, tree-matching join, and fractal-model is promising (100,101), but more work is needed.

Many processing strategies using the overlap predicate have been developed for range queries and spatial join queries. However, a need exists to develop and evaluate strategies for many other frequent queries such as those listed in Table 6. These include queries on objects using predicates other than overlap, queries on fields such as slope analysis, and queries on networks such as the shortest path to a set of destinations.

Depending on the type of spatial data and the nature of the query, other research areas also need to be investigated. A *moving objects query* involves spatial objects that are mobile. Examples of such queries include "Which is the nearest taxi cab to the customer?", "Where is the hurricane expected to hit next?", and "What is a possible location of a serial criminal?" With the increasing availability of streaming data from GPS devices, continuous queries has become an active area of research. Several techniques (25,102,103) have been proposed to execute such queries.

A skyline query (104) is a query to retrieve a set of interesting points (records) from a potentially huge collection of points (records) based on certain attributes. For example, considering a set of hotels to be points, the skyline query may return a set of interesting hotels based on a user's preferences. The set of hotels returned for a user who prefers a cheap hotel may be different from the set of hotels returned for a user who prefers hotels that are closer to the coast. Research needed for skyline query operation includes computation of algorithms and processing for higher dimensions (attributes). Other query processing techniques in which research is required are querying on *3-D spatial data* and *spatio-temporal data.*

Query Optimization. The *query optimizer,* a module in database software, generates different evaluation plans and determines the appropriate execution strategy. Before the query optimizer can operate on the query, the high-level declarative statement must be scanned through a *parser.* The parser checks the syntax and transforms the statement into a *query tree.* In traditional databases, the data types and functions are fixed and the parser is relatively simple. Spatial databases are examples of an extensible database system and have provisions for user-defined types and methods. Therefore, compared with traditional databases, the parser for spatial databases has to be considerably more sophisticated to identify and manage user-defined data types and map them into syntactically correct query trees. In the query tree, the leaf nodes correspond to the relations involved and the internal nodes correspond to the basic operations that constitute the query. Query processing starts at the leaf nodes and proceeds up the tree until the operation at the root node has been performed.

Consider the query, "Find all lakes which have an area greater than 20 sq. km. and are within 50 km. from the campground." Let us assume that the *Area()* function is not precomputed and that its value is computed afresh every time it is invoked. A query tree generated for the query is shown in Fig. 9(a). In the classic situation, the rule "select before join" would dictate that the *Area* function be computed before the join predicate function, *Distance()* [Fig. 9(b)], the underlying assumption being that the computational cost of executing the select and join predicate is equivalent and negligible compared with the I/O cost of the operations. In the spatial situation, the relative cost per tuple of *Area()* and *Distance()* is an important factor in deciding the order of the operations (105). Depending the implementation of these two functions, the optimal strategy may be to process the join before the select operation [Fig. 9(c)]. This approach thus violates the main heuristic rule for relational databases, which states "Apply select and project before the join and binary operations" are no longer unconditional. A cost-based optimization technique exists to determine the optimal execution strategy from a set of execution plans. A quantitative analysis of spatial index structures is used to calculate the expected number of disk accesses that are required to perform a spatial query (106). Nevertheless, in spite of these advances, query optimization techniques for spatial data need more study.

SPATIAL FILE ORGANIZATION AND INDICES

Accomplishments

Space-Filling Curves. The physical design of a spatial database optimizes the instructions to storage devices for

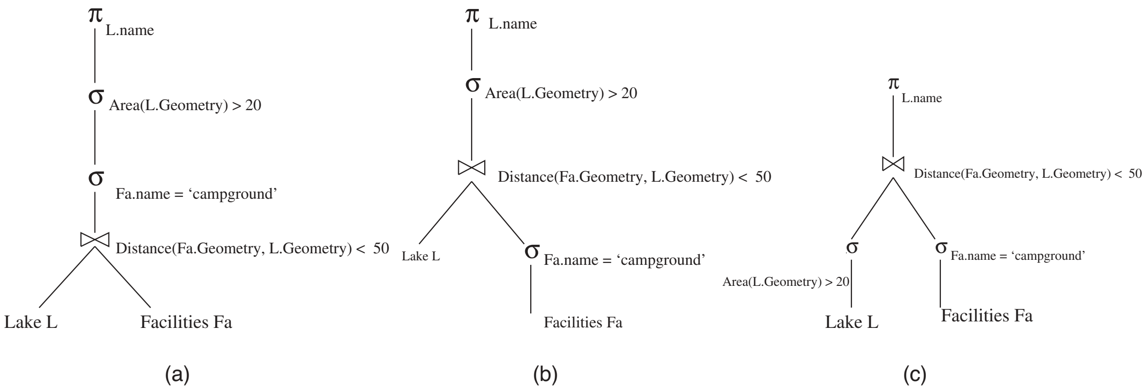

Figure 9. (a) Query tree, (b) "pushing down": select operation, and (c) "pushing down" may not help.

performing common operations on spatial data files. File designs for secondary storage include clustering methods and spatial hashing methods. Spatial clustering techniques are more difficult to design than traditional clustering techniques because no natural order exista in multidimensional space where spatial data resides. This situation is only complicated by the fact that the storage disk is a logical one-dimensional device. Thus, what is needed is a mapping from a higher-dimensional space to a one-dimensional space that is distance-preserving: This mapping ensures that elements that are close in space are mapped onto nearby points on the line and that no two points in the space are mapped onto the same point on the line (107). Several mappings, none of them ideal, have been proposed to accomplish this feat. The most prominent ones include row-order, Z-order, and the Hilbert-curve (Fig. 10).

Metric clustering techniques use the notion of distance to group nearest neighbors together in a metric space. Topological clustering methods like connectivity-clustered access methods (108) use the min-cut partitioning of a graph representation to support graph traversal operations efficiently. The physical organization of files can be supplemented with indices, which are data structures to improve the performance of search operations.

Classical one-dimensional indices such as the B^+-tree can be used for spatial data by linearizing a multidimensional space using a space-filling curve such as the Z-order. Many spatial indices (27) have been explored for multidimensional Euclidean space. Representative indices for point objects include grid files, multidimensional grid files (109), Point-Quad-Trees, and Kd-trees. Representative indices for extended objects include the R-tree family, the Field-tree, Cell-tree, BSP-tree, and Balanced and Nested grid files.

Grid Files. Grid files were introduced by Nievergelt (110). A grid file divides the space into n-dimensional spaces that can fit into equal-size buckets. The structures are not hierarchical and can be used to index static uniformly distributed data. However, because of its structure, the directory of a grid file can be so sparse and large that a large main memory is required. Several variations of grid files, exists to index data efficiently and to overcome these limitations (111,112). An overview of grid files is given in Ref. 27.

Tree indexes. *R-tree* aims to index objects in a hierarchical index structure (113). The R-tree is a height-balanced tree that is the natural extension of the B-tree for k-dimensions. Spatial objects are represented in the R-tree by their minimum bounding rectangle (MBR). Figure 11 illustrates spatial objects organized as an R-tree index. R-trees can be used to process both point and range queries.

Several variants of R-trees exist for better performance of queries and storage use. The R^+-tree (114) is used to store objects by avoiding overlaps among the MBRs, which increases the performance of the searching. R^*-trees (115) rely on the combined optimization of the area, margin, and overlap of each MBR in the intermediate nodes of the tree, which results in better storage use.

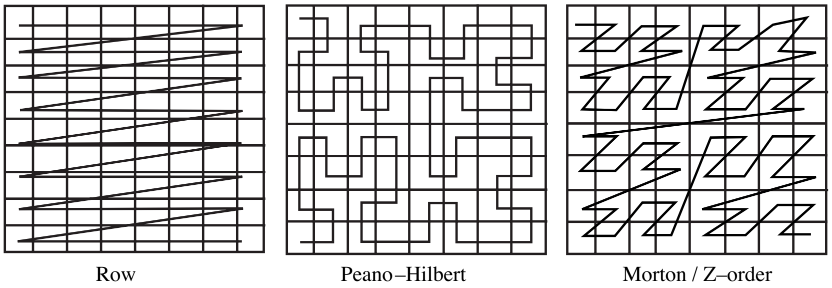

Figure 10. Space-filling curves to linearize a multidimensional space.

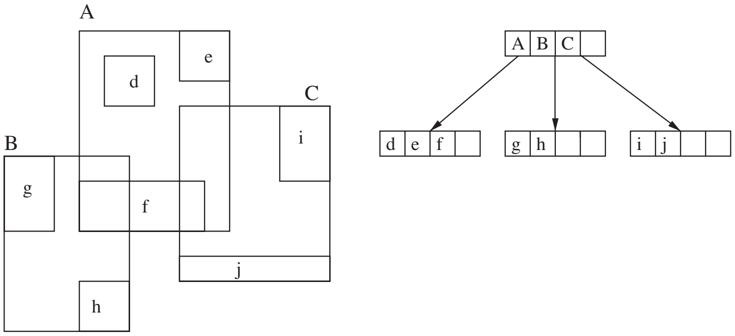

Figure 11. Spatial objects (d, e, f, g, h, and i) arranged in an R-tree hierarchy.

Many R-tree-based index structures (116–119,120,121) have been proposed to index spatio–temporal objects. A survey of spatio–temporal access methods has been provided in Ref. 122.

Quad tree(123) is a space-partitioning index structure in which the space is divided recursively into quads. This recursive process is implemented until each quad is homogeneous. Several variations of quad trees are available to store point data, raster data, and object data. Also, other quad tree structures exist to index spatio–temporal data sets, such as overlapping linear quad trees (24) and multiple overlapping features (MOF) trees (125).

The *Generalized Search Tree* (*GiST*) (126) provides a framework to build almost any kind of tree index on any kind of data. Tree index structures, such as B$^+$-tree and *R*-tree, can be built using GiST. A spatial-partitioning generalized search tree (SP-GiST) (127) is an extensible index structure for space-partitioning trees. Index trees such as quad tree and *k*d-tree can be built using SP-GiST.

Graph Indexes. Most spatial access methods provide methods and operators for point and range queries over collections of spatial points, line segments, and polygons. However, it is not clear if spatial access methods can efficiently support network computations that traverse line segments in a spatial network based on connectivity rather than geographic proximity. *A connectivity-clustered access method for spatial network* (*CCAM*) is proposed to index spatial networks based on graph partitioning (108) by supporting network operations. An auxiliary secondary index, such as B$^+$-tree, *R*-tree, and Grid File, is used to support network operations such as *Find*(), *get-a-Successor*(), and *get-Successors*().

Research Needs

Concurrency Control. The R-link tree (128) is among the few approaches available for concurrency control on the R-tree. New approaches for concurrency-control techniques are needed for other spatial indices. Concurrency is provided during operations such as search, insert, and delete. The R-link tree is also recoverable in a write-ahead logging environment. Reference 129 provides general algorithms for concurrency control for GiST that can also be applied to tree-based indexes. Research is required for concurrency control on other useful spatial data structures.

TRENDS: SPATIAL DATA MINING

Accomplishments

The explosive growth of spatial data and widespread use of spatial databases emphasize the need for the automated discovery of spatial knowledge. Spatial data mining is the process of discovering interesting and previously unknown, but potentially useful, patterns from spatial databases. Some applications are location-based services, studying the effects of climate, land-use classification, predicting the spread of disease, creating high-resolution three-dimensional maps from satellite imagery, finding crime hot spots, and detecting local instability in traffic. A detailed review of spatial data mining can be found in Ref. 130.

The requirements of mining spatial databases are different from those of mining classic relational databases. The difference between classic and spatial data mining parallels the difference between classic and spatial statistics. One fundamental assumption that guides statistical analysis is that the data samples are generated independently, as with successive tosses of a coin or the rolling of a die. When it comes to the analysis of spatial data, the assumption about the independence of samples is generally false. In fact, spatial data tends to be highly self-correlated. For example, changes in natural resources, wildlife, and temperature vary gradually over space. The notion of *spatial autocorrelation,* the idea that similar objects tend to cluster in geographic space, is unique to spatial data mining.

For detailed discussion of spatial analysis, readers are encouraged to refer to Refs. 131 and 132.

Spatial Patterns. This section presents several spatial patterns, specifically those related to location prediction, Markhov random fields, spatial clustering, spatial outliers, and spatial colocation.

Location Prediction. Location prediction is concerned with the discovery of a model to infer locations of a spatial phenomenon from the maps of other spatial features. For example, ecologists build models to predict habitats for endangered species using maps of vegetation, water bodies, climate, and other related species. Figure 12 shows the learning data set used in building a location-prediction

model for red-winged blackbirds in the Darr and Stubble wetlands on the shores of Lake Erie in Ohio. The data set consists of nest location, vegetation durability, distance to open water, and water depth maps. Spatial data mining techniques that capture the spatial autocorrelation (133,134) of nest location such as the spatial autoregression model (SAR) and markov random fields (MRF) are used for location-prediction modeling.

Spatial Autoregression Model. Linear regression models are used to estimate the conditional expected value of a dependent variable y given the values of other variables X. Such a model assumes that the variables are independent. The spatial autoregression model (131,135–137) is an extension of the linear regression model that takes spatial autocorrelation into consideration. If the dependent values y and X are related to each other, then the regression equation (138) can be modified as

$$y = \rho \mathrm{W} y + \mathrm{X}\beta + \varepsilon \tag{1}$$

Here, W is the neighborhood relationship contiguity matrix, and ? is a parameter that reflects the strength of the spatial dependencies between the elements of the dependent variable. Notice that when $\rho = 0$, this equation collapses to the linear regression model. If the spatial autocorrelation coefficient is statistically significant, then SAR will quantify the presence of spatial autocorrelation. In such a case, the spatial autocorrelation coefficient will indicate the extent to which variations in the dependent variable *(y)* are explained by the average of neighboring observation values.

Markov Random Field. Markov random field-based (139) Bayesian classifiers estimate the classification model, $\hat{f}c$, using MRF and Bayes' rule. A set of random variables whose interdependency relationship is represented by an undirected graph (i.e., a symmetric neighborhood matrix) is called a Markov random field. The Markov property specifies that a variable depends only on its neighbors and is independent of all other variables. The location prediction problem can be modeled in this framework by assuming that the class label, $l_i = f_C(s_i)$, of different locations, s_i, constitutes an MRF. In other words, random variable l_i is independent of l_i if $W(s_i, s_j) = 0$.

The Bayesian rule can be used to predict l_i from feature value vector X and neighborhood class label vector L_i as follows:

$$Pr(l_i|X, L_i) = \frac{Pr(X|l_i, L_i)Pr(l_i|L_i)}{Pr(X)} \tag{2}$$

The solution procedure can estimate $Pr(l_i \mid L_i)$ from the training data, where L_i denotes a set of labels in the neighborhood of s_i excluding the label at s_i. It makes this estimate by examining the ratios of the frequencies of class labels to the total number of locations in the spatial framework. $Pr(X \mid l_i, L_i)$ can be estimated using kernel functions from the observed values in the training data set.

A more detailed theoretical and experimental comparison of these methods can be found in Ref. 140. Although MRF and SAR classification have different formulations, they share a common goal of estimating the posterior probability distribution. However, the posterior probability for the two models is computed differently with different assumptions. For MRF, the posterior is computed using Bayes' rule, whereas in SAR, the posterior distribution is fitted directly to the data.

Spatial Clustering. Spatial clustering is a process of grouping a set of spatial objects into clusters so that objects within a cluster have high similarity in comparison with one another but are dissimilar to objects in other clusters.

For example, clustering is used to determine the "hot spots" in crime analysis and disease tracking. Many criminal justice agencies are exploring the benefits provided by computer technologies to identify crime hot spots to take preventive strategies such as deploying saturation patrols in hot-spot areas.

Spatial clustering can be applied to group similar spatial objects together; the implicit assumption is that patterns in space tend to be grouped rather than randomly located. However, the statistical significance of spatial clusters should be measured by testing the assumption in the data. One method to compute this measure is based on quadrats (i.e., well-defined areas, often rectangular in shape). Usually quadrats of random location and orientations in the quadrats are counted, and statistics derived from the counters are computed. Another type of statistics is based on distances between patterns; one such type is Ripley's K-function (141). After the verification of the statistical significance of the spatial clustering, classic clustering algorithms (142) can be used to discover interesting clusters.

Spatial Outliers. A spatial outlier (143) is a spatially referenced object whose nonspatial attribute values differ significantly from those of other spatially referenced objects in its spatial neighborhood. Figure 13 gives an example of detecting spatial outliers in traffic measurements for sensors on highway I-35W (North bound) for a 24-hour time period. Station 9 seems to be a spatial outlier as it exhibits inconsistent traffic flow as compared with its neighboring stations. The reason could be that the sensor at station 9 is malfunctioning. Detecting spatial outliers is useful in many applications of geographic information systems and spatial databases, including transportation, ecology, public safety, public health, climatology, and location-based services.

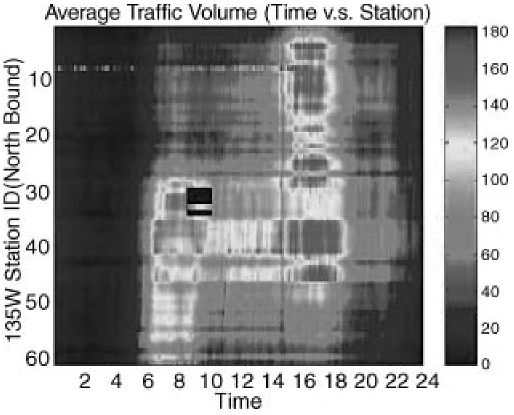

Figure 13. Spatial outlier (station ID 9) in traffic volume data.

Spatial attributes are used to characterize location, neighborhood, and distance. Nonspatial attribute dimensions are used to compare a spatially referenced object with its neighbors. Spatial statistics literature provides two kinds of bipartite multidimensional tests, namely graphical tests and quantitative tests. Graphical tests, which are based on the visualization of spatial data, highlight spatial outliers, for example, variogram clouds (141) and Moran scatterplots (144). Quantitative methods provide a precise test to distinguish spatial outliers from the remainder of data. A unified approach to detect spatial outliers efficiently is discussed in Ref. 145., Referance 146 provides algorithms for multiple spatial-outlier detection.

Spatial Colocation The colocation pattern discovery process finds frequently colocated subsets of spatial event types given a map of their locations. For example, the analysis of the habitats of animals and plants may identify the colocations of predator–prey species, symbiotic species, or fire events with fuel, ignition sources and so forth. Figure 14 gives an example of the colocation between roads and rivers in a geographic region.

Approaches to discovering colocation rules can be categorized into two classes, namely spatial statistics and datamining approaches. Spatial statistics-based approaches use measures of spatial correlation to characterize the relationship between different types of spatial features. Measures of spatial correlation include the cross K-function with Monte Carlo simulation, mean nearest-neighbor distance, and spatial regression models.

Data-mining approaches can be further divided into transaction-based approaches and distance-based approaches. Transaction-based approaches focus on defining transactions over space so that an a priori-like algorithm can be used. Transactions over space can be defined by a reference-feature centric model. Under this model, transactions are created around instances of one user-specified spatial feature. The association rules are derived using the a priori (147) algorithm. The rules formed are related to the reference feature. However, it is nontrivial to generalize the paradigm of forming rules related to a reference feature to the case in which no reference feature is specified. Also, defining transactions around locations of instances of all features may yield duplicate counts for many candidate associations.

In a distance-based approach (148–150), instances of objects are grouped together based on their Euclidean distance from each other. This approach can be considered to be an event-centric model that finds subsets of spatial

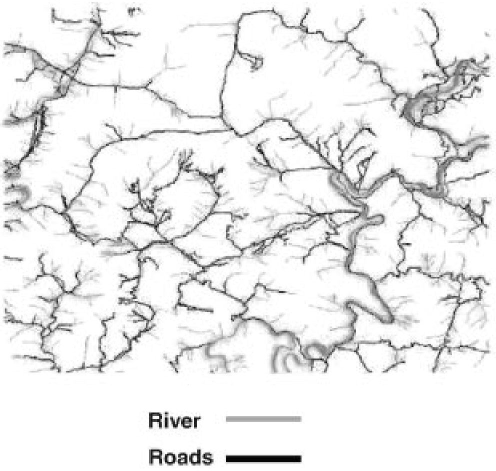

Figure 14. Colocation between roads and rivers in a hilly terrain (Courtesy: Architecture Technology Corporation).

features likely to occur in a neighborhood around instances of given subsets of event types.

Research Needs

This section presents several research needs in the area of spatio–temporal data mining and spatial–temporal network mining.

Spatio–Temporal Data Mining. Spatio–temporal (ST) data mining aims to develop models and objective functions and to discover patterns that are more suited to Spatio–temporal databases and their unique properties (15). An extensive survey of Spatio–temporal databases, models, languages, and access methods can be found in Ref. 152. A bibliography of Spatio–temporal data mining can be found in Ref. 153.

Spatio–temporal pattern mining focuses on discovering knowledge that frequently is located together in space and time. Referances 154, 155, and 156 defined the problems of discovering mixed-drove and sustained emerging Spatio–temporal co-occurrence patterns and proposed interest measures and algorithms to mine such patterns. Other research needs include conflation, in which a single feature is obtained from several sources or representations. The goal is to determine the optimal or best representation based on a set of rules. Problems tend to occur during maintenance operations and cases of vertical obstruction.

In several application domains, such as sensor networks, mobile networks, moving object analysis, and image analysis, the need for spatio–temporal data mining is increasing drastically. It is vital to develop new models and techniques, to define new spatio–temporal patterns, and to formulize monotonic interest measures to mine these patterns (157).

Spatio–Temporal Network Mining. In the post-9/11 world of asymmetric warfare in urban area, many human activities are centered about ST infrastructure networks, such as transportation, oil/gas-pipelines, and utilities (e.g., water, electricity, and telephone). Thus, activity reports, for example, crime/insurgency reports, may often use network-based location references, for exmple, street address such as “200 Quiet Street, Scaryville, RQ 91101.” In addition, spatial interaction among activities at nearby locations may be constrained by network connectivity and network distances (e.g., shortest path along roads or train networks) rather than geometric distances (e.g., Euclidean or Manhattan distances) used in traditional spatial analysis. Crime prevention may focus on identifying subsets of ST networks with high activity levels, understanding underlying causes in terms of ST-network properties, and designing ST-network-control policies.

Existing spatial analysis methods face several challenges (e.g., see Ref. 158). First, these methods do not model the effect of explanatory variables to determine the locations of network hot spots. Second, existing methods for network pattern analysis are computationally expensive. Third, these methods do not consider the temporal aspects of the activity in the discovery of network patterns. For example, the routes used by criminals during the day and night may differ. The periodicity of bus/train schedules can have an impact on the routes traveled. Incorporating the time-dependency of transportation networks can improve the accuracy of the patterns.

SUMMARY

In this chapter we presented the major research accomplishments and techniques that have emerged from the area of spatial databases in the past decade. These accomplishments and techniques include spatial database modeling, spatial query processing, and spatial access methods. We have also identified areas in which more research is needed, such as spatio–temporal databases, spatial data mining, and spatial networks.

Figure 15 provides a summary of topics that continue to drive the research needs of spatial database systems. Increasingly available spatial data in the form of digitized maps, remotely sensed images, Spatio–temporal data (for example, from videos), and streaming data from sensors have to be managed and processed efficiently. New ways of querying techniques to visualize spatial data in more than one dimension are needed. Several advances have been made in computer hardware over the last few years, but many have yet to be fully exploited, including increases in main memory, more effective storage using storage area networks, greater availability of multicore processors, and powerful graphic processors. A huge impetus for these advances has been spatial data applications such as land navigation systems and location-based services. To measure the quality of spatial database systems, new benchmarks have to be established. Some benchmarks (159,160) established earlier have become dated. Newer benchmarks are needed to characterize the spatial data management needs of other systems and applications such as Spatio–temporal databases, moving-objects databases, and location-based services.

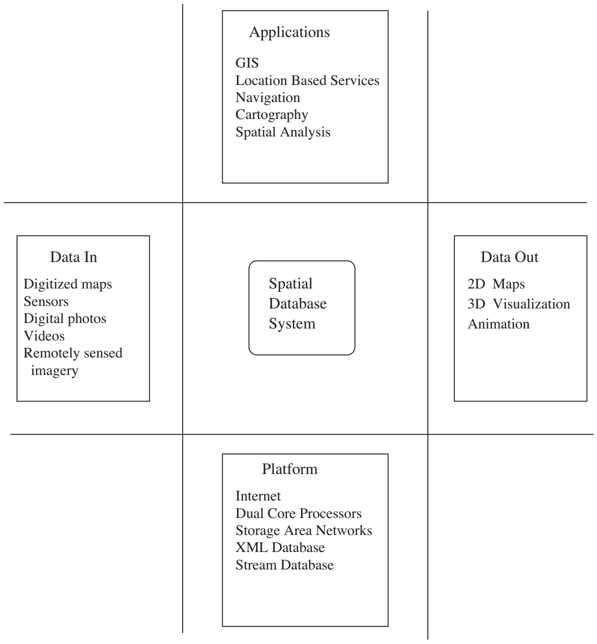

Figure 15. Topics driving future research needs in spatial database systems.

ACKNOWLEDGMENTS

We thank the professional organizations that have funded the research on spatial databases, in particular, the National Science Foundation, Army Research Laboratory, Topographic Engineering Center, Oak Ridge National Laboratory, Minnesota Department of Transportation, and Microsoft Corporation. We thank members of the spatial database and spatial data mining research group at the University of Minnesota for refining the content of this chapter. We also thank Kim Koffolt for improving the readability of this chapter.

STATISTICAL DATABASES

INTRODUCTION

Statistical databases are databases that contain statistical information. Such databases normally are released by national statistical institutes, but on occasion they can also be released by health-care authorities (epidemiology) or by private organizations (e.g., consumer surveys). Statistical databases typically come in three formats:

- *Tabular data*, that is, tables with counts or magnitudes, which are the classic output of official statistics.
- *Queryable databases*, that is, online databases to which the user can submit statistical queries (sums, averages, etc.).
- *Microdata*, that is, files in which each record contains information on an individual (a citizen or a company).

The peculiarity of statistical databases is that they should provide useful *statistical* information, but they should not reveal private information on the individuals to whom they refer (respondents). Indeed, supplying data to national statistical institutes is compulsory in most countries, but in return those institutes commit to preserving the privacy of respondents. Inference control in statistical databases, also known as statistical disclosure control (SDC), is a discipline that seeks to protect data in statistical databases so that they can be published without revealing confidential information that can be linked to specific individuals among those to whom the data correspond. SDC is applied to protect *respondent privacy* in areas such as official statistics, health statistics, and e-commerce (sharing of consumer data). Because data protection ultimately means data modification, the challenge for SDC is to achieve protection with minimum loss of accuracy sought by database users.

In Ref. 1, a distinction is made between SDC and other technologies for database privacy, like privacy-preserving data mining (PPDM) or private information retrieval (PIR): What makes the difference between those technologies is whose privacy they seek. Although SDC is aimed at respondent privacy, the primary goal of PPDM is to protect owner privacy when several database owners wish to cooperate in joint analyses across their databases without giving away their original data to each other. On its side, the primary goal of PIR is user privacy, that is, to allow the user of a database to retrieve some information item without the database exactly knowing which item was recovered.

The literature on SDC started in the 1970s, with the seminal contribution by Dalenius (2) in the statistical community and the works by Schlörer (3) and Denning et al. (4) in the database community. The 1980s saw moderate activity in this field. An excellent survey of the state of the art at the end of the 1980s is in Ref. 5. In the 1990s, renewed interest occurred in the statistical community and the discipline was developed even more under the names of statistical disclosure control in Europe and statistical disclosure limitation in America. Subsequent evolution has resulted in at least three clearly differentiated subdisciplines:

- *Tabular data protection*. The goal here is to publish *static* aggregate information, i.e., tables, in such a way that no confidential information on specific individuals among those to which the table refers can be inferred. See Ref. 6 for a conceptual survey.
- *Queryable databases*. The aggregate information obtained by a user as a result of successive queries should not allow him to infer information on specific individuals. Since the late 1970s, this has been known to be a difficult problem, which is subject to the tracker attack (4,7). SDC strategies here include perturbation, query restriction, and camouflage (providing interval answers rather than exact answers).
- *Microdata protection*. It is only recently that data collectors (statistical agencies and the like) have been persuaded to publish microdata. Therefore, microdata protection is the youngest subdiscipline, and it has experienced continuous evolution in the last few years. Its purpose is to mask the original microdata so that the masked microdata still are useful analytically but cannot be linked to the original respondents.

Several areas of application of SDC techniques exist, which include but are not limited to the following:

- *Official statistics*. Most countries have legislation that compels national statistical agencies to guarantee statistical confidentiality when they release data collected from citizens or companies. It justifies the research on SDC undertaken by several countries, among them the European Union (e.g., the CASC project) and the United States.
- *Health information*. This area is one of the most sensitive regarding privacy. For example, in the United States, the Privacy Rule of the Health Insurance Portability and Accountability Act (HIPAA) requires the strict regulation of protected health information for use in medical research. In most Western countries, the situation is similar.
- *E-commerce*. Electronic commerce results in the automated collection of large amounts of consumer data. This wealth of information is very useful to companies, which are often interested in sharing it with their subsidiaries or partners. Such consumer information transfer should not result in public profiling of individuals and is subject to strict regulation.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

THEORY

Formal Definition of Data Formats

A *microdata* file **X** with s respondents and t attributes is an $s \times t$ matrix, where X_{ij} is the value of attribute j for respondent i. Attributes can be numerical (e.g., age or salary) or categorical (e.g., gender or job).

The attributes in a microdata set can be classified in four categories that are not necessarily disjoint:

- *Identifiers.* These attributes *unambiguously* identify the respondent. Examples are the passport number, social security number, and name-surname.
- *Quasi-identifiers or key attributes.* These attributes identify the respondent with some degree of ambiguity. (Nonetheless, a combination of key attributes may provide unambiguous identification.) Examples are address, gender, age, and telephone number.
- *Confidential outcome attributes.* These attributes contain sensitive information on the respondent. Examples are salary, religion, political affiliation, and health condition.
- *Nonconfidential outcome attributes.* These attributes contain nonsensitive information on the respondent.

From microdata, *tabular data* can be generated by crossing one or more categorical attributes. Formally, a table is a function

$$T : D(X_{i1}) \times D(X_{i2}) \times ... \times D(X_{il}) \rightarrow \mathbb{R} \quad \text{or} \quad \mathbb{N}$$

where $l \leq t$ is the number of crossed categorical attributes and $D(X_{ij})$ is the domain where attribute X_{ij} takes its values.

Two kinds of tables exist: *frequency tables* that display the count of respondents at the crossing of the categorical attributes (in $\mathbb{N}$) and *magnitude tables* that display information on a numeric attribute at the crossing of the categorical attributes (in $\mathbb{R}$). For example, given some census microdata containing attributes "Job" and "Town," one can generate a *frequency table* that displays the count of respondents doing each job type in each town. If the census microdata also contain the "Salary" attribute, one can generate a magnitude table that displays the average salary for each job type in each town. The number n of cells in a table is normally much less than the number s of respondent records in a microdata file. However, tables must satisfy several linear constraints: marginal row and column totals. Additionally, a set of tables is called *linked* if they share some of the crossed categorical attributes: For example, "Job" × "Town" is linked to "Job" × "Gender."

Overview of Methods

Statistical disclosure control will be first reviewed for tabular data, then for queryable databases, and finally for microdata.

Methods for Tabular Data

Even if tables display aggregate information, a risk of disclosure exists in tabular data release. Several attacks are conceivable:

- *External attack.* For example, let a frequency table "Job" × "Town" be released where a single respondent exists for job J_i and town T_j. Then if a magnitude table is released with the average salary for each job type and each town, the exact salary of the only respondent with job J_i working in town T_j is disclosed publicly.
- *Internal attack.* Even if two respondents for job J_i and town T_j exist, the salary of each of them is disclosed to each other.
- *Dominance attack.* If one (or a few) respondents dominate in the contribution to a cell of a magnitude table, the dominant respondent(s) can upper-bound the contributions of the rest (e.g., if the table displays the total salary for each job type and town and one individual contributes 90% of that salary, he knows that his colleagues in the town are not doing very well).

SDC methods for tables fall into two classes: nonperturbative and perturbative. *Nonperturbative methods* do not modify the values in the tables; the best known method in this class is *cell suppression* (CS). *Perturbative methods* output a table with some modified values; well-known methods in this class include *controlled rounding* (CR) and the recent *controlled tabular adjustment* (CTA).

The idea of CS is to suppress those cells that are identified as sensitive, i.e., from which the above attacks can extract sensitive information, by the so-called sensitivity rules (e.g., the dominance rule, which identifies a cell as sensitive if it is vulnerable to a dominance attack). Sensitive cells are the primary suppressions. Then additional suppressions (secondary suppressions) are performed to prevent primary suppressions from being computed or even inferred within a prescribed protection interval using the row and column constraints (marginal row and column totals). Usually, one attempts to minimize either the number of secondary suppressions or their pooled magnitude, which results in complex optimization problems. Most optimization methods used are heuristic, based on mixed integer linear programming or network flows (8), and most of them are implemented in the τ-Argus free software package (9). CR rounds values in the table to multiples of a rounding base, which may entail rounding the marginal totals as well. On its side, CTA modifies the values in the table to prevent the inference of values of sensitive cells within a prescribed protection interval. The idea of CTA is to find the *closest* table to the original one that ensures such a protection for all sensitive cells. It requires optimization methods, which are typically based on mixed linear integer programming. Usually CTA entails less information loss than does CS.

Methods for Queryable Databases

In SDC of queryable databases, three main approaches exist to protect a confidential vector of numeric data from disclosure through answers to user queries:

- *Data perturbation.* Perturbing the data is a simple and effective approach whenever the users do not require deterministically correct answers to queries that are functions of the confidential vector. Perturbation can be applied to the records on which queries are computed (input perturbation) or to the query result after computing it on the original data (output perturbation). Perturbation methods can be found in Refs. 10–12.
- *Query restriction.* This approach is right if the user does require deterministically correct answers and these answers have to be exact (i.e., a number). Because exact answers to queries provide the user with very powerful information, it may become necessary to refuse to answer certain queries at some stage to avoid disclosure of a confidential datum. Several criteria decide whether a query can be answered; one of them is query set size control, that is, to refuse answers to queries that affect a set of records that is too small. An example of the query restriction approach can be found in Ref. 13.
- *Camouflage.* If deterministically correct, nonexact answers (i.e., small-interval answers) suffice, confidentiality via camouflage [CVC, (14)] is a good option. With this approach, unlimited answers to any conceivable query types are allowed. The idea of CVC is to "camouflage" the confidential vector a by making it part of the relative interior of a compact set Π of vectors. Then each query $q = f(a)$ is answered with an inverval $[q^-, q^+]$ that contains $[f^-, f^+]$, where f^- and f^+ are, respectively, the minimum and the maximum of f over Π.

Methods for Microdata

Microdata protection methods can generate the protected microdata set $\mathbf{X}'$

- Either by *masking original data*, i.e., generating a modified version $\mathbf{X}'$ of the original microdata set $\mathbf{X}$.
- Or by *generating synthetic data* $\mathbf{X}'$ that preserve some statistical properties of the original data $\mathbf{X}$.

Masking methods can in turn be divided in two categories depending on their effect on the original data (6):

- *Perturbative.* The microdata set is distorted before publication. In this way, unique combinations of scores in the original dataset may disappear, and new, unique combinations may appear in the perturbed dataset; such confusion is beneficial for preserving statistical confidentiality. The perturbation method used should be such that statistics computed on the perturbed dataset do not differ significantly from the statistics that would be obtained on the original dataset. *Noise addition, microaggregation, data/rank swapping, microdata rounding, resampling, and PRAM* are examples of perturbative masking methods (see Ref. 8 for details).
- *Nonperturbative.* Nonperturbative methods do not alter data; rather, they produce partial suppressions or reductions of detail in the original dataset. Sampling, global recoding, top and bottom coding, and local suppression are examples of nonperturbative masking methods.

Although a reasonable overview of the methods for protecting tables or queryable databases has been given above, microdata protection methods are more diverse, so that a description of some of them is needed.

Some Microdata Protection Methods

Additive Noise. Additive noise is a family of perturbative masking methods. The noise addition algorithms in the literature are as follows:

- *Masking by uncorrelated noise addition.* The vector of observations x_j for the jth attribute of the original dataset X_j is replaced by a vector

$$z_j = x_j + \epsilon_j$$

where ϵ_j is a vector of normally distributed errors drawn from a random variable $\varepsilon_j \sim N(0, \sigma^2_{\varepsilon_j})$, such that $Cov(\varepsilon_t, \varepsilon_l) = 0$ for all $t \neq l$. This algorithm neither preserves variances nor correlations.

- *Masking by correlated noise addition.* Correlated noise addition also preserves means and additionally allows preservation of correlation coefficients. The difference with the previous method is that the covariance matrix of the errors is now proportional to the covariance matrix of the original data, i.e., $\varepsilon \sim N(0, \Sigma_\varepsilon)$, where $\Sigma_\varepsilon = \alpha\Sigma$, with Σ being the covariance matrix of the original data.
- *Masking by noise addition and linear transformation.* In Ref. 15, a method is proposed that ensures by additional transformations that the sample covariance matrix of the masked attributes is an unbiased estimator for the covariance matrix of the original attributes.
- *Masking by noise addition and nonlinear transformation.* Combining simple additive noise and nonlinear transformation has also been proposed in such a way that application to discrete attributes is possible and univariate distributions are preserved. Unfortunately, the application of this method is very time-consuming and requires expert knowledge on the dataset and the algorithm. See Ref. 8 for more details.

In practice, only simple noise addition (two first variants) or noise addition with linear transformation are used. When using linear transformations, a decision has to be made whether to reveal them to the data user to allow for bias adjustment in the case of subpopulations.

In general, additive noise is not suitable to protect categorical data. On the other hand, it is well suited for continuous data for the following reasons:

- It makes no assumptions on the range of possible values for X_i (which may be infinite).
- The noise being added typically is continuous and with mean zero, which suits well continuous original data.

Microaggregation. Microaggregation is a family of SDC techniques for continous microdata. The rationale behind microaggregation is that confidentiality rules in use allow publication of microdata sets if records correspond to groups of k or more individuals, where no individual dominates (i.e., contributes too much to) the group and k is a threshold value. Strict application of such confidentiality rules leads to replacing individual values with values computed on small aggregates (microaggregates) before publication. It is the basic principle of microaggregation.

To obtain microaggregates in a microdata set with n records, these are combined to form g groups of size at least k. For each attribute, the average value over each group is computed and is used to replace each of the original averaged values. Groups are formed using a criterion of maximal similarity. Once the procedure has been completed, the resulting (modified) records can be published.

The optimal k-partition (from the information loss point of view) is defined to be the one that maximizes within-group homogeneity; the higher the within-group homogeneity, the lower the information loss, because microaggregation replaces values in a group by the group centroid. The sum of squares criterion is common to measure homogeneity in clustering. The within-groups sum of squares SSE is defined as

$$\mathrm{SSE} = \sum_{i=1}^{g}\sum_{j=1}^{n_i}(x_{ij}-\bar{x}_i)'(x_{ij}-\bar{x}_i)$$

The lower the SSE, the higher the within-group homogeneity. Thus, in terms of sums of squares, the optimal k-partition is the one that minimizes SSE.

Given a microdata set that consists of p attributes, these can be microaggregated together or partitioned into several groups of attributes. Also, the way to form groups may vary. Several taxonomies are possible to classify the microaggregation algorithms in the literature: *(1)* fixed group size (16–18) versus variable group size (19–21), *(2)* exact optimal [only for the univariate case, (22)] versus heuristic microaggregation (the rest of the microaggregation literature), and *(3)* categorical (18,23) versus continuous (the rest of references cited in this paragraph).

To illustrate, we next give a heuristic algorithm called MDAV [maximum distance to average vector, (18,24)] for multivariate fixed-group-size microaggregation on unprojected continuous data. We designed and implemented MDAV for the μ-Argus package (17).

1. Compute the average record $\bar{x}$ of all records in the dataset. Consider the most distant record x_r to the average record $\bar{x}$ (using the squared Euclidean distance).
2. Find the most distant record x_s from the record x_r considered in the previous step.
3. Form two groups around x_r and x_s, respectively. One group contains x_r and the $k-1$ records closest to x_r. The other group contains x_s and the $k-1$ records closest to x_s.
4. If at least $3k$ records do not belong to any of the two groups formed in Step 3, go to Step 1, taking as a new dataset the previous dataset minus the groups formed in the last instance of Step 3.
5. If between $3k-1$ and $2k$ records do not belong to any of the two groups formed in Step 3: a) compute the average record $\bar{x}$ of the remaining records, b) find the most distant record x_r from $\bar{x}$, c) form a group containing x_r and the $k-1$ records closest to x_r, and d) form another group containing the rest of records. Exit the Algorithm.
6. If less than $2k$ records do not belong to the groups formed in Step 3, form a new group with those records and exit the Algorithm.

The above algorithm can be applied independently to each group of attributes that results from partitioning the set of attributes in the dataset.

Data Swapping and Rank Swapping. Data swapping originally was presented as a perturbative SDC method for databases that contain only categorical attributes. The basic idea behind the method is to transform a database by exchanging values of confidential attributes among individual records. Records are exchanged in such a way that low-order frequency counts or marginals are maintained.

Even though the original procedure was not used often in practice, its basic idea had a clear influence in subsequent methods. A variant of data swapping for microdata is *rank swapping*, which will be described next in some detail.

Although originally described only for ordinal attributes (25), rank swapping can also be used for any numeric attribute. First, values of an attribute X_i are ranked in ascending order; then each ranked value of X_i is swapped with another ranked value randomly chosen within a restricted range (e.g., the rank of two swapped values cannot differ by more than $p\%$ of the total number of records, where p is an input parameter). This algorithm independently is used on each original attribute in the original dataset.

It is reasonable to expect that multivariate statistics computed from data swapped with this algorithm will be less distorted than those computed after an unconstrained swap.

PRAM. The post-randomization method [PRAM, (26)] is a probabilistic, perturbative method for disclosure protection of categorical attributes in microdata files. In the masked file, the scores on some categorical attributes for certain records in the original file are changed to a different score according to a prescribed probability mechanism, namely a Markov matrix called the PRAM matrix. The Markov approach makes PRAM very general because it encompasses noise addition, data suppression, and data recoding.

Because the PRAM matrix must contain a row for each possible value of each attribute to be protected, PRAM cannot be used for continuous data.

Sampling. This approach is a nonperturbative masking method. Instead of publishing the original microdata file, what is published is a sample S of the original set of records (6).

Sampling methods are suitable for categorical microdata, but for continuous microdata they probably should be combined with other masking methods. The reason is that sampling alone leaves a continuous attribute X_i unperturbed for all records in S. Thus, if attribute X_i is present in an external administrative public file, unique matches with the published sample are very likely: Indeed, given a continuous attribute X_i and two respondents o_1 and o_2, it is highly unlikely that X_i will take the same value for both o_1 and o_2 unless $o_1 = o_2$ (this is true even if X_i has been truncated to represent it digitally).

If, for a continuous identifying attribute, the score of a respondent is only approximately known by an attacker, it might still make sense to use sampling methods to protect that attribute. However, assumptions on restricted attacker resources are perilous and may prove definitely too optimistic if good-quality external administrative files are at hand.

Global Recoding. This approach is a nonperturbative masking method, also known sometimes as generalization. For a categorical attribute X_i, several categories are combined to form new (less specific) categories, which thus result in a new X_i' with $|D(X_i')| < |D(X_i)|$, where $| \cdot |$ is the cardinality operator. For a continuous attribute, global recoding means replacing X_i by another attribute X_i', which is a discretized version of X_i. In other words, a potentially infinite range $D(X_i)$ is mapped onto a finite range $D(X_i')$. This technique is used in the μ-Argus SDC package (17).

This technique is more appropriate for categorical microdata, where it helps disguise records with strange combinations of categorical attributes. Global recoding is used heavily by statistical offices.

Example. If a record exists with "Marital status = Widow/er" and "Age = 17," global recoding could be applied to "Marital status" to create a broader category "Widow/er or divorced" so that the probability of the above record being unique would diminish. □

Global recoding can also be used on a continuous attribute, but the inherent discretization leads very often to an unaffordable loss of information. Also, arithmetical operations that were straightforward on the original X_i are no longer easy or intuitive on the discretized X_i'.

Top and Bottom Coding. Top and bottom coding are special cases of global recoding that can be used on attributes that can be ranked, that is, continuous or categorical ordinal. The idea is that top values (those above a certain threshold) are lumped together to form a new category. The same is done for bottom values (those below a certain threshold). See Ref. 17.

Local Suppression. This approach is a nonperturbative masking method in which certain values of individual attributes are suppressed with the aim of increasing the set of records agreeing on a combination of key values. Ways to combine local suppression and global recoding are implemented in the μ-Argus SDC package (17).

If a continuous attribute X_i is part of a set of key attributes, then each combination of key values probably is unique. Because it does not make sense to suppress systematically the values of X_i, we conclude that local suppression is oriented to categorical attributes.

Synthetic Microdata Generation. Publication of synthetic —i.e.,simulated— data was proposed long ago as a way to guard against statistical disclosure. The idea is to generate data randomly with the constraint that certain statistics or internal relationships of the original dataset should be preserved.

More than ten years ago, Rubin suggested in Ref. 27 to create an entirely synthetic dataset based on the original survey data and multiple imputation. A simulation study of this approach was given in Ref. 28.

We next sketch the operation of the original proposal by Rubin. Consider an original microdata set X of size n records drawn from a much larger population of N individuals, where background attributes A, nonconfidential attributes B, and confidential attributes C exist. Background attributes are observed and available for all N individuals in the population, whereas B and C are only available for the n records in the sample X. The first step is to construct from X a multiply-imputed population of N individuals. This population consists of the n records in X and M (the number of multiple imputations, typically between 3 and 10) matrices of (B, C) data for the $N - n$ nonsampled individuals. The variability in the imputed values ensures, theoretically, that valid inferences can be obtained on the multiply-imputed population. A model for predicting (B, C) from A is used to multiply-impute (B, C) in the population. The choice of the model is a nontrivial matter. Once the multiply-imputed population is available, a sample Z of n' records can be drawn from it whose structure looks like the one of a sample of n' records drawn from the original population. This process can be done M times to create M replicates of (B, C) values. The result are M multiply-imputed synthetic datasets. To make sure no original data are in the synthetic datasets, it is wise to draw the samples from the multiply-imputed population excluding the n original records from it.

Synthetic data are appealing in that, at a first glance, they seem to circumvent the reidentification problem: Because published records are invented and do not derive from any original record, it might be concluded that no individual can complain from having been reidentified. At a closer look this advantage is less clear. If, by chance, a published synthetic record matches a particular citizen's nonconfidential attributes (age, marital status, place of residence, etc.) and confidential attributes (salary, mortgage, etc.), reidentification using the nonconfidential attributes is easy and that citizen may feel that his confidential attributes have been unduly revealed. In that case, the citizen is unlikely to be happy with or even understand the explanation that the record was generated synthetically.

On the other hand, limited data utility is another problem of synthetic data. Only the statistical properties explicitly captured by the model used by the data protector are preserved. A logical question at this point is why not directly publish the statistics one wants to preserve rather than release a synthetic microdata set.

One possible justification for synthetic microdata would be whether valid analyses could be obtained on several subdomains; i.e., similar results were obtained in several subsets of the original dataset and the corresponding subsets of the synthetic dataset. Partially synthetic or hybrid microdata are more likely to succeed in staying useful for subdomain analysis. However, when using partially synthetic or hybrid microdata, we lose the attractive feature of purely synthetic data that the number of records in the protected (synthetic) dataset is independent from the number of records in the original dataset.

EVALUATION

Evaluation of SDC methods must be carried out in terms of data utility and disclosure risk.

Measuring Data Utility

Defining what a generic utility loss measure is can be a tricky issue. Roughly speaking, such a definition should capture the amount of information loss for a reasonable range of data uses.

We will attempt a definition on the data with maximum granularity, that is, microdata. Similar definitions apply to rounded tabular data; for tables with cell suppressions, utility normally is measured as the reciprocal of the number of suppressed cells or their pooled magnitude. As to queryable databases, they can be viewed logically as tables as far as data utility is concerned: A denied query answer is equivalent to a cell suppression, and a perturbed answer is equivalent to a perturbed cell.

We will say little information loss occurs if the protected dataset is analytically valid and interesting according to the following definitions by Winkler (29):

- A protected microdata set is *analytically valid* if it approximately preserves the following with respect to the original data (some conditions apply only to continuous attributes):

  1. Means and covariances on a small set of subdomains (subsets of records and/or attributes)
  2. Marginal values for a few tabulations of the data
  3. At least one distributional characteristic

- A microdata set is *analytically interesting* if six attributes on important subdomains are provided that can be validly analyzed.

More precise conditions of analytical validity and analytical interest cannot be stated without taking specific data uses into account. As imprecise as they may be, the above definitions suggest some possible measures:

- Compare raw records in the original and the protected dataset. The more similar the SDC method to the identity function, the less the impact (but the higher the disclosure risk!). This process requires pairing records in the original dataset and records in the protected dataset. For masking methods, each record in the protected dataset is paired naturally to the record in the original dataset from which it originates. For synthetic protected datasets, pairing is less obvious.
- Compare some statistics computed on the original and the protected datasets. The above definitions list some statistics that should be preserved as much as possible by an SDC method.

A strict evaluation of information loss must be based on the data uses to be supported by the protected data. The greater the differences between the results obtained on original and protected data for those uses, the higher the loss of information. However, very often microdata protection cannot be performed in a data use-specific manner, for the following reasons:

- Potential data uses are very diverse, and it may be even hard to identify them all at the moment of data release by the data protector.
- Even if all data uses could be identified, releasing several versions of the same original dataset so that the ith version has an information loss optimized for the ith data use may result in unexpected disclosure.

Because data often must be protected with no specific data use in mind, generic information loss measures are desirable to guide the data protector in assessing how much harm is being inflicted to the data by a particular SDC technique.

Information loss measures for numeric data. Assume a microdata set with n individuals (records) $I_1, I_2, \ldots, I_n$ and p continuous attributes $Z_1, Z_2, \ldots, Z_p$. Let X be the matrix that represents the original microdata set (rows are records and columns are attributes). Let X' be the matrix that represents the protected microdata set. The following tools are useful to characterize the information contained in the dataset:

- Covariance matrices V (on X) and V' (on X').
- Correlation matrices R and R'.
- Correlation matrices RF and RF' between the p attributes and the p factors $PC_1, \ldots, PC_p$ obtained through principal components analysis.
- Communality between each p attribute and the first principal component PC_1 (or other principal components PC_i's). Communality is the percent of each attribute that is explained by PC_1 (or PC_i). Let C be the vector of communalities for X and C' be the corresponding vector for X'.
- Factor score coefficient matrices F and F'. Matrix F contains the factors that should multiply each

	Mean square error	Mean absolute error	Mean variation
$X - X'$	$\frac{\sum_{j=1}^{p}\sum_{i=1}^{n}(x_{ij}-x'_{ij})^2}{n\,p}$	$\frac{\sum_{j=1}^{p}\sum_{i=1}^{n}\lvert x_{ij}-x'_{ij}\rvert}{n\,p}$	$\frac{\sum_{j=1}^{p}\sum_{i=1}^{n}\frac{\lvert x_{ij}-x'_{ij}\rvert}{\lvert x_{ij}\rvert}}{n\,p}$
$V - V'$	$\frac{\sum_{j=1}^{p}\sum_{1\le i\le j}(v_{ij}-v'_{ij})^2}{\frac{p(p+1)}{2}}$	$\frac{\sum_{j=1}^{p}\sum_{1\le i\le j}\lvert v_{ij}-v'_{ij}\rvert}{\frac{p(p+1)}{2}}$	$\frac{\sum_{j=1}^{p}\sum_{1\le i\le j}\frac{\lvert v_{ij}-v'_{ij}\rvert}{\lvert v_{ij}\rvert}}{\frac{p(p+1)}{2}}$
$R - R'$	$\frac{\sum_{j=1}^{p}\sum_{1\le i<j}(r_{ij}-r'_{ij})^2}{\frac{p(p-1)}{2}}$	$\frac{\sum_{j=1}^{p}\sum_{1\le i<j}\lvert r_{ij}-r'_{ij}\rvert}{\frac{p(p-1)}{2}}$	$\frac{\sum_{j=1}^{p}\sum_{1\le i<j}\frac{\lvert r_{ij}-r'_{ij}\rvert}{\lvert r_{ij}\rvert}}{\frac{p(p-1)}{2}}$
$RF - RF'$	$\frac{\sum_{j=1}^{p}w_j\sum_{i=1}^{p}(rf_{ij}-rf'_{ij})^2}{p^2}$	$\frac{\sum_{j=1}^{p}w_j\sum_{i=1}^{p}\lvert rf_{ij}-rf'_{ij}\rvert}{p^2}$	$\frac{\sum_{j=1}^{p}w_j\sum_{i=1}^{p}\frac{\lvert rf_{ij}-rf'_{ij}\rvert}{\lvert rf_{ij}\rvert}}{p^2}$
$C - C'$	$\frac{\sum_{i=1}^{p}(c_i-c'_i)^2}{p}$	$\frac{\sum_{i=1}^{p}\lvert c_i-c'_i\rvert}{p}$	$\frac{\sum_{i=1}^{p}\frac{\lvert c_i-c'_i\rvert}{\lvert c_i\rvert}}{p}$
$F - F'$	$\frac{\sum_{j=1}^{p}w_j\sum_{i=1}^{p}(f_{ij}-f'_{ij})^2}{p^2}$	$\frac{\sum_{j=1}^{p}w_j\sum_{i=1}^{p}\lvert f_{ij}-f'_{ij}\rvert}{p^2}$	$\frac{\sum_{j=1}^{p}w_j\sum_{i=1}^{p}\frac{\lvert f_{ij}-f'_{ij}\rvert}{\lvert f_{ij}\rvert}}{p^2}$

attribute in X to obtain its projection on each principal component. F' is the corresponding matrix for X'.

A single quantitative measure does not seem to reflect completely those structural differences. Therefore, we proposed in Refs. 30 and 31 to measure information loss through the discrepancies between matrices X, V, R, RF, C, and F obtained on the original data and the corresponding X', V', R', RF', C', and F' obtained on the protected dataset. In particular, discrepancy between correlations is related to the information loss for data uses such as regressions and cross tabulations.

Matrix discrepancy can be measured in at least three ways:

Mean square error. Sum of squared component-wise differences between pairs of matrices, divided by the number of cells in either matrix.

Mean absolute error. Sum of absolute component-wise differences between pairs of matrices, divided by the number of cells in either matrix.

Mean variation. Sum of absolute percent variation of components in the matrix computed on protected data with respect to components in the matrix computed on original data, divided by the number of cells in either matrix. This approach has the advantage of not being affected by scale changes of attributes.

The following table summarizes the measures proposed in the above references. In this table, p is the number of attributes, n is the number of records, and the components of matrices are represented by the corresponding lowercase letters (e.g., x_{ij} is a component of matrix X). Regarding $X - X'$ measures, it also makes sense to compute those on the averages of attributes rather than on all data (call this variant $\overline{X} - \overline{X}'$). Similarly, for $V - V'$ measures, it would also be sensible to use them to compare only the variances of the attributes, i.e., to compare the diagonals of the covariance matrices rather than the whole matrices (call this variant $S - S'$).

Information loss measures for categorical data. These measures can be based on a direct comparison of categorical values, or on a comparison of contingency tables or on Shannon's entropy. See Ref. 30 for more details.

Bounded information loss measures. The information loss measures discussed above are unbounded, (i.e., they do not take values in a predefined interval) On the other hand, as discussed below, disclosure risk measures are bounded naturally (the risk of disclosure is bounded naturally between 0 and 1). Defining bounded information loss measures may be convenient to enable the data protector to trade off information loss against disclosure risk. In Ref. 32, probabilistic information loss measures bounded between 0 and 1 are proposed for continuous data.

Measuring Disclosure Risk

In the context of statistical disclosure control, disclosure risk can be defined as the risk that a user or an intruder can use the protected dataset $\mathbf{X}'$ to derive confidential information on an individual among those in the original dataset $\mathbf{X}$.

Disclosure risk can be regarded from two different perspectives:

1. **Attribute disclosure.** This approach to disclosure is defined as follows. Disclosure takes place when an attribute of an individual can be determined more accurately with access to the released statistic than it is possible without access to that statistic.
2. **Identity disclosure.** Attribute disclosure does not imply a disclosure of the identity of any individual.

Identity disclosure takes place when a record in the protected dataset can be linked with a respondent's identity. Two main approaches usually are employed for measuring identity disclosure risk: uniqueness and reidentification.

2.1 Uniqueness. Roughly speaking, the risk of identity disclosure is measured as the probability that rare combinations of attribute values in the released protected data are indeed rare in the original population from which the data come. This approach is used typically with nonperturbative statistical disclosure control methods and, more specifically, with sampling. The reason that uniqueness is not used with perturbative methods is that when protected attribute values are perturbed versions of original attribute values, it does not make sense to investigate the probability that a rare combination of protected values is rare in the original dataset, because *that* combination is most probably *not found* in the original dataset.

2.2 Reidentification. This empirical approach evaluates the risk of disclosure. In this case, record linkage software is constructed to estimate the number of reidentifications that might be obtained by a specialized intruder. Reidentification through record linkage provides a more unified approach than do uniqueness methods because the former can be applied to any kind of masking and not just to nonperturbative masking. Moreover, reidentification can also be applied to synthetic data.

Trading off Information Loss and Disclosure Risk

The mission of SDC to modify data in such a way that sufficient protection is provided at minimum information loss suggests that a good SDC method is one achieving a good tradeoff between disclosure risk and information loss. Several approaches have been proposed to handle this tradeoff. We discuss *SDC scores, R-U maps*, and *k-anonymity*.

Score Construction. Following this idea, Domingo-Ferrer and Torra (30) proposed a score for method performance rating based on the average of information loss and disclosure risk measures. For each method M and parameterization P, the following score is computed:

$$\mathrm{Score}(\mathbf{X},\mathbf{X}') = \frac{\mathrm{IL}(\mathbf{X},\mathbf{X}') + \mathrm{DR}'(\mathbf{X},\mathbf{X}')}{2}$$

where IL is an information loss measure, DR is a disclosure risk measure, and $\mathbf{X}'$ is the protected dataset obtained after applying method M with parameterization P to an original dataset $\mathbf{X}$.

In Ref. 30, *IL* and *DR* were computed using a weighted combination of several information loss and disclosure risk measures. With the resulting score, a ranking of masking methods (and their parameterizations) was obtained. To illustrate how a score can be constructed, we next describe the particular score used in Ref. 30.

Example. Let X and X' be matrices that represent original and protected datasets, respectively, where all attributes are numeric. Let V and R be the covariance matrix and the correlation matrix of X, respectively; let $\overline{X}$ be the vector of attribute averages for X, and let S be the diagonal of V. Define V', R', $\overline{X}'$, and S' analogously from X'. The Information Loss (IL) is computed by averaging the mean variations of $X - X'$, $\overline{X} - \overline{X}'$, $V - V'$, $S - S'$, and the mean absolute error of $R - R'$ and by multiplying the resulting average by 100. Thus, we obtain the following expression for information loss:

$$\mathrm{IL} = \frac{100}{5}\left(\frac{\sum_{j=1}^{p}\sum_{i=1}^{n}\frac{|x_{ij}-x'_{ij}|}{|x_{ij}|}}{np} + \frac{\sum_{j=1}^{p}\frac{|\overline{n}\,^1_j - \overline{x}'_j|}{|\overline{n}\,^1{}_j|}}{p} \right.$$
$$+\frac{\sum_{j=1}^{p}\sum_{1\le i\le j}\frac{|v_{ij}-v'_{ij}|}{|v_{ij}|}}{\frac{p(p+1)}{2}} + \frac{\sum_{j=1}^{p}\frac{|v_{jj}-v'_{jj}|}{|v_{jj}|}}{p}$$
$$\left. + \frac{\sum_{j=1}^{p}\sum_{1\le i\le j}|r_{ij}-r'_{ij}|}{\frac{p(p-1)}{2}} \right)$$

The expression of the overall score is obtained by combining information loss and information risk as follows:

$$\mathrm{Score} = \frac{\mathrm{IL} + \frac{(0.5DLD+0.5PLD)+ID}{2}}{2}$$

Here, DLD (distance linkage disclosure risk) is the percentage of correctly linked records using distance-based record linkage (30), PLD (probabilistic linkage record disclosure risk) is the percentage of correctly linked records using probabilistic linkage (33), ID (interval disclosure) is the percentage of original records falling in the intervals around their corresponding masked values, and IL is the information loss measure defined above.

Based on the above score, Domingo-Ferrer and Torra (30) found that, for the benchmark datasets and the intruder's external information they used, two good performers among the set of methods and parameterizations they tried were as follows: *(1)* rankswapping with parameter p around 15 (see the description above) and *(2)* multivariate microaggregation on unprojected data taking groups of three attributes at a time (Algorithm MDAV above with partitioning of the set of attributes). □

Using a score permits regarding the selection of a masking method and its parameters as an optimization problem. A masking method can be applied to the original data file, and then a postmasking optimization procedure can be applied to decrease the score obtained.

On the negative side, no specific score weighting can do justice to all methods. Thus, when ranking methods, the values of all measures of information loss and disclosure risk should be supplied along with the overall score.

R-U maps. A tool that may be enlightening when trying to construct a score or, more generally, to optimize the tradeoff between information loss and disclosure risk is a graphical representation of pairs of measures (disclosure risk, information loss) or their equivalents (disclosure risk, data utility). Such maps are called R-U confidentiality maps (34). Here, R stands for disclosure risk and U stands for data utility. In its most basic form, an R-U confidentiality map is the set of paired values (R,U), of disclosure risk and data utility that correspond to various strategies for data release (e.g., variations on a parameter). Such (R,U) pairs typically are plotted in a two-dimensional graph, so that the user can grasp easily the influence of a particular method and/or parameter choice.

***k*-Anonymity.** A different approach to facing the conflict between information loss and disclosure risk is suggested by Samarati and Sweeney (35). A protected dataset is said to satisfy k-anonymity for $k > 1$ if, for each combination of key attribute values (e.g., address, age, and gender), at least k records exist in the dataset sharing that combination. Now if, for a given k, k-anonymity is assumed to be enough protection, one can concentrate on minimizing information loss with the only constraint that k-anonymity should be satisfied. This method is a clean way of solving the tension between data protection and data utility. Because k-anonymity usually is achieved via generalization (equivalent to global recoding, as said above) and local suppression, minimizing information loss usually translates to reducing the number and/or the magnitude of suppressions.

k-Anonymity bears some resemblance to the underlying principle of multivariate microaggregation and is a useful concept because key attributes usually are categorical or can be categorized, [i.e., they take values in a finite (and ideally reduced) range] However, reidentification is not based on necessarily categorical key attributes: Sometimes, numeric outcome attributes, which are continuous and often cannot be categorized, give enough clues for reidentification. Microaggregation was suggested in Ref. 18 as a possible way to achieve k-anonymity for numeric, ordinal, and nominal attributes: The idea is to use multivariate microaggregation on the key attributes of the dataset.

Future

Many open issues in SDC exist, some of which hopefully can be solved with additional research and some of which are likely to stay open because of the inherent nature of SDC. We first list some of the issues that probably could and should be settled in the near future:

- Identifying a comprehensive listing of data uses (e.g., regression models, and association rules) that would allow the definition of data use-specific information loss measures broadly accepted by the community; those new measures could complement and/or replace the generic measures currently used. Work in this line was started in Europe in 2006 under the CENEX SDC project sponsored by Eurostat.
- Devising disclosure risk assessment procedures that are as universally applicable as record linkage while being less greedy in computational terms.
- Identifying, for each domain of application, which are the external data sources that intruders typically can access to attempt reidentification. This capability would help data protectors to figure out in more realistic terms which are the disclosure scenarios they should protect data against.
- Creating one or several benchmarks to assess the performance of SDC methods. Benchmark creation currently is hampered by the confidentiality of the original datasets to be protected. Data protectors should agree on a collection of nonconfidential, original-looking datasets (financial datasets, population datasets, etc.), which can be used by anybody to compare the performance of SDC methods. The benchmark should also incorporate state-of-the-art disclosure risk assessment methods, which requires continuous update and maintenance.

Other issues exist whose solution seems less likely in the near future, because of the very nature of SDC methods. If an intruder knows the SDC algorithm used to create a protected data set, he can mount algorithm-specific reidentification attacks that can disclose more confidential information than conventional data mining attacks. Keeping secret the SDC algorithm used would seem a solution, but in many cases, the protected dataset gives some clues on the SDC algorithm used to produce it. Such is the case for a rounded, microaggregated, or partially suppressed microdata set. Thus, it is unclear to what extent the SDC algorithm used can be kept secret.

SYSTEM MONITORING

The term *system* refers to a computer system that is composed of hardware and software for data processing. *System monitoring* collects information about the behavior of a computer system while the system is running. What is of interest here is run-time information that cannot be obtained by static analysis of programs. All collected information is essentially about system correctness or performance. Such information is vital for understanding how a system works. It can be used for dynamic safety checking and failure detection, program testing and debugging, dynamic task scheduling and resource allocation, performance evaluation and tuning, system selection and design, and so on.

COMPONENTS AND TECHNIQUES FOR SYSTEM MONITORING

System monitoring has three components. First, the jobs to be run and the items to be measured are determined. Then, the system to be monitored is modified to run the jobs and take the measurements. This is the major component. Monitoring is accomplished in two operations: triggering and recording (1). *Triggering,* also called *activation,* is the observation and detection of specified events during system execution. *Recording* is the collection and storage of data pertinent to those events. Finally, the recorded data are analyzed and displayed.

The selection and characterization of the jobs to be run for monitoring is important, because it is the basis for interpreting the monitoring results and guaranteeing that the experiments are repeatable. A collection of jobs to be run is called a *test workload* (2–4); for performance monitoring, this refers mainly to the *load* rather than the *work,* or *job.* A workload can be real or synthetic. A *real workload* consists of jobs that are actually performed by the users of the system to be monitored. A *synthetic workload,* usually called a *benchmark,* consists of batch programs or interactive scripts that are designed to represent the actual jobs of interest. Whether a workload is real or synthetic does not affect the monitoring techniques.

Items to be measured are determined by the applications. They can be about the entire system or about different levels of the system, from user-level application programs to operating systems to low-level hardware circuits. For the entire system, one may need to know whether jobs are completed normally and performance indices such as job completion time, called *turnaround time* in batch systems and *response time* in interactive systems, or the number of jobs completed per unit of time, called *throughput* (3). For application programs, one may be interested in how often a piece of code is executed, whether a variable is read between two updates, or how many messages are sent by a process. For operating systems, one may need to know whether the CPU is busy at certain times, how often paging occurs, or how long an I/O operation takes. For hardware circuits, one may need to know how often a cache element is replaced, or whether a network wire is busy.

Monitoring can use either event-driven or sampling techniques (3). *Event-driven monitoring* is based on observing changes of system state, either in software programs or hardware circuits, that are caused by events of interest, such as the transition of the CPU from busy to idle. It is often implemented as special instructions for interrupt–intercept that are inserted into the system to be monitored. *Sampling monitoring* is based on probing at selected time intervals, into either software programs or hardware circuits, to obtain data of interest, such as what kinds of processes occupy the CPU. It is often implemented as timer interrupts during which the state is recorded. Note that the behavior of the system under a given workload can be simulated by a simulation tool. Thus monitoring that should be performed on the real system may be carried out on the simulation tool. Monitoring simulation tools is useful, or necessary, for understanding the behavior of models of systems still under design.

Monitoring can be implemented using software, hardware, or both (1,3–5). *Software monitors* are programs that are inserted into the system to be monitored. They are triggered upon appropriate interrupts or by executing the inserted code. Data are recorded in buffers in the working memory of the monitored system and, when necessary, written to secondary storage. *Hardware monitors* are electronic devices that are connected to specific system points. They are triggered upon detecting signals of interest. Data are recorded in separate memory independent of the monitored system. *Hybrid monitors* combine techniques from software and hardware. Often, the triggering is carried out using software, and the data recording is carried out using hardware.

The data collected by a monitor must be analyzed and displayed. Based on the way in which results are analyzed and displayed, a monitor is classified as an on-line monitor or a batch monitor. *On-line monitors* analyze and display the collected data in real-time, either continuously or at frequent intervals, while the system is still being monitored. This is also called *continuous monitoring* (6). *Batch monitors* collect data first and analyze and display them later using a batch program. In either case, the analyzed data can be presented using many kinds of graphic charts, as well as text and tables.

ISSUES IN SYSTEM MONITORING

Major issues of concern in monitoring are at what levels we can obtain information of interest, what modifications to the system are needed to perform the monitoring, the disturbance of such modifications to the system behavior, and the cost of implementing such modifications. There are also special concerns for monitoring real-time systems, parallel architectures, and distributed systems.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Activities and data structures visible to the user process can be monitored at the application-program level. These include function and procedure calls and returns, assignments to variables, loopings and branchings, inputs and outputs, as well as synchronizations. Activities and data structures visible to the kernel can be monitored at the operating-system level; these include system state transitions, external interrupts, system calls, as well as data structures such as process control blocks. At the hardware level, various patterns of signals on the buses can be monitored. Obviously, certain high-level information cannot be obtained by monitoring at a lower level, and vice versa. It is worth noting that more often high-level information can be used to infer low-level information if one knows enough about all the involved components, such as the compilers, but the converse is not true, simply because more often multiple high-level activities are mapped to the same low-level activity.

In general, the software and hardware of a system are not purposely designed to be monitored. This often restricts what can be monitored in a system. To overcome these restrictions, modifications to the system, called *instrumentation,* are often required, for example, inserting interrupt instructions or attaching hardware devices. The information obtainable with a monitor and the cost of measurements determine the *measurability* of a computer system (3,7). At one extreme, every system component can be monitored at the desired level of detail, while at the other extreme, only the external behavior of the system as a whole can be monitored. When a low degree of detail is required, a *macroscopic* analysis, which requires measurement of global indices such as turnaround time and response time, is sufficient. When a high degree of detail is needed, a *microscopic* analysis, which requires, say, the time of executing each instruction or loading each individual page, must be performed.

Monitoring often interferes with the system behavior, since it may consume system resources, due to the time of performing monitoring activities and the space of storing collected data, which are collectively called the *overhead* of monitoring. A major issue in monitoring is to reduce the perturbation. It is easy to see that a macroscopic analysis incurs less interference than a microscopic analysis. Usually, sampling monitoring causes less interference than event-driven monitoring. In terms of implementation, software monitors always interfere and sometimes interfere greatly with the system to be monitored, but hardware monitors cause little or no interference.

Implementing monitoring usually has a cost, since it requires modification to the system to be monitored. Therefore, an important concern is to reduce the cost. Software monitors are simply programs, so they are usually less costly to develop and easier to change. In contrast, hardware monitors require separate hardware devices and thus are usually more difficult to build and modify.

Finally, special methods and techniques are necessary for monitoring real-time systems, parallel architectures, and distributed systems. Real-time systems have real-time constraints, so interference becomes much more critical. For parallel architectures, monitoring needs to handle issues arising from interprocessor communication and scheduling, cache behavior, and shared memory behavior. For distributed systems, monitoring must take into account ordering of distributed events, message passing, synchronization, as well as various kinds of failures.

MONITORING PRINCIPLES

A set of principles is necessary to address all the issues involved in monitoring. The major task is to determine the monitoring techniques needed based on the applications and the trade-offs. Methods and tools that facilitate monitoring are also needed.

Consider the major task. Given the desired information, one first needs to determine all levels that can be monitored to obtain the information. For each possibility, one determines all modifications of the system that are needed to perform the monitoring. Then one needs to assess the perturbation that the monitoring could cause. Finally, one must estimate the cost of the implementations. Clearly, unacceptable perturbation or cost helps reduce the possibilities. Then, one needs to evaluate all possibilities based on the following trade-offs.

First, monitoring at a higher level generally requires less modification to the system and has smaller implementation cost, but it may have larger interference with the system behavior. Thus one principle is to monitor at the highest level whose interference is acceptable. This implies that, if a software monitor has acceptable interference, one should avoid using a hardware monitor. Furthermore, to reduce implementation cost, for a system being designed or that is difficult to measure, one can use simulation tools instead of the real system if credibility can be established.

Second, macroscopic analysis generally causes less perturbation to the system behavior than microscopic analysis, and it often requires less modification to the system and has smaller cost. Therefore, a second principle is to use macroscopic analysis instead of microscopic analysis if possible. While sampling is a statistical technique that records data only at sampled times, event detection is usually used to record all potentially interesting events and construct the execution trace. Thus one should avoid using tracing if the desired information can be obtained by sampling.

Additionally, one should consider workload selection and data analysis. Using benchmarks instead of real workload makes the experiments repeatable and facilitates comparison of monitoring results. It can also reduce the cost, since running real jobs could be expensive or impossible. Thus using benchmarks is preferred, but a number of common mistakes need to be carefully avoided (4). Data analysis involves a separate trade-off: the on-line method adds time overhead but can reduce the space overhead. Thus even when monitoring results do not need to be presented in an on-line fashion, on-line analysis can be used to reduce the space overhead and, when needed, separate processors can be used to reduce also the time overhead.

Finally, special applications determine special monitoring principles. For example, for monitoring real-time systems, perturbation is usually not tolerable, but a full trace is often needed to understand system behavior. To address this problem, one may perform microscopic monitoring based on event detection and implement monitoring in hardware so as to sense signals on buses at high speed and with low overhead. If monitoring results are needed in an on-line fashion, separate resources for data analysis must be used. Of course, all these come at a cost.

To facilitate monitoring, one needs methods and tools for instrumenting the system, efficient data structures and algorithms for storing and manipulating data, and techniques for relating monitoring results to the source program to identify problematic code sections. Instrumentation of programs can be done via program transformation, by augmenting the source code, the target code, the run-time environment, the operating system, or the hardware. Often, combinations of these techniques are used. Efficient data structures and algorithms are needed to handle records of various execution information, by organizing them in certain forms of tables and linked structures. They are critical for reducing monitoring overhead. Additional information from the compiler and other involved components can be used to relate monitoring results with points in source programs. Monitoring results can also help select candidate jobs for further monitoring.

In summary, a number of trade-offs are involved in determining the monitoring techniques adopted for a particular application. Tools should be developed and used to help instrument the system, reduce the overhead, and interpret the monitoring results.

WORKLOAD SELECTION

To understand how a complex system works, one first needs to determine what to observe. Thus before determining how to monitor a system, one must determine what to monitor and why it is important to monitor them. This enables one to determine the feasibility of the monitoring, based on the perturbation and the cost, and then allows repeating and justifying the experiments.

Selecting candidate jobs to be run and measurements to be taken depends on the objectives of monitoring. For monitoring that is aimed at performance behavior, such as system tuning or task scheduling, one needs to select the representative load of work. For monitoring that is aimed at functional correctness, such as for debugging and fault-tolerance analysis, one needs to isolate the “buggy” or faulty parts.

A real workload best reflects system behavior under actual usage, but it is usually unnecessarily expensive, complicated, or even impossible to use as a test workload. Furthermore, the test results are not easily repeated and are not good for comparison. Therefore, a synthetic workload is normally used. For monitoring the functional correctness of a system, a *test suite* normally consists of data that exercise various parts of the system, and monitoring at those parts is set up accordingly. For performance monitoring, the load of work, rather than the actual jobs, is the major concern, and the approaches below have been used for obtaining test workloads (3,4,8).

Addition instruction was used to measure early computers, which had mainly a few kinds of instructions. *Instruction mixes,* each specifying various instructions together with their usage frequencies, were used when the varieties of instructions grew. Then, when pipelining, instruction caching, and address translation mechanisms made computer instruction times highly variable, *kernels,* which are higher-level functions, such as matrix inversion and Ackermann’s function, which represent services provided by the processor, came into use. Later on, as input and output became an important part of real workload, *synthetic programs,* which are composed of exerciser loops that make a specified number of service calls or I/O requests, came into use. For domain-specific kinds of applications, such as banking or airline reservation, *application benchmarks,* representative subsets of the functions in the application that make use of all resources in the system, are used. Kernels, synthetic programs, and application benchmarks are all called benchmarks. Popular benchmarks include the sieve kernel, the LINPACK benchmarks, the debit–credit benchmark, and the SPEC benchmark suite (4).

Consider monitoring the functional behavior of a system. For general testing, the test suite should have complete coverage, that is, all components of the system should be exercised. For debugging, one needs to select jobs that isolate the problematic parts. This normally involves repeatedly selecting more specialized jobs and more focused monitoring points based on monitoring results. For correctness checking at given points, one needs to select jobs that lead to different possible results at those points and monitor at those points. Special methods are used for special classes of applications; for example, for testing fault-tolerance in distributed systems, message losses or process failures can be included in the test suite.

For system performance monitoring, selection should consider the services exercised as well as the level of detail and representativeness (4). The starting point is to consider the system as a service provider and select the workload and metrics that reflect the performance of services provided at the system level and not at the component level. The amount of detail in recording user requests should be determined. Possible choices include the most frequent request, the frequency of request types, the sequence of requests with time stamps, and the average resource demand. The test workload should also be representative of the real application. Representativeness is reflected at different levels (3) at the physical level, the consumptions of hardware and software resources should be representative; at the virtual level, the logical resources that are closer to the user’s point of view, such as virtual memory space, should be representative; at the functional level, the test workload should include the applications that perform the same functions as the real workload.

Workload characterization is the quantitative description of a workload (3,4). It is usually done in terms of workload parameters that can affect system behavior. These parameters are about service requests, such as arrival rate and duration of request, or about measured quantities, such as CPU time, memory space, amount of read and write, or amount of communication, for which system independent parameters are preferred. In addition, various techniques have been used to obtain statistical quantities, such as frequencies of instruction types, mean time for executing certain I/O operations, and probabilities of accessing certain devices. These techniques include averaging, histograms, Markov models, and clustering. *Markov models* specify the dependency among requests using a transition diagram. *Clustering* groups similar components in a workload in order to reduce the large number of parameters for these components.

TRIGGERING MECHANISM

Monitoring can use either event-driven or sampling techniques for triggering and data recording (3). Event-driven techniques can lead to more detailed and accurate information, while sampling techniques are easier to implement and have smaller overhead. These two techniques are not mutually exclusive; they can coexist in a single tool.

Event-Driven Monitoring

An *event* in a computer system is any change of the system's state, such as the transition of a CPU from busy to idle, the change of content in a memory location, or the occurrence of a pattern of signals on the memory bus. Therefore, a way of collecting data about system activities is to capture all associated events and record them in the order they occur. A software event is an event associated with a program's function, such as the change of content in a memory location or the start of an I/O operation. A hardware event is a combination of signals in the circuit of a system, such as a pattern of signals on the memory bus or signals sent to the disk drive.

Event-driven monitoring using software is done by inserting a special trap code or hook in specific places of the application program or the operating system. When an event to be captured occurs, the inserted code causes control to be transferred to an appropriate routine. The routine records the occurrence of the event and stores relevant data in a buffer area, which is to be written to secondary storage and/or analyzed, possibly at a later time. Then the control is transferred back. The recorded events and data form an *event trace*. It can provide more information than any other method on certain aspects of a system's behavior.

Producing full event traces using software has high overhead, since it can consume a great deal of CPU time by collecting and analyzing a large amount of data. Therefore, event tracing in software should be selective, since intercepting too many events may slow down the normal execution of the system to an unacceptable degree. Also, to keep buffer space limited, buffer content must be written to secondary storage with some frequency, which also consumes time; the system may decide to either wait for the completion of the buffer transfer or continue normally with some data loss.

In most cases, event-driven monitoring using software is difficult to implement, since it requires that the application program or the operating system be modified. It may also introduce errors. To modify the system, one must understand its structure and function and identify safe places for the modifications. In some cases, instrumentation is not possible when the source code of the system is not available.

Event-driven monitoring in hardware uses the same techniques as in software, conceptually and in practice, for handling events. However, since hardware uses separate devices for trigger and recording, the monitoring overhead is small or zero. Some systems are even equipped with hardware that makes event tracing easier. Such hardware can help evaluate the performance of a system as well as test and debug the hardware or software. Many hardware events can also be detected via software.

Sampling Monitoring

Sampling is a statistical technique that can be used when monitoring all the data about a set of events is unnecessary, impossible, or too expensive. Instead of monitoring the entire set, one can monitor a part of it, called a *sample*. From this sample, it is then possible to estimate, often with a high degree of accuracy, some parameters that characterize the entire set. For example, one can estimate the proportion of time spent in different code segments by sampling program counters instead of recording the event sequence and the exact event count; samples can also be taken to estimate how much time different kinds of processes occupy CPU, how much memory is used, or how often a printer is busy during certain runs.

In general, sampling monitoring can be used for measuring the fractions of a given time interval each system component spends in its various states. It is easy to implement using periodic interrupts generated by a timer. During an interrupt, control is transferred to a data-collection routine, where relevant data in the state are recorded. The data collected during the monitored interval are later analyzed to determine what happened during the interval, in what ratios the various events occurred, and how different types of activities were related to each other. Besides timer interrupts, most modern architectures also include hardware performance counters, which can be used for generating periodic interrupts (9). This helps reduce the need for additional hardware monitoring.

The accuracy of the results is determined by how representative a sample is. When one has no knowledge of the monitored system, random sampling can ensure representativeness if the sample is sufficiently large. It should be noted that, since the sampled quantities are functions of time, the workload must be stationary to guarantee validity of the results. In practice, operating-system workload is rarely stationary during long periods of time, but relatively stationary situations can usually be obtained by dividing the monitoring interval into short periods of, say, a minute and grouping homogeneous blocks of data together.

Sampling monitoring has two major advantages. First, the monitored program need not be modified. Therefore, knowledge of the structure and function of the monitored program, and often the source code, is not needed for sampling monitoring. Second, sampling allows the system to spend much less time in collecting and analyzing a much smaller amount of data, and the overhead can be kept less than 5% (3,9,10). Furthermore, the frequency of the interrupts can easily be adjusted to obtain appropriate sample size and appropriate overhead. In particular, the overhead can also be estimated easily. All these make sampling monitoring particularly good for performance monitoring and dynamic system resource allocation.

IMPLEMENTATION

System monitoring can be implemented using software or hardware. Software monitors are easier to build and modify and are capable of capturing high-level events and relating them to the source code, while hardware monitors can capture rapid events at circuit level and have lower overhead.

Software Monitoring

Software monitors are used to monitor application programs and operating systems. They consist solely of instrumentation code inserted into the system to be monitored. Therefore, they are easier to build and modify. At each activation, the inserted code is executed and relevant data are recorded, using the CPU and memory of the monitored system. Thus software monitors affect the performance and possibly the correctness of the monitored system and are not appropriate for monitoring rapid events. For example, if the monitor executes 100 instructions at each activation, and each instruction takes 1 μs, then each activation takes 0.1 ms; to limit the time overhead to 1%, the monitor must be activated at intervals of 10 ms or more, that is, less than 100 monitored events should occur per second.

Software monitors can use both event-driven and sampling techniques. Obviously, a major issue is how to reduce the monitoring overhead while obtaining sufficient information. When designing monitors, there may first be a tendency to collect as much data as possible by tracing or sampling many activities. It may even be necessary to add a considerable amount of load to the system or to slow down the program execution. After analyzing the initial results, it will be possible to focus the experiments on specific activities in more detail. In this way, the overhead can usually be kept within reasonable limits. Additionally, the amount of the data collected may be kept to a minimum by using efficient data structures and algorithms for storage and analysis. For example, instead of recording the state at each activation, one may only need to maintain a counter for the number of times each particular state has occurred, and these counters may be maintained in a hash table (9).

Inserting code into the monitored system can be done in three ways: (*1*) adding a program, (*2*) modifying the application program, or (*3*) modifying the operating system (3). Adding a program is simplest and is generally preferred to the other two, since the added program can easily be removed or added again. Also, it maintains the integrity of the monitored program and the operating system. It is adequate for detecting the activity of a system or a program as a whole. For example, adding a program that reads the system clock before and after execution of a program can be used to measure the execution time.

Modifying the application program is usually used for event-driven monitoring, which can produce an execution trace or an exact profile for the application. It is based on the use of *software probes,* which are groups of instructions inserted at critical points in the program to be monitored. Each probe detects the arrival of the flow of control at the point it is placed, allowing the execution path and the number of times these paths are executed to be known. Also, relevant data in registers and in memory may be examined when these paths are executed. It is possible to perform sampling monitoring by using the kernel interrupt service from within an application program, but it can be performed more efficiently by modifying the kernel.

Modifying the kernel is usually used for monitoring the system as a service provider. For example, instructions can be inserted to read the system clock before and after a service is provided in order to calculate the turnaround time or response time; this interval cannot be obtained from within the application program. Sampling monitoring can be performed efficiently by letting an interrupt handler directly record relevant data. The recorded data can be analyzed to obtain information about the kernel as well as the application programs.

Software monitoring, especially event-driven monitoring in the application programs, makes it easy to obtain descriptive data, such as the name of the procedure that is called last in the application program or the name of the file that is accessed most frequently. This makes it easy to correlate the monitoring results with the source program, to interpret them, and to use them.

There are two special software monitors. One keeps *system accounting logs* (4,6) and is usually built into the operating system to keep track of resource usage; thus additional monitoring might not be needed. The other one is *program execution monitor* (4,11), used often for finding the performance bottlenecks of application programs. It typically produces an execution profile, based on event detection or statistical sampling. For event-driven precise profiling, efficient algorithms have been developed to keep the overhead to a minimum (12). For sampling profiling, optimizations have been implemented to yield an overhead of 1% to 3%, so the profiling can be employed continuously (9).

Hardware Monitoring

With *hardware monitoring,* the monitor uses hardware to interface to the system to be monitored (5,13–16). The hardware passively detects events of interest by snooping on electric signals in the monitored system. The monitored system is not instrumented, and the monitor does not share any of the resources of the monitored system. The main advantage of hardware monitoring is that the monitor does not interfere with the normal functioning of the monitored system and rapid events can be captured. The disadvantage of hardware monitoring is its cost and that it is usually machine dependent or at least processor dependent. The snooping device and the signal interpretation are bus and processor dependent.

In general, hardware monitoring is used to monitor the run-time behavior of either hardware devices or software modules. Hardware devices are generally monitored to examine issues such as cache accesses, cache misses, memory access times, total CPU times, total execution times, I/O requests, I/O grants, and I/O busy times. Software modules are generally monitored to debug the modules or to examine issues such as the bottlenecks of a program, the deadlocks, or the degree of parallelism.

A hardware monitor generally consists of a probe, an event filter, a recorder, and a real-time clock. The probe is high-impedance detectors that interface with the buses of the system to be monitored to latch the signals on the buses. The signals collected by the probe are manipulated by the event filter to detect events of interest. The data relevant to the detected event along with the value of the real-time clock are saved by the recorder. Based on the implementation of the event filter, hardware tools can be classified as fixed hardware tools, wired program hardware tools, and stored program hardware tools (5,13).

With *fixed hardware tools,* the event filtering mechanism is completely hard-wired. The user can select neither the events to be detected nor the actions to be performed upon detection of an event. Such tools are generally designed to measure specific parameters and are often incorporated into a system at design time. Examples of fixed hardware tools are timing meters and counting meters. *Timing meters* or *timers* measure the duration of an activity or execution time, and *counting meters* or *counters* count occurrences of events, for example, references to a memory location. When a certain value is reached in a timer (or a counter), an electronic pulse is generated as an output of the timer (or the counter), which may be used to activate certain operations, for instance, to generate an interrupt to the monitored system.

Wired-program hardware tools allow the user to detect different events by setting the event filtering logic. The event filter of a wired-program hardware tool consists of a set of logic elements of combinational and sequential circuits. The interconnection between these elements can be selected and manually manipulated by the user so as to match different signal patterns and sequences for different events. Thus wired-program tools are more flexible than fixed hardware tools.

With *stored-program hardware tools,* filtering functions can be configured and set up by software. Generally, a stored-program hardware tool has its own processor, that is, its own computer. The computer executes programs to set up filtering functions, to define actions in response to detected events, and to process and display collected data. Their ability to control filtering makes stored-program tools more flexible and easier to use. *Logical state analyzers* are typical examples of stored-program hardware tools. With a logical state analyzer, one can specify states to be traced, define triggering sequences, and specify actions to be taken when certain events are detected. In newer logical state analyzers, all of this can be accomplished through a graphical user interface, making them very user-friendly.

Hybrid Monitoring

One of the drawbacks of the hardware monitoring approach is that as integrated circuit techniques advance, more functions are built on-chip. Thus desired signals might not be accessible, and the accessible information might not be sufficient to determine the behavior inside the chip. For example, with increasingly sophisticated caching algorithms implemented for on-chip caches, the information collected from external buses may be insufficient to determine what data need to be stored. Prefetched instructions and data might not be used by the processor, and some events can only be identified by a sequence of signal patterns rather than by a single address or instruction. Therefore passively snooping on the bus might not be effective. Hybrid monitoring is an attractive compromise between intrusive software monitoring and expensive nonintrusive hardware monitoring.

Hybrid monitoring uses both software and hardware to perform monitoring activities (5,16–18). In hybrid monitoring, triggering is accomplished by instrumented software and recording is performed by hardware. The instrumented program writes the selected data to a hardware interface. The hardware device records the data at the hardware interface along with other data such as the current time. Perturbation to the monitored system is reduced by using hardware to store the collected data into a separate storage device.

Current hybrid monitoring techniques use two different triggering approaches. One has a set of selected memory addresses to trigger data recording. When a selected address is detected on the system address bus, the monitoring device records the address and the data on the system data bus. This approach is called *memory-mapped monitoring*. The other approach uses the coprocessor instructions to trigger event recording. The recording unit acts as a coprocessor that executes the coprocessor instructions. This is called *coprocessor monitoring.*

With memory-mapped monitoring, the recording part of the monitor acts like a memory-mapped output device with a range of the computer's address space allocated to it (5,16,17). The processor can write to the locations in that range in the same way as to the rest of the memory. The system or program to be monitored is instrumented to write to the memory locations representing different events. The recording section of the monitor generally contains a comparator, a clock and timer, an overflow control, and an event buffer. The clock and timer provide the time reference for events. The resolution of the clock guarantees that no two successive events have the same time stamp. The comparator is responsible for checking the monitored system's address bus for designated events. Once such an address is detected, the matched address, the time, and the data on the monitored system's data bus are stored in the event buffer. The overflow control is used to detect events lost due to buffer overflow.

With coprocessor monitoring, the recording part is attached to the monitored processor through a coprocessor interface, like a floating-point coprocessor (18). The recorder contains a set of data registers, which can be accessed directly by the monitored processor through coprocessor instructions. The system to be monitored is instrumented using two types of coprocessor instructions: data instructions and event instructions. Data instructions are used to send event-related information to the data registers of the recorder. Event instructions are used to inform the recorder of the occurrence of an event. When an event instruction is received by the recorder, the recorder saves its data registers, the event type, and a time stamp.

DATA ANALYSIS AND PRESENTATION

The collected data are voluminous and are usually not in a form readable or directly usable, especially low-level data collected in hardware. Presenting these data requires automated analyses, which may be simple or complicated, depending on the applications. When monitoring results are not needed in an on-line fashion, one can store all collected data, at the expense of the storage space, and analyze them off-line; this reduces the time overhead of monitoring caused by the analysis. For monitoring that requires on-line data analysis, efficient on-line algorithms are needed to incrementally process the collected data, but such algorithms are sometimes difficult to design.

The collected data can be of various forms (4). First, they can be either qualitative or quantitative. *Qualitative data* form a finite category, classification, or set, such as the set {busy, idle} or the set of weekdays. The elements can be ordered or unordered. *Quantitative data* are expressed numerically, for example, using integers or floating-point numbers. They can be discrete or continuous. It is easy to see that each kind of data can be represented in a high-level programming language and can be directly displayed as text or numbers.

These data can be organized into various data structures during data analysis, as well as during data collection, and presented as tables or diagrams. Tables and diagrams such as line charts, bar charts, pie charts, and histograms are commonly used for all kinds of data presentation, not just for monitoring. The goal is to make the most important information the most obvious, and concentrate on one theme in each table or graph; for example, concentrate on CPU utilization over time, or on the proportion of time various resources are used. With the advancement of multimedia technology, monitored data are now frequently animated. Visualization helps greatly in interpreting the measured data. Monitored data may also be presented using hypertext or hypermedia, allowing details of the data to be revealed in a step-by-step fashion.

A number of graphic charts have been developed specially for computer system performance analysis. These include Gantt charts and Kiviat graphs (4).

Gantt charts are used for showing system resource utilization, in particular, the relative duration of a number of Boolean conditions, each denoting whether a resource is busy or idle. Figure 1 is a sample Gantt chart. It shows the utilization of three resources: CPU, I/O channel, and network. The relative sizes and positions of the segments are arranged to show the relative overlap. For example, the CPU utilization is 60%, I/O 50%, and network 65%. The overlap between CPU and I/O is 30%, all three are used during 20% of the time, and the network is used alone 15% of the time.

A Kiviat graph is a circle with unit radius and in which different radial axes represent different performance metrics. Each axis represents a fraction of the total time during which the condition associated with the axis is true. The points corresponding to the values on the axis can be connected by straight-line segments, thereby defining a polygon. Figure 2 is a sample Kiviat graph. It shows the utilization of CPU and I/O channel. For example, the CPU unitization is 60%, I/O 50%, and overlap 30%. Various typical shapes of Kiviat graphs indicate how loaded and balanced a system is. Most often, an even number of metrics are used, and metrics for which high is good and for which low is good alternate in the graph.

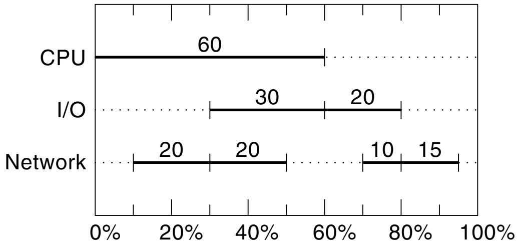

Figure 1. A sample Gantt chart for utilization profile.

APPLICATIONS

From the perspective of application versus system, monitoring can be classified into two categories: that required by the user of a system and that required by the system itself. For example, for performance monitoring, the former concerns the utilization of resources, including evaluating performance, controlling usage, and planning additional resources, and the latter concerns the management of the system itself, so as to allow the system to adapt itself dynamically to various factors (3).

From a user point of view, applications of monitoring can be divided into two classes: (*1*) testing and debugging, and (*2*) performance analysis and tuning. Dynamic system management is an additional class that can use techniques from both classes.

Testing and Debugging

Testing and debugging are aimed primarily at system correctness. Testing checks whether a system conforms to its requirements, while debugging looks for sources of bugs. They are two major activities of all software development.

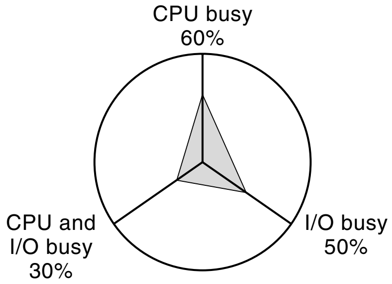

Figure 2. A sample Kiviat graph for utilization profile.

Systems are becoming increasingly complex, and static methods, such as program verification, have not caught up. As a result, it is essential to look for potential problems by monitoring dynamic executions.

Testing involves monitoring system behavior closely while it runs a test suite and comparing the monitoring results with the expected results. The most general strategy for testing is bottom-up: unit test, integration test, and system test. Starting by running and monitoring the functionality of each component separately helps reduce the total amount of monitoring needed. If any difference between the monitoring results and the expected results is found, then debugging is needed.

Debugging is the process of locating, analyzing, and correcting suspected errors. Two main monitoring techniques are used: single stepping and tracing. In single-step mode, an interrupt is generated after each instruction is executed, and any data in the state can be selected and displayed. The user then issues a command to let the system take another step. In trace mode, the user selects the data to be displayed after each instruction is executed and starts the execution at a specified location. Execution continues until a specified condition on the data holds. Tracing slows down the execution of the program, so special hardware devices are needed to monitor real-time operations.

Performance Evaluation and Tuning

A most important application of monitoring is performance evaluation and tuning (3,4,8,13). All engineered systems are subject to performance evaluation. Monitoring is the first and key step in this process. It is used to measure performance indices, such as turnaround time, response time, throughput, and so forth.

Monitoring results can be used for performance evaluation and tuning in as least the following six ways (4,6). First, monitoring results help identify heavily used segments of code and optimize their performance. They can also lead to the discovery of inefficient data structures that cause excessive amount of memory access. Second, monitoring can be used to measure system resource utilization and find performance bottleneck. This is the most popular use of computer system monitoring (6). Third, monitoring results can be used to tune system performance by balancing resource utilization and favoring interactive jobs. One can repeatedly adjust system parameters and measure the results. Fourth, monitoring results can be used for workload characterization and capacity planning; the latter requires ensuring that sufficient computer resources will be available to run future workloads with satisfactory performance. Fifth, monitoring can be used to compare machine performance for selection evaluation. Monitoring on simulation tools can also be used in evaluating the design of a new system. Finally, monitoring results can be used to obtain parameters of models of systems and to validate models. They can also be used to validate models, that is, to verify the representativeness of a model. This is done by comparing measurements taken on the real system and on the model.

Dynamic System Management

For a system to manage itself dynamically, typically monitoring is performed continuously, and data are analyzed in an on-line fashion to provide dynamic feedback. Such feedback can be used for managing both the correctness and the performance of the system.

An important class of applications is dynamic safety checking and failure detection. It is becoming increasingly important as computers take over more complicated and safety-critical tasks, and it has wide applications in distributed systems, in particular. Monitoring system state, checking whether it is in an acceptable range, and notifying appropriate agents of any anomalies are essential for the correctness of the system. Techniques for testing and debugging can be used for such monitoring and checking.

Another important class of applications is dynamic task scheduling and resource allocation. It is particularly important for real-time systems and service providers, both of which are becoming increasingly widely used. For example, monitoring enables periodic review of program priorities on the basis of their CPU utilization and analysis of page usage so that more frequently used pages can replace less frequently used pages. Methods and techniques for performance monitoring and tuning can be used for these purposes. They have low overhead and therefore allow the system to maintain a satisfactory level of performance.

MONITORING REAL-TIME, PARALLEL, AND DISTRIBUTED SYSTEMS

In a sequential system, the execution of a process is deterministic, that is, the process generates the same output in every execution in which the process is given the same input. This is not true in parallel systems. In a parallel system, the execution behavior of a parallel program in response to a fixed input is indeterminate, that is, the results may be different in different executions, depending on the race conditions present among processes and synchronization sequences exercised by processes (1). Monitoring interference may cause the program to face different sets of race conditions and exercise different synchronization sequences. Thus instrumentation may change the behavior of the system. The converse is also true: removing instrumentation code from a monitored system may cause the system to behave differently.

Testing and debugging parallel programs are very difficult because an execution of a parallel program cannot easily be repeated, unlike sequential programs. One challenge in monitoring parallel programs for testing and debugging is to collect enough information with minimum interference so the execution of the program can be repeated or replayed. The execution behavior of a parallel program is bound by the input, the race conditions, and synchronization sequences exercised in that execution. Thus data related to the input, race conditions, and synchronization sequences need to be collected. Those events are identified as process-level events (1). To eliminate the behavior change caused by removing instrumentation code, instrumentation code for process-level events may be kept in the monitored system permanently. The performance penalty can be compensated for by using faster hardware.

To monitor a parallel or distributed system, all the three approaches—software, hardware, and hybrid—may be employed. All the techniques described above are applicable. However, there are some issues special to parallel, distributed, and real-time systems. These are discussed below.

To monitor single-processor systems, only one event-detection mechanism is needed because only one event of interest may occur at a time. In a multiprocessor system, several events may occur at the same time. With hardware and hybrid monitoring, detection devices may be used for each local memory bus and the bus for the shared memory and I/O. The data collected can be stored in a common storage device. To monitor distributed systems, each node of the system needs to be monitored. Such a node is a single processor or multiprocessor computer in its own right. Thus each node should be monitored accordingly as if it were an independent computer.

Events generally need to be recorded with the times at which they occurred, so that the order of events can be determined and the elapsed time between events can be measured. The time can be obtained from the system being monitored. In single-processor or tightly coupled multiprocessor systems, there is only one system clock, so it is guaranteed that an event with an earlier time stamp occurred before an event with a later time stamp. In other words, events are totally ordered by their time stamps. However, in distributed systems, each node has its own clock, which may have a different reading from the clocks on other nodes. There is no guarantee that an event with an earlier time stamp occurred before an event with a later time stamp in distributed systems (1).

In distributed systems, monitoring is distributed to each node of the monitored system by attaching a monitor to each node. The monitor detects events and records the data on that node. In order to understand the behavior of the system as a whole, the global state of the monitored system at certain times needs to be constructed. To do this, the data collected at each individual node must be transferred to a central location where the global state can be built. Also, the recorded times for the events on different nodes must have a common reference to order them. There are two options for transferring data to the central location. One option is to let the monitor use the network of the monitored system. This approach can cause interference to the communication of the monitored system. To avoid such interference, an independent network for the monitor can be used, allowing it to have a different topology and different transmission speed than the network of the monitored system. For the common time reference, each node has a local clock and a synchronizer. The clock is synchronized with the clocks on other nodes by the synchronizer.

The recorded event data on each node can be transmitted immediately to a central collector or temporarily stored locally and transferred later to the central location. Which method is appropriate depends on how the collected data will be used. If the data are used in an on-line fashion for dynamic display or for monitoring system safety constraints, the data should be transferred immediately. This may require a high-speed network to reduce the latency between the system state and the display of that state. If the data are transferred immediately with a high-speed network, little local storage is needed. If the data are used in an off-line fashion, they can be transferred at any time. The data can be transferred after the monitoring is done. In this case, each node should have mass storage to store its local data. There is a disadvantage with this approach. If the amount of recorded data on nodes is not evenly distributed, too much data could be stored at one node. Building a sufficiently large data storage for every node can be very expensive.

In monitoring real-time systems, a major challenge is how to reduce the interference caused by the monitoring. Real-time systems are those whose correctness depends not only on the logical computation but also on the times at which the results are generated. Real-time systems must meet their timing constraints to avoid disastrous consequences. Monitoring interference is unacceptable in most real-time systems (1,14), since it may change not only the logical behavior but also the timing behavior of the monitored system. Software monitoring generally is unacceptable for real-time monitoring unless monitoring is designed as part of the system (19). Hardware monitoring has minimal interference to the monitored system, so it is the best approach for monitoring real-time systems. However, it is very expensive to build, and sometimes it might not provide the needed information. Thus hybrid monitoring may be employed as a compromise.

CONCLUSION

Monitoring is an important technique for studying the dynamic behavior of computer systems. Using collected run-time information, users or engineers can analyze, understand, and improve the reliability and performance of complex systems. This article discussed basic concepts and major issues in monitoring, techniques for event-driven monitoring and sampling monitoring, and their implementation in software monitors, hardware monitors, and hybrid monitors. With the rapid growth of computing power, the use of larger and more complex computer systems has increased dramatically, which poses larger challenges to system monitoring (20–22). Possible topics for future study include:

- New hardware and software architectures are being developed for emerging applications. New techniques for both hardware and software systems are needed to monitor the emerging applications.
- The amount of data collected during monitoring will be enormous. It is important to determine an appropriate level for monitoring and to represent this information with abstractions and hierarchical structures.
- Important applications of monitoring include using monitoring techniques and results to improve the adaptability and reliability of complex software systems and using them to support the evolution of these systems.

- Advanced languages and tools for providing more user-friendly interfaces for system monitoring need to be studied and developed.

TEMPORAL DATABASES

A temporal database keeps time-varying data (past, present, and/or future) and the capabilities to query the stored data in contrast to a conventional database that stores only the current and recent data. The maintenance of temporal data is required in many application domains, such as document management, medicine, spatial data, insurance, financial data, and others.

Temporal extensions to common data models are available: relational, entity relationship, and object oriented data models. Relational databases, because of their widespread use and availability, are a good vehicle for demonstrating the subtle issues in modeling and querying temporal data. It also provides a base for handling temporal data.

An obvious approach for handling temporal data within the relational databases is to add one or more time columns to a relation. Although this solution seems to be simple, it does not address many subtle issues peculiar to temporal data (i.e., comparing database states at two different time instances or periods, capturing the periods for concurrent events and accessing the times beyond these periods, handling attributes with multiple values at a time instance, grouping and restructuring temporal data, etc). Addressing these issues and their implications for modeling and querying temporal data is important for the management of temporal data.

Research in modeling and querying temporal data started in the early 1980s and gained momentum from then on. Several conferences were dedicated to the temporal databases such as Temporal Aspects of Information Systems (1987), Time Conferences (1994 and on), workshops on an Infrastructure on Temporal Databases (1993), and Spatiotemporal Databases (1999–2006), as well as the Dagstuhl Seminar on Temporal Databases (1997). In the mean time, several books on temporal databases were published.

REPRESENTING TEMPORAL DATA

Time

Time is continuous, dense, linearly increasing, and a total order under $\leq$. So, time is the set of time points (instances) $T = \{\ldots t_0 \ldots t_i, t_i + 1, t_i + n, Now \ldots \infty\}$ where the symbol *Now* represents the current time and its value advances as the clock ticks. Time points beyond *Now* represent the future until infinity (∞). Figure 1 gives the time line. The difference between two consecutive time points (t_i and $t_i + 1$) is one unit depending on the time granularity used, such as day, month, year, and so on. Moreover, the inside of a time unit is invisible regardless of its duration unless a finer time granularity is used. It is also customary to designate a relative time origin such as t_0 depending on the application domain.

Any subset of *T* is a *temporal set*. Time between two time points, t_i and $t_i + n$, is represented either as a *closed interval* $[t_i, t_i + n]$ or as a *half-open interval* $[t_i, t_i + n + 1)$. An example for the temporal set is {2/07, 3/07, 4/07, 7/07, 8/07, 11/07} and [2/07, 4/07], [7/07, 9/07), and [11/07 12/07) are the corresponding intervals. A *temporal element* (1) is a finite union of intervals and it allows different representations for the same set of time points depending on the intervals used. A noteworthy representation for a temporal element is the one that contains the maximal intervals that are not adjacent or do not overlap. One possible temporal element, the maximal one for the temporal set given earlier is {[2/07, 5/07) ∪ [7/07, 9/07) ∪ [11/07 12/07)}. Temporal elements are closed under set-theoretic operations whereas intervals are not. Any interval, temporal element, or temporal set that includes *Now* expands as the time advances. Moreover, *Now* can be replaced by the special symbols, "*Until changed*" or infinity (∞).

Various aspects of objects and their attribute values exist with respect to time (2). The time at which an attribute value becomes effective is called *valid time*. However, *transaction time* refers to the time a data value is recorded in the database. Other times of interest are available depending on the application domain, such as birth date, delivery date, or decision date, that can be stored as the *user defined time,* which is an ordinary attribute whose data type is "date". The rest of this entry focuses on the valid time and transaction time aspects of temporal data.

Temporal Data

Events (transactions) take place concurrently or in increasing time order and may cause a change in the database state in the form of insertions, deletions, or modifications. In Fig. 1, related events e_1, e_2, and e_3 take place at time instances t_2, t_5, and t_6, respectively. The effect of event e_1 starts at time instant t_2 and continues until time instant t_5 at which time a new value is created by the event e_2. At time instance t_6 there is another value created by the event e_3 whose effect continues until another event changes it.

Attribute values may have different behaviors. An attribute value, once assigned, may never change anytime afterwards (i.e., it stays constant). The attribute value may only be valid at that time instance only. Still another possibility is that it may change continuously with time. Finally, the attribute value is valid for a while and then changes to different values at other times.

The set *U* is all of the atomic values such as reals, integers, character strings, and the value null. Time-varying data are commonly represented by time-stamping values in *U*. A fact has a time and a value component. It can be represented as a temporal atom (3), which has three forms. A *bitemporal atom* is a triplet, $<Tt, Vt, v>$ where Tt and Vt are timestamps $Tt \subseteq T$, $Vt \subseteq T$, and $v \in U$. The symbol Tt is the transaction time, Vt is the valid time, and v is a value. A bitemporal atom asserts that the value v is valid during Vt and is recorded in the database at time Tt. One

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

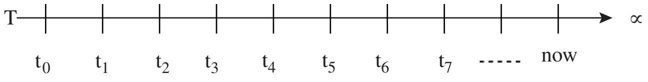

Figure 1. Time Points.

timestamp in a bitemporal atom may be omitted. $<Tt, v>$ is a *transaction time atom* and asserts that the value v is recorded in the data base at time Tt. Similarly, $<Vt, v>$ is a *valid time atom* that asserts that the value v is valid during Vt. In a temporal atom, the timestamps can be time points, time intervals, temporal sets or temporal elements. As an example, consider the projects and their budgets. Figure 2 depicts the budget history of a project as temporal atoms [Fig. 2(b)] and the sequence of events that created that history [Fig. 2(a)]. Note that the valid time atoms give the history after the most recent changes [Fig. 2(d)]. However, transaction time atoms [Fig. 2(c)] reflect the changes on the most recent values but not changes in the past values. In other words, event e_6 can not be stored in a transaction time database. Note that Fig. 2(b) is a complete bitemporal history of the events given in Fig. 2(a).

Types of Temporal Databases

Transaction time and valid time are the two time dimensions commonly used in a temporal database (2). A traditional database is a database of snapshot relations because it does not contain any time dimensions and keeps the most recent data [Fig. 3(a)]. A database that has relations with only valid time dimension is called a *Valid Time* Database or a *Historical* Database [Fig. 3(b)]. It gives a correct state of the history as we know it as of *Now*. Considering the data given in Fig. 2(d), events e_5 and e_6 replace the past values. Any correction in an attribute value replaces it, and there is no trace of the correction in the database. A *Transaction Time* database stores relations with only the transaction time and it is append-only [Fig. 3(c)]. Valid time and transaction time relations have the same form, but their content evolves differently; the former allows replacement of stored (past) data, and the latter does not. Transactions append attribute values that are new values or corrections for the most recent attribute value stored in the database. Past values may not be corrected as in the case of event e_5 in Fig. 2(c), which can not be recorded in the database. It is possible to roll back a transaction time database to any of its states in the past. A *bitemporal* database supports both the transaction time and the valid time [Fig. 3(d)]. It allows retroactive and postactive changes and keeps a complete history of these changes. A bitemporal database can be rolled back to any of its states in the past. The term temporal database is used loosely in the literature to mean a bitemporal, transaction time, or valid time database.

REPRESENTING TEMPORAL DATA

A fundamental issue in modeling temporal data is the representation of temporal atoms in the relational data model or in other data models. Representing a temporal atom involves adding timestamps to the relations, tuples, or attributes. The choice has implications for both modeling—the type of relations used and querying the temporal data. It also determines the expressive power of a temporal data model and its query languages (4).

For the sake of simplicity, valid time relations are considered to demonstrate temporal issues. The discussion extends to the transaction-time databases in a straightforward manner. The same applies to bitemporal databases, although it is more complicated.

In tuple time stamping (TTS), temporal atoms are broken into their time and value components. The relation scheme is augmented with two additional columns to represent the end points of time intervals (periods). It is also possible to store a time interval, temporal element, or a temporal set in one column as a composite data type. Figure 4 gives the project data in TTS: Project_N(P_No, P_Name), Project_B(P_No, P_Budget), and Project_M(P_No, P_Manager) relations. P_No, P_Name, P_Budget, and P_Manager denote project number, project name, project budget, and project manager, respectively. Obviously, budget and manager are temporal attributes, whereas project number and project name

Posting Time	**(a)** Events	**(b)** Bitemporal atoms
2/07	e_1: The project starts with a budget of 50K at 2/2007.	<[2/07, 5/07), [2/07, 5/07), 50K>
5/07	e_2: Project's budget increases to 60K at 5/2007.	<[5/07, 7/07), [5/07, 7/07), 60K>
7/07	e_3: Project is suspended at 7/2007.	
10/07	e_4: Project resumes with a budget of 50K at 10/2007.	<[10/07, 11/07), [10/07, 11/07), 50K>
12/07	e_5: At 11/2007, an error is discovered. The project's last budget is 70K.	<[12/07, *Now*], [10/07, *Now*], 70K>
2/08	e_6: At 12/2007 an error is discovered. The project's budget at 2/2007 was 55K, not 50K.	<[2/08, *Now*], [2/07, 5/07), 55K>

are not. Project_B and Project_M relations are augmented with two additional attributes, *Start* and *End*. These columns can be explicit (i.e., like any other ordinary attribute) or implicit (i.e., special time attributes maintained by the system) (2). This, causes limitations as explained below.

In attribute time stamping (ATS), attribute values are temporal atoms, and the entire history of an attribute is stored as a set of temporal atoms that requires N1NF relations that allow relations as attribute values in contrast to 1NF (flat) relations. Moreover, it is possible to attach a timestamp to any part of a N1NF relation. In this case, the value part of a temporal atom becomes a N1NF relation which is beyond the focus of this entry. Figure 5 gives the project data in attribute time stamping. Three separate relations in tuple timestamping are combined into one single relation, namely Project in ATS: Project(P_No, P_Name, P_Budget, P_Manager). Temporal attributes P_Budget and P_Manager are sets of temporal atoms, whereas P_No and P_Name are constant and atomic. These attributes can also be represented as temporal atoms where the timestamp is the life of the database (i.e., <$[t_0,\infty)$, p1> where t_0 is the time origin) (5). The choice depends on the type of temporal query language designed.

Time stamping a relation visualizes a temporal relation as a sequence of snapshot relation instances at each time point (i.e., indexed by time).

In case of tuple and attribute timestamping, time points cannot capture the full extent of the temporal reality. Time points have limitations as a timestamp because extrapolating the attribute values beyond the time points creates undue complications. These complications occur because the starting time of a value is not sufficient to indicate the whole period over which that value is valid, as the end of this period is indicated by the starting time of the value in another tuple. If the history is discontinuous, then it requires special null values to determine the validity period of a data value correctly. However, handling these null values in a query language is complicated (6). In the special case when an attribute is valid over just one time point, time points may be used as a timestamp. In the literature, this special case is called an *Event* relation (2).

One noteworthy aspect of data presented in Fig. 5 is that the timestamps are glued to values in temporal atoms (7). In forming new relations, these timestamps stay with the attribute values. However, in implicit tuple time stamping, a timestamp is glued to a tuple. Therefore, it restricts the time of a new tuple created from two constituent tuples, that is, each tuple may not keep its own timestamp, and a new timestamp needs to be assigned to the resulting tuple. It is possible to consider unglued timestamps (i.e., explicit timestamp attributes) and allow multiple timestamps in a tuple. In this case, two tuples may be combined to form a new tuple, each of which carries its own time reference. However, it would be difficult to provide support for this in a query language, and the user would need to keep track of these separate time references.

(c) Project_M Relation

Figure 4. Project data in tuple time stamping.

Note that in tuple time stamping, a relation may only contain attributes that change at the same time (i.e., attributes that change at different times require different relations).

Temporal Grouping

In both tuple and attribute timestamping, there is a unique representation of temporal data (5, 7, 8). The Project relation of Fig. 5 is a unique and compact representation of the projects' data in which each tuple contains the entire history of a project. This represantation is called *temporally grouped* (1). The same data are broken into several tuples in Fig. 4. Tuples that have the same project number are related and belong to the same object (entity) or relationship. This table is also a unique representation of temporal data in tuple timestamping. Hence, tuple time stamping is *temporally ungrouped* (1).

The project number is a *temporal grouping identifier* because it is unique. It does not change with time and identifies the tuples that belong to the same object. In case of attribute timestamping, only one tuple exists for each project number value. Temporal grouping identifier also serves as a temporal primary key, which is the attribute(s) that serves as a primary key for each snapshot of a temporal relation. Unique representations in TTS and ATS, as given in Figs. 4 and 5 are suitable for most applications. However, other temporal relation forms in between may be of theoretical significance or suitable for certain type of applications.

In a conventional database, the primary key values are expected to be constant. However, in a temporal database the value of a temporal grouping (object) identifier may change. In this case, a temporal grouping (object) identifier becomes a set of values, and a N1NF temporal relation can store it (8). However, using 1NF relations requires a separate tuple for each change in the temporal grouping (object) identifier value. The fact that these tuples are related and belong to the same object (temporal group) is lost, and this information can only be recovered by adding an artificial, nonchanging object identifier to each tuple.

p2	Star	<[4/07, *Now*], 70K>	<[4/07, *Now*], Ann>

Figure 5. Project relation in attribute time stamping.

Weak Temporal Relations. For the temporal data in unique representation, many other possible representations can be obtained by taking subsets of timestamps and creating several tuples for the same unique tuple. In other words, one tuple in the unique representations is broken into several tuples whose timestamps are the subsets of the timestamp(s) of the original tuple. These relations are called *weak relations* (4, 9) because they contain the same data but are not identical to a relation in its unique representation. For instance, a weak relation may contain tuples (p1, 55K, 2/07, 4/07) and (p1, 55K, 3/07, 5/7) in place of the first tuple of the relation Project_B in Fig. 4. These two tuples are *value equivalent* because their values are identical, but their timestamps are different. Value equivalent tuples can be combined (collapsed) back to a unique tuple (6).

Homogenous Temporal Relations. A homogenous tuple has the same time reference in its attributes (5). A temporal relation is homogenous if all its tuples are homogeneous. This restriction simplifies the model and allows modeling and querying the homogeneous part of the real world unambiguously. If an object's attributes have values over different periods of time, then the attributes of that object can only be represented over the common time periods of its attributes. Moreover, Cartesian product operation can only be defined for the common time period of the operand tuples. Let t_1 and t_2 be tuples from homogenous temporal relations and τ_1 and τ_2 be their timestamps, respectively. Cartesian product of these two tuples can only be defined over $\tau_1 \cap \tau_2$. Parts of τ_1 and τ_2 outside of their intersection are not accessible (i.e., $\tau_1 - \tau_2$ or $\tau_1 - \tau_2$. If τ_1 and τ_2 do not intersect, then it is not even possible to extract information from these two tuples at all. Temporal relations in TTS are homogenous by definition, whereas temporal relations in ATS may or may not be homogenous (8).

Entities and Relationships

In tuple timestamping, 1NF relations are sufficient to represent both the entity types and their relationships. Each temporal attribute generally requires a separate relation. However, in attribute timestamping, N1NF relations are needed, and one level of nesting can model an entity type where a temporal attribute is a set of temporal atoms.

One or two levels of nesting can represent the history of a relationship. In modeling a many-to-many relationship, identifiers of the related objects form a grouping identifier for the relationship. Consider a relationship relation between projects and the tools they use, Project_Tool(P_No, T_No, Budget) where Budget denotes the allocation of a tool to a project. The attribute combination (P_No, T_No) is a temporal grouping identifier for the relationship between projects, and Tools and Budget will be a set of temporal atoms. However, this relationship can be embedded into Project or Tool relations, which requires two levels of nesting: one level for the history of the relationship and another level for the history of budget.

TEMPORAL QUERY LANGUAGES

Many Temporal Relational Algebra (TRA) and Temporal Relational Calculus (TRC) languages are available for temporal databases. The languages depend on how the temporal data are represented (i.e., how the temporal atoms are stored in relations, and the type of timestamps and where they are attached). This in turn determines how temporal data are processed and possible evaluation (semantics) of temporal query languages. Two commonly adopted approaches are as follows: Snapshot (point or sequenced) evaluation that manipulates the snapshot relation at each time point, like temporal logic (1, 5, 6) or traditional (nonsequenced) evaluation that manipulates the entire temporal relation much like the traditional relational languages (7). It is also possible to mix these approaches. Snapshot evaluation requires homogeneous tuples; otherwise, it may have null values that leads to complications (5).

If temporal relations are in 1NF and temporal atoms are already broken into their components (i.e., TTS), then these components are referred directly in TRA and TRC. Moreover, for reaching time points, interval or temporal elements can be expanded to time points or vice versa. In case N1NF relations and temporal atoms are used (i.e., ATS), operations are needed to flatten (unnest) them to 1NF relations or transforming (nesting) 1NF relations back to N1NF relations. Operations for breaking and forming new temporal atoms are also required.

Temporal query languages are defined independent of time granularities. However, if operand relations are defined on different time granularities, then a granularity conversion is required as part of processing the operation.

Temporal Relational Algebras

The syntax of temporal algebras closely follows the syntax of traditional relational algebra. The five basic Temporal Algebra operations, $\cup^t$, $-^t$, π^t, σ^t, and x^t in snapshot evaluation are given below (1, 5). Let Q, R, and S be relations that may be defined in ATS or TTS. Assume Q, R, and S in ATS are Project, $\pi_{\text{P\_No, Buget}}$(Project_Tool), and $\pi_{\text{P\_No, Buget}}$(Project), respectively.

- $R \cup^t S_t$ is $R_t \cup S_t$ for all t in T
- $R -^t S_t$ is R_t-S_t for all t in T
- $\pi^t{}_{A1,A2,\ldots,An}$ (R) is $\pi_{A1,A2,\ldots,An}$ (R_t) for all t in T
- $\sigma^t_F(R)$ is $\sigma_F(R_t)$ for all t in T; Formula F includes traditional predicates and temporal predicates like *Before*, *After*, *Overlaps*, etc
- $R \times^t Q$ is $R_t \times Q_t$ for all t in T

In temporal algebras that use traditional evaluation, $\cup^t$, $-^t$, π^t, σ^t, and x^t may be defined exactly the same as the relational algebra operations or they may include temporal semantics. The temporal set-theoretic operations may be defined by considering the value equivalent tuples. Let {(p1, <[2/07,11/07), 55K>)} and {(p1, <[6/07,8/07), 55K>)} be tuples in R and S, respectively. These two tuples are value equivalent. Set union operation, $R \cup^t S$ combines value equivalent tuples into one single tuple and carries the remaining tuples directly into the result. Considering the former tuples the result is {(p1,<[2/07,11/07), 55K>)}. Set difference however, $R -^t S$ removes the common portion of the timestamps for the value equivalent tuples. For the above tuples the result is {p1, <[2/07,6/07), 55K>), (p1, <[8/07,11/07), 55K>)}. If the temporal semantics is not included in operations, the temporal coalescing operation combines value equivalent tuples into a single tuple.

The definition of temporal projection (π^t) is straightforward. However, it may generate value-equivalent tuples much like the traditional projection operation creates duplicate tuples, and it is costly to eliminate them.

The formula F in the Selection operation [$\sigma^t_F(Q)$] may include time points, the end points of intervals, or temporal elements as well as temporal predicates like *Before*, *After*, *Overlaps*, and so on. It is possible to simulate the temporal predicates by conditions referring to time points or end points of intervals.

Other temporal algebra operations, such as temporal set intersection or temporal join, are defined similarly. Many different versions of temporal join are available. Intersection join is computed over the common time of operand relations. For instance, if {(p1, Moon, <[1/07, 5/07), 80K>, <[1/07, 4/07), Tom>)} is a tuple in Q, then the natural join ($Q \bowtie R$) contains the tuple {(p1, Moon, <[1/07, 5/07), 80K>, <[1/07, 4/07), Tom>, <[2/07,11/07), 55K>)}. If this were an intersection natural join, times of the attributes in this tuple would be restricted to their common time period [2/07, 4/07). It is also possible to define temporal outer joins. Temporal aggregates may be calculated at each time point or cumulatively over a period(s) of time. Temporal query optimization is based on temporal algebraic identities similar to traditional query optimization.

Time Slice operation in valid time databases slices (cuts) the timestamp of a temporal attribute by a specified constant timestamp or by the timestamp of another temporal attribute (7). Time slicing every attribute in a temporal relation by a time point (or timestamp) generates a snapshot (or temporal relation) at that time point (or timestamp). The time slice operation conveniently implements the "when" predicate in natural languages. The symmetric operation in transaction time databases is *Rollback* (10). Applied on a temporal attribute, this operation rolls it back to the designated time point (or timestamp). Applying it on all the attributes of a temporal relation rolls it back to designated time point (or timestamp). In a bitemporal algebra, both operations are available.

Temporal Relational Calculus

A temporal tuple (domain) relational calculus expression is $\{t \mid \psi(t)\}$, where t is a free tuple (domain) variable and $\psi(t)$ is a well-formed formula that contains traditional relational calculus terms and formulas in addition to their temporal counterparts. They provide references to the end points of intervals or time points in temporal elements or temporal sets. In case of N1NF temporal relations, a set membership operator ($\in$) is needed for reaching the elements in a set. Additionally, set formation is achieved by assigning a well-formed formula to a component of a tuple variable or a domain variable, much like the aggregation operation in relational calculus. However, the calculus language with the set membership operator and the set formation formula is more expressive than the relational algebra that has nest and unnest operators (8). The capability to refer to the time reference of an attribute or a formula is useful in temporal relational calculus and algebra expressions

Temporal Structured Query Language (SQL)

SQL2 includes a diverse set of temporal data types: date, time, timestamp, and interval. However, temporal support in SQL2 is limited and left mostly for the applications programming. Temporal atoms cannot be implemented directly, and only tuple timestamping is available. However, SQL3 allows direct implementation of temporal atoms and therefore supports both attribute and tuple time stamping. Temporal atoms can be defined easily as new data types. Thus, current database systems that contain object relational features and adhere to SQL3 standard can be used to implement any of the relations given in Figs. 4 and 5. Moreover, SQL2 and SQL3 include a period data type whose values are time durations in contrast to time instants. Other than some basic operations on temporal types, the details of temporal support are again left for the applications.

Several temporal extension proposals to SQL have been suggested. One noteworthy example is TSQL2 (8). These extensions augment SQL statements with "*when*" clauses for valid time or bitemporal atoms formation and/or to implement temporal conditions. Another addition is the "*as of*" clause that accomplishes rollback to a time in the past in case of transaction time or bitemporal relations. Time-by-example temporal query language proposal follows the syntax and semantics of Query by Example (QBE) and QBE-like languages (11).

REQUIRMENTS FOR TEMPORAL DATA MODELS

Many properties are desirable for temporal databases (4). Let DB_t denote the database state at time t, where t may be a time point, time interval, temporal element, or temporal set):

1. The data model should be capable of modeling and querying the database at any instance of time (i.e., D_t). The data model should at least provide the modeling and querying power of a 1NF relational data model. Note that when t is *now*, D_t corresponds to traditional database.
2. The data model should be capable of modeling and querying the database at two different times (i.e., D_t and D'_t, where $t \neq t'$). This model should be the case for the different types of timestamps.
3. The data model should allow different periods of existence in attributes within a tuple (i.e., nonhomogenous (heterogeneous) tuples should be allowed).
4. The data model should allow multivalued attributes at any time point (i.e., in D_t).
5. A temporal query language should have the capability to return the same type of objects it operates on.
6. A temporal query language should have the capability to regroup the temporal data according to a different temporal attribute. Homogenous relations simplify the regrouping operation.
7. The data model should be capable of expressing set-theoretic operations, as well as set comparison tests, on the timestamps, be it time points, time intervals, temporal sets, or temporal elements.

TEMPORAL INTEGRITY CONSTRAINTS

Each object, such as a project, exists in a certain period of time, which is a subset of $[0, \infty)$. Call this period as the object's *life*, denoted as $l(o)$ for the object o. Any temporal atom that is the value of an attribute of object o contains a timestamp that is a subset of $l(o)$. Constant attributes of an object o do not change during $l(o)$, whereas time-dependent attributes assume different values during this period. They may even be null in parts or all of $l(o)$. Moreover, a constant attribute, such as a project name, can be represented with no timestamp, in which its time reference is implied as $l(o)$ or a temporal atom whose time reference is $l(o)$.

Existence and referential integrity also have their temporal counterparts. Temporal grouping identifier or temporal key in a temporal relation may not be null at any time instance. Also, an object may only participate in a relationship only during its life. Let p and t be the tuples in Project and Project_Tool relations, respectively. Referential integrity requires that $l(p) \subseteq l(t)$ in addition to the restrictions on the respective attribute components of p and t.

DESIGNING TEMPORAL RELATIONS

Traditional relational database design into BCNF and 4NF, and the design of N1NF relations are based on the functional and multivalued dependencies. The same principles can also be applied on the design of temporal databases. A functional dependency in a snapshot database turns into a multivalued dependency in a temporal database. A multivalued dependency in a snapshot database is still a multivalued dependency in a temporal database.

In attribute time stamping, temporal relations that are in nested normal form (10) do not suffer from insertion, deletion, and update anomalies. The Project relation in Fig. 5 is in nested normal form.

In tuple timestamping, 4NF decomposition places each temporal attribute into a separate relation because the temporal grouping identifier functionally determines constant attributes (i.e., P_Name) and multidetermines each temporal attribute (i.e., P_Budget, and P_Manager). Decomposing Project relation of Fig. 5 gives the Project_N, Project_B, and Project_M relations of Fig. 4. Project_N is in BCNF, and Project_B and Project_M are in 4NF.

CURRENT STATE OF TEMPORAL DATABASES

Many index structures have been proposed for accessing temporal data. Modeling and index structures for spatiotemporal data are also studied. Research in temporal query processing and optimization has been limited and needs more investigation.

Proof-of-concept temporal prototypes have been implemented on top of commercial database management systems. However, no commercial temporal database product or a temporal add-on is available in the market yet. Developing temporal database applications or temporal database add-ons are within the reach of application developers through the use of recent object relational database management systems that are available in the market.

TRANSACTION PROCESSING IN MOBILE, HETEROGENEOUS DATABASE SYSTEMS

INTRODUCTION

The proliferation of mobile devices has brought about the realization of ubiquitous access to information through the wide breadth of devices with different memory, storage, network, power, and display capabilities. Additionally, with the explosion of data available via the Internet and in private networks, the diversity of information that is accessible to a user at any given time is expanding rapidly.

Current multi-database systems (MDBS) are designed to allow timely and reliable access to large amounts of heterogeneous data from different data sources. Within the scope of these systems, multi-database researchers have addressed issues such as autonomy, heterogeneity, transaction management, concurrency control, transparency, and query resolution (1). These solutions were based on fixed clients and servers connected over a reliable network infrastructure. However, the concept of *mobility*, where a user accesses data through a remote connection with a portable device, has introduced additional complexities and restrictions (2). These include (*1*) limited network connections, (*2*) processing and resource constraints, and (*3*) the problem of effectively locating and accessing information from a multitude of sources. An MDBS with such additional restrictions is called a mobile data access system (MDAS). Within the scope of this infrastructure, two types of services are available to the user: on demand-based services and broadcast-based services (3).

Broadcast-Based Services

Many applications are directed toward public information (i.e., news, weather information, traffic information, and flight information) that are characterized by (*1*) the massive number of users, (*2*) the similarity and simplicity in the requests solicited by the users, and (*3*) the fact that data are modified by a few. The reduced bandwidth attributed to the wireless environment places limitations on the rate and amount of communication. Broadcasting is a potential solution to this limitation. In broadcasting, information is generated and broadcast to all users on the air channels. Mobile users are capable of searching the air channels and pulling the information they want. The main advantage of broadcasting is that it scales up as the number of users increases. In addition, the broadcast channel can be considered as an additional storage available over the air for the mobile clients. Finally, it is shown that pulling information from the air channel consumes less power than pushing information to the air channel. Broadcasting is an attractive solution, because of the limited storage, processing capability, and power sources of the mobile unit. Further discussion about the broadcasting is beyond the scope of this article, and the interested reader is referred to ref. (3).

On-Demand-Based Services

Private data (personal schedules, phone numbers, etc.) and shared data (i.e., a group data, replicated, data or fragmented data of a database) are the subject of these services in which users obtain answers to requests through a two-way communication with the database server; the user request is pushed to the system, data sources are accessed, query operations are performed, partial results are collected and integrated, and generated information is communicated back to the user. This requires a suitable solution that addresses issues such as security and access control, isolation, semantic heterogeneity, autonomy, query processing and query optimization, transaction processing and concurrency control, data integration, browsing, distribution and location transparency, and limited resources (3).

Among these issues, this article concentrates on transaction processing and concurrency control. Traditionally, in a distributed environment, to achieve high performance and throughput, transactions are interleaved and executed concurrently. Concurrent execution of transactions should be coordinated such that there is no interference among them. In an MDAS environment, the concurrent execution of transactions is a more difficult task to control than in distributed database systems, due to the conflicts among global transactions, conflicts among global and local transactions, local autonomy of each site, and frequent network disconnections. Furthermore, some form of data replication should be used at the mobile unit to provide additional availability in case of a weak connection or disconnection.

Researchers have extensively studied caching and replication schemes that may be used to address the constraints of a wireless link. Current distributed database replication and caching schemes are not suitable for an MDAS environment because consistency cannot be effectively maintained due to local autonomy requirements and communication constraints. In addition, because of the autonomy requirements of the local DBMS, the local information about the validity of a page or file is not available globally. Accordingly, any type of invalidation, polling, or timestamp-based method would be too impractical and inefficient to use and, in many cases, impossible.

The use of a hierarchical concurrency control algorithm reduces the required communication overhead in an MDAS and offers higher overall throughput and faster response times. The concurrency control for global transactions is performed at the global level in a hierarchical, distributed manner. The application of the hierarchical structure to enforce concurrency control offers higher performance and reliability.

The limited bandwidth and local autonomy restrictions of an MDAS can be addressed by using an *automated queued queriys* (AQ^2) and caching of data in the form of a *bundled query* (BUNQ). An AQ^2 is a form of prefetching that preloads data onto the mobile unit. A bundled query is an object that consists of a query and its associated data. Read-only queries are cached as a bundled query and are

validated using a simple parity-checking scheme. Guaranteeing write consistency while disconnected is extremely difficult or impossible due to local autonomy requirements in an MDAS. Consequently, any transactions containing write operations are directly submitted to the MDAS system or are queued during disconnection and submitted during reconnection. The caching and prefetching policies reduce the access latency and provide timely access to data, notwithstanding the limited bandwidth restrictions imposed by an MDAS environment.

BACKGROUND

Accessing a large amount of data over a limited capability network connection involves two general aspects: the mobile networking environment and mobility issues. The mobile environment includes the physical network architecture and access devices. Mobility issues include adaptability to a mobile environment, autonomy, and heterogeneity. A mobile application must be able to adapt to changing conditions including the network environment and resources available to the application. A resource-scarce mobile system is better served by relying on a server. However, frequent network disconnections, limited network bandwidth, and power restrictions argue for some degree of autonomy.

Multi-databases

An (MDBS) provides a logical integrated view and method to access multiple preexisting local database systems, providing the hardware and software transparencies and maintaining the local autonomy. In addition to autonomy, heterogeneity is also an important aspect of a multi-database system. Support for heterogeneity is a tradeoff between developing and making changes in both hardware and software and limiting participation (1). Consequently, as the number of systems and the degree of heterogeneity among these systems increases, the cost of integration into the global MDBS increases. Access to the local DBMS through a much more diverse and restrictive communication and access device is the natural extension to a traditional MDBS environment, i.e., an MDAS environment (5).

The Summary Schemas Model for Multidatabase Systems. The summary schemas model (SSM) has been proposed as an efficient means to access data in a heterogeneous multi-database environment (4). The identification of the terms that are semantically similar is one key concept in SSM. SSM uses the taxonomy of the English language that contains at least hypernym/hyponym and synonym links among terms to build a hierarchical meta-data. This hierarchical meta-structure provides an incrementally concise view of the data in the form of summary schemas. The SSM hierarchy consists of leaf-node schemas and summary schemas. A leaf-node schema represents an actual database, whereas a summary schema gives an abstract view of the information available at the schemas of its children. The hypernyms of terms in the children of a particular SSM node form the summary schema of that node. As hypernyms are more general or abstract than their hyponyms, many terms could map into a common hypernym. This reduces the overall memory requirements of the SSM meta-data as compared with the global schema approach. The semantic distance metric between the hypernym and their respective hyponyms are relatively small; hence, even though each summary schema does not contain exact information of its children but only an abstracted version, it preserves the semantic contents of its children. The ability to browse/view the global data and to perform an imprecise query, and the small size of the meta-data of the SSM provide several benefits to the traditional multi-database systems that can be directly applied to an MDAS.

SSM can also play an interesting role in the arena of the semantic web. As Tim Berners-Lee pointed out in his 1998 draft “Semantic Web Roadmap” (5), the rationale behind the semantic web is to express information in a machine-understandable form. To this end, a set of standards and tools of the eXtensible Markup Language (XML) (6) is used to create structured web pages: the XML Schema (6), the Resource Description Framework (RDF) (7), the RDF Schema (7), and the Web Ontology Language (OWL) (8). SSM provides a semi-automated solution for millions of existing web pages, which are only human-understandable, to enter the semantic web world. In this application, existing web pages act as local databases and SSM as the portal for information exchange between traditional web pages and the semantic web space.

The MDAS Environment. Overall, the main differentiating feature between an MDAS and an MDBS is the connection of servers and/or clients through a wireless environment and the devices used to access the data. However, both environments are intended to provide timely and reliable access to the globally shared data. Due to the similarities in the objectives of effectively accessing data in a multi-database and a wireless-mobile computing environment, a wireless-mobile computing environment can be easily superimposed on an MDBS. The resulting system is called an MDAS. By superimposing an MDBS onto a mobile computing environment, solutions from one environment are easily mapped to another.

Transaction Management and Concurrency Control

Data access in an MDBS is accomplished through *transactions*. Concurrency control involves coordinating the operations of multiple transactions that operate in parallel and access shared data. By interleaving the operations in such a manner, the potential of interference between transactions arises. The concurrent execution of transactions is considered correct when the ACID properties (atomicity, consistency, isolation, and durability) hold for each transaction (9). The autonomy requirement of local databases in an MDAS introduces additional complexities in maintaining serializable histories because the local transactions are not visible at the global level. Consequently, the operations in a transaction can be subjected to large delays, frequent or unnecessary aborts, inconsistency, and deadlock. Two types of conflicts may arise due to the concurrent execution of transactions—*direct* and *indirect* conflicts (10).

Definition 1. A direct conflict between two transactions T_a and T_b exists if and only if an operation of T_a on data item x [(denoted $o(T_a(x))$)] is followed by $o(T_b(x))$, where T_a does not commit or abort before $o(T_b(x))$, and either $o(T_a(x))$ or $o(T_b(x))$ is a write operation.

Definition 2. An indirect conflict between two transactions T_a and T_b exists if, and only if, a sequence of transactions T_1, T_2, ... T_n exists such that T_a is in direct conflict with T_1, T_1 is in direct conflict with T_2, ..., and T_n is in direct with T_b.

An MDAS should maintain a globally serializable history for correct execution of concurrent transactions, which means that the global history should be conflict free while preserving as much local autonomy as possible. Although the MDBS is responsible for producing a globally serializable history, it is assumed that the local concurrency control system will produce a locally serializable history as well. It is important to note that the MDBS needs to address both direct and indirect conflicts between global transactions. For more information about the concurrency control algorithms that have been advanced in the literature, the reader is referred to ref. 11.

Data Replication for Weak Connections and Disconnection. The communication limitations of an MDAS environment may require that a portion of the data in some form be made readily available to the mobile unit. A large amount of related work has been reported in the area of distributed file systems, distributed replication, and distributed/web caches. The local autonomy requirement of an MDAS environment does not lend itself to the direct application of these works. Data consistency and access time are two main objectives in maintaining replicated data in a mobile or distributed environment.

Replication schemes differ slightly from caching schemes in that the replicated data are accessible by other systems outside of the system on which the data resides. Two types of general replication schemes exist: primary/secondary copy (PSC) replication and voting-based replication schemes. PSC replication does not work in an MDAS environment because write operations to replicated data do not reach the primary copy when disconnected. Therefore, write consistency is not guaranteed. In a distributed system, data consistency is guaranteed with voting-based replications; however, they tend to be more expensive and require much more communication. In an MDAS environment, the local replica, while disconnected, cannot participate in the decision/voting process, and any changes to the local data may result in an inconsistency.

Caching is an effective means of data duplication that is used to reduce the latency of read and write operations on data. Early research on the disconnected operation was done with file system-based projects. When a disconnection occurs, a cache manager services all file system requests from the cache contents. As with replication, the invalidation of data is not possible when disconnected, and thus, consistency cannot be guaranteed. Web-based caching (12) offers the two most common forms of cache consistency mechanisms, i.e., time-to-live (TTL) and client polling (13). The disconnected operation of a mobile system and the local autonomy requirements of the local systems make the application of these schemes impractical in an MDAS environment. Some schemes try to use the concept of compensating transactions (or operations) to keep replicated data consistent. However, compensating transactions are difficult to implement, and in some cases, a compensating transaction cannot semantically undo the transaction (or operation) (10).

CONCURRENCY CONTROL AND DATA REPLICATION FOR MDAS

The proposed concurrency control algorithm is defined in an environment where information sources are stationary and user requests are aimed at shared data sources. Under these conditions, the v-locking algorithm is intended to reduce the amount of communication and hence to reduce the effect of frequent disconnections in wireless environment.

The V-Locking Concurrency Control Scheme

The proposed v-locking algorithm uses a global locking scheme (GLS) to serialize conflicting operations of global transactions. Global locking tables are used to lock data items involved in a global transaction in accordance to the two-phase locking (2PL) rules. In typical multi-database systems, maintaining a global locking table would require communication of information from the local site to the global transaction manager (GTM). In an MDAS environment, this is impractical due to the delay, amount of communication overhead, and frequent disconnections involved. In our underlying infrastructure, software is distributed in a hierarchical structure similar to the hierarchical structure of the SSM. Subsequently, transaction management is performed at the global level in a hierarchical, distributed manner. A global transaction is submitted at any node in the hierarchy—either at a local node or at a summary schema node. The transaction is resolved and mapped into subtransactions, and its global transaction coordinator is determined by the SSM structure (4).

The v-locking algorithm is based on the following assumptions:

1. There is no distinction between local and global transactions at the local level.
2. A local site is completely isolated from other local sites.
3. Each local system ensures local serializability and freedom from local deadlocks.
4. A local database may abort any transaction at any time within the constraints of a distributed atomic commit protocol.
5. Information pertaining to the type of concurrency control used at the local site will be available. For systems to provide robust concurrency and consistency, in most systems, a *strict* history is produced

> through the use of a strict 2PL scheme. Therefore, most local sites will use a strict 2PL scheme for local concurrency control.

Consequently, the MDAS coordinates the execution of global transactions without the knowledge of any control information from local DBMS. The only information (loss of local autonomy) required by the algorithm is the type of concurrency control protocol performed at the local sites. The semantic information contained in the summary schemas is used to maintain global locking tables. As a result, the "data" item being locked is reflected either exactly or as a hypernym term in the summary schema of the transaction's GTM. The locking tables can be used in an aggressive manner where the information is used only to detect potential global deadlocks. A more conservative approach can be used where the operations in a transaction are actually delayed at the GTM until a global lock request is granted. Higher throughput at the expense of lower reliability is the direct consequence of the application of semantic contents rather than exact contents for an aggressive approach. In either case, the global locking table is used to create a global wait-for-graph, which is subsequently used to detect and resolve potential global deadlocks. In the proposed v-locking algorithm, due to the hierarchical nature of the summary schemas model, the global wait-for-graphs are maintained in hierarchical fashion within the summary schemas nodes. In addition, edges in the wait-for-graphs as discussed later are labeled as exact or imprecise.

During the course of operations, the wait-for-graph is constructed based on the available communication. Three cases are considered: (*1*) Each operation in the transaction is individually acknowledged; (*2*) write operations are only acknowledged; and (*3*) only the commit or abort of the transaction is acknowledged. For the first case, based on the semantic contents of the summary schema node, an edge inserted into the wait-for-graph is marked as being an exact or imprecise data item. For each acknowledgment signal received, the corresponding edge in the graph is marked as exact. In the second case, where each write operation generates an acknowledgment signal, for each signal only the edges preceding the last known acknowledgment are marked as being exact. Other edges that have been submitted but that have not been acknowledged are marked as pending. As in the previous two cases, in the third case, the edges are marked as representing exact or imprecise data. However, all edges are marked as pending until the commit or abort signal is received. Keeping the information about the data and status of the acknowledgment signals enables one to detect cycles in the wait-for-graph. The wait-for-graph is checked for cycles after a time threshold for each transaction. For all transactions involved in a cycle, if the exact data items are known and all acknowledgments have been received, then a deadlock is precisely detected and broken. When imprecise data items are present within a cycle, the algorithm will consider the cycle a deadlock only after a longer time threshold has passed. Similarly, a pending acknowledgment of a transaction is only used to break a deadlock in a cycle after an even longer time threshold has passed. The time thresholds can be selected and adjusted dynamically to prevent as many false deadlocks as possible.

Handling Unknown Local Data Sources

The v-locking algorithm has been extended to handle the local "black box" site in which the global level knows nothing about the local concurrency control. As nearly every commercial database system uses some form of 2PL, this case will only comprise a small percentage of local systems. The algorithm merely executes global transactions at such a site in a serial order. This is done by requiring any transaction involving the "black-box" to obtain a site lock before executing any operations in the transaction. These types of locks will be managed by escalating any lock request to these sites to the highest level (site lock).

Data Replication Protocol

Communication Protocol. Maintaining the ACID properties of a transaction with replicated data in an MDAS environment is very difficult. The proposed scheme considers three levels of connectivity in which a mobile unit operates. During a *strong connection*, the mobile unit sends/receives all transactions and returns data directly to/from land-based, fixed sites for processing. When the communication link degrades to a *weak connection*, transactions are queued at the mobile unit and passed through the system according to the availability of bandwidth. Returned data are also queued at the fixed site. The queuing of operations during a weak connection allows a mobile unit to continue processing at the expense of increased latency.

In the disconnected state, a user may perform read-only queries on any cached data. For this case, the consistency of the data is not guaranteed, i.e., the user may receive stale data. Any transaction that contains a write operation is queued and submitted to the system when the connection is reestablished. Naturally, if a read-only access does not find the data locally, the query is queued and submitted later when the connection is established.

Cached Data—Bundled Queries (BUNQ). Data that are cached on the mobile unit consist of a query and its associated data. Several reasons exist for using a BUNQ instead of page-based or file-based data. In a tightly coupled distributed system, it is possible to cache data at the local unit. However, in a multi-database system, the structure of the data at the local databases will vary (*structural differences*—the information may be stored as structured data, unstructured data, web pages, files, objects, etc.). This variation of data at each local site makes it difficult to cache the data in a uniform manner. In addition, the *autonomy requirement* of the local database imposes further restrictions for caching data. It may not be possible to determine the underlying structure of the data at the local site without violating local autonomy requirements. Consequently, instead of caching individual data items from each local source, the data set associated with a particular transaction is cached—a bundled query. By caching a BUNQ, the resolution of the structural differences is done at the

MDAS level, while maintaining the local autonomy requirements. The primary advantage is the ease and simplicity of implementation, which comes at the expense of retaining data in the cache at a very coarse-grained level.

Prefetching and Replacement/Invalidation Policy

Prefetching. The prefetching algorithms can be developed based on user profiles and usage histories. The limited power, storage, processing capability, and bandwidth of a mobile unit make the incorrect prefetch of data extremely expensive. The idea is to prefetch enough data such that the user can still operate during a disconnection (albeit with relaxed consistency requirements) while minimizing the use of additional energy and bandwidth.

Allowing the user to specify a particular read-only transaction as an automated queued query prefetches the data. An AQ^2 has a relaxed requirement for consistency, which is defined by the user. The user sets a valid time threshold for each AQ^2 when defining such a transaction. The mobile unit automatically submits the transaction to the MDAS when the threshold has expired, i.e., prefetches the data. The results are stored as a BUNQ. If the user requests the data in the AQ^2 before the BUNQ is invalidated, the query is serviced from the local cache.

Replacement. The data in the cache consists of both automated queued queries and other user-submitted read-only queries. The data in the cache are replaced based on the least recently used (LRU) policy. The LRU policy has its advantages in that it is well understood and easy to implement. Moreover, other than some web-based caching algorithms, the LRU policy is the most widely used replacement policy in DBMS caches (13).

Invalidation. To maintain consistency between the copies of data residing on the fixed and mobile units, the data in the cache must be correctly invalidated when the main copy changes. A parity-based signature could be used to accomplish this task for each BUNQ in the cache (p-caching). When the user submits a transaction, if a corresponding BUNQ is present in the cache, the transaction (along with the parity code) is sent to the fixed node. The fixed node then performs the query and delays the transmission of the information back to the mobile unit until it generates and compares the two parity codes. If they are identical, only an acknowledgment is sent back to the mobile unit and the data are read locally from the cache. Otherwise, the resultant data, along with its new parity sequence, is returned and replaced in the cache. The old copy of the BUNQ is invalidated according to the LRU rules.

PERFORMANCE EVALUATION

Simulator Design

The performance of the proposed v-locking and p-caching algorithms was evaluated through a simulator written in C^{++} using CSIM. The simulator measures performance in terms of global transaction throughput, response time, and CPU, disk I/O, and network utilization. In addition, the simulator was extended to compare and contrast the behavior of the v-lock algorithm against the site-graph, potential conflict graph, and the forced conflict algorithms. This includes an evaluation with and without the cache. It should be noted that the simulator is designed to be versatile to evaluate the v-locking algorithm based on various system configurations. At each moment in time, a fixed number of active global and local transactions is present in the system. Each operation of the transaction is scheduled and is communicated to the local system based on the available bandwidth. The global scheduler acquires the necessary global virtual locks and processes the operation. The operation(s) then uses the CPU and I/O resources and is communicated to the local system based on the available bandwidth. When acknowledgments or commit/abort signals are received from the local site, the algorithm determines whether the transaction should proceed, commit, or abort. For read-only transactions after a global commit, a parity code is generated for the resultant data and compared with the parity code of the BUNQ. For a matching code, only an acknowldgment signal is sent back to the mobile unit. Otherwise, the data and the new parity code are sent back to the mobile unit. Transactions containing a write operation are placed directly in the ready queue. If a deadlock is detected, or an abort message is received from a local site, the transaction is aborted at all sites and the global transaction is placed in the restart queue. After a specified time elapses, the transaction is again placed on the active queue.

System Parameters

The underlying global information-sharing process is composed of 10 local sites. The size of the local databases at each site can be varied and has a direct effect on the overall performance of the system. The simulation is run for 5000 time units. The global workload consists of randomly generated global queries, spanning over a random number of sites. Each operation of a subtransaction (read, write, commit, or abort) may require data and/or acknowledgments to be sent from the local DBMS. The frequency of messages depends on the quality of the network link. To determine the effectiveness of the proposed algorithm, several parameters are varied for different simulation runs.

A collection of mobile units submits global queries (selected from a pool of 500 queries) to the MDAS. The connection between the mobile unit and the MDAS has a 50% probability of having a strong connection and a 30% probability of having a weak connection. There is a 20% probability of being disconnected. A strong connection has a communication service time of 0.1 to 0.3 seconds, whereas a weak connection has a service time range of 0.3 to 3 seconds. When a disconnection occurs, the mobile unit is disconnected for 30 to 120 seconds. Initially, one third of the pool consists of read-only queries, which are locally cached as a BUNQ. Additionally, 10% of the read-only queries are designated as an AQ^2. For read-only queries, the local cache is first checked for an existing BUNQ. If present, the query is submitted along with the associated parity sequence. The MDAS returns either the

data or an acknowledgment signal for a matching BUNQ. Subsequently, if signatures do not match, the mobile unit updates the cache with the new data according to the LRU scheme. Upon termination of a transaction, a new query is selected and submitted to the MDAS.

The local systems perform two types of transactions—local and global. Global subtransactions are submitted to the local DBMS and appear as local transactions. Local transactions generated at the local sites consist of a random number of read/write operations. The only difference between the two transactions is that a global subtransaction will communicate with the global system, whereas the local transaction terminates upon a commit or abort. The local system may abort a transaction, global or local, at any time. If a global subtransaction is aborted locally, it is communicated to the global system and the global transaction is aborted at all sites. Table 1 summarizes all parameters used in the simulation. It should be noted that Table 1 shows the default values; however, the simulator is flexible enough to simulate the behavior of the v-locking algorithm for various system parameters.

Simulation Results and Analysis

The v-locking algorithm has been simulated and compared against some other concurrency control algorithms, i.e., potential conflict graph (PCG), forced-conflict, and site-graph algorithms with and without the proposed p-caching scheme. Figures 1 and 2 show the results. As expected, the v-locking algorithm offers the highest throughput. This result is consistent with the fact that the v-locking algorithm is better able to detect global conflicts and thus

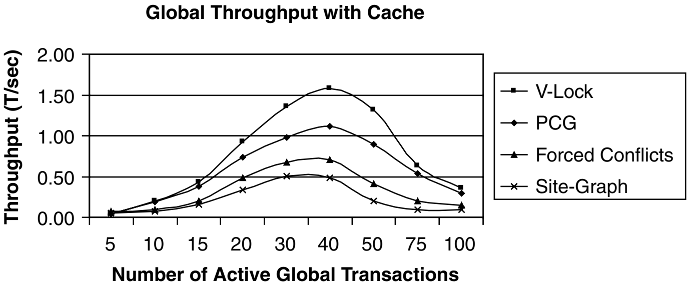

Figure 1. Global throughput with P-Caching.

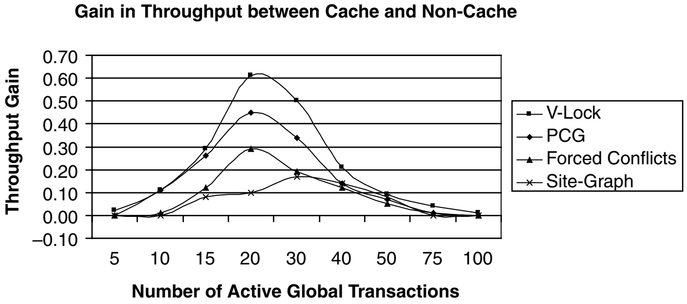

Figure 3. Comparison of the sensitivity of the P-Caching algorithm.

achieves higher concurrency than the other algorithms. As can be abserved, the maximum throughput occurs at a multi-programming level approximately equal to 40. As the number of concurrent global transactions increases, the number of completed global transactions decreases due to the increase in the number of conflicts. The peak throughput for each concurrency control scheme is slightly higher with the use of caching. Furthermore, for all simulated algorithms, the caching scheme allows a higher number of active global transactions and, hence, higher throughput. This characteristic is attributed to the cache hits on the read-only data. For the non-cache case, the throughput is low until the active number of global transactions reaches about 30, with a rapid increase of the throughput from 30 to 40 active transactions. This occurs because of the weak connections and disconnections. With the p-caching algorithm, the rate of the increase in throughput is more gradual because the local cache can service the read-only queries under weak connectivity or disconnection.

The gain in the throughput, sensitivity, of the p-caching algorithm for different concurrency control schemes, is shown in Fig. 3. The v-locking scheme shows the greatest sensitivity to the caching algorithm. At 20 active global transactions, there is an improvement in the throughput of approximately 0.6 when using a cache. At the peak throughput of 40 simultaneous transactions, the throughput is increased by 0.2. The PCG, site-graph, and forced conflict algorithms show similar characteristics to the v-locking algorithm; however, the sensitivity of these algorithms is less. The caching becomes ineffective for all schemes when the number of active global transactions is greater than 75.

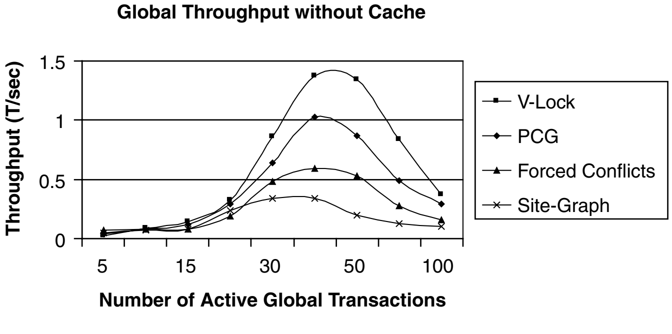

Figure 2. Global throughput without P-Caching.

The simulator also measured the percentage of completed transactions for the various concurrency control algorithms. In general, for all schemes, the number of completed transactions decreased as the number of concurrent transactions increased, due to more conflicts among the transactions. However, the performance of both the forced conflict and the site-graph algorithms decreased at a faster rate, which is due to the increase in the number of false aborts detected by these algorithms. The v-locking algorithm more accurately detects deadlocks by differentiating between global and indirect conflicts and, therefore, performs better than the PCG algorithm.

The simulator also measured the communication utilization. It was found that the communication utilization decreases with the use of the cache. At 20 active global transactions, the v-locking algorithm uses 40% of the communication bandwidth versus 69% utilization without the cache. Similarly, with 30 active global transactions, there is a 75% versus 91% communication utilization with and without the cache, respectively. This result is attributed to the reduction in transferred data from parity acknowledgments and local accesses to the cache. At peak throughput, both locking algorithms (v-locking and PCG) were using nearly 100% of the communication channel. The communication utilization was about 100% at peak throughput and decreased slightly as the number of concurrent transactions increased. It is easy to determine from this result that the communication requirements for the v-locking algorithm represent the bottleneck of the system for both the caching and the non-caching case.

FUTURE RESEARCH DIRECTIONS

The requirements of an "anytime, anywhere" computing environment motivate new concepts that effectively allow a user to access information in a timely and reliable manner. In such an environment, a potentially large number of users may simultaneously access a rapidly increasing amount of aggregate, distributed data. This usage motivates the need for a proper concurrency control algorithm that offers higher throughput in the face of the limitations imposed by technology. A distributed, hierarchically organized concurrency control algorithm was presented and evaluated that satisfies these limitations. The semantic information contained within the SSM was used to maintain the global locking tables to serialize conflicting operations of global transactions and to detect and break deadlocked transactions. Data duplication in the form of replication and caches was also used to lessen the effects of weak communications or disconnection. The duplicated data at the mobile node allow the user to continue to work in case of a weak connection or disconnection. Automated queued queries and bundled queries could be used to address the limited bandwidth and local autonomy restrictions in an MDAS environment.

The work presented in this article can be extended in several directions:

- *Application of mobile agents*: Recently the literature has shows a growing interest in the application and incorporation of mobile agent paradigm in an information retrieval system (14). When mobile agents are introduced into the system, mobile agents can roam the network and fulfill their tasks without the owner's intervention; consequently, mobile users only need to maintain the communication connection during the agent submission and retraction. In addition, by migrating from the mobile device to the core network, the agents can take full advantage of the high bandwidth of the wired portion of the network and the high computation capability of servers/workstations. Moreover, mobile agents' migration capability allows them to handle tasks locally instead of passing messages between the involved data sources and, hence, reduce the number of messages that are needed in accomplishing a task. To summarize, the use of mobile agents relaxes requirements on mobile users' critical resources such as connectivity, bandwidth, and energy. Therefore, within the scope of the MDAS, it would be of interest to investigate concurrency control algorithms at the presence of the mobile agents in the system.
- *Multimedia databases*: The demand of image data management has raised the research on content-based retrieval models (15, 16). In contrast to the traditional text-based systems, these applications usually consist of a large volume of image data whose semantic contents cannot be represented efficiently using the traditional database models. Most of the present content-based image retrieval approaches employ the feature vectors to facilitate content-based query processing—the features are extracted from image pixels, heuristically or empirically, and combined into vectors according to the application criterion. However, these low-level features cannot represent the semantic contents and therefore do not provide an ideal basis for semantic-based image retrieval. To introduce novel schemes to facilitate semantic-based image content query/transaction management in a distributed heterogeneous database environment, i.e., MDAS, will be of great interest to both academia and industry.
- *Quality-of-Service Cache Coherence*: The p-caching strategy showed promising results in improving the performance of the read-only query and hence overall system's throughput. The effect of the cache on the MDAS environment should be studied. This could be done by changing the cache-hit ratio to a raw probability that a read-only query is valid or invalid. A quality-of-service QOS approach is ideally suited for such a general-purpose cache coherence protocol, providing strong consistency for those data items that require it while permitting weaker consistency for less critical data (12). Therefore, it would be interesting to investigate the effectiveness of such a QOS approach on the performance metrics that determine the effectiveness of the concurrency control policies.

VERY LARGE DATABASES

A growing number of database applications require online, interactive access to very large volumes of data to perform a variety of data analysis tasks. As an example, large telecommunication and Internet service providers typically collect and store Gigabytes or Terabytes of detailed usage information (Call Detail Records, SNMP/RMON packet flow data, etc.) from the underlying network to satisfy the requirements of various network management tasks, including billing, fraud/anomaly detection, and strategic planning. Such large datasets are typically represented either as massive *alphanumeric data tables* (in the relational data model) or as massive *labeled data graphs* (in richer, semistructured data models, such as extensible markup language (XML)). In order to deal with the huge data volumes, high query complexities, and interactive response time requirements characterizing these modern data analysis applications, the idea of *effective, easy-to-compute approximations over precomputed, compact data synopses* has recently emerged as a viable solution. Due to the exploratory nature of most target applications, there are a number of scenarios in which a (reasonably accurate) fast approximate answer over a small-footprint summary of the database is actually preferable over an exact answer that takes hours or days to compute. For example, during a drill-down query sequence in ad hoc data mining, initial queries in the sequence frequently have the sole purpose of determining the truly interesting queries and regions of the database. Providing fast approximate answers to these initial queries gives users the ability to focus their explorations quickly and effectively, without consuming inordinate amounts of valuable system resources. The key, of course, behind such approximate techniques for dealing with massive datasets lies in the use of appropriate *data reduction techniques* for constructing compact *data synopses* that can accurately approximate the important features of the underlying data distribution. In this article, we provide an overview of date reduction and approximation methods for massive databases and discuss some of the issues that develop from different types of data, large data volumes, and applications-specific requirements.

APPROXIMATION TECHNIQUES FOR MASSIVE RELATIONAL DATABASES

Consider a relational table R with d data attributes X_1, $X_2, \dots X_d$. We can represent the information in R as a d-dimensional array A_R , whose *jth* dimension is indexed by the values of attribute X_j and whose cells contain the count of tuples in R having the corresponding combination of attribute values. A_R is essentially the *joint frequency distribution* of all the data attributes of R. More formally, let $D = \{D_1, D_2, \dots, D_d\}$ denote the set of dimensions of A_R, where dimension D_j corresponds to the *value domain* of attribute X_j . Without loss of generality, we assume that each dimension D_j is indexed by the set of integers $\{0, 1, \dots, |D_j| - 1\}$, where $|D_j|$ denotes the size of dimension D_j. We assume that the attributes $\{X_1, \dots, X_d\}$ are ordinal in nature, that is, their domains are naturally ordered, which captures all numeric attributes (e.g., age, income) and some categorical attributes (e.g., education). Such domains can always be mapped to the set of integers mentioned above while preserving the natural domain order and, hence, the locality of the distribution. It is also possible to map unordered domains to integer values; however, such mappings do not always preserve locality. For example, mapping countries to integers using alphabetic ordering can destroy data locality. There may be alternate mappings that are more locality preserving, (e.g., assigning neighboring integers to neighboring countries). (Effective mapping techniques for unordered attributes are an open research issue that lies beyond the scope of this article.) The d-dimensional joint-frequency array A_R comprises $N = \Pi_{i=1}^{d} |D_i|$ cells with cell $A_R[i_1, i_2, \dots, i_d]$ containing the count of tuples in R having $X_j = i_j$ for each attribute $1 \le j \le d$.

The common goal of all relational data reduction techniques is to produce compact synopsis data structures that can effectively approximate the d-dimensional joint-frequency distribution A_R. In what follows, we give an overview of a few key techniques for relational data reduction, and discuss some of their main strengths and weaknesses as well as recent developments in this area of database research. More exhaustive and detailed surveys can be found elsewhere; see, for example, Refs. 1 and 2.

Sampling-Based Techniques

Sampling methods are based on the notion that a large dataset can be represented by a small *uniform random sample* of data elements, an idea that dates back to the end of the nineteenth century. In recent years, there has been increasing interest in the application of sampling ideas as a tool for data reduction and approximation in relational database management systems (3–8). Sample synopses can be either precomputed and incrementally maintained (e.g., Refs. 4 and 9) or they can be obtained progressively at run-time by accessing the base data using specialized data access methods (e.g., Refs. 10 and 11). Appropriate *estimator functions* can be applied over a random sample of a data collection to provide approximate estimates for quantitative characteristics of the entire collection (12). The adequacy of sampling as a data-reduction mechanism depends crucially on how the sample is to be used. Random samples can typically provide accurate estimates for aggregate quantities (e.g., COUNTs or AVERAGEs) of a (sub)population (perhaps determined by some selection predicate), as witnessed by the long history of successful applications of random sampling in population surveys

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

(12,13). An additional benefit of random samples is that they can provide probabilistic guarantees (i.e., *confidence intervals*) on the quality of the approximation (7,11). On the other hand, as a query approximation tool, random sampling is limited in its query processing scope, especially when it comes to the "workhorse" operator for correlating data collections in relational database systems, the *relational join*. The key problem here is that a join operator applied on two uniform random samples results in a *nonuniform* sample of the join result that typically contains *very few tuples*, even when the join selectivity is fairly high (9). Furthermore, for *nonaggregate* queries, execution over random samples of the data is guaranteed to always produce a small subset of the exact answer, which is often *empty* when joins are involved (9,14). The recently proposed "join synopses" method (9) provides a (limited) sampling-based solution for handling *foreign-key joins that are known beforehand* (based on an underlying "star" or "snowflake" database schema). Techniques for appropriately biasing the base-relation samples for effective approximate join processing have also been studied recently (3).

Histogram-Based Techniques

Histogram synopses or approximating *one-dimensional* data distributions have been extensively studied in the research literature (15–19), and have been adopted by several commercial database systems. Briefly, a histogram on an attribute X is constructed by employing a *partitioning rule* to partition the data distribution of X into a number of mutually disjoint subsets (called *buckets*), and approximating the frequencies and values in each bucket in some common fashion. Several partitioning rules have been proposed for the bucketization of data distribution points—some of the most effective rules seem to be ones that explicitly try to minimize the overall variance of the approximation in the histogram buckets (17–19). The summary information stored in each bucket typically comprises (1) *the number of distinct data values* in the bucket, and (2) *the average frequency* of values in the bucket, which are used to approximate the actual bucket contents based on appropriate *uniformity assumptions* about the spread of different values in the bucket and their corresponding frequencies (19).

One-dimensional histograms can also be used to approximate a (multidimensional) joint-frequency distribution A_R through a *mutual-independence assumption* for the data attributes $\{X_1, \ldots, X_d\}$. Mutual independence essentially implies that the joint-frequency distribution can be obtained as a product of the one-dimensional marginal distributions of the individual attributes X_i. Unfortunately, experience with real-life datasets offers overwhelming evidence that this independence assumption is almost always invalid and can lead to gross approximation errors in practice (20,21). Rather than relying on heuristic independence assumptions, *multidimensional histograms* [originally introduced by Muralikrishna and DeWitt (22)] try to directly approximate the joint distribution of $\{X_1,\ldots, X_d\}$ by strategically partitioning the data space into d-dimensional buckets in a way that captures the variation in data frequencies and values. Similar to the one-dimensional case, uniformity assumptions are made to approximate the distribution of frequencies and values within each bucket (21). Finding optimal histogram bucketizations is a hard optimization problem that is typically *NP*-complete even for two dimensions (23). Various greedy heuristics for multidimensional histogram construction have been proposed (21,22,24) and shown to perform reasonably well for low to medium data dimensionalities (e.g., $d = 2$–5).

Recent work has demonstrated the benefits of histogram synopses (compared with random samples) as a tool for providing fast, approximate answers to both *aggregate* and *nonaggregate* (i.e., "set-valued") user queries over low-dimensional data (14). Other studies have also considered the problem of *incrementally* maintaining a histogram synopsis over updates (25,26) or using query feedback (27,28), and the effectiveness of random sampling for approximate histogram construction (29). Unfortunately, like most techniques that rely on space partitioning (including the wavelet-based techniques of the next section), multidimensional histograms also fall victim to the "*curse of dimensionality*," which renders them ineffective above 5–6 dimensions (24).

Wavelet-Based Techniques

Wavelets are a mathematical tool for the hierarchical decomposition of functions with several successful applications in signal and image processing (30,31). Broadly speaking, the wavelet decomposition of a function consists of a coarse overall approximation along with detail coefficients that influence the function at various scales (31). A number of recent studies have also demonstrated the effectiveness of the wavelet decomposition (and Haar wavelets, in particular) as a data reduction tool for database problems, including selectivity estimation (32) and approximate query processing over massive relational tables (33–35).

Suppose we are given the one-dimensional data frequency vector A containing the $N = 8$ values $A = [2, 2, 0, 2, 3, 5, 4, 4]$. The Haar wavelet decomposition of A can be computed as follows. We first average the values together pairwise to get a new "lower-resolution" representation of the data with the following average values [2,1,4,4]. In other words, the average of the first two values (that is, 2 and 2) is 2, that of the next two values (that is, 0 and 2) is 1, and so on. Obviously, some information has been lost in this averaging process. To be able to restore the original values of the frequency array, we need to store some *detail coefficients* that capture the missing information. In Haar wavelets, these detail coefficients are simply the differences of the (second of the) averaged values from the computed pairwise average. Thus, in our simple example, for the first pair of averaged values, the detail coefficient is 0 because $2 - 2 = 0$; for the second sample, we again need to store -1 because $1 - 2 = -1$. Note that no information has been lost in this process—it is fairly simple to reconstruct the eight values of the original data frequency array from the lower-resolution array containing the four averages and the four detail coefficients. Recursively applying the above pairwise averaging and differencing process on the lower-resolution array containing the averages, we get the following full decomposition:

Resolution	Averages	Detail Coefficients
3	[2, 2, 0, 2, 3, 5, 4, 4]	—
2	[2, 1, 4, 4]	[0, −1, −1, 0]
1	[3/2, 4]	[1/2, 0]
0	[11/4]	[−5/4]

The *Haar wavelet decomposition* of A is the single coefficient representing the overall average of the frequency values followed by the detail coefficients in the order of increasing resolution. Thus, the one-dimensional Haar wavelet transform of A is given by $W_A = [11/4, -5/4, 1/2, 0, 0, -1, -1, 0]$. Each entry in W_A is called a *wavelet coefficient*. The main advantage of using W_A instead of the original frequency vector A is that for vectors containing similar values most of the detail coefficients tend to have very small values. Thus, eliminating such small coefficients from the wavelet transform (i.e., treating them as zeros) introduces only small errors when reconstructing the original data, resulting in a very effective form of lossy data compression (31). Furthermore, the Haar wavelet decomposition can also be extended to *multidimensional* joint-frequency distribution arrays through natural generalizations of the one-dimensional decomposition process described above (33,35). Thus, the key idea is to apply the decomposition process over an input dataset along with a thresholding procedure in order to obtain a compact data synopsis comprising of a selected small set of *Haar wavelet coefficients*. The results of several research studies (32–37) have demonstrated that fast and accurate approximate query processing engines (for both aggregate and nonaggregate queries) can be designed to operate solely over such compact *wavelet synopses*.

Other recent work has proposed probabilistic counting techniques for the efficient online maintenance of wavelet synopses in the presence of updates (38), as well as time- and space-efficient techniques for constructing wavelet synopses for datasets with multiple measures (such as those typically found in OLAP applications) (39). All the above-mentioned studies rely on conventional schemes for eliminating small wavelet coefficients in an effort to minimize the overall sum-squared error (SSE). Garofalakis and Gibbons (34,36) have shown that such conventional wavelet synopses can suffer from several important problems, including the introduction of severe bias in the data reconstruction and wide variance in the quality of the data approximation, as well as the lack of nontrivial guarantees for individual approximate answers. In contrast, their proposed *probabilistic wavelet synopses* rely on a probabilistic thresholding process based on *randomized rounding* that tries to *probabilistically* control the maximum relative error in the synopsis by minimizing appropriate probabilistic metrics.

In more recent work, Garofalakis and Kumar (40) show that the pitfalls of randomization can be avoided by introducing efficient schemes for *deterministic* wavelet thresholding with the objective of optimizing a *general class of error metrics* (e.g., maximum or mean relative error). Their optimal and approximate thresholding algorithms are based on novel Dynamic-Programming (DP) techniques that take advantage of the *coefficient-tree structure* of the Haar decomposition. This turns out to be a fairly powerful idea for wavelet synopsis construction that can handle a broad, natural class of *distributive error metrics* (which includes several useful error measures for approximate query answers, such as maximum or mean weighted relative error and weighted L_p-norm error) (40). The above wavelet thresholding algorithms for non-SSE error metrics consider only the *restricted* version of the problem, where the algorithm is forced to select values for the synopsis from the standard Haar coefficient values. As observed by Guha and Harb (41), such a restriction makes little sense when optimizing for non-SSE error, and can, in fact, lead to suboptimal synopses. Their work considers *unrestricted* Haar wavelets, where the values retained in the synopsis are specifically chosen to optimize a general (weighted) L_p-norm error metric. Their proposed thresholding schemes rely on a DP over the coefficient tree (similar to that in (40) that *also iterates over the range of possible values for each coefficient*. To keep time and space complexities manageable, techniques for bounding these coefficient-value ranges are also discussed (41).

Advanced Techniques

Recent research has proposed several sophisticated methods for effective data summarization in relational database systems. Getoor et al. (42) discuss the application of *Probabilistic Relational Models (PRMs)* (an extension of Bayesian Networks to the relational domain) in computing accurate selectivity estimates for a broad class of relational queries. Deshpande et al. (43) pro-posed *dependency-based histograms*, a novel class of histogram-based synopses that employs the solid foundation of *statistical interaction models* to explicitly identify and exploit the statistical characteristics of the data and, at the same time, address the dimensionality limitations of multidimensional histogram approximations. Spiegel and Polyzotis (44) propose the Tuple-Graph synopses that view the relational database as a semi-structured data graph and employ summarization models inspired by XML techniques in order to approximate the joint distribution of join relationships and values. Finally, Jagadish et al. (45) and Babu et al. (46) develop semantic compression techniques for massive relational tables based on the idea of extracting *data mining models* from an underlying data table, and using these models to effectively compress the table to within user-specified, per-attribute error bounds.

Traditional database systems and approximation techniques are typically based on the ability to make multiple passes over *persistent datasets* that are stored reliably in stable storage. For several emerging application domains, however, data arrives at high rates and needs to be processed on a continuous (24 × 7) basis, without the benefit of several passes over a static, persistent data image. Such *continuous data streams* occur naturally, for example, in the network installations of large telecom and Internet service providers where detailed usage information (call detail records (CDRs), SNMP/RMON packet-flow data, etc.) from different parts of the underlying network needs to be continuously collected and analyzed for interesting trends. As a result, we are witnessing a recent surge of interest in data stream computation, which has led to several (theoretical and practical) studies proposing novel one-pass algorithms for effectively summarizing massive relational data streams in a limited amount of memory (46–55).

APPROXIMATION TECHNIQUES FOR MASSIVE XML DATABASES

XML (56) has rapidly evolved from a markup language for web documents to an emerging standard for data exchange and integration over the Internet. The simple, self-describing nature of the XML standard promises to enable a broad suite of next-generation Internet applications, ranging from intelligent web searching and querying to electronic commerce. In many respects, XML represents an instance of *semistructured data* (57): The underlying data model comprises a labeled graph of *element* nodes, where each element can be either an atomic data item (i.e., raw character data) or a composite data collection consisting of references (represented as graph edges) to other elements in the graph. More formally, an XML database can be modeled as a directed graph $G(V_G, E_G)$, where each node $u \in V_G$ corresponds to a document element, or an element attribute, with label `label`(u). If u is a leaf node, then it can be associated with a value `value`(u). An edge (u, v) denotes either the nesting of v under u in the XML document, or a reference from u to v, through `ID/IDREF` attributes or XLink constructs (58–60).

XML query languages use two basic mechanisms for navigating the XML data graph and retrieving qualifying nodes, namely, *path expressions* and *twig queries*. A path expression specifies a sequence of navigation steps, where each step can be predicated on the existence of sibling paths or on the value content of elements, and the elements at each step can be linked through different structural relationships (e.g., parent-child, ancestor-child, or relationships that involve the order of elements in the document). As an example, the path expression `//author [/book//year = 2003] //paper` will select all paper elements with an author ancestor, which is the root of at least one path that starts with book and ends in year, and the value of the ending element is 2003. The example expression is written in the XPath (61) language, which lies at the core of XQuery (62) and XSLT (63), the dominant proposals from W3C for querying and transforming XML data.

A twig query uses multiple path expressions in order to express a complex navigation of the document graph and retrieve combinations of elements that are linked through specific structural relationships. As an example, consider the following twig query, which is expressed in the XQuery (62) language: `for $a in //author, $p in $a//paper/title, $b in $a//book/title`. The evaluation of the path expressions proceeds in a nested-loops fashion, by using the results of "parent" paths in order to evaluate "nested" paths. Thus, the first expression retrieves all authors, and, for each one, the nested paths retrieve the titles of their papers and books. The final result contains all possible combinations of an author node, with a paper title node and a book title node that it reaches. Twig queries represent the equivalent of the SQL `FROM` clause in the XML world, as they model the generation of element tuples, which will eventually be processed to compute the final result of the XML query.

The goal of existing XML data reduction techniques is to summarize, in limited space, the key statistical properties of an XML database in order to provide *selectivity estimates* for the result size of path expressions or twig queries. Selectivity estimation is a key step in the optimization of declarative queries over XML repositories and is thus key for the effective implementation of high-level query languages (64–66). Given the form of path expressions and twig queries, an effective XML summary needs to capture accurately both the path structure of the data graph and the value distributions that are embedded therein. In that respect, summarizing XML data is a more complex problem than relational summarization, which focuses mainly on value distributions. As with any approximation method, the proposed XML techniques store compressed distribution information on specific characteristics of the data, and use statistical assumptions in order to compensate for the loss of detail due to compression. Depending on the specifics of the summarization model, the proposed techniques can be broadly classified in three categories: (1) techniques that use a graph synopsis, (2) techniques that use a relational summarization method, such as histograms or sampling, and (3) techniques that use a Markovian model of path distribution. It should be noted that, conceptually, the proposed summarization techniques can also be used to provide approximate answers for XML queries; this direction, however, has not been explored yet in the current literature and it is likely to become an active area of research in the near future.

Graph-Synopsis-Based Techniques

At an abstract level, a graph synopsis summarizes the basic path structure of the document graph. More formally, given a data graph $G = (V_G, E_G)$, a graph synopsis $S(G) = (V_S, E_S)$ is a directed node-labeled graph, where (1) each node $v \in V_S$ corresponds to a subset of element (or attribute) nodes in V_G (termed the *extent* of) that have the *same label*, and (2) an edge in $(u, v) \in E_G$ is represented in E_S as an edge between the nodes whose extents contain the two endpoints u and v. For each node u, the graph synopsis records the common tag of its elements and a count field for the size of its extent.

In order to capture different properties of the underlying path structure and value content, a graph synopsis is augmented with appropriate, localized distribution information. As an example, the structural XSKETCH-summary mechanism (67), which can estimate the selectivity of simple path expressions with branching predicates, augments the general graph-synopsis model with localized per-edge stability information, indicating whether the synopsis edge is *backward-stable or forward-stable*. In short, an edge (u, v) in the synopsis is said to be *forward-stable* if all the elements of u have at least one child in v; similarly, (u, v) is backward-stable if all the elements in v have at least one parent in u [note that backward/forward (B/F) stability is essentially a localized form of *graph bisimilarity* (68)]. Overall, edge stabilities capture key properties of the connectivity between different synopsis nodes and can summarize the underlying *path structure* of the input XML data.

In a follow-up study (69), the structural XSketch model is augmented with localized per-node value distribution summaries. More specifically, for each node u that represents elements with values, the synopsis records a summary $H(u)$, which captures the corresponding value distribution and thus enables selectivity estimates for value-based predicates. Correlations among different value distributions can be captured by a multidimensional summary $H(u)$, which approximates the *joint* distribution of values under u and under different parts of the document. It should be noted that, for the single-dimensional case, $H(u)$ can be implemented with any relational summarization technique; the multidimensional case, however, imposes certain restrictions due to the semantics of path expressions, and thus needs specialized techniques that can estimate the number of *distinct* values in a distribution [examples of such techniques are range-histograms (69), and distinct sampling (70)].

The TwigXSketch (71) model is a generalization of the XSketch synopses that deals with selectivity estimation for twig queries. Briefly, the key idea in TwigXSketches is to capture, in addition to localized stability information, the distribution of document edges for the elements in each node's extent. In particular, each synopsis node records an *edge histogram*, which summarizes the distribution of child counts across different stable ancestor or descendant edges. As a simple example, consider a synopsis node u and two emanating synopsis edges (u, v) and (u, w); a two-dimensional edge histogram $H_u(c_1, c_2)$ would capture the fraction of data elements in $\mathtt{extent}(u)$ that have exactly c_1 children in $\mathtt{extent}(v)$ and c_2 children in $\mathtt{extent}(w)$. Overall, TwigXSketches store more fine-grained information on the path structure of the data, and can thus capture, in more detail, the *joint* distribution of path counts between the elements of the XML dataset.

Recent studies (73–75) have proposed a variant of graph-synopses that employ a clustering-based model in order to capture the path and value distribution of the underlying XML data. Under this model, each synopsis node is viewed as a "cluster" and the enclosed elements are assumed to be represented by a corresponding "centroid," which is derived in turn by the aggregate characteristics of the enclosed XML elements. The TreeSketch (72) model, for instance, defines the centroid of a node u_i as a vector of average child counts $(c_1, c_2, \cdots, c_n)$, where c_j is the average child count from elements in A_i to every other node u_j. Thus, the assumption is that each element in u_i has exactly c_j children to node u_j. Furthermore, the clustering error, that is, the difference between the actual child counts in u_i and the centroid, provides a measure of the error of approximation. The TreeSketch study has shown that a partitioning of elements with low clustering error provides an accurate approximation of the path distribution, and essentially enables low-error selectivity estimates for structural twig queries. A follow-up study has introduced the XClusters (73) model that extends the basic TreeSketch synopses with information on element content. The main idea is to augment the centroid of each cluster with a value-summary that approximates the distribution of values in the enclosed elements. The study considers three types of content: numerical values queried with range predicates, string values queried with substring predicates, and text values queried with term-containment predicates. Thus, the key novelty of XClusters is that they provide a unified platform for summarizing the structural and heterogeneous value content of an XML data set. Finally, Zhang et al. have proposed the XSeed (74) framework for summarizing the recursive structure of an XML data set. An XSeed summary resembles a TreeSketch synopsis where all elements of the same tag are mapped to a single cluster. The difference is that each synopsis edge may be annotated with multiple counts, one per recursive level in the underlying data. To illustrate this, consider an element path $/e_1/e'_1/e_2/e'_2$ where e_1 and e_2 correspond to cluster u and e'_1 and e'_2 to cluster u'. The sub-path e_1/e'_1 will map to an edge between u and u' and will contribute to the first-level child count. The sub-path e_2/e'_2 will map to the same edge, but will contribute to the second-level child count from u to u'. Hence, XSeed stores more fine-grained information compared to a TreeSketch synopsis that uses a single count for all possible levels. This level-based information is used by the estimation algorithm in order to approximate more accurately the selectivity of recursive queries (i.e., with the "//" axis) on recursive data.

Histogram- and Sampling-Based Techniques

Several XML-related studies attempt to leverage the available relational summarization techniques by casting the XML summarization problem into a relational context. More specifically, the proposed techniques represent the path structure and value content of the XML data in terms of flat value distributions, which are then summarized using an appropriate relational technique.

The StatiX (75) framework uses histogram-based techniques and targets selectivity estimation for twig queries over tree-structured data (note, however, that StatiX needs the schema of the XML data in order to determine the set of histograms, which makes the technique nonapplicable to the general case of schema-less documents). StatiX partitions document elements according to their schema type and represents each group as a set of (*pid*, *count*) pairs, where *pid* is the id of some element p and *count* is the number of elements in the specific partition that have p as parent. Obviously, this scheme encodes the joint distribution of children counts for the elements of each partition. This information is then compressed using standard relational histograms, by treating *pid* as the value and *count* as the frequency information.

A similar approach is followed in *position histograms* (76), which target selectivity estimation for two-step path expressions of the form A//B. In this technique, each element is represented as a point (s, e) in 2-dimensional space, where s and e are the start and end values of the element in the depth-first traversal of the document tree; thus, (s_a, e_a) is an ancestor of (s_b, e_b), if $s_a < s_b < e_b < e_a$. The proposed summarization model contains, for each tag in the document, one spatial histogram that summarizes the distribution of the corresponding element points. A spatial join between histograms is then sufficient to approximate the ancestor-descendant relationship between elements of different tags.

A recent study (77) has introduced two summarization models, namely the Position Model and the Interval Model, which are conceptually similar to position histograms but use a different encoding of structural relationships. Again, the focus is on selectivity estimation for two-step paths of the form A//B. The Position Model encodes each element in A as a point (s_a, e_a), and each element in B as a point s_b; the selectivity is then computed as the number of s_b points contained under an (s_a, e_a) interval. In the Interval Model, a covering matrix C records the number of points in A whose interval includes a specific start position, whereas a position matrix P includes the start positions of elements in B; the estimate is then computed by joining the two tables and summing up the number of matched intervals. Clearly, both models reduce the XML estimation problem to operations on flat value distributions, which can be approximated using relational summarization techniques.

Markov-Model-Based Techniques

At an abstract level, the path distribution of an XML dataset can be modeled with the probability of observing a specific tag as the next step of an existing path. Recent studies have investigated data reduction techniques that summarize the path structure by approximating, in limited space, the resulting path probability distribution. The principal idea of the proposed techniques is to compress the probability distribution through a Markovian assumption: If p is a path that appears in the document and l is a tag, then the probability that p/l is also a path depends only on a suffix $\bar{p}$ of p (i.e., the next step is not affected by distant ancestor tags). Formally, this assumption can be expressed as $P[p/l] = P[p] \cdot P[l|\bar{p}]$, where $P[q]$ is the probability of observing path q in the data. Of course, the validity of this independence assumption affects heavily the accuracy of the summarization methods.

Recent studies (78,79) have investigated the application of a k-order Markovian assumption, which limits the statistically correlated suffix of p to a maximum predefined length of k. Thus, only paths of length up to k need to be stored in order to perform selectivity estimation. The proposed techniques further compress this information with a *Markov histogram*, which records the most frequently occurring such paths. Less frequent paths are grouped together, either according to their prefix (if the aggregate frequency is high enough), or in a generic ’*’ bucket. In order to estimate the occurrence probability of a longer path, the estimation framework identifies subpaths that are present in the Markov histogram and combines the recorded probabilities using the Markovian independence assumption.

Correlated Suffix Trees (CSTs) (80) employ a similar Markovian assumption in order to estimate the selectivity of twig queries. The path distribution of the document is stored in a tree structure, which records the most frequently occurring suffixes of root-to-leaf paths; thus, the tree encodes frequent paths of variable lengths, instead of using a predefined fixed length as the Markov Histogram approach. In addition to frequent path suffixes, the summary records a *hash signature* for each outgoing path of a tree node, which encodes the set of elements in the node’s extent that have at least one matching outgoing document path. Intuitively, an “intersection” of hash signatures, where each signature corresponds to a different label path, approximates the number of elements that have descendants along all represented paths. Combined with path frequency information, this information yields an approximation of the joint path-count distribution for different subsets of document elements.

VISUAL DATABASE

INTRODUCTION

We humans are most adept and comfortable with visual information, using our vision for routine activities as well as for sophisticated reasoning and planning. The increased use of images, video, and graphics in computing environments has catalyzed the development of data management tools for accessing, retrieving, and presenting visual information or alphanumeric information in visual ways. Some of these tools are developed to create, store, and retrieve visual data in the form of images or video to realize advanced multimedia applications. Other tools use extensively visual representation in user interfaces and provide essential visual mechanisms to access alphanumeric or visual data in databases. The development of these tools involves concepts, algorithms, and techniques from diversified fields such as database management systems, image processing, information retrieval, and data visualization. Consequently, the field of visual database represents several diversified areas. These areas include at least the following:

1. Database systems to manage visual information in the form of images, video, or geometric entities; that is, the data subject is visual.
2. Visual interfaces to query databases; that is, the query interface is visual.
3. Visual interfaces to interpret information retrieved from databases; that is, the data presentation is visual.

The first area is related closely to the study of image and multimedia databases. The second area has an impact beyond databases and has been studied in programming languages and programming environments. The third area is the focus of data visualization study. These areas are related closely with each other: The management of visual data needs visual queries and visual presentation of query results; on the other hand, the last two areas are applicable not only to databases managing visual data but also to alphanumeric databases. This article focuses on the first area and the visual query interfaces of databases in the first area. In other words, this article introduces principles and techniques developed for the management of visual data and techniques on visual interfaces to formulate queries against databases that manage the visual data.

In a database system that manages visual data, many issues exist to consider beyond those in alphanumeric databases. Using image database as an example, these issues typically include:

- Image features—what image features are most useful in each particular application?
- Content-based retrieval—how are images searched effectively and efficiently based on image contents?
- Storage and indexing—what are the proper storage techniques for large amounts of image data, and what are the proper indexing techniques to support content-based retrieval of image data?
- User interface—how should the user browse and search for images? What is a suitable user interface? How is an image database made accessible through the World Wide Web?

Other issues include those unique to visual databases in query processing, transaction management, and database recovery. In recent years, researchers have paid attention to bridging the semantic gap between low-level image features and high-level semantic concepts. This article gives an overview of principles and techniques on these topics. Given the broad and fast-expanding nature of this field, we are bound to have omitted significant contents and references. In addition, we devote a disproportionate amount of attention to some issues at the expense of others. It is better to introduce basic concepts and techniques well rather than to give a quick run-through of broad topics. To give real-world examples, nevertheless, this article presents an overview of three visual database systems. For more comprehensive coverage and technical details, interested readers are invited to consult the survey papers listed in the last section.

HISTORY AND THE STATE OF THE ART

Database management systems, especially relational database management systems, have been extensively studied in the past 40 years. Rigorous theory has been discovered, and efficient techniques have been developed for the management of alphanumeric data. When new types of data such as images and video were first brought into a database environment, it was natural that the data needed to be transformed so that they could be represented in existing database management systems. In a relational database, therefore, visual data are usually represented by their alphanumeric attributes, which are stored as tuples over relations. Kunii et al. (1) first attempted extending a relational database scheme to accommodate visual information by describing the color and textural properties of images. Physical visual data were stored in a separate storage and were linked through references to their tuples in the relational database. The alphanumeric attributes of a visual object are called *features* of the object. The features, which act together as a proxy of the object, are used in answering a user's queries. In the 1970s and the early 1980s, several image database systems (2–5) were developed to manage images and graphics using relational databases. Researchers believed initially that this setting is all what they would need for the management of visual data. They also believed

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

that most relational database techniques, including indexing, query optimization, concurrency control, and recovery, would also work in parallel in the intended environments of visual data management.

It was only after some experience working with visual data that researchers realized the mismatch between the nature of visual data and the way both the user and the system were forced to query and operate on them. One major technical challenge to visual database management is data retrieval. The creation of mere visual data repositories is of little value unless methods are available for flexible retrieval of visual data based on their contents. *Content-based retrieval* means that the search will analyze the actual contents of the image. The term "content" in this context might refer to image features, such as colors, shapes, textures, or any other information that can be derived from the image itself. Without the ability to examine image content, searches must rely on textual information, such as captions or keywords, which in many applications have to be entered manually for every image in the database.

The way people access visual information is fundamentally different to the way they access alphanumeric information. Relational queries and operations are not enough for querying visual data, for which browsing, descriptive query, and query by examples are important query paradigms. Therefore, unique issues in visual database query include how to support the content-based retrieval, how to support image manipulations such as browsing and zooming, and how to support image processing operations for feature extraction. Visual database systems differentiate from each other in their ways to work around these issues. As an example, the QBIC (6) system has a visual user interface in which queries are posed by drawing, selection, and other graphical means. It supports image queries using image features such as color, texture, shape, and motion of images and video. Researchers also attempted to manage geometric and spatial data in relational databases. For example, PSQL (7) extends the relational model in a disciplined way over three spatial data types: points, line segments, and regions. Geometric and spatial data pose unique problems to visual data management. These problems include storage and indexing of spatial data and database query supported by spatial operations.

For relational databases, a classic example of a visual query interface is QBE (8). It is a very user-friendly tabular query language based on domain relational calculus. To formulate a query, a user enters example elements and fills out tables supplied by the system. QBE has influenced the graphical query facilities in modern database products, particularly personal database software. As an extension of QBE to the image database, QPE (9) introduced built-in support of image operations. PICQUERY (10) proposed a comprehensive list of image operations that should be supported by an image database system and classified these operations into image manipulation operations, pattern recognition operations, spatial operations, function operations, user-defined operations, and input/output operations.

After the development of object-oriented databases and logical databases, attempts were made to deal with semantic modeling of images with complex structures (11) and logic for visual databases (12). PROBE (13) is a spatial object-oriented database system whose data model supports two basic types of data, objects and functions, where functions uniformly represent properties, relationships, and operations associated with objects. Chang et al.(14) presented an image database system based on spatial reasoning by two-dimensional (2-D) strings and image database operations. Brink et al. (15) developed a multimedia system that provides a shell/compiler to build metadata atop the physical medium for most media data. With this kind of independence, visual database systems can be built for a variety of applications.

Once image features were extracted, the question remained as to how they could be matched against each other for retrieval. The success of content-based image retrieval depends on the definition of similarity measures to measure quantitatively the similarities between images. A summary of similarity measures was given in Ref. (16), where similarity measures were grouped as feature-based matching, object silhouette-based matching, structural feature matching, salient feature matching, matching at the semantic level, and learning-based approaches for similarity matching.

In addition to designing powerful low-level feature extraction algorithms, researchers have also focused on reducing the semantic gap (16,17) between the image features and the richness of human semantics. One common approach is to use object ontology, which is a simple vocabulary providing qualitative definitions of high-level concepts. Images are classified into different categories by mapping descriptions of image features to semantic keywords. Such an association of low-level features with high-level semantic concepts can take advantages of classification and clustering algorithms developed in machine learning and data mining. In addition to object ontology, query results can be refined by learning the user's intention using *relevance feedback*, which is an interactive process of automatically adjusting the execution of a query using information fed back from the user about the relevance of the results of the query.

In recent years, image retrieval on the World Wide Web has become an active area of research. Systems like Webseer (18) and WebSEEK (19) can locate images on the Web using image contents in addition to texts. MetaSEEK (20) can distribute a user query to several independent image search engines on the Web and then combine the results to give the benefits of all of them. An image search on the Web has enormous commercial potential. Many popular commercial search engines have image and video search functionalities. These search engines include Google Image Search (http://images.google.com), Lycos Search (http://search.lycos.com), AltaVista Image Search (http://www.altavista.com/image), MSN Search (http://www.msn.com), and Yahoo! Image Search (http://images.search.yahoo.com). These search engines use text to search for images or video, with little or no consideration of image contents. Recently, Web-based communities become popular where developers and end users use the Web as a platform for collaboration and resource sharing. Popular examples include Flickr (http://www.flickr.com), which is a photo-sharing website, and YouTube (http://www.youtube.com), which is a video-sharing website. Both websites support image or video search as part of the services they offer.

Given distinct methods and solutions to a problem as open-ended as visual data retrieval, a natural question that develops is how to make a fair comparison among them. Evaluation of visual data retrieval has been an ongoing challenging problem. Perhaps the most complete video evaluation project has been the TRECVID evaluation (21) (http://www-nlpir.nist.gov/projects/trecvid). The project keeps close connections between private industry and academic research where a realistic task-specific test set is gathered, discussed, and agreed to. Several research teams then attempt to provide the best video retrieval system for the test set. TRECVID participants meet regularly for continual evolution toward improving the test sets.

IMAGE FEATURES

Features of an image are a set of terms or measurements that can be used to represent the image. An image can be assigned features either manually or automatically.

A simple and reliable way to catch the content of an image is to annotate manually the image with keywords. In fact, it may be the only way to describe images in many applications. A good example is the San Francisco de Young Museum (http://www.thinker.org), which uses manual annotation to identify images. Each image in the museum's extensive collection has a description, and some descriptions are remarkably detailed. Free text retrieval techniques are used to search for images based on the text descriptions.

Many kinds of images cannot be annotated manually. A typical example is a database of human facial images where it is sometimes impossible to assign a unique keyword to each facial image. Manual annotation is impractical for very large databases or for images that are generated automatically or streamed, for example, from surveillance cameras. In such applications, it is attractive to extract automatically features of visual data for content-based retrieval. However, automatic extraction of image contents is difficult. Except for a few special applications, such as optical character recognition, the current state of the art in image understanding cannot label an image with descriptive terms that convincingly characterize the content of the image. Furthermore, objects in an image can be occluded by other objects or by shadows, be articulated, or have a shape that is difficult to describe. The fundamental problem is that so far it is not clear how human beings recognize images and what features are used by human beings to distinguish one image from another. It is not yet possible for cognitive science to provide practical hints to computer recognition of images.

An image in a database is represented typically by multiple measures. According to the scope on the image these measures are collected, image features can be classified as follows:

- Global features, which include average values, standard derivations, and histograms of measurements calculated for the entire image.
- Regional features, which are measured on fixed regions or regions having homogeneous properties.
- Object features, which are calculated for each object in the image. Objects can be segmented either manually, semiautomatically or automatically. Segmentation techniques include thresholding, flood-fill using seed points, and manual segmentation using shape models.

Image features are calculated typically off-line, and thus, efficient computation is not a critical criterion as opposed to efficient feature matching in answering user queries. Commonly used primitive features include color histogram, texture, shape, and contour measures. These image features are well explained in image processing textbooks such as Refs. (22 and 23).

A histogram of a grayscale image is a plot of the number of pixels for each particular intensity value in the image. A color image can be characterized by three histograms, one for each of the three color components, in terms of either RGB (red, green, and blue) or HSV (hue, saturation, and value). Location information is lost totally in a histogram. A histogram of an given image can be compared with the stored set of histograms in the database to find an image that is similar in color distribution to the given image.

Texture measures include almost all local features such as energy, entropy, contrast, coarseness, correlation, anisotropy, directionality, stripes, and granularity. Texture measures have been used to browse large-scale aerial photographs (24), where each photograph is segmented to obtain a texture image thesaurus. The texture image thesaurus is clustered. The user can indicate a small region of interest on a photograph, and the system will retrieve photographs that have similar textured regions.

Edges and their directions in images are also valuable features. Edge information can be extracted in several ways, for example, by using Gabor filters, Sobel operators, or various edge detectors.

An effective method for representing an image is image transformation, for example, wavelet transformation. The low-frequency coefficients of the transform of an image often represent objects in the image and can be used as features of the image.

The above primitive features can be used to derive new features, for example, curvatures, shapes of regions or objects, locations, and spatial relations. In fact, these "intermediate" features are primitive building blocks of object ontology, which provides qualitative descriptions of image contents and associates images with semantic concepts. The user can continue to mark interesting areas, not necessarily objects, from which features are calculated. An example is a physician marking interesting areas in the positions of lung in chest x-ray images and calculating texture features only from the marked areas.

In addition to the above features that are extracted from individual images, features can also be extracted from a set of images by analysis of correlations among the images. Statistical and machine learning techniques are often applied to a set of images to find uncorrelated components that best describe the set of images. For example, the eigenface technique (25) applies principal component analysis for image feature extraction. Given a set of images and by arranging pixel values of each image into a vector, one can form a covariance matrix of the set of images. Eigenvectors that correspond to the largest eigenvalues of the covariance matrix contain the principal components of the set of images. Each image is then approximated with a linear combination of these eigenvectors and can be represented by the weights of these eigenvectors in the combination. Recently, researchers have developed nonlinear methods (26–28) in manifold learning for feature extraction and dimensionality reduction. By assuming images as points distributed on a manifold in high-dimensional space, these methods can often unfold the manifold to a very low-dimensional space and use the coordinates in the low-dimensional space as image features.

Techniques have also been proposed for feature extraction and matching of three-dimensional (3-D) shapes (29). A histogram can be used as a feature for 3-D shapes in the same way as it is used for 2-D images. Curvature and curvature histogram have also been used as features of 3-D shapes. Another promising way to represent 3-D shapes is to use skeletal structures. One widely used skeletal structure is the medial axis model (30). Recently, an interesting approach called topological matching (31) has been proposed to represent 3-D shapes using multiresolution Reeb graphs. The graphs represent skeletal and topological structures of 3-D shapes, are invariant to geometrical transformations, and are particularly useful for interactive search of 3-D objects.

A video is often characterized by selecting key frames that form a “story board” of the video (32). Once key frames are obtained, one can use image retrieval techniques to search a video database for frames that match a key frame. The story-board frames can be obtained by carrying out a frame-to-frame analysis that looks for significant changes and by taking advantage of domain knowledge of how a video is constructed.

Using an improper set of features may get irrelevant query results. For example, an image histogram loses location information of image pixels. If the query image contains a small region of particular importance, the region will get lost in an overall histogram. A solution to the problem is to partition the image and to calculate the features for each partition of the image. The user can indicate a region of interest in the query image, and only features of that portion will be used in the similarity measure.

Different image features are often used together for image retrieval. In a human facial image retrieval system (33), for example, a human facial image is characterized by six facial aspects: chin, hair, eyes, eyebrows, nose, and mouth. Each facial aspect contains numerical attributes as well as possibly descriptive values (such as large and small) for each attribute. In practice, these feature measures are often used together with other statistical measures, such as textures or principal components of colors.

Matching long complex feature vectors is often expensive computationally. Because some features are usually more useful than the others, a subset of the most useful feature measures can often be selected manually in practice to accelerate the matching process. Techniques such as principal component analysis and vector quantization can be applied to a set of image feature vectors. Principal component analysis is applied to find a subset of significant feature measures. Vector quantization is used to quantize the feature space. For instance, a set of images can be clustered, and each cluster is represented by a prototype vector. The search starts by comparing the query feature vector with the prototype vectors to find the closest cluster and then to find the closest feature vectors within that cluster. In this way, a visual data search can be directed in a hierarchical manner.

VISUAL DATA RETRIEVAL

One of the biggest challenges for a visual database comes from the user requirement for visual retrieval and techniques to support visual retrieval. Visual retrieval has to support more retrieval methods in addition to those conventional retrieval methods in alphanumeric databases. Correspondingly, these extra retrieval methods call for new data indexing mechanisms. Figure 1 summarizes typical retrieval methods for image databases and their relationships with different kinds of data indexes. Retrieval by attributes is a conventional data access method. The user selects features that might characterize the type of expected images; for example, use color and texture measures to find dresses or wallpapers. The user can also select the weight of each feature for feature matching. Image retrieval can then be made by the comparison of weighted differences of the features of the query image against the features of the images in the database.

Other retrieval methods, namely, free text retrieval, fuzzy retrieval, visual browsing, and similarity retrieval, are content-based retrieval and are special to visual databases. Free text retrieval and fuzzy retrieval are descriptive. Visual browsing and similarity retrieval are visual and require visual interfaces. Unlike query processing with well-defined formalities in alphanumeric databases, similarity retrieval intends to combine image features and texts to retrieve images similar to an example image. A user can specify the example image in several ways. Usually, the user shows a real image and tells the system what is important in the image by selecting features of or regions/objects in the image (the regions/objects can either be automatically or manually segmented). Alternatively, the user can sketch an example image. The sketch can be a contour sketch showing the shapes of the objects to retrieve or in the form of colored boxes indicating colors, sizes, and positions of the objects to retrieve. Using a well-defined set of features and a good similarity measure, the system retrieves images similar to the one supplied by the user.

One problem in content-based retrieval is how to define the similarity measure. In general, we cannot expect to find a generic similarity measure that suites all user needs.

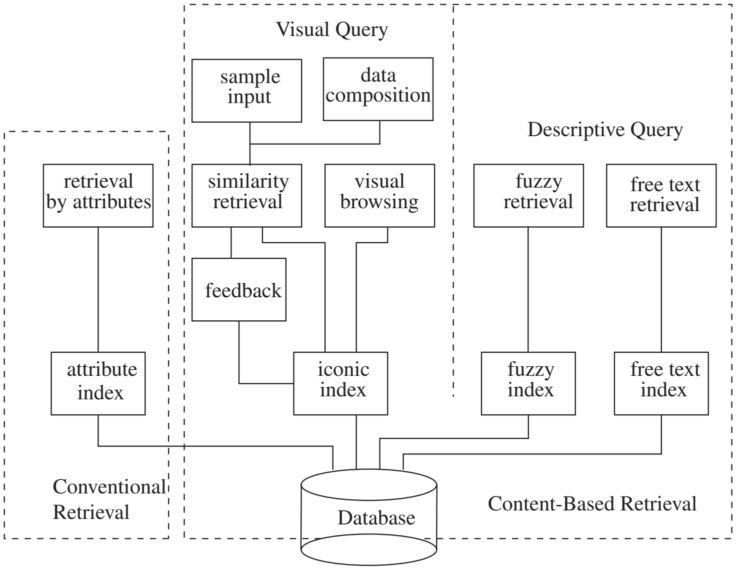

Figure 1. Visual retrieval methods.

Manually selecting relevant features and weights in a similarity measure can be difficult, especially when the features are complicated. A user should therefore be given a chance to interact with the system and to have the similarity learned by the system. This interaction can be more or less natural for the user. *Relevance feedback*(34) is a technique that removes the burden of specifying manually the weights of features. It allows the user to grade the retrieved images by their relevance, for example, highly relevant, relevant, nonrelevant, or highly nonrelevant. The system then uses the grades to learn relevant features and similarity metrics. The grading can be made after each retrieval, thereby progressively improving the quality of the retrieved results.

Other problems in content-based retrieval include how to organize and index the extracted features, how to incorporate these features and indexes into existing databases, and how to formulate visual queries through user interfaces.

Descriptive Retrieval

Free text retrieval uses text descriptions of visual data to retrieve the visual data. Many techniques, typically those (35) developed for and used in Web search engines, can be used for free text retrieval of visual data. Many of these approaches work in similar ways. First, every word in the text description is checked against a list of stop words. The list consists of the commonly used words, such as “the”, and “a,” which bear little semantic significance within the context. Words in the stop word list are ignored. Words such as “on,” “in,” and “near” are essential to represent the location of special features, and therefore, they cannot be included in the stop word list. The remaining words are then stemmed to remove the word variants. Stemmed words are indexed using conventional database indexing techniques. In free text retrieval, users are asked to submit a query in free text format, which means that the query can be a sentence, a short paragraph, or a list of keywords and/or phrases. After initial search, records that are among the best matches are presented to the user in an sorted order according to their relevances to the search words.

Human descriptions of image contents are neither exact nor objective. Image retrieval based on fuzzy queries (36) is a natural way to get information in many applications. An image is represented by a set of segmented regions, each of which is characterized by a fuzzy feature (fuzzy set) reflecting color, texture, and shape properties. As a result, an image is associated with a family of fuzzy sets corresponding to regions. The fuzzy sets together define a *fuzzy space*. When a fuzzy query is defined incompletely, it represents a hypercube in the fuzzy space. To evaluate a fuzzy query is to map image feature measures from the feature space to the fuzzy space. After mapping, images in the database are represented as points in the fuzzy space. The similarity between a fuzzy query and an image can then be computed as the distance between the point that represents the image and the hypercube that represents the fuzzy query. Images that are close to the query definition are retrieved. The fuzzy query processing produces an ordered set of images that best fit a query. Fuzzy space is not Cartesian; ordinary correlation and Euclidean distance measurements may not be used as similarity measures.

Visual Retrieval

Two types of visual retrievals exist: similarity retrieval and visual browsing. Similarity retrieval allows users to search for images most similar to a given sample image. Visual browsing allows users to browse through the entire collection of images in several different ways based on similarities between images.

Similarity retrieval uses similarity measures to search for similar images. To accelerate the search process, similarity retrieval is often implemented by traversing a multidimensional tree index. It behaves in a similar way as pattern classification via a decision tree. At each level of the tree, a decision is made by using a similarity measure. At the leaf node level, all leaf nodes similar to the sample image will be selected. By modifying weights of different features, one gets different similarity measures and, consequently, different query results.

Visual browsing allows a user to thumb through images, which again can be achieved via a traversal of the index tree, where each internal node piggybacks an iconic image representing the node. The system presents the user with the root of the index tree by displaying the icons of its descendants. At each node of the tree, the user chooses browsing directions: up, down, left, and right. Going up is implemented via a pointer to its parent node, whereas moving down is accomplished by selecting the icon representing a specific descendant node. The selected descendant node is then considered as the current node, and the icons of its children are displayed. This process is vertical browsing. By selecting icons of sibling nodes, a user can perform horizontal browsing in a similar way.

A graphic user interface is required to retrieve images or video in an interactive “thumb through” mode. The system displays to the user retrieved icons of images that are relevant to the query image, and the user can iterate by clicking an image that best satisfies the query. Such an intuitive user interface combines browsing, search, navigation, and relevance feedback. It may address demands from a wide variety of users, including nontechnical users.

VISUAL DATA INDEXING

Indexing is a process of associating a key with corresponding data records. In addition to traditional tree-based and hash-based indexing techniques used in alphanumeric databases, visual databases need special indexing techniques to manage, present, and access visual data. Over the years, many indexing techniques have been proposed for various types of applications. Using image database as an example, we can classify these indexing techniques into two categories: interimage indexing and intraimage indexing. Interimage indexing assumes each image as an element and indexes a set of such images by using their features. A representative interimage indexing technique is feature-based iconic indexing (33). It indexes a set of visual data to support both feature-based similarity query and visual browsing in addition to exact-match query and range query on the set of data. On the other hand, intraimage indexing indexes elements (regions, points, and lines) within an image. Representative techniques are quadtree and related hierarchical data structures.

Feature-Based Iconic Indexing

Because features can be assumed as vectors in high-dimensional space, any multidimensional indexing mechanisms (37) that support a nearest-neighbor search can be used to index visual data. Although this generic mechanism is universal, various specialized, more efficient indexing methodologies may develop for particular types of visual database applications.

An image indexing mechanism should support both a feature-based similarity search and visual browsing. As an example, feature-based iconic indexing (33) is an indexing mechanism that is specialized for visual retrieval. In alphanumeric databases, tree indexes are organized such that (*1*) a tree is built on a set of key attributes; (*2*) key attributes are of primitive data types, such as string, integer, or real; and (*3*) the grouping criterion usually specifies a range of values on a particular attribute. To make index trees applicable to visual features, feature-based iconic indexing makes the following generalizations:

1. The first generalization is to allow attributes to be structured data. For example, an attribute can be a feature vector that is a multidimensional array.
2. As a result of the first generalization, the grouping criteria are defined on similarity measures. The most commonly used similarity measure is distance in the feature space.
3. The third generalization is that different levels of the index tree may have different key attributes. This generalization facilitates visual browsing and navigation.

The iconic index tree can be built either top-down or bottom-up. A top-down algorithm typically consists of two steps. The first step selects a feature aspect and clusters the images into *m* classes. Many approaches are available to do this step, for example, the *k*-means clustering algorithm (38) or the self-organization neural network (39). The second step repeats the first step until each node has at most *m* descendants. Each node of the index tree has the following fields: (*1*) node type: root, internal, or leaf node; (*2*) feature vector; (*3*) iconic image; (*4*) pointer to its parent node; (*5*) number of children and pointers to its children; and (*6*) number of sibling nodes and pointers to the sibling nodes. The pointers to sibling nodes are referred to as horizontal links and provide a means for horizontal browsing. An example node structure of a feature-based iconic index tree is shown in Fig. 2. Horizontal links are created only for the feature aspects that have already been used as the key feature aspect at levels above the current level. For example, if F3 is the key feature aspect at the current level, F1 and F2 are key feature aspects at above levels; then the nodes under the same parent node at this level represent images having similar F1, similar F2, and different F3s. For horizontal browsing of images of similar F1, similar F2, and different F3s, a horizontal link is created to link these nodes at this level. Other horizontal links such as a link for similar F1, similar F3, and different F2 can be created as well.

Quadtree and Other Hierarchical Data Structures

Quadtree and related hierarchical data structures provide mechanisms for intraimage indexing. As an example of the type of problems to which these data structures are applicable, consider a geographical information system that consists of several of maps, each of which contains images, regions, line segments, and points. A typical query is to

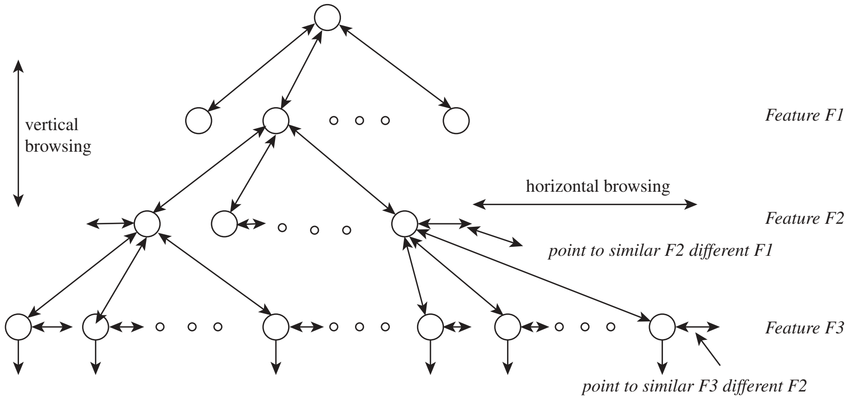

Figure 2. Feature-based iconic index tree facilitates similarity search and visual browsing. Reprinted with permission from Ref. 33.

determine all hotels within 20 miles from the user's current location. Another typical query is to determine the regions that are within 1000 feet above sea level in a geographic area. Such analyses could be costly, depending on the way the data are represented. Hierarchical data structures are based on the principle of recursive decomposition of space. They are useful because of their ability to organize recursively subparts of an image in a hierarchical way.

Quadtree has been studied extensively to represent regional data. It is based on successive subdivision of a binary image into four equal-sized quadrants. If the binary image does not consist entirely of 1s or 0s, it is then divided into quadrants, subquadrants, and so on, until blocks (single pixels in extreme cases) that consist entirely of 1s or 0s are obtained. Each nonleaf node of a quadtree has four children. The root node corresponds to the entire image. Each child of a node represents a quadrant of the region represented by the node. Leaf nodes of the tree correspond to those blocks for which no additional subdivision is necessary.

Hierarchical data structures have been studied extensively, and many variants have been proposed (37). They are differentiated mainly on the following aspects: (*1*) the type of data (points, line segments, or regions) that they are used to represent, (*2*) the principle guiding the decomposition process, and (*3*) tree balance (fixed or variable depth). Hierarchical data structures have been used to represent point data, regions, curves, surfaces, and volumes. It is worthwhile to mention that, instead of equal subdivision in quadtrees, the decomposition process may divide a binary image according to the distribution of elements in the image. Furthermore, the idea of decomposition is not restricted to 2-D images and can be extended to data distributions in high-dimensional space. For example, kd-tree and its derivatives are studied extensively to index point data in high-dimensional space. These techniques have other applications beyond visual databases. These applications include alphanumeric databases, data warehousing, and data visualization.

OTHER DATABASE ISSUES

A typical database management system consists of modules for query processing, transaction management, crash recovery, and buffer management. For a complete discussion of technical details, readers may refer to a database textbook such as Ref. (40). These modules in a visual database management system are different from the corresponding ones in traditional alphanumeric databases.

Query Processing

As we have introduced, query processing in visual databases must support a similarity match in addition to an exact match. Similarity measures between visual objects are usually real valued, say, ranging from 0 (completely different) to 1 (exactly the same). Strictly speaking, the result of a visual query can be all images in the entire database, each ranked from 0 to 1 based on its similarity to the query image. The user will specify a threshold so that an image is not retrieved if its rank is below the threshold value. Images with ranks above the threshold value are then ordered according to their ranks. A similarity search is often computing intensive. For query optimization, therefore, visual database systems supporting a similarity search and user-defined access methods need to know the costs associated with these methods. The costs of user-defined functions in terms of low-level access methods, such as those related to similarity search, must also be made known to the database system (41).

Transaction Management

In visual databases, traditional lock-based and timestamp-based concurrency control techniques can be used; the results would still be correct. However, the concurrency of the overall system would suffer because transactions in visual databases tend to be long, computing-intensive, interactive, cooperative, and to refer to many other database objects. Suppose an updating transaction inserts interactively subtitles to a video, for example; traditional lock-based concurrency control locks the entire video, which decreases the throughput of other transactions referring to other frames in the same video. Visual data are large in size, making it impractical to create multiple copies of the data, as is necessary in the multiversion approach to concurrency control. Optimistic methods for concurrency control are not suitable either, as frequent abortion and restart of a visual presentation would be unacceptable to the viewer.

To increase system concurrency in such an environment, transaction models defined for object-oriented environments, long cooperative activities, real-time database applications, and workflow management are usually considered. Techniques developed for nested transactions are particularly useful, in which a transaction consists of subtransactions, each of which can commit or abort independently. Another observation is that even though a nonserializable schedule may leave the database in an inconsistent state, the inconsistent state may not be fatal. If a few contiguous frames of a video presentation have been changed by another transaction, then, such subtle changes usually would not cause any problem to the viewers.

Storage Management

One challenge of storage management of visual data is to serve multiple requests for multiple data to guarantee that these requests do not starve while minimizing the delay and the buffer space used. Techniques such as data striping, data compression, and storage hierarchies have been employed to reduce this bottleneck. Data striping, as is used in redundant array of inexpensive disks (RAIDs), allocates space for a visual object across several parallel devices to maximize data throughput. Also studied are storage hierarchies in which tertiary storage can be used for less frequently used or high-resolution visual objects and faster devices for more frequently used or low-resolution visual objects. As hard disks become larger and cheaper, however, tertiary storage is less necessary than it was before.

Recovery

Many advanced transaction models have generalized recovery methods. In a long cooperative design environment, undoing complete transactions is wasteful. A potentially large amount of work, some of it correct, might not have to be undone. It makes more sense to remove the effects of individual operations rather than undo a whole transaction. To do so, however, the log must contain not only the history of a transaction but also the dependencies among individual operations.

Advanced transaction models for long-running activities include compensating transactions and contingency transactions. A compensating transaction undoes the effect of an already committed transaction. In video delivery, for example, a unique concern is how to compensate a transaction with acceptable quality of service. Unlike compensating transaction, a contingency transaction provides alternative routes to a transaction that could not be committed. For example, a contingency transaction for showing an image in GIF format might show the image in JPEG format.

EXAMPLE VISUAL DATABASE SYSTEMS

Because of space limitations, this section introduces three example visual database systems: QBIC (6) by IBM; MARS (34) developed at the University of Illinois at Urbana-Champaign; and VisualSEEK (19,42) developed at Columbia University. The last section gives references to other visual database systems

QBIC

QBIC was probably the first commercial content-based image retrieval system. It is available either in stand-alone form or as part of other IBM DB2 database products. The features it uses include color, texture, shape, and keywords.

QBIC quantizes each color in the RGB color space into k predefined levels, giving the color space a total of k^3 cells. Color cells are aggregated into super cells using a clustering algorithm. The color histogram of an image represents the normalized count of pixels falling into each super cell. To answer a similarity query, the histogram of the query image is matched with the histograms of images in the database. The difference z_i is computed for each color super cell.The similarity measure is given as $\sum_{i,j} a_{ij} z_i z_j$, where a_{ij} measures the similarity of the ith and the jth colors.

Texture measures used by QBIC include coarseness, contrast, and directionality. Coarseness measures texture scale (average size of regions that have the same intensity). Contrast measures vividness of the texture (depending on the variance of the gray-level histogram). Directionality gives the main direction of the image texture (depending on the number and shape of peaks of the distribution of gradient directions).

QBIC also uses shape information, such as area, major axis orientation (eigenvector of the principal component), and eccentricity (ratio of the largest eigenvalue against the smallest eigenvalue); various invariants; and tangent angles as image features. It also supports search of video data by using motion and shot detection.

QBIC supports queries based on example images, user-constructed sketches and drawings, and color and texture patterns. The user can select colors and color distributions, select textures, and adjust relative weights among the features. Segmentation into objects can be done either fully automatically (for a restricted class of images) or semiautomatically. In the semiautomatic approach, segmentation is made in a flood-fill manner where the user starts by marking a pixel inside an object and the system grows the area to include adjacent pixels with sufficiently similar colors. Segmentation can also be made by snakes (active contours) where the user draws an approximate contour of the object that is aligned automatically with nearby image edges.

MARS

MARS uses relevance feedback to learn similarity measures. The system has access to a variety of features and similarity measures and learns the best ones for a particular query by letting the user grade retrieved images as highly relevant, relevant, no-opinion, nonrelevant, or highly nonrelevant. MARS uses image features such as color, texture, shape and wavelet coefficients. MARS calculates color histogram and color moments represented in the HSV color space. It uses co-occurrence matrices in different directions to extract textures such as coarseness, contrast, directionality, and inverse difference moments. It also uses Fourier transform and wavelet coefficients to characterize images. The information in each type of features (e.g., color) is represented by a set of subfeatures (e.g., color histogram or color moments). The subfeatures and similarity measures are normalized. Users from various disciplines have been invited to compare the performance between the relevance feedback approach in MARS and the computer centric approach where the user specifies the relative feature weights. Almost all users have rated the relevance feedback approach much higher than the computer-centric approach in terms of capturing their perception subjectivity and information needed.

VisualSEEK/WebSEEK

VisualSEEK is an image database system that integrates feature-based image indexing with spatial query methods. Because global features such as color histograms lack spatial information, VisualSEEK uses salient image regions and their colors, sizes, spatial locations, and relationships, to describe images. The integration of global features and spatial locations relies on the representation of color regions by color sets. Because color sets can be indexed for retrieval of similar color sets, unconstrained images are decomposed into nearly symbolic images that lend to efficient spatial query.

VisualSEEK quantizes the HSV color space into 166 regions. Quantized images are then filtered morphologically and analyzed to reveal spatially localized color regions. A region is represented by the dominant colors in the region. The color distribution in a region is represented by a color set, which is a 166-dimensional binary vector approximating the color histogram of the region. The similarity between two color sets, c_1 and c_2, is given by $(c_1 - c_2)^T A(c_1 - c_2)$, where elements of the matrix A denote the similarity between colors. In addition, VisualSEEK uses features such as centroid and minimum bounding box of each region. Measurements such as distances between regions and relative spatial locations are also used in the query.

VisualSEEK allows the user to sketch spatial arrangements of color regions, position them on the query grid, and assign them properties of color, size, and absolute location. The system then finds the images that contain the most similar arrangements of regions. The system automatically extracts and indexes salient color regions from the images. By using efficient indexing techniques on color, region sizes, and both absolute and relative spatial locations, a wide variety of color/spatial visual queries can be computed.

WebSEEK searches the World Wide Web for images and video by looking for file extensions such as .jpg, .mov, .gif, and .mpeg. The system extracts keywords from the URL and hyperlinks. It creates a histogram on the keywords to find the most frequent ones, which are put into classes and subclasses. An image can be put into more than one classes. An image taxonomy is constructed in a semiautomatic way using text features (such as associated html tags, captions, and articles) and visual features (such as color, texture, and spatial layout) in the same way as they are used in VisualSEEK. The user can search for images by walking through the taxonomy. The system displays a selection of images, which the user can search by using similarity of color histograms. The histogram can be modified either manually or through relevance feedback.

BIBLIOGRAPHIC NOTES

Comprehensive surveys exist on the topics of content-based image retrieval, which include surveys by Aigrain et al. (43), Rui et al. (44), Yoshitaka and Ichikawa (45), Smeulders et al. (16), and recently, Datta et al. (46,47). Multimedia information retrieval as a broader research area covering video, audio, image, and text analysis has been surveyed extensively by Sebe et al. (48), Snoek and Worring (32), and Lew et al. (49). Surveys also exist on closely related topics such as indexing methods for visual data by Marsicoi et al. (50), face recognition by Zhao et al. (51), applications of content-based retrieval to medicine by Müller et al. (52), and applications to cultural and historical imaging by Chen et al. (53).

Image feature extraction is of ultimate importance to content-based retrieval. Comparisons of different image measures for content-based image retrieval are given in Refs. (16,17 and 54).

Example visual database systems that support content-based retrieval include IBM QBIC (6), Virage (55), and NEC AMORE (56) in the commercial domain and MIT Photobook (57), UIUC MARS (34,58), Columbia VisualSEEK (42), and UCSB NeTra (59) in the academic domain. Practical issues such as system implementation and architecture, their limitations and how to overcome them, intuitive result visualization, and system evaluation were discussed by Smeulders et al. in Ref. (16). Many of these systems such as AMORE or their extensions such as UIUC WebMARS (60) and Columbia WebSEEK (19) support image search on the World Wide Web. Webseer (18) and ImageScape (61) are systems designed for Web-based image retrieval. Kherfi et al. (62) provides a survey of these Web-based image retrieval systems.

Interested readers may refer to Refs. (16,17, 49 and 63) for surveys and technical details of bridging the semantic gap. Important early work that introduced relevance feedback into image retrieval included Ref. (34), which was implemented in the MARS system (58). A review of techniques for relevance feedback is given by Zhou and Huang (64).

Readers who are interested in the quadtree and related hierarchical data structures may consult the survey (65) by Samet. An encyclopedic description of high-dimensional metric data structures was published recently as a book (37). Bohm et al. (66) give a review of high-dimensional indexing techniques of multimedia data.

Relational database management systems have been studied extensively for decades and have resulted in numerous efficient optimization and implementation techniques. For concepts and techniques in relational database management, readers may consult popular database textbooks, such as Ref. (40). Common machine learning and data mining algorithms for data clustering and classification can be found in data mining textbooks, such as Ref. (61). Image feature extraction depends on image processing algorithms and techniques, which are well explained in image processing textbooks, such as Refs. (22 and 23).

ALGEBRAIC GEOMETRY

INTRODUCTION

Algebraic geometry is the mathematical study of geometric objects by means of algebra. Its origins go back to the coordinate geometry introduced by Descartes. A classic example is the circle of radius 1 in the plane, which is the geometric object defined by the algebraic equation $x^2 + y^2 = 1$. This generalizes to the idea of a systems of polynomial equations in many variables. The solution sets of systems of equations are called *varieties* and are the geometric objects to be studied, whereas the equations and their consequences are the algebraic objects of interest.

In the twentieth century, algebraic geometry became much more abstract, with the emergence of *commutative algebra* (rings, ideals, and modules) and *homological algebra* (functors, sheaves, and cohomology) as the foundational language of the subject. This abstract trend culminated in Grothendieck's *scheme theory*, which includes not only varieties but also large parts of algebraic number theory. The result is a subject of great power and scope—Wiles' proof of Fermat's Last Theorem makes essential use of schemes and their properties. At the same time, this abstraction made it difficult for beginners to learn algebraic geometry. Classic introductions include Refs. 1 and 2, both of which require a considerable mathematical background.

As the abstract theory of algebraic geometry was being developed in the middle of the twentieth century, a parallel development was taking place concerning the algorithmic aspects of the subject. Buchberger's theory of *Gröbner bases* showed how to manipulate systems of equations systematically, so (for example) one can determine algorithmically whether two systems of equations have the same solutions over the complex numbers. Applications of Gröbner bases are described in Buchberger's classic paper [3] and now include areas such as computer graphics, computer vision, geometric modeling, geometric theorem proving, optimization, control theory, communications, statistics, biology, robotics, coding theory, and cryptography.

Gröbner basis algorithms, combined with the emergence of powerful computers and the development of *computer algebra* (see SYMBOLIC COMPUTATION), have led to different approaches to algebraic geometry. There are now several accessible introductions to the subject, including Refs. 4–6.

In practice, most algebraic geometry is done over a field, and the most commonly used fields are as follows:

- The rational numbers $\mathbf{Q}$ used in symbolic computation.
- The real numbers $\mathbf{R}$ used in geometric applications.
- The complex numbers $\mathbf{C}$ used in many theoretical situations.
- The finite field $\mathbf{F}_q$ with $q = p^m$ elements (p prime) used in cryptography and coding theory.

In what follows, k will denote a field, which for concreteness can be taken to be one of the above. We now explore the two main flavors of algebraic geometry: *affine* and *projective*.

AFFINE ALGEBRAIC GEOMETRY

Given a field k, we have *n-dimensional affine space* k^n, which consists of all n-tuples of elements of k. In some books, k^n is denoted $\mathrm{A}^n(k)$. The corresponding algebraic object is the *polynomial ring* $k[\mathrm{x}_1, \ldots, x_n]$ consisting of all polynomials in variables $x_1, \ldots, x_n$ with coefficients in k. By *polynomial*, we mean a finite sum of terms, each of which is an element of k multiplied by a *monomial*

$$x_1^{a_1} x_2^{a_2} \cdots x_n^{a_n}$$

where $a_1, \ldots, a_n$ are non-negative integers. Polynomials can be added and multiplied, and these operations are commutative, associative, and distibutive. This is why $k[x_1, \ldots, x_n]$ is called a *commutative ring*.

Given polynomials $f_1, \ldots, f_s$ in $k[x_1, \ldots, x_n]$, the *affine variety* $\mathbf{V}(f_1, \ldots, f_s)$ consists of all points $(u_1, \ldots, u_n)$ in k^n that satisfy the system of equations

$$f_1(u_1, \ldots, u_n) = \cdots = f_s(u_1, \ldots, u_n) = 0.$$

Some books (such as Ref. 1) call $\mathbf{V}(f_1, \ldots, f_s)$ an *affine algebraic set*.

The algebraic object corresponding to an affine variety is called an *ideal*. These arise naturally from a system of equations $f_1 = \cdots = f_s = 0$ as follows. Multiply the first equation by a polynomial h_1, the second by h_2, and so on. This gives the equation

$$h = h_1 f_1 + \cdots + h_s f_s = 0,$$

which is called a *polynomial consequence* of the original system. Note that $h(u_1, \ldots, u_n) = 0$ for every $(u_1, \ldots, u_n)$ in $\mathbf{V}(f_1, \ldots, f_s)$. The *ideal* $\langle f_1, \ldots, f_s \rangle$ consists of all polynomial consequences of the system $f_1 = \cdots = f_s = 0$. Thus, elements of $\langle f_1, \ldots, f_s \rangle$ are linear combinations of $f_1, \ldots, f_s$, where the coefficients are allowed to be arbitrary polynomials.

A general definition of ideal applies to any commutative ring. The *Hilbert Basis Theorem* states that all ideals in a polynomial ring are of the form $\langle f_1, \ldots, f_s \rangle$. We say that $f_1, \ldots, f_s$ is a *basis* of $\langle f_1, \ldots, f_s \rangle$ and that $\langle f_1, \ldots, f_s \rangle$ is *generated* by $f_1, \ldots, f_s$. This notion of "basis" differs from how the term is used in linear algebra because linear independence fails. For example, x, y is a basis of the ideal $\langle x, y \rangle$ in $k[x, y]$, even though $y \cdot x + (-x) \cdot y = 0$.

A key result is that if $\mathbf{V}(f_1, \ldots, f_s) = \mathbf{V}\{g_1, \ldots, g_t)$ whenever $\langle f_1, \ldots, f_s \rangle = \langle g_1, \ldots, g_t \rangle$. This is useful in practice because switching to a different basis may make it easier to understand the solutions of the equations. From the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

theoretical point of view, this shows that an affine variety depends on the ideal I generated by the defining equations, so that the affine variety can be denoted $\mathbf{V}(I)$. Thus, every ideal gives an affine variety.

We can also reverse this process. Given an affine variety V, let $\mathbf{I}(V)$ consist of all polynomials that vanish on all points of V. This satisfies the abstract definition of ideal. Thus, every affine variety gives an ideal, and one can show that we always have

$$V = \mathbf{V}(\mathbf{I}(V)).$$

However, the reverse equality may fail. In other words, there are ideals I such that

$$I \neq \mathbf{I}(\mathbf{V}(I)).$$

An easy example is provided by $I = \langle x^2 \rangle$ in $k\,|\,x\,|$, because $\mathbf{I}(\mathbf{V}(I)) = \langle x \rangle \neq I$. Hence, the correspondence between ideals and affine varieties is not a perfect match. Over the complex numbers, we will see below that there is nevertheless a nice relation between I and $\mathbf{I}(\mathbf{V}(I))$.

One can prove that the *union* and *intersection* of affine varieties are again affine varieties. In fact, given ideals I and J, one has

$$\begin{aligned} V(I) \cup V(J) &= V(I \cap J) \\ V(I) \cap V(J) &= V(I + J), \end{aligned}$$

where

$$\begin{aligned} I \cap J &= \{g \mid g \text{ is in both } I \text{ and } J\} \\ I + J &= \{g + h \mid g \text{ is in } I \text{ and } h \text{ is in } J\} \end{aligned}$$

are the *intersection* and *sum* of I and J (note that $I \cap J$ and $I + J$ are analgous to the intersection and sum of subspaces of a vector space). In this way, algebraic operations on ideals correspond to geometric operations on varieties. This is part of the *ideal-variety correspondence* explained in Chapter 4 of Ref. 4.

Sometimes an affine variety can be written as a union of strictly smaller affine varieties. For example,

$$\mathbf{V}((x - y)(x^2 + y^2 - 1)) = \mathbf{V}(x - y) \cup \mathbf{V}(x^2 + y^2 - 1)$$

expresses the affine variety $\mathbf{V}((x - y)(x^2 + y^2 - 1))$ as the union of the line $y = x$ and the unit circle (Fig. 1).

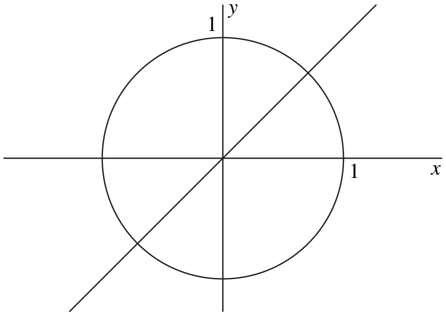

Figure 1. Union of a line and a circle.

In general, an affine variety is *irreducible* if it has no such decomposition. In books such as Ref. 1, varieties are always assumed to be irreducible.

One can show that every affine variety V can be written as

$$V = V_1 \cup \cdots \cup V_m$$

where each V_i is irreducible and no V_i is contained in V_j for $j \neq i$. We say that the V_i are the *irreducible components* of V. Thus, irreducible varieties are the "building blocks" out of which all varieties are built. Algebraically, the above decomposition means that the ideal of V can be written as

$$\mathbf{I}(V) = P_1 \cap \cdots \cap P_m$$

where each P_i is *prime* (meaning that if a product ab lies in P_i, then so does a or b) and no P_i contains P_j for $j \neq i$. This again illustrates the close connection between the algebra and geometry. (For arbitrary ideals, things are a bit more complicated: The above intersection of prime ideals has to be replaced with what is called a *primary decomposition*—see Chapter 4 of Ref. 4).

Every variety has a *dimension*. Over the real numbers $\mathbf{R}$, this corresponds to our geometric intuition. But over the complex numbers $\mathbf{C}$, one needs to be careful. The affine space $\mathbf{C}^2$ has dimension 2, even though it looks four-dimensional from the real point of view. The dimension of a variety is the maximum of the dimensions of its irreducible components, and irreducible affine varieties of dimensions 1, 2, and 3 are called curves, surfaces, and 3-folds, respectively. An affine variety in k^n is called a *hypersurface* if every irreducible component has dimension $n - 1$.

PROJECTIVE ALGEBRAIC GEOMETRY

One problem with affine varieties is that intersections sometimes occur "at infinity." An example is given by the intersection of a hyperbola with one of its asymptotes in Fig. 2. (Note that a line has a single point at infinity.)

Points at infinity occur naturally in computer graphics, where the horizon in a perspective drawing is the "line at infinity" where parallel lines meet. Adding points at infinity to affine space leads to the concept of projective space.

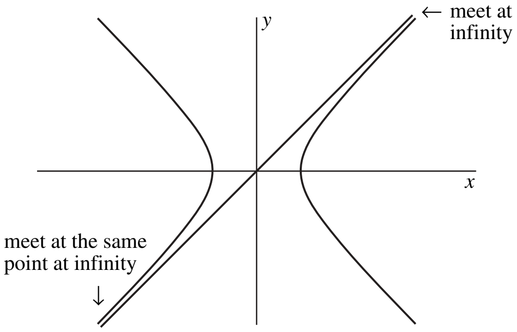

Figure 2. A hyperbola and one of its asymptotes.

The most common way to define *n-dimensional projective space* $\mathbf{P}^n(k)$ is via *homogeneous coordinates*. Every point in $\mathbf{P}^n(k)$ has homogeneous coordinates $[u_0, \ldots, u_n]$, where $(u_0, \ldots, u_n)$ is an element of k^{n+1} different from the zero element $(0, \ldots, 0)$. The square brackets in $[u_0, \ldots, u_n]$ indicate that homogeneous coordinates are *not* unique; rather,

$$[u_0, \ldots, u_n] = [v_0, \ldots, v_n]$$

if and only if there is a nonzero λ in k such that $\lambda u_i = v_i$ for $i = 0, \ldots, n$, i.e., $\lambda(u_0, \ldots, u_n) = (v_0, \ldots, v_n)$. This means that two nonzero points in k^{n+1} give the same point in $\mathbf{P}^n(k)$ if and only if they lie on the same line through the origin.

Consider those points in $P^n(k)$ where $u_0 \neq 0$. As $(1/u_0)$ $(u_0, u_1, \ldots, u_n) = (1, u_1/u_0, \ldots, u_n/u_n)$, one sees easily that

$$\mathbf{P}^n(k) = k^n \cup \mathbf{P}^{n-1}(k).$$

We call $\mathbf{P}^{n-1}$ (k) the *hyperplane at infinity* in this situation. One virtue of homogeneous coordinates is that they have a rich supply of coordinate changes. For example, an invertible 4 × 4 matrix with real entries gives an invertible transformation from $\mathbf{P}^3(\mathbf{R})$ to itself. The reason you see 4 × 4 matrices in computer graphics is that you are really working in three-dimensional projective space $\mathbf{P}^3(\mathbf{R})$, although this is rarely mentioned explicitly. See **THREE-DIMENSIONAL GRAPHICS**.

Now that we have $\mathbf{P}^n(k)$, we can define projective varieties as follows. A polynomial F in $k[x_0, \ldots, x_n]$ is *homogeneous of degree d* if every monomial $x_0^{a_0} \ldots x_n^{a_n}$ appearing in F has degree d, i.e., $a_0 + \cdots + a_n = d$. Such a polynomial has the property that

$$F(\lambda x_0, \ldots, \lambda x_n) = \lambda^d F(x_0, \ldots, x_n).$$

For a point $[u_0, \ldots, u_n]$ of $\mathbf{P}^n(k)$, the quantity $F(u_0, \ldots, u_n)$ is not well defined because of the ambiguity of homogeneous coordinates. But when F is homogeneous, the equation $F(u_0, \ldots, u_n) = 0$ is well defined. Then, given homogeneous polynomials $F_1, \ldots, F_s$, the *projective variety* $\mathbf{V}(F_1, \ldots, F_s)$ consists of all points $[u_0, \ldots, u_n]$ in $\mathbf{P}^n(k)$ that satisfy the system of equations

$$F_1(u_1, \ldots, u_n) = \cdots = F_s(u_1, \ldots, u_n) = 0.$$

Some books (such as Ref. 1) call $\mathbf{V}(F_1, \ldots, F_s)$ a *projective algebraic set*.

The algebraic object corresponding to $\mathbf{P}^n(k)$ is the polynomial ring $k[x_0, \ldots, x_n]$, which we now regard as a *graded ring*. This means that by grouping together terms of the same degree, every polynomial f of degree d can be uniquely written as

$$f = f_0 + f_1 + \cdots + f_d,$$

where f_i is homogeneous of degree i (note that f_i may be zero). We call the f_i the *homogeneous components* of f. An ideal I is *homogeneous* if it is generated by homogeneous polynomials. If I is homogeneous, then a polynomial lies in I if and only if its homogeneous components lie in I.

Most concepts introduced in the affine context carry over to the projective setting. Thus, we can ask whether a projective variety is irreducible and what is its dimension. We also have a projective version of the ideal-variety correspondence, where homogeneous ideals correspond to projective varieties. This is a bit more sophisticated than the affine case, in part because the ideal $\langle x_0, \ldots, x_n \rangle$ defines the empty variety because homogeneous coordinates are not allowed to all be zero.

Given a projective variety V in $\mathbf{P}^n(k)$, we get a homogeneous ideal $I = \mathbf{I}(V)$ in $k[x_0, \ldots, x_n]$. Let I_d consist of all homogeneous polynomials of degree d that lie in I. Then I_d is a finite-dimensional vector space over k, and by a theorem of Hilbert, there is a polynomial $P(x)$, called the *Hilbert polynomial*, such that for all sufficiently large integers d sufficiently large, we have

$$\binom{n+d}{n} - \dim_k I_d = P(d),$$

where the binomial coefficient $\binom{n+d}{n}$ is the dimension of the space of all homogeneous polynomials of degree n. Then one can prove that the dimension m of V equals the degree of $P(x)$. Furthermore, if we write the Hilbert polynomial $P(x)$ in the form

$$P(x) = \frac{D}{m!}x^m + \text{terms of lower degree},$$

then D is a positive integer called the *degree* of V. For example, when V is defined by $F = 0$ over the complex numbers, where F is irreducible and homogeneous of degree d, then V has degree d according to the above definition. This shows just how much information is packed into the ideal I. Later we will discuss the algorithmic methods for computing Hilbert polynomials.

THE COMPLEX NUMBERS

Although many applications of algebraic geometry work over the real numbers $\mathbf{R}$, the theory works best over the complex numbers $\mathbf{C}$. For instance, suppose that $V = \mathbf{V}(f_1, \ldots, f_s)$ is a variety in $\mathbf{R}^n$ of dimension d. Then we expect V to be defined by at least $n - d$ equations because (roughly speaking) each equation should lower the dimension by one. But if we set $f = f_1^2 + \cdots + f_s^2$, then $f = 0$ is equivalent to $f_1 = \cdots = f_s = 0$ because we are working over $\mathbf{R}$. Thus, $V = \mathbf{V}(f_1, \ldots, f_s)$ can be defined by one equation, namely $f = 0$. In general, the relation between ideals and varieties is complicated when working over $\mathbf{R}$.

As an example of why things are nicer over $\mathbf{C}$, consider an ideal I in $\mathbf{C}[x_1, \ldots, x_n]$ and let $V = \mathbf{V}(I)$ be the corresponding affine variety in $\mathbf{C}^n$. The polynomials in I clearly vanish on V, but there may be others. For example, suppose that f is not in I but some power of f, say f^ℓ, is in I. Then f^ℓ and hence f vanish on V. The *Hilbert Nullstellensatz* states that these are the only polynomials that vanish on V, i.e.,

$$\begin{aligned}\mathbf{I}(V) &= \mathbf{I}(\mathbf{V}(I)) \\ &= \{\, f \text{ in } \mathbf{C}[x_1, \ldots, x_n] \,|\, f^\ell \text{ is in } I \text{ for some integer } \ell \geq 0\}.\end{aligned}$$

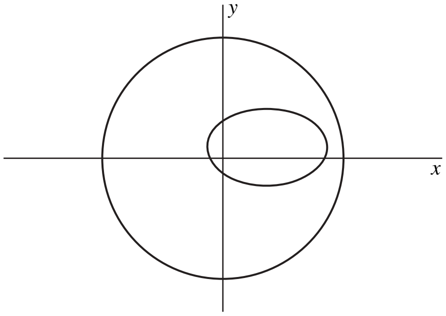

Figure 3. A circle and an ellipse.

The ideal on the right is called the *radical* of I and is denoted $\mathrm{rad}(I)$. Thus, the Nullstellensatz asserts that over $\mathbf{C}$, we have $\mathbf{I}(\mathbf{V}(I)) = \mathrm{rad}(I)$. It is easy to find examples where this fails over $\mathbf{R}$.

Another example of why $\mathbf{C}$ is nice comes from *Bézout's Theorem* in Fig. 3. In its simplest form, this asserts that distinct irreducible plane curves of degrees m and n intersect in mn points, counted with multiplicity. For example, consider the intersection of a circle and an ellipse. These are curves of degree 2, so we should have four points of intersection. But if the ellipse is really small, it can fit entirely inside the circle, which makes it seem that there are no points of intersection, as in Fig. 3. This is because we are working over $\mathbf{R}$; over $\mathbf{C}$, there really are four points of intersection.

Bézout's Theorem also illustrates the necessity of working over the projective plane. Consider, for example, the intersection of a hyperbola and one of its asymptotes in Fig. 4. These are curves of degree 2 and 1, respectively, so there should be 2 points of intersection. Yet there are none in $\mathbf{R}^2$ or $\mathbf{C}^2$. But once we go to $\mathbf{P}^2(\mathbf{R})$ or $\mathbf{P}^2(\mathbf{C})$, we get one point of intersection at infinity, which has multiplicity 2 because the asymptote and the hyperbola are tangent at infinity. We will say more about multiplicity later in the article.

In both the Nullstellensatz and Bézout's theorem, we can replace $\mathbf{C}$ with any *algebraically closed field*, meaning a field where every nonconstant polynomial has a root. A large part of algebraic geometry involves the study of irreducible projective varieties over algebraically closed fields.

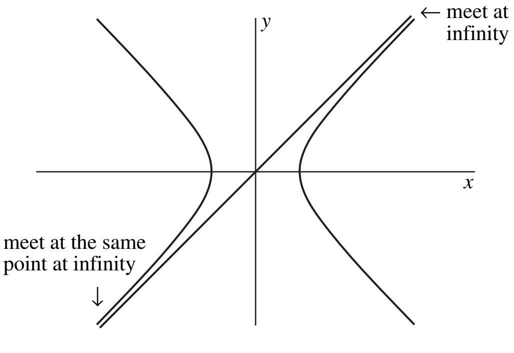

Figure 4. A hyperbola and one of its asymptotes.

FUNCTIONS ON AFFINE AND PROJECTIVE VARIETIES

In mathematics, one often studies objects by considering the functions defined on them. For an affine variety V in k^n, we let $k[V]$ denote the set of functions from V to k given by polynomials in $k[x_1,\dots,x_n]$. One sees easily that $k[V]$ is a ring, called the *coordinate ring* of V.

An important observation is that two distinct polynomials f and g in $k[x_1,\dots,x_n]$ can give the same function on V. This happens precisely when $f-g$ vanishes on V, i.e., when $f-g$ is in the ideal $\mathbf{I}(V)$. We express this by writing

$$f \equiv g \bmod \mathbf{I}(V),$$

similar to the congruence notation introduced by Gauss. It follows that computations in $k[x_1,\dots,x_n]$ modulo $\mathbf{I}(V)$ are equivalent to computations in $k[V]$. In the language of abstract algebra, this is expressed by the ring isomorphism

$$k[x_1,\dots,x_n]/\mathbf{I}(V) \simeq k[V],$$

where $k[x_1,\dots,x_n]/\mathbf{I}(V)$ is the set of equivalence classes of the equivalence relation $f \equiv g$ mod $\mathbf{I}(V)$. More generally, given any ideal I in $k[x_1,\dots,x_n]$, one gets the *quotient ring* $k[x_1,\dots,\mathrm{x}_\mathrm{n}]/I$ coming from the equivalence relation $f \equiv g$ mod I. We will see later that Gröbner bases enable us to compute effectively in quotient rings.

We can use quotients to construct finite fields as follows. For a prime p, we get $\mathbf{F}_p$ by considering the integers modulo p. To get $\mathbf{F}_{p^m}$ when $m > 1$, take an irreducible polynomial f in $\mathbf{F}_p[x]$ of degree m. Then the quotient ring $\mathbf{F}_p[x]/\langle f\rangle$ is a model of F_{p^m}. Thus, for example, computations in $\mathbf{F}_2[x]$ modulo x^2+x+1 represent the finite field $\mathbf{F}_4$. See ALGEBRAIC CODING THEORY for more on finite fields.

The coordinate ring $\mathbf{C}[V]$ of an affine variety V in $\mathbf{C}^n$ has an especially strong connection to V. Given a point $(u_1,\dots,u_n)$ of V, the functions in $\mathbf{C}[V]$ vanishing at $(u_1,\dots,u_n)$ generate a *maximal ideal*, meaning an ideal of $\mathbf{C}[V]$ not equal to the whole ring but otherwise as big as possible with respect to inclusion. Using the Nullstellensatz, one can show that *all* maximal ideals of $\mathbf{C}[V]$ arise this way. In other words, there is a one-to-one correspondence

$$\text{points of } V \longleftrightarrow \text{maximal ideals of } \mathbf{C}[V].$$

Later we will use this correspondence to motivate the definition of *affine scheme*.

Functions on projective varieties have a different flavor, since a polynomial function defined everywhere on a connected projective variety must be constant. Instead, two approaches are used, which we will illustrate in the case of $\mathbf{P}^n(k)$. In the first approach, one considers *rational functions*, which are quotients

$$\frac{F(x_0,\dots,x_n)}{G(x_0,\dots,x_n)}$$

of homogeneous polynomials of the same degree, say d. This function is well defined despite the ambiguity of homogeneous coordinates, because

$$\frac{F(\lambda x_0,\ldots,\lambda x_n)}{G(\lambda x_0,\ldots,\lambda x_n)}=\frac{\lambda^d F(x_0,\ldots,x_n)}{\lambda^d G(x_0,\ldots,x_n)}=\frac{F(x_0,\ldots,x_n)}{G(x_0,\ldots,x_n)}.$$

However, this function is *not* defined when the denominator vanishes. In other words, the above quotient is only defined where $G \neq 0$. The set of all rational functions on $\mathbf{P}^n(k)$ forms a field called the *field of rational functions on* $\mathbf{P}^n(k)$. More generally, any irreducible projective variety V has a field of rational functions, denoted $k(V)$.

The second approach to studying functions on $\mathbf{P}^n(k)$ is to consider the polynomial functions defined on certain large subsets of $\mathbf{P}^n(k)$. Given projective variety V in $\mathbf{P}^n(k)$, its *complement* U consists of all points of $\mathbf{P}^n(k)$ not in V. We call U a *Zariski open subset* of $\mathbf{P}^n(k)$. Then let $\Gamma(U)$ be the ring of all rational functions on $\mathbf{P}^n(k)$ defined at all points of U. For example, the complement U_0 of $\mathbf{V}(x_0)$ consists of points where $x_0 \neq 0$, which is a copy of k^n. So here $\Gamma(U_0)$ is the polynomial ring $k[x_1/x_0,\ldots,x_n/x_0]$. When we consider the rings $\Gamma(U)$ for all Zariki open subsets U, we get a mathematical object called the *structure sheaf of* $\mathbf{P}^n(k)$. More generally, any projective variety V has a structure sheaf, denoted O_V. We will see below that sheaves play an important role in abstract algebraic geometry.

GRÖBNER BASES

Buchberger introduced Gröbner bases in 1965 in order to do algorithmic computations on ideals in polynomial rings. For example, suppose we are given polynomials f, $f_1,\ldots,f_s \in k[x_1,\ldots,x_n]$, where k is a field whose elements can be represented exactly on a computer (e.g., k is a finite field or the field of rational numbers). From the point of view of pure mathematics, either f lies in the ideal $\langle f_1,\ldots,f_s\rangle$ or it does not. But from a practical point of view, one wants an algorithm for deciding which of these two possibilities actually occurs. This is the *ideal membership question*.

In the special case of two univariate polynomials f, g in $k[x]$, f lies in $\langle g\rangle$ if and only if f is a multiple of g, which we can decide by the division algorithm from high-school algebra. Namely, dividing g into f gives $f = qg + r$, where the remainder r has degree strictly smaller than the degree of g. Then f is a multiple of g if and only if the remainder is zero. This solves the ideal membership question in our special case.

To adapt this strategy to $k[x_1,\ldots,x_n]$, we first need to order the monomials. In $k[x]$, this is obvious: The monomials are $1, x, x^2$, etc. But there are many ways to do this when there are two or more variables. A *monomial order* $>$ is an order relation on monomials $U, V, W,\ldots$ in $k[x_1,\ldots,x_n]$ with the following properties:

1. Given monomials U and V, exactly one of $U > V$, $U = V$, or $U < V$ is true.
2. If $U > V$, then $UW > VW$ for all monomials W.
3. If $U \neq 1$, then $U > 1$; i.e., 1 is the least monomial with respect to $>$.

These properties imply that $>$ is a *well ordering*, meaning that any strictly decreasing sequence with respect to $>$ is finite. This is used to prove termination of various algorithms. An example of a monomial order is *lexicographic order*, where

$$x_1^{a_1}x_2^{a_2}\ldots x_n^{a_n} > x_1^{b_1}x_2^{b_2}\ldots x_n^{b_n}$$

provided

$$a_1 > b_1;\ \text{or}\ a_1 = b_1\ \text{and}\ a_2 > b_2;\ \text{or}\ a_1 = b_1,\\ a_2 = b_2\ \text{and}\ a_3 > b_3;\ \text{etc.}$$

Other important monomial orders are *graded lexicographic order* and *graded reverse lexicographic order*. These are described in Chapter 2 of Ref. 4.

Now fix a monomial order $>$. Given a nonzero polynomial f, we let $\mathrm{lt}(f)$ denote the *leading term* of f, namely the nonzero term of f whose monomial is maximal with respect to $>$ (in the literature, $\mathrm{lt}(f)$ is sometimes called the *initial term* of f, denoted $\mathrm{in}(f)$). Given $f_1,\ldots,f_s$, the *division algorithm* produces polynomials $q_1,\ldots,q_s$ and r such that

$$f = q_1 f_1 + \cdots + q_s f_s + r$$

where every nonzero term of r is divisible by none of $\mathrm{lt}(f_1),\ldots,\mathrm{lt}(f_s)$. The remainder r is sometimes called the *normal form* of f with respect to $f_1,\ldots,f_s$. When $s = 1$ and f and f_1 are univariate, this reduces to the high-school division algorithm mentioned earlier.

In general, multivariate division behaves poorly. To correct this, Buchberger introduced a special kind of basis of an ideal. Given an ideal I and a monomial order, its *ideal of leading terms* $\mathrm{lt}(I)$ (or *initial ideal* $\mathrm{in}(I)$is the ideal generated by $\mathrm{lt}(f)$ for all f in I. Then elements $g_1,\ldots,g_t$ of I form a *Gröbner basis* of I provided that $\mathrm{lt}(g_1),\ldots,\mathrm{lt}(g_t)$ form a basis of $\mathrm{lt}(I)$. Buchberger showed that a Gröbner basis is in fact a basis of I and that, given generators $f_1,\ldots,f_s$ of I, there is an algorithm (the *Buchberger algorithm*) for producing the corresponding Gröbner basis. A description of this algorithm can be found in Chapter 2 of Ref. 4.

The complexity of the Bucherger algorithm has been studied extensively. Examples are known where the input polynomials have degree $\leq d$, yet the corresponding Gröbner basis contains polynomials of degree 2^{2^d}. Theoretical results show that this doubly exponential behavior is the worst that can occur (for precise references, see Chapter 2 of Ref. 4). However, there are many geometric situations where the complexity is less. For example, if the equations have only finitely many solutions over $\mathbf{C}$, then the complexity drops to a single exponential. Furthermore, obtaining geometric information about an ideal, such as the dimension of its associated variety, often has single exponential complexity. When using graded reverse lexicographic order, complexity is related to the *regularity* of the ideal. This is discussed in Ref. 7. Below we will say more about the practical aspects of Gröbner basis computations.

Using the properties of Gröbner bases, one gets the following *ideal membership algorithm*: Given $f, f_1, \ldots, f_s$, use the Buchberger algorithm to compute a Gröbner basis $g_1, \ldots, g_t$ of $\langle f_1, \ldots, f_s \rangle$ and use the division algorithm to compute the remainder of f on division by $g_1, \ldots, g_t$. Then f is in the ideal $\langle f_1, \ldots, f_s \rangle$ if and only if the remainder is zero.

Another important use of Gröbner bases occurs in *elimination theory*. For example, in geometric modeling, one encounters surfaces in $\mathbf{R}^3$ parametrized by polynomials, say

$$x = f(s,t), \quad y = g(s,t), \quad z = h(s,t).$$

To obtain the equation of the surface, we need to eliminate s, t from the above equations. We do this by considering the ideal

$$\langle x - f(s,t), y - g(s,t), z - h(s,t) \rangle$$

in the polynomial ring $\mathbf{R}[s, t, x, y, z]$ and computing a Gröbner basis for this ideal using lexicographic order, where the variables to be eliminated are listed first. The *Elimination Theorem* (see Chapter 3 of Ref. 4) implies that the equation of the surface is the only polynomial in the Gröbner basis not involving s, t. In practice, elimination is often done by other methods (such as *resultants*) because of complexity issues. See also the entry on SURFACE MODELING.

Our final application concerns a system of equations $f_1 = \cdots = f_s = 0$ in n variables over $\mathbf{C}$. Let $I = \langle f_1, \ldots, f_s \rangle$, and compute a Gröbner basis of I with respect to any monomial order. The *Finiteness Theorem* asserts that the following are equivalent:

1. The equations have finitely many solutions in $\mathbf{C}^n$.
2. The Gröbner basis contains elements whose leading terms are pure powers of the variables (i.e., x_1 to a power, x_2 to a power, etc.) up to constants.
3. The quotient ring $\mathbf{C}[x_1, \ldots, x_n]/I$ is a finite-dimensional vector space over $\mathbf{C}$.

The equivalence of the first two items gives an algorithm for determining whether there are finitely many solutions over $\mathbf{C}$. From here, one can find the solutions by several methods, including *eigenvalue methods* and *homotopy continuation*. These and other methods are discussed in Ref. 8. The software PHCpack (9) is a freely available implementation of homotopy continuation. Using homotopy techniques, systems with 10^5 solutions have been solved. Without homotopy methods but using a robust implementation of the Buchberger algorithm, systems with 1000 solutions have been solved, and in the context of computational biology, some highly structured systems with over 1000 equations have been solved.

However, although solving systems is an important practical application of Gröbner basis methods, we want to emphasize that many theoretical objects in algebraic geometry, such as Hilbert polynomials, free resolutions (see below), and sheaf cohomology (also discussed below), can also be computed by these methods. As more and more of these theoretical objects are finding applications, the ability to compute them is becoming increasingly important.

Gröbner basis algorithms have been implemented in computer algebra systems such as Maple (10) and Mathematica (11). For example, the solve command in Maple and Solve command in Mathematica make use of Gröbner basis computations. We should also mention CoCoA (12), Macaulay 2 (13), and Singular (14), which are freely available on the Internet. These powerful programs are used by researchers in algebraic geometry and commutative algebra for a wide variety of experimental and theoretical computations. With the help of books such as Ref. 5 for Macaulay 2, Ref. 15 for CoCoA, and Ref. 16 for Singular, these programs can be used by beginners. The program Magma (17) is not free but has a powerful implementation of the Buchberger algorithm.

MODULES

Besides rings, ideals, and quotient rings, another important algebraic structure to consider is the concept of *module over a ring*. Let R denote the polynomial ring $k[x_0, \ldots, x_n]$. Then saying that M is an R-module means that M has addition and scalar multiplication with the usual properties, except that the "scalars" are now elements of R. For example, the *free R-module* R^m consists of m-tuples of elements of R. We can clearly add two such m-tuples and multiply an m-tuple by an element of R.

A more interesting example of an R-module is given by an ideal $I = \langle f_1, \ldots, f_s \rangle$ in R. If we choose the generating set $f_1, \ldots, f_s$ to be as small as possible, we get a minimal basis of I. But when $s \geq 2$, $f_1, \ldots, f_s$ cannot be linearly independent over R, because $f_j \cdot f_i + (-f_i) \cdot f_j = 0$ when $i \neq j$. To see how badly the f_i fail to be independent, consider

$$R^s \to I \to 0,$$

where the first arrow is defined using dot product with $(f_1, \ldots, f_s)$ and the second arrow is a standard way of saying the first arrow is onto, which is true because $I = \langle f_1, \ldots, f_s \rangle$. The kernel or nullspace of the first arrow measures the failure of the f_i to be independent. This kernel is an R-module and is called the *syzygy module* of $f_1, \ldots, f_s$, denoted $\mathrm{Syz}(f_1, \ldots, f_s)$.

The *Hilbert Basis Theorem* applies here so that there are finitely many syzygies $\mathbf{h}_1, \ldots, \mathbf{h}_\ell$ in Syz $(f_1, \ldots, f_s)$ such that every syzygy is a linear combination, with coefficients in R, of $\mathbf{h}_1, \ldots, \mathbf{h}_\ell$. Each h_i is a vector of polynomials; if we assemble these into a matrix, then matrix multiplication gives a map

$$R^\ell \to R^s$$

whose image is $\mathrm{Syz}(f_1, \ldots, f_s)$. This looks like linear algebra, except that we are working over a ring instead of a field. If we think of the variables in $R = k[x_1, \ldots, x_n]$ as parameters, then we are doing *linear algebra with parameters*.

The generating syzgyies $\mathbf{h}_i$ may fail to be independent, so that the above map may have a nonzero kernel. Hence we can iterate this process, although the *Hilbert Syzygy Theorem* implies that kernel is eventually zero. The result is a collection of maps

$$0 \to R^t \to \cdots \to R^\ell \to R^s \to I \to 0,$$

where at each stage, the image of one map equals the kernel of the next. We say that this is a *free resolution* of I. By adapting Gröbner basis methods to modules, one obtains algorithms for computing free resolutions.

Furthermore, when I is a homogeneous ideal, the whole resolution inherits a graded structure that makes it straightforward to compute the Hilbert polynomial of I. Given what we know about Hilbert polynomials, this gives an algorithm for determining the dimension and degree of a projective variety. A discussion of modules and free resolutions can be found in Ref. 18.

Although syzygies may seem abstract, there are situations in geometric modeling where syzygies arise naturally as *moving curves* and *moving surfaces* (see Ref. 19). This and other applications show that algebra needs to be added to the list of topics that fall under the rubric of applied mathematics.

LOCAL PROPERTIES

In projective space $\mathbf{P}^n(k)$, let U_i denote the Zariski open subset where $x_i \neq 0$. Earlier we noted that U_0 looks the affine space k^n; the same is true for the other U_i. This means that $\mathbf{P}^n(k)$ locally looks like affine space. Furthermore, if V is a projective variety in $\mathbf{P}^n(k)$, then one can show that $V_i = V \cap U_i$ is a affine variety for all i. Thus, every projective variety locally looks like an affine variety.

In algebraic geometry, one can get even more local. For example, let $\mathbf{p} = [u_0, \ldots, u_n]$ be a point of $\mathbf{P}^n(k)$. Then let O_{p} consist of all rational functions on $\mathbf{P}^n(k)$ defined at $\mathbf{p}$. Then O_{p} is clearly a ring, and the subset consisting of those functions that vanish at $\mathbf{p}$ is a maximal ideal. More surprising is the fact that this is the unique maximal ideal of O_{p}. We call O_{p} the *local ring* of $\mathbf{P}^n(k)$ at $\mathbf{p}$, and in general, a commutative ring with a unique maximal ideal is called a *local ring*. In a similar way, a point $\mathbf{p}$ of an affine or projective variety V has a local ring $O_{V,\mathbf{p}}$.

Many important properties of a variety at a point are reflected in its local ring. As an example, we give the definition of *multiplicity* that occurs in Bézout's Theorem. Recall the statement: Distinct irreducible curves in $\mathbf{P}^2(\mathbf{C})$ of degrees m and n intersect at mn points, counted with multiplicity. By picking suitable coordinates, we can assume that the points of intersection lie in $\mathbf{C}^2$ and that the curves are defined by equations $f = 0$ and $g = 0$ of degrees m and n, respectively. If $\mathbf{p}$ is a point of intersection, then its *multiplicity* is given by

$$\mathrm{mult}(\mathbf{p}) = \dim_{\mathbf{C}} O_{\mathbf{p}}/\langle f, g\rangle, \quad O_{\mathbf{p}} = \text{local ring of } \mathbf{P}^2(\mathbf{C}) \text{ at } \mathbf{p},$$

and the precise version of Bézout's Theorem states that

$$m\,n = \sum_{f(\mathbf{p})=g(\mathbf{p})=0} \mathrm{mult}(\mathbf{p}).$$

A related notion of multiplicity is the *Hilbert–Samuel multiplicity* of an ideal in O_{p}, which arises in geometric modeling when considering the influence of a basepoint on the degree of the defining equation of a parametrized surface.

SMOOTH AND SINGULAR POINTS

In multivariable calculus, the *gradient* $\nabla f = \frac{\partial f}{\partial x}\mathbf{i} + \frac{\partial f}{\partial y}\mathbf{j}$ is perpendicular to the level curve defined by $f(x, y) = 0$. When one analzyes this carefully, one is led to the following concepts for a point on the level curve:

- A *smooth point*, where ∇f is nonzero and can be used to define the tangent line to the level curve.
- A *singular point*, where ∇f is zero and the level curve has no tangent line at the point.

These concepts generalize to arbitrary varieties. For any variety, most points are smooth, whereas others—those in the *singular locus*—are singular. Singularities can be important. For example, when one uses a variety to describe the possible states of a robot arm, the singularities of the variety often correspond to positions where the motion of the arm is less predictable (see Chapter 6 of Ref. 4 and the entry on ROBOTICS).

A variety is *smooth* or *nonsingular* when every point is smooth. When a variety has singular points, one can use *blowing up* to obtain a new variety that is less singular. When working over an algebraically closed field of *characteristic* 0 (meaning fields that contain a copy of $\mathbf{Q}$), Hironaka proved in 1964 that one can always find a sequence of blowing up that results in a smooth variety. This is called *resolution of singularities*. Resolution of singularities over a field of *characteristic p* (fields that contain a copy of $\mathbf{F}_p$) is still an open question. Reference 20 gives a nice introduction to resolution of singularities. More recently, various groups of people have figured out how to do this algorithmically, and work has been done on implementing these algorithms, for example, the software desing described in Ref. 21. We also note that singularities can be detected numerically using condition numbers (see Ref. 22).

SHEAVES AND COHOMOLOGY

For an affine variety, modules over its coordinate ring play an important role. For a projective variety V, the corresponding objects are *sheaves of O_V-modules*, where O_V is the structure sheaf of V. Locally, V looks like an affine variety, and with a suitable hypothesis called *quasi-coherence*, a sheaf of O_V-modules locally looks like a module over the coordinate ring of an affine piece of V.

From sheaves, one is led to the idea of *sheaf cohomology*, which (roughly speaking) measures how the local pieces of the sheaf fit together. Given a sheaf F on V, the sheaf cohomology groups are denoted $H^i(V,F)$. We will see below that the sheaf cohomology groups are used in the classification of projective varieties. For another application of sheaf cohomology, consider a finite collection V of points in $\mathbf{P}^n(k)$. From the sheaf point of view, V is defined by an *ideal sheaf* I_V. In interpolation theory, one wants to model arbitrary functions on V using polynomials of a fixed degree, say m. If m is too small, this may not be possible, but we always succeed if m is large enough. A precise description of which degrees m work is given by sheaf cohomology. The ideal sheaf I_V has a *twist* denoted $I_V(m)$. Then all functions on V come from polynomials of degree m if and only if $H^1(\mathbf{P}^n(k), I_V(m)) = \{0\}$. We also note that vanishing theorems for sheaf cohomology have been used in geometric modeling (see Ref. 23).

References 1, 2, and 24 discuss sheaves and sheaf cohomology. Sheaf cohomology is part of *homological algebra*. An introduction to homological algebra, including sheaves and cohomology, is given in Ref. 5.

SPECIAL VARIETIES

We next discuss some special types of varieties that have been studied extensively.

1. *Elliptic Curves and Abelian Varieties*. Beginning with the middle of the eighteenth century, *elliptic integrals* have attracted a lot of attention. The study of these integrals led to both *elliptic functions* and *elliptic curves*. The latter are often described by an equation of the form

$$y^2 = ax^3 + bx^2 + cx + d,$$

where $ax^3 + bx^2 + cx + d$ is a cubic polynomial with distinct roots. However, to get the best properties, one needs to work in the projective plane, where the above equation is replaced with the homogeneous equation

$$y^2z = ax^3 + bx^2z + cxz^2 + dz^3.$$

The resulting projective curve E has an extra structure: Given two points on E, the line connecting them intersects E at a third point by Bézout's Theorem. This leads to a group structure on E where the point at infinity is the identity element.

Over the field of rational numbers $\mathbf{Q}$, elliptic curves have a remarkably rich theory. The group structure is related to the *Birch–Swinnerton-Dyer Conjecture*, and Wiles's proof of Fermat's Last Theorem was a corollary of his solution of a large part of the *Taniyama–Shimura Conjecture* for elliptic curves over $\mathbf{Q}$. On the other hand, elliptic curves over finite fields are used in cryptography (see Ref. 25). The relation between elliptic integrals and elliptic curves has been generalized to *Hodge theory*, which is described in Ref. 24. Higher dimensional analogs of elliptic curves are called *abelian varieties*.

2. *Grassmannians and Schubert Varieties*. In $\mathbf{P}^n(k)$, we use homogeneous coordinates $[u_0, \ldots, u_n]$, where $[u_0, \ldots, u_n] = [v_0, \ldots, v_n]$ if both lie on the same line through the origin in k^{n+1}. Hence points of $\mathbf{P}^n(k)$ correspond to one-dimensional subspaces of k^{n+1}. More generally, the *Grassmannian* $G(N, m)(k)$ consists of all m-dimensional subspaces of k^n. Thus, $G(n+1, 1)(k) = \mathbf{P}^n(k)$.

Points of $G(N, m)(k)$ have natural coordinates, which we describe for $m = 2$. Given a two-dimensional sub-space W of k^N, consider a $2 \times N$ matrix

$$\begin{pmatrix} u_1 & u_2 & \ldots & u_N \\ v_1 & v_2 & \ldots & v_N \end{pmatrix}$$

whose rows give a basis of W. Let p_{ij}, $i < j$, be the determinant of the 2×2 matrix formed by the ith and jth columns. The $M = \binom{N}{2}$ numbers p_{ij} are the *Plücker coordinates* of W. These give a point in $\mathbf{P}^{M-1}(k)$ that depends only on W and not on the chosen basis. Furthermore, the subspace W can be reconstructed from its Plücker coordinates. The Plücker coordinates satisfy the *Plücker relations*

$$p_{ij}p_{kl} - p_{ik}p_{jl} + p_{il}p_{jk} = 0,$$

and any set of numbers satisfying these relations comes from a subspace W. It follows that the Plücker relations define $G(N, 2)(k)$ as a projective variety in $\mathbf{P}^{M-1}(k)$. In general, $G(N, m)(k)$ is a smooth projective variety of dimension $m(N - m)$.

The Grassmannian $G(N, m)(k)$ contains interesting varieties called *Schubert varieties*. The *Schuberi calculus* describes how these varieties intersect. Using the Schubert calculus, one can answer questions such as how many lines in $\mathbf{P}^3(k)$ intersect four lines in general position? (The answer is two.) An introduction to Grassmannians and Schubert vareties can be found in Ref. 26.

The question about lines in $\mathbf{P}^3(k)$ is part of *enumerative algebraic geometry*, which counts the number of geometrically interesting objects of various types. Bezout's Theorem is another result of enumerative algebraic geometry. Another famous enumerative result states that a smooth cubic surface in $\mathbf{P}^3(\mathbf{C})$ contains exactly 27 lines.

3. *Rational and Unirational Varieties*. An irreducible variety V of dimension n over $\mathbf{C}$ is *rational* if there is a one-to-one rational parametrization $U \to V$, where U is a Zariski open subset of $\mathbf{C}^n$. The simplest example of a rational variety is $\mathbf{P}^n(\mathbf{C})$. Many curves and surfaces that occur in geometric modeling are rational.

More generally, an irreducible variety of dimension n is *unirational* if there is a rational parametrization $U \to V$ whose image fills up most of V, where U is a Zariski open subset of $\mathbf{C}^m$, $m \geq n$. For varieties of dimension 1 and 2, unirational and rational coincide, but in dimensions 3 and greater, they differ. For example, a smooth cubic hypersurface in $\mathbf{P}^4(\mathbf{C})$ is unirational but not rational.

A special type of rational variety is a *toric variety*. In algebraic geometry, a *torus* is $(\mathbf{C}^*)^n$, which is the Zariski open subset of $\mathbf{C}^n$ where all coordinates are nonzero. A toric variety V is an n-dimensional irreducible variety that contains a copy of $(\mathbf{C}^*)^n$ as a Zariski open subset in a suitably nice manner. Both $\mathbf{C}^n$ and $\mathbf{P}^n(\mathbf{C})$ are toric varieties. There are strong relations between toric varieties and polytopes, and toric varieties also have interesting applications in geometric modeling (see Ref. 27), algebraic statistics, and computational biology (see Ref. 28). The latter includes significant applications of Gröbner bases.

4. *Varieties over Finite Fields*. A set of equations defining a projective variety V over $\mathbf{F}_p$ also defines V as a projective variety over $\mathbf{F}_{p^m}$ for every $m \geq 1$. As $\mathbf{P}^n(\mathbf{F}_{p^m})$ is finite, we let N_m denote the number of points of V when regarded as lying in $\mathbf{P}^n(\mathbf{F}_{p^m})$. To study the asymptotic behavior of N_m as m gets large, it is convenient to assemble the N_m into the *zeta function*

$$Z(V,\, t) = \exp\left(\sum_{m=1}^{\infty} N_m t^m/m\right).$$

The behavior of $Z(V,\, t)$ is the subject of some deep theorems in algebraic geometry, including the *Riemann hypothesis* for smooth projective varieties over finite fields, proved by Deligne in 1974.

Suppose for example that V is a smooth curve. The *genus* g of V is defined to be the dimension of the sheaf cohomology group $H^1(V,\, O_V)$. Then the Riemann hypothesis implies that

$$|N_m - p^m - 1| \leq 2g\, p^{m/2}.$$

Zeta functions, the Riemann hypothesis, and other tools of algebraic geometry such as the *Riemann–Roch Theorem* have interesting applications in algebraic coding theory. See Ref. 29 and the entry on ALGEBRAIC CODING THEORY. References 18 and 30 discuss aspects of coding theory that involve Gröbner bases.

CLASSIFICATION QUESTIONS

One of the enduring questions in algebraic geometry concerns the classification of geometric objects of various types. Here is a brief list of some classification questions that have been studied.

1. *Curves*. For simplicity, we work over $\mathbf{C}$. The main invariant of smooth projective curve is its genus g, defined above as the dimension of $H^1(V,\, O_V)$. When the genus is 0, the curve is $\mathbf{P}^1(\mathbf{C})$, and when the genus is 1, the curve is an elliptic curve E. After a coordinate change, the affine equation can be written as

$$y^2 = x^3 + ax + b, \quad 4a^3 + 27b^2 \neq 0.$$

The *j-invariant* $j(E)$ is defined to be

$$j(E) = \frac{2^8 3^3 a^3}{4a^3 + 27b^2}$$

and two elliptic curves over $\mathbf{C}$ are isomorphic as varieties if and only if they have the same j-invariant. It follows that isomorphism classes of elliptic curves correspond to complex numbers; one says that $\mathbf{C}$ is the *moduli space* for elliptic curves. Topologically, all elliptic curves look like a torus (the surface of a donut), but algebraically, they are the same if and only if they have the same j-invariant.

Now consider curves of genus $g \geq 2$ over $\mathbf{C}$. Topologically, these look like a surface with g holes, but algebraically, there is a moduli space of dimension $3g - 3$ that records the algebraic structure. These moduli spaces and their compactifications have been studied extensively. Curves of genus $g \geq 2$ also have strong connections with non-Euclidean geometry.

2. *Surfaces*. Smooth projective surfaces over $\mathbf{C}$ have a richer structrure and hence a more complicated classification. Such a surface S has its *canonical bundle* ω_S, which is a sheaf of O_S-modules that (roughly speaking) locally looks like multiples of $dxdy$ for local coordinates $x,\, y$. Then we get the associated bundle ω_S^m, which locally looks like multiples of $(dxdy)^m$. The dimension of the sheaf cohomology group $H^0(S,\, \omega_S^m)$ grows like a polynomial in m, and the degree of this polynomial is the *Kodaira dimension*κ of S, where the zero polynomial has degree $-\infty$. Using the Kodaira dimension, we get the following *Enriques-Kodaira classification*:

$\kappa = -\infty$: Rational surfaces and ruled surfaces over curves of genus > 0.

$\kappa = 0$: K3 surfaces, abelian surfaces, and Enriques surfaces.

$\kappa = 1$: Surfaces mapping to a curve of genus ≥ 2 whose generic fiber is an elliptic curve.

$\kappa = 2$: Surfaces of general type.

One can also define the Kodaira dimension for curves, where the possible values $\kappa = -\infty$, 0, 1 correspond to the classication by genus $g = 0$, 1 or ≥ 2. One difference in the surface case is that blowing up causes problems. One needs to define the *minimal model* of a surface, which exists in most cases, and then the minimal model gets "classified" by describing its moduli space. These moduli spaces are well understood except for surfaces of general type, where many unsolved problems remain.

To say more about how this classification works, we need some terminology. Two irreducible varieties are *birational* if they have Zariski open subsets that are isomorphic. Thus, a variety over $\mathbf{C}$ is rational if and only if it is birational to $\mathbf{P}^n(\mathbf{C})$, and two smooth projective surfaces are birational if and only if they have the same minimal model. As for moduli, consider the equation

$$a\left(x_0^4 + x_1^4 + x_2^4 + x_3^4\right) + x_0x_1x_2x_3 = 0.$$

This defines a K3 surface in $\mathbf{P}^3(\mathbf{C})$ provided $a \neq 0$. As we vary a, we get different K3 surfaces that can be *deformed* into each other. This (very roughly) is what happens in a moduli space, although a lot of careful work is needed to make this idea precise.

The Enriques–Kodaira classification is described in detail in Ref. 31. This book also discuss the closely related classication of smooth complex surfaces, not necessarily algebraic.

1. *Higher Dimensions*. Recall that a three-fold is a variety of dimension 3. As in the surface case, one uses the Kodaira dimension to break up all three-folds into classes, this time according to $k = -\infty$, 0, 1, 2, 3. One new feature for three-folds is that although minimal models exist, they may have certain mild singularities. Hence, the whole theory is more sophisticated than the surface case. The general strategy of the *minimal model program* is explained in Ref. 32.
2. *Hilbert Schemes*. Another kind of classification question concerns varieties that live in a fixed ambient space. For example, what sorts of surfaces of small degree exist in $\mathbf{P}^4(\mathbf{C})$? There is also the *Hartshorne conjecture*, which asserts that a smooth variety V of dimension n in $\mathbf{P}^N(\mathbf{C})$, where $N < \frac{3}{2}n$, is a *complete intersection*, meaning that V is defined by a system of exactly $N - n$ equations.

   In general, one can classify *all* varieties in $\mathbf{P}^n(\mathbf{C})$ of given degree and dimension. One gets a better classification by looking at all varieties with given Hilbert polynomial. This leads to the concept of a *Hilbert scheme*. There are many unanswered questions about Hilbert schemes.
3. *Vector Bundles*. A *vector bundle of rank r* on a variety V is a sheaf that locally looks like a free module of rank r. For example, the tangent planes to a smooth surface form its *tangent bundle*, which is a vector bundle of rank 2.

   Vector bundles of rank 1 are called *line bundles* or *invertible sheaves*. When V is smooth, line bundles can be described in terms of *divisors*, which are formal sums $a_1D_1 + \cdots + a_mD_m$, where a_i is an integer and D_i is an irreducible hypersurface. Furthermore, line bundles are isomorphic if and only if their corresponding divisors are *rationally equivalent*. The set of isomorphism classes of line bundles on V forms the *Picard group* Pic(V).

   There has also been a lot of work classifying vector bundles on $\mathbf{P}^n(\mathbf{C})$. For $n = 1$, a complete answer is known. For $n > 2$, one classifies vector bundles E according to their rank r and their *Chern classes* $c_i(E)$. One important problem is understanding how to compactify the corresponding moduli spaces. This involves the concepts of *stable* and *semistable* bundles. Vector bundles also have interesting connections with mathematical physics (see Ref. 33).
4. *Algebraic Cycles*. Given an irreducible variety V of dimension n, a variety W contained in V is called a *subvariety*. Divisors on V are integer combinations of irreducible subvarieties of dimension $n - 1$. More generally, an *m-cycle* on V is an integer combination of irreducible subvarieties of dimension m. Cycles are studied using various equivalence relations, including *rational equivalence, algebraic equivalence, numerical equivalence*, and *homological equivalence*. The *Hodge Conjecture* concerns the behavior of cycles under homological equivalence, whereas the *Chow groups* are constructed using rational equivalence.

   Algebraic cycles are linked to other topics in algebraic geometry, including *motives, intersection theory*, and *variations of Hodge structure*. An introduction to some of these ideas can be found in Ref. 34.

REAL ALGEBRAIC GEOMETRY

In algebraic geometry, the theory usually works best over **C** or other algebraically closed fields. Yet many applications of algebraic geometry deal with real solutions of polynomial equations. We will explore several aspects of this question.

When dealing with equations with finitely many solutions, there are powerful methods for estimating the number of solutions, including a multivariable version of Bézout's Theorem and the more general *BKK bound*, both of which deal with complex solutions. But these bounds can differ greatly from the number of real solutions. An example from Ref. 35 is the system

$$\begin{aligned} axyz^m &+ bx &+ cy &+ d &= 0\\ a'xyz^m &+ b'x &+ c'y &+ d' &= 0\\ a''xyz^m &+ b''x &+ c''y &+ d'' &= 0 \end{aligned}$$

where m is a positive integer and $a, b, \ldots, c'', d''$ are random real coefficients. The BKK bound tells us that there are m complex solutions, and yet there are at most two real solutions.

Questions about the number of real solutions go back to *Descartes' Rule of Signs* for the maximum number of positive and negative roots of a real univariate polynomial. There is also *Sturm's Theorem*, which gives the number of real roots in an interval. These results now have multivariable generalizations. Precise statements can be found in Refs. 18 and 30.

Real solutions also play an important role in enumerative algebraic geometry. For example, a smooth cubic surface S defined over **R** has 27 lines when we regard S as lying in $\mathbf{P}^3(\mathbf{C})$. But how many of these lines are real? In other words, how many lines lie on S when it is regarded as lying in $\mathbf{P}^3(\mathbf{R})$? (The answer is 27, 15, 7, or 3, depending on the equation of the surface.) This and other examples from *real enumerative geometry* are discussed in Ref. 35.

Over the real numbers, one can define geometric objects using inequalities as well as equalities. For example, a solid sphere of radius 1 is defined by $x^2 + y^2 + z^2 \leq 1$. In general, a finite collection of polynomial equations and inequalities define what is known as a *semialgebraic variety*. Inequalities arise naturally when one does *quantifier elimination*. For example, given real numbers a and b, the question

$$\text{Does there exist } x \text{ in } \mathbf{R} \text{ with } x^2 + bx + c = 0?$$

is equivalent to the inequality

$$b^2 - 4c \geq 0$$

by the quadratic formula. The theory of real quantifier elimination is due to Tarksi, although the first practical algorithmic version is Collin's *cylindrical algebraic decomposition*. A brief discussion of these issues appears in Ref. 30. Semialgebraic varieties arise naturally in robotics and motion planning, because obstructions like floors and walls are defined by inequalities (see ROBOTICS).

SCHEMES

An affine variety V is the geometric object corresponding to the algebraic object given by its coordinate ring $k[V]$. More generally, given *any* commutative ring R, Grothendieck defined the *affine scheme* Spec (R) to be the geometric object corresponding to R. The points of Spec(R) correspond to prime ideals of R, and Spec(R) also has a structure sheaf $O_{\mathrm{Spec(R)}}$ that generalizes the sheaves O_V mentioned earlier.

As an example, consider the coordinate ring $\mathbf{C}[V]$ of an affine variety V in $\mathbf{C}^n$. We saw earlier that the points of V correspond to maximal ideals of $\mathbf{C}[V]$. As maximal ideals are prime, it follows that Spec$(\mathbf{C}[V])$ contains a copy of V. The remaining points of Spec$(\mathbf{C}[V])$ correspond to the other irreducible varieties lying in V. In fact, knowing Spec$(\mathbf{C}[V])$ is equivalent to knowing V in a sense that can be made precise.

Affine schemes have good properties with regard to maps between rings, and they can be patched together to get more general objects called *schemes*. For example, every projective variety has a natural scheme structure. One way to see the power of schemes is to consider the intersection of the curves in $\mathbf{C}^2$ defined by $f = 0$ and $g = 0$, as in our discussion of Bezout's Theorem. As varieties, this intersection consists of just points, but if we consider the intersection as a scheme, then it has the additional structure consisting of the ring $O_{\mathbf{p}}/\langle f, g\rangle$ at every intersection point $\mathbf{p}$. So the scheme–theoretic intersection knows the multiplicities. See Ref. 36 for an introduction to schemes. Scheme theory is also discussed in Refs. 1 and 2.

CHOICE UNCERTAINTY PRINCIPLE[1]

The choice uncertainty principle says that it is impossible to make an unambiguous choice between near-simultaneous events under a deadline. This principle affects the design of logic circuits in computer hardware, real-time systems, and decision systems.

One of the first persons to notice that a fundamental principle might be at work in circuits that make decisions was David Wheeler of the University of Cambridge. In the early 1970s, he sought to build a computer whose hardware did not suffer from "hardware freezes" that were common in earlier computers. Wheeler noticed the lockups never occurred when the interrupts were turned off. Interrupt signals were recorded on a flip-flop the CPU consulted between instructions: The CPU decided either to enter the next instruction cycle or to jump to a dedicated subroutine that responded to the interrupt signal. He suspected that the timing of the interrupt signal's arrival to that flip-flop occasionally caused it to misbehave and hang the computer. Imagine that: The simplest, most fundamental memory circuit of a computer could malfunction.

THE HALF-SIGNAL

A digital machine consists of storage elements interconnected by logic circuits. The storage elements, implemented as arrays of flip-flops, hold the machine's state. The machine operates in a cycle: (1) flip-Flops enter a state; the switching time is 10^{-12} to 10^{-15} seconds. (2) The logic circuits take the state as input and produce a new state; the propagation time of all inputs through the circuits is slower, 10^{-9} to 10^{-10} seconds. (3) The new state is read into the flip-flops. A clock sends pulses that tell the flip-flops when to read in the next state.

The clock cycle must be longer than the propagation delay of the logic circuits. If it is any shorter, the inputs to some flip-flops may still be changing at the moment the clock pulse arrives. If an input voltage is changing between the 0 and 1 values at the time the clock pulse samples it, the flip-flop sees a "half signal"—an in-between voltage but not a clear 0 or 1. Its behavior becomes unpredictable. A common malfunction is that the flip-flop ends up in the wrong state: The clock-sampled value of an input intended to switch the flip-flop to 1 might not be strong enough, so the flip-flop remains 0.

THE METASTABLE STATE

Unfortunately, there is a worse malfunction. A half-signal input can cause the flip-flop to enter a "metastable state" for an indeterminate time that may exceed the clock interval by a large amount. The flip-flop eventually settles into a stable state, equally likely to be 0 or 1.

A flip-flop's state is actually a voltage that moves continuously between the 0 and 1 values. The 0 and 1 states are stable because they are attractors: Any small perturbation away from either is pulled back. A flip-flop switches because the input adds enough energy to push the state voltage closer to the other attractor. However, a half-signal input can sometimes leave the state voltage poised precisely at the midpoint between the attractors. The state balances precariously there until some noise pushes it closer to one of the attractors. That midpoint is called the metastable state. The metastable state is like a ball poised perfectly on the peak of a roof: It can sit there for a long time until air molecules or roof vibrations cause it to lose its balance, causing it to roll down one side of the roof.

In 1973, Chaney and Molnor at Washington University in St Louis measured the occurrence rate and holding times of metastable states (1); see Fig. 1. By synchronizing clock frequency with external signal frequency, they attempted to induce a metastable event on every external signal change. They saw frequent metastable events on their oscilloscope, some of which persisted 5, 10, or even 20 clock intervals. Three years later, Kinniment and Woods documented metastable states and mean times until failure for a variety of circuits (2).

In 2002, Sutherland and Ebergen reported that contemporary flip-flops switched in about 100 picoseconds (10^{-10} seconds) and that a metastable state lasting 400 picoseconds or more occurred once every 10 hours of operation (3).

Xilinx.com reports that its modern flip-flops have essentially zero chance of observing a metastable state when clock frequencies are 200 MHz or less (4). At these frequencies, the time between clock pulses (5 nanoseconds) is longer than all metastable events. But in experiments with interrupt signals arriving 50 million times a second, a metastable state occurs about once a minute at a clock frequency of 300 MHz, and about once every two milliseconds at a clock frequency of 400 MHz.

WHEELER'S THRESHOLD FLIP-FLOP

Aware of the Chaney–Molnor experiments, Wheeler realized that an interrupt flip-flop-driven metastable by an ill-timed interrupt signal can still be metastable at the next clock tick. Then the CPU reads neither a definite 0 nor a definite 1 and can malfunction.

Wheeler saw he could prevent the malfunction if he could guarantee that the CPU could only read the interrupt flip-flop while it was stable. He made an analogy with the common situation of two people about to collide on a sidewalk. On sensing their imminent collision, they both stop. They exchange eye signals, gestures, head bobs, sways, dances, and words until finally they reach an agreement that one person goes to the right and the other to the left. This could take a fraction or a second or minutes. They then

[1] This article is adapted from the author's article of the same title, ACM *Communications 50* 50: 9–14, 2007.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

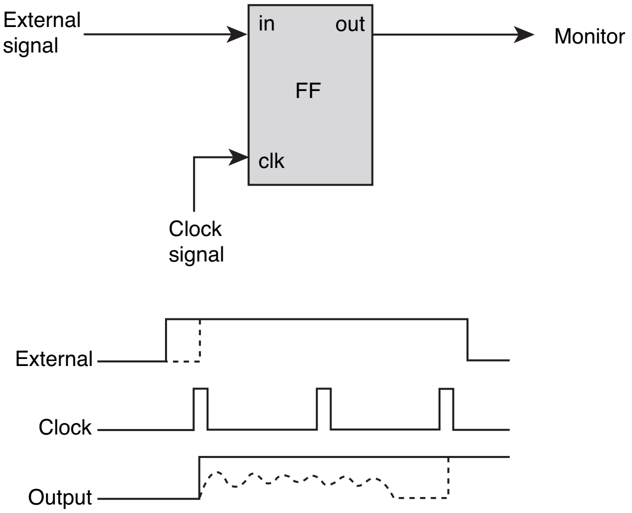

Figure 1. Experimental setup for observing flip-flop (FF) metastability. Each clock pulse triggers the FF state to match the input signal. If the input signal is changing when the clock pulse arrives, FF may enter an indefinite state that lasts more than one clock interval (dotted lines). The test repeats cyclically after the external signal returns to 0. To maximize metastable events, the clock frequency is tuned to a multiple of the external signal frequency. In a digital computer, the indefinite output becomes the input of other logic circuits at the next clock pulse, causing half-signal malfunctions.

resume walking and pass one another without a collision. The key is that the two parties stop for as long as is needed until they decide.

Wheeler designed a flip-flop with an added threshold circuit that output 1 when the flip-flop state was near 0 or 1. He used this for the interrupt flip-flop with the threshold output wired to enable the clock to tick (see Fig. 2). The CPU could not run as long as the interrupt flip-flop was in a metastable state, and thus, it could observe that flip-flop only when it was stable.

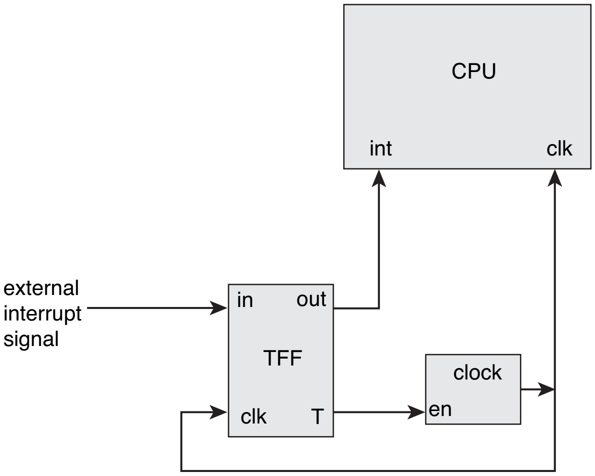

Figure 2. Threshold flip-flop (TFF) output T is 1 when the state is 0 or 1 and is 0 when the state is metastable. Output T enables the clock. TFF can become metastable if the external interrupt signal changes just as the clock pulse arrives. Since the CPU does not run when the clock is off, it always sees a definite 0 or 1 when it samples for interrupts.

With threshold interrupt flip-flops, Wheeler's computer achieved the reliability he wanted.

ARBITER CIRCUIT

Unambiguous choices between near-simultaneous signals must be made in many parts of computing systems, not just at interrupt flip-flops. Examples:

- Two CPUs request access to the same memory bank.
- Two transactions request a lock on the same record of a database.
- Two external events arrive at an object at the same time.
- Two computers try to broadcast on an Ethernet at the same time.
- Two packets arrive together to the network card.
- An autonomous agent receives two request signals at the same time.
- A robot perceives two alternatives at the same time.

In each case, a chooser circuit must select one of the alternatives for immediate action and defer the other for later action. There is no problem if the signals are separated enough that the chooser can tell which one came first. But if the two signals are near simultaneous, the chooser must make an arbitrary selection. This selection problem is also called the arbitration problem, and the circuits that accomplish it are called arbiter or synchronizer circuits (5,6). Ran Ginosar gives a nice account of modern synchronizers (7).

The arbiter incorporates circuits, as in the Wheeler flip-flop, that will prevent it from sending signals while in a metastable state. Therefore, all entities interacting with the arbiter will be blocked while the arbiter is metastable, and there is no need to stop a clock. The main effect of the metastable state is to add an unknown delay to the access time to the shared entity.

THE UNCERTAINTY PRINCIPLE

We can summarize the analysis above as the Choice Uncertainty Principle (8): "No choice between near-simultaneous events can be made unambiguously within a preset deadline." The source of the uncertainty is the metastable state that can be induced in the chooser by conflicting forces generated when two distinct signals change at the same time.

In 1984, Leslie Lamport stated this principle in a slightly different way: "A discrete decision based upon an input having a continuous range of values cannot be made within a bounded length of time" (9). He gave numerous examples of decision problems involving continuous inputs with inherent uncertainty about decision time. The source of the uncertainty, however, is not necessarily the attempt to sample a continuous signal; it is the decision procedure itself. A device that selects among alternatives can become metastable if the signals denoting alternatives arrive at nearly the same time.

It might be asked whether there is a connection between the choice uncertainty principle and the Heisenberg Uncertainty Principle (HUP) of quantum physics. The HUP says that the product of the standard deviations of position and momentum is lower-bounded by a number on the order of 10^{-34} joule-seconds. Therefore, an attempt to reduce the uncertainty of position toward zero may increase the uncertainty of momentum; we cannot know the exact position and speed of a particle at once. This principle manifests at quantum time scales and subatomic particle sizes—look at how small that bound is—but does not say much about the macro effects of millions of electrons flowing in logic circuits.

The HUP is sometimes confused with a simpler phenomenon, which might be called the observer principle. This principle states that if the process of observing a system either injects or withdraws energy from the system, the act of observation may influence the state of the system. There is, therefore, uncertainty about whether what is observed is the same as what is in the system when there is no observer. The observer principle plays an important role in quantum cryptography, where the act of reading the quantum state of a photon destroys the state. The information of the state is transferred to the observer and is no longer in the system.

The choice uncertainty principle is not an instance of the Heisenberg principle because it applies to macrolevel choices as well as to microscopic circuit choices. Neither is it an instance of the observer principle because the metastable state is a reaction of the observer (arbiter) to the system and does not exchange information with the system. (Neither is it related to the Axiom of Choice in mathematics, which concerns selecting one representative from each of an infinite number of sets.)

CHOICE UNCERTAINTY AS A GREAT PRINCIPLE

The choice uncertainty principle is not about how a system reacts to an observer, but how an observer reacts to a system. It also applies to choices at time scales much slower than computer clocks. For example,

- A teenager must choose between two different, equally appealing prom invitations.
- Two people on a sidewalk must choose which way each goes to avoid a collision.
- A driver approaching an intersection must choose to brake or accelerate on seeing the traffic light change to yellow.
- The commander in the field must choose between two adjutants, both demanding quick decisions on complex tactical issues at different locations.
- A county social system must choose between a development plan that limits growth and one that promotes growth.

These examples all involve perceptions; the metastable (indecisive) state occurs in single or interacting brains as they try to choose between equally attractive perceptions. At these levels, a metastable (indecisive) state can persist for seconds, hours, days, months, or even years.

The possibility of indefinite indecision is often attributed to the fourteenth century philosopher Jean Buridan, who described the paradox of the hungry dog that, being placed midway between two equal portions of food, starved (5). [Some authors use the example of an ass (donkey) instead of a dog, but it is the same problem (3,9)]. If he were discussing this today with cognitive scientists, Buridan might say that the brain can be immobilized in a metastable state when presented with equally attractive alternatives.

At these levels, it is not normally possible to turn off clocks until the metastable state is resolved. What happens if the world is impatient and demands a choice from a metastable chooser? A common outcome is that no choice is made and the opportunities represented by the choices are lost. For example, the teenager gets no prom date, the pedestrians collide, the driver runs a red light, the commander loses both battles, or the county has no plan at all. Another outcome is that the deciding parties get flustered, adding to the delay of reaching a conclusion.

CONCLUSION

Modern software contains many external interactions with a network and must frequently choose between near-simultaneous signals. The process of choosing will always involve the possibility of a metastable state and, therefore, a long delay for the decision. Real-time control systems are particularly challenging because they constantly make choices under deadlines.

The metastable state can occur in any choice process where simultaneous alternatives are equally attractive. In that case, the choosing hardware, software, brain, or social process cannot make a definitive choice within any preset interval. If we try to force the choice before the process exits a metastable state, we are likely to get an ambiguous result or no choice at all.

The choice uncertainty principle applies at all levels, from circuits, to software, to brains, and to social systems. Every system of interactions needs to deal with it. It, therefore, qualifies as a Great Principle.
