***Parse Table for String* $x = aabb$.** Construction of an example parse table is shown in Fig. 7. Recall cell entry (i,j) corresponds to the possibility of production of a string of length j, starting with symbol x_i. The table is formed from the bottom row ($j = 1$) upward. Entries for cells (1, 1), (2, 1), (3, 1), and (4, 1) are relatively easy to determine because they each correspond with production of a single terminal. For the second ($j = 2$) row of the table, all nonterminals that could yield derivations of substrings of length 2, beginning with $x_i i = 1, 2, 3$, must be considered. For example, cell (1, 2) corresponds with production of two-terminal long-string beginning with "a." Alternately, it is only necessary to consider nonterminals that produce *AA*, as shown in the $j = 1$ row of the table. From Fig. 7, only nonterminal "*C*," in the production $C \rightarrow BA|AA|b$ satisfies this parameter.

Forming the third and fourth ($j = 3$ and $j = 4$, respectively) rows of the table is slightly more complicated. For example, cell (1, 3) corresponds with strings of length 3, beginning with terminal x_1 ("a") in this case, which requires examination of cells (1, 1) and (2, 2), corresponding to producing the desired string with 1 nonterminal followed by 2 nonterminals, (denoted {1 + 2} hereafter) as well as cells (1, 2) and (3, 1) (denoted the {2 + 1} derivation). For the former, it is necessary to consider production of "*AS*," and "*AA*," and nonterminal "*C*" is applicable. For the latter, the production of "*CB*" and "*CC*" is considered, yielding "*A*." Thus, cell (1, 3) contains nonterminals "*C*" and "*A*." Similarly, for cell (2, 3), cells (2, 1) and (3, 2) (the {1 + 2} derivation) as well as cells (2, 2) and (4, 1) (the {2 + 1} derivation) must be considered.

Finally, formation of cell (1, 4) is considered. Possible cell pairings to consider are summarized below:

(1, 1) and (2, 3) $\{1 + 3\} \rightarrow AS, AC, \underline{AA} : C$

(1, 2) and (3, 2) $\{2 + 2\} \rightarrow CS, CB, \underline{CA} : B$

(1, 3) and (4, 1) $\{3 + 1\} \rightarrow CB, \underline{CC}, \underline{AB}, AC : A, S$

Cell pairings that yield a possible nonterminal are shown underlined. Thus, (1, 4) contains nonterminals C, B, A, S. As this cell pairing includes the starting symbol, the parse succeeds and "*aabb*" is a valid string in the language of this grammar. Note that because the grammar is in CNF, it is never necessary to consider more than two-cell pairings (although as we increase j, the number of possible pairings increases).

String Matching. A somewhat simpler approach to classification or recognition of entities using syntactic descriptions is a matching procedure. Consider the c class case. Class-specific grammars $G_1, G_2, \ldots G_c$ are developed. Given an unknown description, x, to classify, it is necessary to determine if $x \in L(G_i)$ for $i = 1, 2, \ldots c$. Suppose the language of each G_i could be generated and stored in a class-specific *library* of patterns. By matching x against *each pattern in each library*, the class membership of x could be determined. String matching metrics yield classification strategies that are a variant of the 1-NNR rule for feature vectors, in which a matching metric using strings instead of vectors is employed.

There are several shortcomings to this procedure. First, often $|L(G_i)| = \infty$, therefore the cataloging or library-based procedure is impossible. Second, even if $L(G_i)$ for each i is denumerable, it usually requires very large libraries. Consequently, the computational effort in matching is excessive. Third, it is an inefficient procedure. Alternatives that employ efficient search algorithms, prescreening of the data, the use of hierarchical matching, and prototypical strings are often preferable. *Note that in SyntPR, the similarity measure(s) used must account for the similarity of primitives as well as similarity of structure.*

Graphical Approaches Using Attributed Relational Graphs

Digraphs and Attributed Relational Graphs (ARGs). *Directed graphs or digraphs* are valuable tools for representing relational information. Here we represent graph G as $G = \{N, R\}$ where N is a set of nodes (or vertices) and R is a subset of $N \times N$, indicating arcs (or edges) in G.

In addition to representing pattern structure, the representation may be extended to include *numerical and perhaps symbolic attributes* of pattern primitives (i.e., relational graph nodes). An extended representation includes features or properties as well as relations with other entities. An *attributed graph*, as defined below, results.

Attributed Graphs. An attributed graph, G_i, is a 3-tuple and is defined as follows:

$$G_i = \{N_i, P_i, R_i\}$$

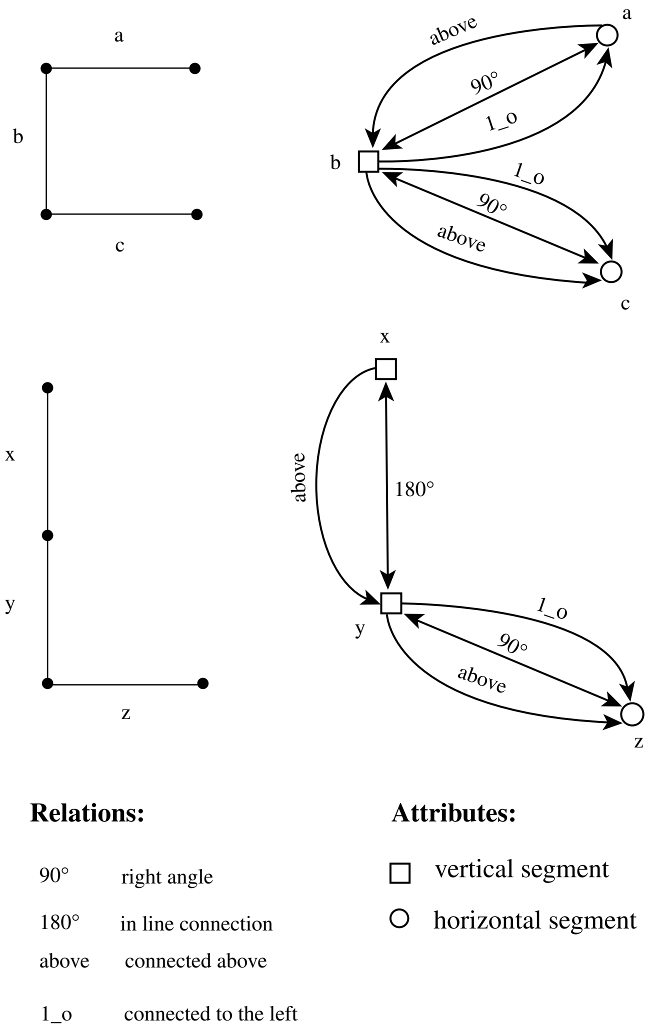

Figure 8. Example of ARGs used to quantify the structure of block characters.

where N_i is a set of nodes, P_i is a set of properties of these nodes, and R_i is a set of relations between nodes. (An alternative viewpoint is that R_i indicates the labeled arcs of G_i, where if an arc exists between nodes a and b, then R_i contains element (a, b).)

ARG Example: Character Recognition. Figure 8 (courtesy of R.D. Ferrell) shows an example of ARGs used to quantify the structure of block characters "*C*" and "*L*." Each line segment of the character is an attributed node in the corresponding graph, with a single attribute indicating either horizontal or vertical spatial orientation. Node relations used indicate whether the segments meet at a 90-or 180-degree angle, as well as connectedness above or to the left.

Comparing ARGs. One way to recognize structure using graphs is to let each pattern (structural) class be represented by a prototypical relational graph. An unknown input pattern is then converted into a structural representation in the form of a representational graph, and this graph is then *compared* with the relational graphs for each class. Notice that "compared" does not necessarily mean matched verbatim.

ARG Matching Measures that Allow Structural Deformations. In order to allow structural deformations, numerous match or "distance" measures have been proposed. These measures include (29, 30)

1. Extraction of *features* from G_1 and G_2, thereby forming feature vectors, $\underset{\sim}{x}_1$ and $\underset{\sim}{x}_2$, respectively, which is followed by the use of StatPR techniques to compare $\underset{\sim}{x}_1$ and $\underset{\sim}{x}_2$. Note the features are *graph features* as opposed to direct pattern features.
2. Using as a matching metric *the minimum number of transformations necessary to transform*G_1 (*the input*) *into*G_2 (*the reference*). Common transformations include: node insertion, node deletion, node splitting, node merging, vertex insertion, and vertex deletion.

Graph Transformation Approaches. Here we consider a set of *comparisons, transformations*, and *associated costs* in deriving a measure $D(G_i, G_j)$. Desirable attributes of $D(G_i, G_j)$ are

1. $D(G_i, G_j) = 0$.
2. $D(G_i, G_j) > 0$ if $i \neq j$.
3. $D(G_i, G_j) = D(G_j, G_i)$.
4. $D(G_i, G_j) \leq D(G_i, G_k) + D(G_k, G_j)$.

Property 4 is referred to as the triangle inequality. Property 3 requires $w_{ni} = w_{nd}$ and $w_{ei} = w_{ed}$, where w_{ni} is the cost of node insertion, w_{nd} is the cost of node deletion, w_{ei} is the cost of edge insertion, and w_{ed} is the cost of edge deletion.

Node Matching Costs and Overall Cost in Matching ARGs. As nodes possess attributes and, therefore, even without considering relational constraints "all nodes are not equal," a similarity measure between node p_i of G_i and node q_j of G_j is required. Denote this cost $f_n(p_i, q_j)$. For candidate match between G_1 and G_2, denoted x, with p nodes, the total cost is

$$c_n(x) = \sum f_n(p_i, q_j)$$

where the summation is over all corresponding node pairs, under node mapping x. For a candidate match configuration (i.e., some pairing of nodes and subsequent transformations), the overall cost for configuration x is

$$D_S(x) = w_{ni}c_{ni} + w_{nd}c_{nd} + w_{bi}c_{bi} + w_{bd}c_{bd} + w_n c_n(x)$$

and the distance measure, D, is defined as

$$D = \overset{min}{x}\{D_s(x)\}$$

NEURAL PATTERN RECOGNITION

Modern digital computers do not emulate the computational paradigm of biological systems. The alternative of *neural computing* emerged from attempts to draw upon knowledge of how biological neural systems store and manipulate information, which leads to a class of *artificial neural systems* termed *neural networks* and involves an amalgamation of research in many diverse fields such as psychology, neuroscience, cognitive science, and systems theory. Neural networks are a relatively new computational paradigm, and it is probably safe to say that the advantages, disadvantages, applications, and relationships to traditional computing are not fully understood. Neural networks are particularly well suited for some pattern association applications.

Fundamental neural network architecture and application information are available in Refs. 2, 31–34. Rosenblatt (35) is generally credited with initial perceptron research. The general feed-forward structure is also an extension of the work of Minsky and Papert (36) and the early work of Nilsson (37) on the transformations enabled by layered machines, as well as the effort of Widrow and Hoff (38) in adaptive systems. A comparison of standard and neural classification approaches is found in Ref. (39).

ANN Components

Basically, three entities characterize an ANN

1. The network topology, or interconnection of neural "units;"
2. The characteristics of individual units or artificial neurons; and
3. The strategy for pattern learning or training.

As in the SyntPR and StatPR approaches to PR, the success of the NeurPR approach is likely to be strongly influenced by the quality of the training data and algorithm. Furthermore, existence of a training set and a training algorithm does not guarantee that a given network will "train" or *generalize* correctly for a specific application.

Key Aspects of Neural Computing

The following are key aspects of neural computing. The overall computational model consists of a *variable interconnection of simple elements, or units*. Modifying patterns of inter-element connectivity as a function of training data is the key learning approach. In other words, the system knowledge, experience, or training is stored in the form of network interconnections.

To be useful, neural systems must be capable of storing information ("trainable"). Neural PR systems are trained with the hope that they will subsequently display correct "generalized" behavior, when presented with new patterns to recognize or classify. That is, the objective is for the network (somehow) in the training process to develop an internal structure that enables it to correctly identify or classify new similar patterns.

Many open questions regarding neural computing and its application to PR problems exist. Furthermore, the mapping of a PR problem into the neural domain (i.e., the design of a problem-specific neural architecture) is a challenge that requires considerable engineering judgment. A fundamental problem is selection of the network parameters, as well as the selection of critical and representable problem features.

Neural Network Structures for PR. Several different "generic" neural network structures are useful for a class of PR problems. Examples are:

The Pattern Associator (PA). This neural implementation is exemplified by feed-forward networks (see Feed-forward Networks). The most commonly used learning (or training) mechanism for FF networks is the backpropagation approach using the *generalized delta rule*.

The Content-Addressable or Associative Memory Model (CAM or AM). This neural network structure is best exemplified by the recurrent network often referred to as the Hopfield model. Typical usage includes recalling stored patterns when presented with incomplete or corrupted initial patterns. (see Hopfield (Recurrent) Networks for PR).

Self-Organizing Networks. These networks exemplify neural implementations of unsupervised learning in the sense that they typically cluster or self-organize input patterns into classes or clusters based on some form of similarity.

Perceptrons

Perceptron and ADALINE Unit Structure. The *Perceptron* is a regular feed-forward network layer with adaptable weights and hardlimiter activation function. Rosenblatt (35) is generally credited with initial perceptron research. The efforts of Widrow and Hoff in adaptive systems, specifically the Adaline and Madeline structures presented in Refs. 40 and 41 are also relevant. For brevity, we will consider them as one generic structure.

The units in the perceptron form a *linear threshold unit, linear* because of the computation of the activation value (inner product) and *threshold* to relate to the type of activation function (hardlimiter). Training of a perceptron is possible with the *perceptron learning rule*. As shown in Fig. 9, the basis for the perceptron/adaline element is a

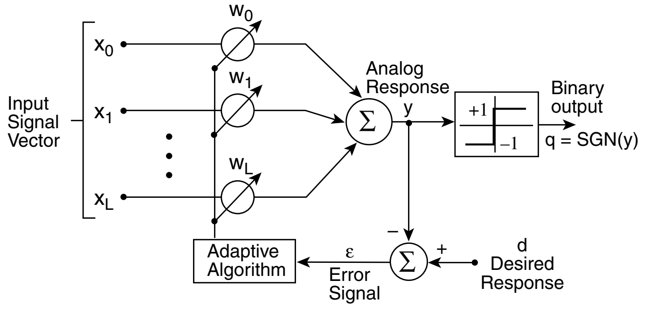

Figure 9. Basic perceptron/adaline element (Adapted from Ref. 41).

single unit whose net activation is computed using

$$net_i = \sum_j w_{ij}x_j = \underline{w}^T\underline{x} \tag{3}$$

The unit output is computed by using a "hard limiter," threshold-type nonlinearity, namely the signum function, for example, for unit i with output o_i

$$o_i = \begin{cases} +1 & if \quad net_i \geq 0 \\ -1 & if \quad net_i < 0 \end{cases} \tag{4}$$

The unit has a *binary output*; however, the formation of net_i (as well as weight adjustments in the training algorithm) is based on the linear portion of the unit (i.e., the mapping obtained before application of the nonlinear activation function).

Combination of Perceptrons or Adaline Units to Achieve More Complex Mappings. Layers of adaline units, often referred to as *multilayer perceptrons* or MLPs may be used to overcome the problems associated with nonlinearly separable mappings. One of the biggest shortcomings of MLPs, however, is the availability of suitable training algorithms. This shortcoming often reduces the applicability of the MLP to small, "hand-worked" solutions. As shown in Fig. 10, combinations of adaline units yield the madaline (modified adaline) or MLP structure, which may be used to form more complex decision regions.

Feed-forward Networks

The *feed-forward (FF) network* is in some sense an extension of the madeline/perceptron structure composed of a hierarchy of processing units, organized in a series of two or more mutually exclusive sets of neurons or layers. The first, or input layer, serves as a holding site for the values applied to the network. The last, or output, layer is the point at which the final state of the network is read. Between these two extremes lie zero or more layers of hidden units; it is here that the real mapping or computing takes place. Links, or weights, connect each unit in one layer to only those in the next higher layer. There is an implied directionality in these connections, in that the output of a unit, scaled by the value of a connecting weight, is fed forward to provide a portion of the activation for the units in the next higher layer. Figure 11 illustrates the typical feed-forward network. The network as shown consists of a layer of d input units (L_i), a layer of c output units (L_o), and a variable number (5 in this example) of internal or "hidden" layers (L_{h_i}) of units. Observe the *feed-forward* structure in which the inputs are directly connected to only units in L_o and the outputs of layer L_k units are only connected to units in layer L_{k+1} or are outputs if $L_k = L_o$.

Training Feed-forward Networks. Once an appropriate network structure is chosen, much of the effort in designing a neural network for PR concerns the design of a reasonable training strategy. Often, for example, while observing a particular training experiment, the designer will notice the weight adjustment strategy "favoring" particular S-R patterns, becoming "painfully" slow (perhaps while stuck in a local minimum), becoming unstable, or oscillating between solutions, which necessitates engineering judgment in considering the following training parameters:

- train by pattern or epoch;
- use of momentum and corresponding weight;
- learning weight/weight changes over time;
- sequential versus random ordering of training vectors;
- whether the training algorithm is "stuck" at a local energy minimum;
- "suitable" unit biases (if applicable); and
- appropriate initial conditions on biases, weights, and so on.

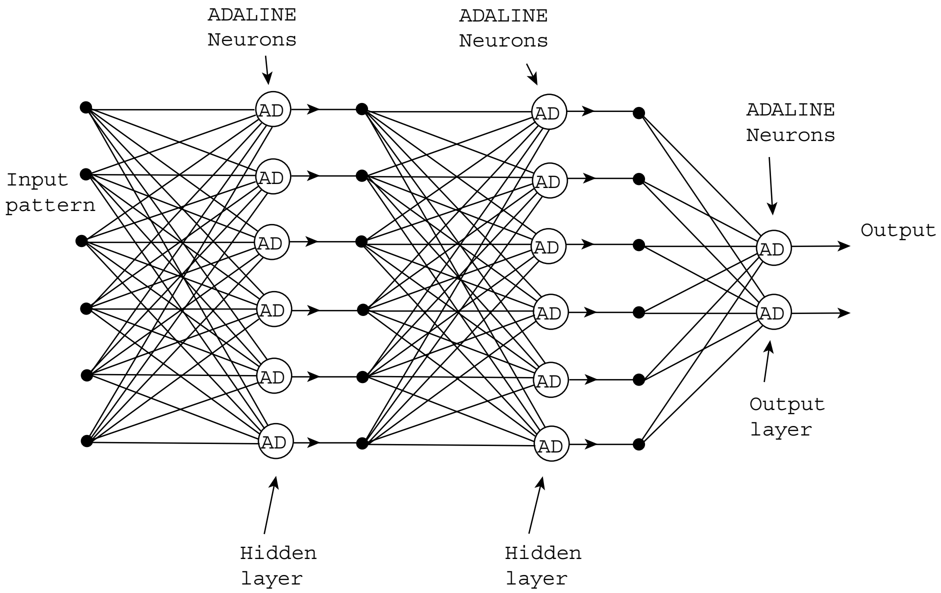

Figure 10. Using combinations of adaline units yield the MLP (madaline) (Adapted from Ref. 41).

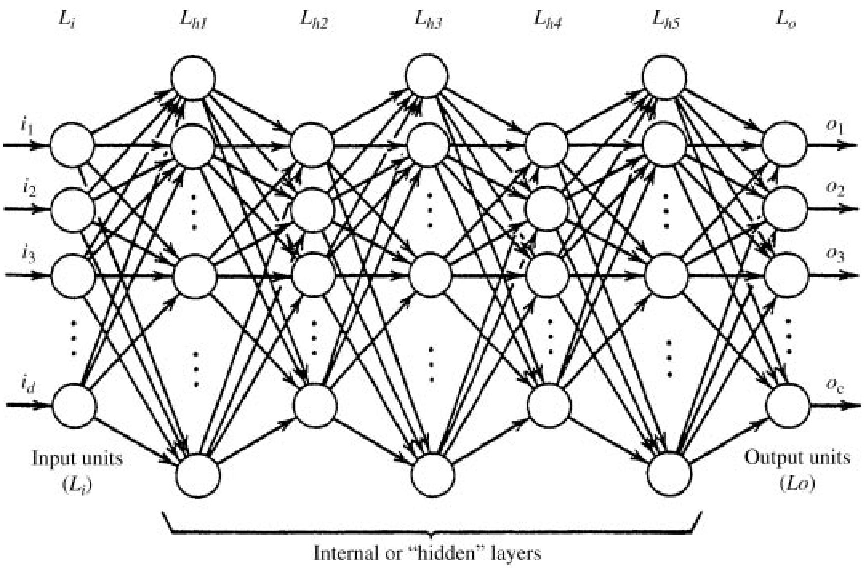

Figure 11. The typical feed-forward network, consisting of layers of simple units. (Adapted from Ref. 1).

Backpropagation - A Multistep Procedure for Training FF Networks. Beginning with an initial (possibly random) weight assignment for a three-layer feed-forward network, proceed as follows:

Step 1: Present input $\underline{x}^p$, form outputs, o_i, of all units in network.
Step 2: Update w_{ji} for output layer.
Step 3: Update w_{ji} for hidden layer(s).
Step 4: Stop if updates are insignificant or error is below a preselected threshold, otherwise proceed to Step 1.

This process leads to an adjustment scheme based on *backpropagation*. A summary of the GDR equations is given below in Table 1.

Hopfield (Recurrent) Networks for Pattern Recognition

Hopfield (42,43) characterized a neural computational paradigm for using a neural net as an autoassociative memory. The following variables are defined:

o_i: the output state of the ith neuron
α_i: the activation threshold of the ith neuron
w_{ij}: the interconnection weight (i.e., the strength of the connection FROM the output of neuron j TO neuron i).

Thus, $\sum_j w_{ij}o_j$ is the total input or activation (net_i) to neuron i. Typically, $w_{ij} \in R$, although other possibilities (e.g., binary interconnections) are possible. With the constraints developed below, for a d-unit network there are $\frac{d(d-1)}{2}$ possibly nonzero and unique weights.

In the Hopfield network, every neuron is allowed to be connected to all other neurons, although the value of w_{ij} varies (it may also be zero to indicate no unit interconnection). To avoid false reinforcement of a neuron state, the constraint $w_{ii} = 0$ is also employed. The w_{ij} values, therefore, play a fundamental role in the structure of the network. In general, a Hopfield network has significant interconnection (i.e., practical networks seldom have sparse W matrices, where $W = [w_{ij}]$).

Table 1. Summary of the GDR Equations for Training Using Backpropagation

(pattern) error measure:	$E^p = \frac{1}{2}\sum_j \left(t_j^p - o_j^p\right)^2$
(pattern) weight correction	$\Delta^p w_{ji} = \epsilon \delta_j^p \tilde{o}_i^p$
(output units)	$\delta_j^p = \left(t_j^p - o_j^p\right) f_j'\left(net_j^p\right)$
(internal units)*	$\delta_j^p = f_j'(net_j^p) \sum_n \delta_n^p w_{nj}$
	*where δ_n^p are from next layer (L^{k+1})
output derivative (assumes sigmoidal characteristic)	$f_j'(net_j^p) = o_j^p(1 - o_j^p)$

Network Dynamics, Unit Firing Characteristic, and State Propagation. A simple form for Hopfield neuron firing characteristics is the nonlinear threshold device

$$o_i = \begin{cases} 1 & \text{if } \sum_{j;\, j \neq i} w_{ij} o_j > \alpha_i \\ 0 & \text{otherwise} \end{cases}$$

Notice the neuron activation characteristic is nonlinear. Commonly, the threshold $\alpha_i = 0$. Viewing the state of a d-neuron Hopfield network at time (or iteration) t_k as an $d \times 1$ vector, $\underline{o}(t_k)$, the state of the system at time t_{k+1} (or iteration $k+1$ in the discrete case) may be described by the nonlinear state transformation

$$W\underline{o}(t_k) \overset{*}{\Rightarrow} \underline{o}(t_{k+1})$$

where the $\overset{*}{\Rightarrow}$ operator indicates the element by element state transition characteristic used to form $\underline{o}(t_{k+1})$. The model may be generalized for each unit to accommodate an additional vector of unit bias inputs.

The network state propagation suggests that the unit transitions are synchronous, that is, each unit, in lockstep fashion with all other units, computes its net activation and subsequent output. Although this is achievable in (serial) simulations, it is not necessary. Also empirical results have shown that it is not even necessary to update all units at each iteration. Surprisingly, network convergence is relatively insensitive to the fraction of units (15–100%) updated at each step.

Hopfield Energy Function and Storage Prescription. For the case of $\alpha_i = 0$, stable (stored) states correspond to minima of the following energy function

$$E = -\left(\frac{1}{2}\right) \sum \sum_{i \neq j} w_{ij} o_i o_j$$

which leads to the rule for determination of w_{ij} and a set of desired stable states $\underline{o}^s, s = 1, 2, \ldots n$, (i.e., the training set (stored states) $H = \{\underline{o}^1, \underline{o}^2, \ldots, \underline{o}^n\}$) as

$$w_{ij} = \sum_{s=1}^{n} (2o_i^s - 1)(2o_j^s - 1) \quad i \neq j$$

(with the previous constraint $w_{ii} = 0$). The convergence of the network to a stable state involves the Hamming distance between the initial state and the desired stable state. Different stable states that are close in Hamming distance are undesirable, because convergence to an incorrect stable state may result. Reference 42 suggests that an n-neuron network allows approximately $0.15n$ stable states; other researchers have proposed more conservative bounds (44).

Hopfield PR Example: Character Recall. Figure 12 shows a Hopfield network used as associative memory for recall of character data. A 10 × 10 pixel array is used to represent the character, yielding 100 pixels. Each pixel value is the state of a single, totally interconnected unit in a Hopfield network. Thus, the network consists of 100 units and approximately 100 × 100 interconnection weights. The network was trained using characters "A,' "C,' "E," and "P.' The top row of Fig. 12 shows initial states for the network; these are distorted patterns corresponding to the training patterns. Succeeding rows show the state evolution of the network. Note that the network converged to elements of H in at most two iterations in this example.

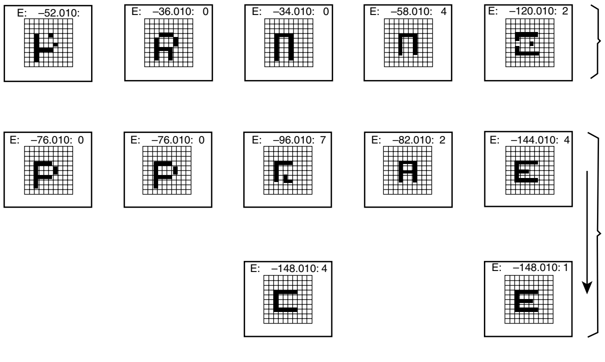

Figure 12. Use of a Hopfield network for character assocaition/ completion/recognition (Adapted from Ref. 2).

Kohonen Self-Organizing Feature Maps (SOFMs)

Kohonen (45) and Kangas et al. (46) have shown an alternative neural learning structure involving networks that perform dimensionality reduction through conversion of feature space to yield *topologically ordered* similarity graphs or maps or clustering diagrams (with potential statistical interpretations). In addition, a lateral unit interaction function is used to implement a form of local competitive learning.

1-D and 2-D spatial configurations of units are used to form feature or pattern dimensionality reducing maps. For example, a 2-D topology yields a planar map, indexed by a 2-D coordinate system. Of course, 3-D and higher-dimensional maps are possible. Notice each unit, regardless of the topology, receives the input pattern $\underline{x} = (x_1, x_2 \ldots x_d)^T$ in parallel. Considering the topological arrangement of the chosen units, the d-dimensional feature space is mapped into 1-D, 2-D, 3-D, and so on. The coordinate axes used to index the unit topology, however, have no explicit meaning or relation to feature space. They may, however, reflect a similarity relationship between units in the reduced dimensional space, where topological distance is proportional to dissimilarity.

Choosing the dimension of the feature map involves engineering judgment. Some PR applications naturally lead to a certain dimension; for example, a 2-D map may be developed for speech recognition applications, where 2-D unit clusters represent phonemes (47). The dimensions of the chosen topological map may also influence the training time of the network. Once a topological dimension is chosen, the concept of a network neighborhood (or cell or bubble) around each neuron may be introduced. The neighborhood, denoted N_c, is centered at neuron u_c, and the cell or neighborhood size (characterized by its radius in 2-D, for example) may vary with time (typically in the training phase). For example, initially N_c may start as the entire 2-D network, and the radius of N_c shrinks as iteration (described subsequently) proceeds. As a practical matter, the discrete nature of the 2-D net allows the neighborhood of a neuron to be defined in terms of nearest neighbors (e.g., with a square array the four nearest neighbors of u_c are its N, S, E, and W neighbors; the eight nearest neighbors would include the "corners").

Training the SOFM. Each unit, u_i, in the network has the same number of weights as the dimension of the input vector and receives the input pattern $\underline{x} = (x_1, x_2 \ldots x_d)^T$ in parallel. The goal of the self-organizing network, given a large, unlabeled training set, is to have individual neural clusters self-organize to reflect input pattern similarity. Defining a weight vector for neural unit u_i as $\underline{m}_i = (w_{i1}, w_{i2}, \ldots w_{id})^T$, the overall structure may be viewed as

an array of matched filters, which competitively adjust unit input weights on the basis of the current weights and goodness of match. A useful viewpoint is that each unit tries to become a matched filter in competition with other units.

Assume the network is initialized with the weights of all units chosen randomly. Thereafter, at each training iteration, denoted k for an input pattern $\underline{x}(k)$, a distance measure $d(\underline{x}, \underline{m}_i)$ between $\underline{x}$ and $\underline{m}_i \, \forall i$ in the network is computed, which may be an inner product measure (correlation), Euclidean distance, or another suitable measure. For simplicity, we proceed using the Euclidean distance. For pattern $\underline{x}(k)$, a *matching phase* is used to define a "winner" unit u_c, with weight vector $\underline{m}_c$, using

$$\|\underline{x}(k) - \underline{m}_c(k)\| = \overset{\min}{i} \{\|\underline{x}(k) - \underline{m}_i(k)\|\}$$

Thus, at iteration k, given $\underline{x}$, c is the index of the best matching unit, which affects all units in the currently defined cell, bubble, or cluster surrounding u_c, $N_c(k)$ through the global network *updating phase* as follows

$$\underline{m}_i(k+1) = \begin{cases} \underline{m}_i(k) + \alpha(k)[\underline{x}(k) - \underline{m}_i(k)] & i \in N_c \\ \underline{m}_i(k) & i \notin N_c \end{cases}$$

The updating strategy bears a strong similarity to the c-means algorithm. $d(\underline{x}, \underline{m}_i)$ is decreased for units inside N_c by moving $\underline{m}_i$ in the direction $(\underline{x} - n_i)$. Therefore, after the adjustment, the weight vectors in N_c are closer to input pattern $\underline{x}$. Weight vectors for units outside N_c are left uncharged. The competitive nature of the algorithm is evident as after the training iteration units outside N_c are *relatively* further from $\underline{x}$. That is, there is an opportunity cost of not being adjusted. Again, α is a possibly iteration-dependent design parameter.

The resulting accuracy of the mapping depends on the choices of N_c, $\alpha(k)$ and the number of iterations. Kohonen cites the use of 10,000–100,000 iterations as typical. Furthermore, $\alpha(k)$ should start with a value close to 1.0 and gradually decrease with k. Similarly, the neighborhood size, $N_c(k)$, deserves careful consideration in algorithm design. Too small a choice of $N_c(0)$ may lead to maps without topological ordering. Therefore, it is reasonable to let $N_c(0)$ be fairly large (Kohonen suggests one half the diameter of the map) shrinking $N_c(k)$ (perhaps linearly) with k to the fine-adjustment phase, where N_c only consists of the nearest neighbors of unit u_c. Of course, a limiting case is where $N_c(k)$ becomes one unit. Additional details of the self-organizing algorithm are summarized in the cited references.

Example: SOFM Application to Unsupervised Learning. - Figure 13(48) shows sample results for a 5-D feature vector case. Uppercase characters are presented as unlabeled training data to a 2-D SOFM. Figure 13(a) shows the unlabeled training set samples H_u; Fig. 13(b) shows the self-organized map resulting from the algorithm. As evidenced by Fig. 13(b), 2-D clustering of the different dimensionality-reduced input patterns occurs. As in other learning examples, vectors were chosen randomly from H_u at each iteration. $\alpha(k)$ decreased linearly with k from $0.5 (= \alpha(o))$ to 0.04 for $k \leq 10,000$. Similarly, for this simulation, the 2-D map was chosen to be of hexagonal structure with 7×10 units. For $k \leq 1000$, the radius of N_c decreased from 6 (almost all of the network) to 1 (u_c and its six nearest neighbors).

REASON MAINTENANCE SYSTEMS: TOOLS FOR FOUNDATIONS-BASED BELIEF REVISION

INTRODUCTION

The development of computational systems that can model and solve problems in dynamic nonstructured environments, which are faced with unexpected changes and incomplete knowledge, or in intrinsically distributed scenarios, where information from multiple disparate or even conflicting sources needs to be merged, requires appropriate knowledge representation and reasoning (KRR) systems. The KRR systems that can handle sets of dynamic beliefs are sensitive to communicated and perceived changes in the environment and may drop current beliefs in face of new findings or disregard new data in conflict with existing firm beliefs.

When knowledge is represented by beliefs, some classic reasoning properties no longer hold. In a classic deductive reasoning system, which is also known as a monotonic reasoning system, what is deduced from an initial set of facts still is deduced from an enlarged set of those facts (i.e., the set of logic consequences will hold forever). In a nonmonotonic reasoning system, what is inferred from an initial set of beliefs is a new set of beliefs that may or may not be revised in the future. Although belief revision and nonmonotonic reasoning are different, both deal with beliefs and incomplete knowledge. Belief revision handles the dynamics of belief change (i.e., how an agent changes its current belief state in face of new information) and nonmonotonic reasoning draws conclusions from a set of beliefs.

As a KRR system gathers information to reason about, it has to update its belief space (1). A rational agent, when faced with new data, selects the resulting epistemic state based on the preferences established between its belief states. To establish the preferences between belief states, an agent can rely on symbolic or numeric approaches. In symbolic approaches, the revision is based on the logic content of the propositions—the revision is performed according to the epistemic relevance of the involved propositions; in the numeric approaches, the logic content of formulas is irrelevant—the propositions are ordered according to their certainty (2), possibility (3), credibility (4) or probability (5). The goal of any one of these approaches is to establish the "relative" strength between the represented beliefs and, thus, allow the agent to choose the resulting preferred belief state.

Most belief revision models, symbolic or numeric, follow some rationality principles (6): (*1*) consistency of the information—the agent's resulting belief state must be consistent, (*2*) minimal changes—the changes between consecutive belief states should be minimal, (*3*) preservation of the information—the resulting belief state should preserve as much information as possible from the previous belief state, and (*4*) priority of the most recent information—the resulting belief state should contain the information that triggered the belief revision. Depending on the problem domain features, different principles can be adopted. Whereas in dynamic environments the preference goes to the most recent information (i.e., existing beliefs are dropped in face of new findings), in distributed scenarios, where the merge of data from multiple sources is performed, the preference is based on other principles, such as the reliability of the sources (4), and so on.

Two main approaches to the modeling of epistemic states (7) include the theory of belief revision based on foundations (8) and the theory of belief revision based on coherence (6). In the foundations approach, a belief holds as long as the system finds a justification in its support. In the coherence approach, a belief holds as long as it is coherent with the remaining beliefs of the system. We will only address the first—the theory of belief revision based on foundations—because it is the theory behind the reason maintenance systems (RMS), which are also known as truth maintenance systems (TMS) or belief maintenance systems (BMS).

REASON MAINTENANCE SYSTEMS

The foundations-based theory regards a belief as a temporary knowledge item, which is exclusively supported by valid foundations. This theory distinguishes between core beliefs or foundations—also called base beliefs or hypothesis (9)—that have an independent standing and derived beliefs (1). According to this theory, first, all beliefs without a valid justification are abandoned, and then, the new beliefs (either self-supported or derived beliefs) are added to the system.

RMSs are computational units supported by the foundations-based theory. According to this theory, a belief is always a justified belief: It is either an assumption (a self-supporting core belief) or a derived belief with at least one valid justification. Typically, KRR systems that require consistency maintenance have two main modules: the problem solver and the RMS. The problem-solver module submits assumptions (core beliefs) as well as conclusions (derived beliefs) together with their respective foundations to the RMS; the RMS stores and associates with each belief (core or derived belief) the corresponding set of supporting foundations. The RMS maintains the consistency of the overall reasoning by keeping, for each represented belief, the supporting justifications. The relationship between the problem solver and the RMS is Master/Slave.

Two main categories of TMS are as follows: single- and multiple-context systems. According to Mason (10), these two categories result from the different approaches each type adopts to represent the dependencies between beliefs: In the single context systems, each belief is associated to the beliefs that directly generated it—it is the case of the justification-based TMS (JTMS) (8) or the logic-based TMS (LTMS) (11). In the multiple-context counterparts,

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

each belief is associated with the minimal set of assumptions from which it can be inferred—it is the case of the assumption-based TMS (ATMS) (12) or the multiple belief reasoner (MBR) (9).

Justification-Based TMS

In 1979, Jon Doyle presented the first reason maintenance system—the JTMS (8)—which was designed as an independent module for belief maintenance (13). It works with a single context—the current set of beliefs. The JTMS records *nodes*, which represent the existing beliefs, and *justifications*, which represent the dependencies between the represented beliefs, and, then, labels each node as *in*–believed— or *out*–disbelieved—according to the node's supporting justification. The JTMS can (*1*) add nodes to represent new beliefs, (*2*) add and retract justifications that represent the reasons for holding a belief, and (*3*) identify and mark every contradiction as a *nogood* node. By maintaining the justifications of each belief, the JTMS can establish at all times the current set of believed nodes.

In a JTMS, two sorts of nodes are as follows: ordinary nodes and contradiction nodes. Contradiction nodes are explicitly labeled as such by the user or by the problem-solver module. Ordinary nodes have no special meaning to RMS. In contrast, contradiction nodes have a crucial meaning to the JTMS (14). They should be excluded from any belief context.

Although a node may have multiple justifications, the labeling algorithm selects just one—the supporting justification. As a result, each node *in* has only one set of supporting nodes, which are the nodes that the JTMS uses to establish its belief state.

The foundations set of a node is made of all its antecedents: The direct antecedent nodes, the antecedents of its antecedents, and so forth (the transitive closure of the set of antecedents). This set is also called the node's well-founded argument. A node's set of consequents is obtained through the transitive closure of its consequents. The system builds a dependency network that includes all represented propositions (nodes) and available justifications (directed arcs).

The addition of a new justification may have a profound impact in a JTMS, because it triggers the labeling algorithm: Contradiction nodes may become ordinary nodes and *vice-versa*. The most generic type of justification in a JTMS is the so-called nonmonotonic justification. A nonmonotonic justification of a proposition c is an ordered pair composed of two sets of propositions A_M and A_{NM} such that $<(A_N, A_{NM}) \rightarrow c>$ where c is the consequent, A_M is the monotonic set of antecedents $(a_1, \ldots, a_n)$, or *in*-list of c and A_{NM} is the nonmonotonic set of antecedents $(a_{n+1}, \ldots, a_m)$ or *out*-list of c. Given such a nonmonotonic justification, the JTMS labels proposition c as *in* if all propositions of A_M are *in* and all propositions of A_{NM} are *out*. In other words, if the system believes in the propositions of the first set and has no reasons to believe in the propositions of the second set, then it has found a valid justification to believe in the consequent proposition. A justification may support several types of nodes: (*1*) premises, when both the monotonic set and nonmonotonic set of antecedent propositions are empty; (*2*) deductions, when the nonmonotonic set of antecedent propositions is empty; (*3*) assumptions, when both the monotonic set and nonmonotonic set of antecedent propositions are nonempty. A node has the following structure: <*Node—Id, Proposition, Justification, Label*>, where *Node-Id* is the node identifier, *Proposition* is the problem solver proposition, *Justification* specifies the corresponding *in*-list and *out*-list ($<A_M, A_{NM}>$), *Label* holds the proposition belief state (*{believed, disbelieved / unknown}*).

When the JTMS uses such a type of justification to label a node, the resulting state can either be *in* or *out*. If the node is labeled *in*, then the set of supporting nodes is made of the union of the elements of both A_M and A_{NM}; otherwise, when the node is *out*, the set of supporting nodes is made of one *out* node from A_M or one *in* node from A_{NM}.

Assumption-Based TMS

In 1986, Johan de Kleer (12) proposes a new type of reason maintenance system—the ATMS. For de Kleer, assumptions are self-supported propositions that play the role of foundational nodes, which are believed as long as the system is not confronted with contradictory evidences that play the role of foundational nodes. Each derived proposition has for foundations the set(s) of assumptions from which it was inferred. Each set of foundations/assumptions is called an environment. The ATMS represents all propositions—assumptions, premises, and derived propositions—as nodes and keeps record of the respective sets of foundations, which include the supporting sets of assumptions/hypothesis, in a structure called label. For each proposition in the knowledge base, there is a node in the ATMS, and for each justification the ATMS records a dependency describing how the node was inferred from other nodes. A node has the following structure: <*Proposition, Type, Label, State*>, where *Proposition* is the proposition identification, *Type* specifies the node type (*{assumption node, inferred node, premise node}*), *Label* contains all sets of assumptions from which the proposition was inferred, and *State* represents proposition belief state (*{believed, disbelieved}*).

In an ATMS, justifications are monotonic and define the dependency between a set of antecedent propositions and the consequent proposition. Formally, a justification is of the type: $a_1, \ldots, a_n \rightarrow c$ where $a_1, \ldots, a_n$ is the set of antecedent nodes and c is the consequent node.

The goal of an ATMS is to keep track of all consistent contexts through the (*1*) creation of assumption nodes whenever the problem solver decides to adopt new assumptions/hypothesis; (*2*) creation of ordinary nodes when the problem solver infers new propositions; and (*3*) addition of new justifications to existing nodes when the problem solver finds a new way of inferring the corresponding propositions (15).

On reception of a new node justification, the ATMS triggers the labeling update algorithm. First, it updates the label of the consequent node by adding the new supporting set of assumptions composed of the union of the labels of the antecedent nodes. The new supporting set of assumptions is the minimal set from which, using the provided justification, it is possible to infer the node. Next, recursively, it updates the dependency network by relabeling all nodes that depend on this consequent node. Finally, the

ATMS sets the belief state according to the determined foundations: (*1*) a node is *believed* when it has a non-empty label, that is, the system identified a consistent set of assumptions (foundations) from which it is possible to infer the node; and (*2*) a node is *disbelieved* when its label is empty, that is, the system was unable to find a reason to believe in the proposition.

Logic-Based TMS

The LTMS is a reason-maintenance system proposed by McAllester (11). This reason-maintenance system computes truth values assignments (*true*, *false*, and *unknown*) rather than belief statuses (*believed* or *disbelieved*) to all represented nodes and does not use justifications to establish the dependencies between nodes; instead, it uses logic clauses to specify the constraints between the nodes.

The LTMS approach is similar to JTMS except that in the LTMS: (*1*) the nodes assume no relationships among them except the ones explicitly stated in justifications and (*2*) it is not possible to represent simultaneously a proposition and its negation because it throws a contradiction. If the latter case happens, then the dependency network has to be reconstructed.

Each node in a LTMS has two labels: *Lt* and *Lf*. The label *Lt* can take values *true* or *unknown*, which indicates that the system knows the node is true or that it does not know if the node is true. Similarly, the label *Lf* can take values *true* or *unknown*, which indicates that the system knows the negated node is true or that it does not know whether the negated node is true (16). As a result, there are four possibilities: the node is *true*, the negated node is *true*, the node has an *unknown* truth value or the node is a *contradiction* (both the node and the negated node labels are set to *true*).

Two approaches are used to handle these labels. One is identical to the current context approach applied in the JTMS, where the label values are evaluated according to the current assumption set. The other is similar to the assumption-based approach, where the label on a literal reflects all combinations of assumptions that make it true. Contradiction handling relies in the dependency-directed backtracking algorithm and in the maintenance of a *nogood* database that contains all detected contradictions (when both node and negated node labels are set to true in one assumption set) (16).

BELIEF REVISION SYSTEMS

Belief revision systems (BRSs) are KRR systems that assume, infer, represent, handle, and maintain beliefs. BRSs can adopt a *reason maintenance system* as an external tool to represent, handle, and maintain beliefs or, alternatively, be designed to include the ability "to detect contradictions, identify the culprits and readjust their knowledge bases as to eliminate any contradiction (9)".

Belief Revision Supported by JTMS

The problem solver commands the JTMS operation through the submission of new nodes and the addition or removal of justifications. These operations trigger the JTMS consistency maintenance process—labeling algorithm—which starts with the premise and assumption nodes and uses the justifications to find noncircular arguments in support of every node. These noncircular arguments are called well-founded belief-support justifications.

When the JTMS receives a new justification for a represented node, the updating process depends on the node belief status. If the node is already believed (*in*) and regardless of the validity of the justification, Then few changes occur. However, if the node is disbelieved (*out*) and the new justification is valid, then the labels of this node and all its consequents need to be updated. The JTMS builds a new list that contains the node and all its consequents and initializes/resets their labels to *nil*. Next, using only well-founded nodes, it verifies whether the current node has at least one valid justification. In case of success, it updates the node's label to *in*; otherwise, if no valid justification was found in support of the node, the node is labeled *out*. Then, sequentially, it applies the same procedure to the remaining nodes in the list, to establish their well-founded support: either *in* or *out*. Sometimes, because of existing circularities, some nodes remain unlabeled (*nil*). In these cases, the JTMS applies a relaxation procedure with the intent to label all nodes.

Finally, the JTMS looks for contradictions/inconsistencies. If a contradiction is identified, then the system tries immediately to find the culprit. The blame can be placed on the decision that caused the contradiction or on the last decision, leading to dependency-directed backtracking or chronological backtracking, respectively. The JTMS performs dependency-directed backtracking. When the JTMS finds a believed node in contradiction, it creates a contradiction node and its justification, which contains the identified set of incompatible nodes. Then, it invokes the dependency-directed backtracking algorithm to find and remove the minimal set of assumptions that puts the contradiction node *out*. This procedure consists of (*1*) examining the justification of the contradiction node, (*2*) identifying the underlying set of assumption nodes, (*3*) registering the resulting set of assumptions as inconsistent, and (*4*) changing the label of one of these assumptions. This operation changes the label of the contradiction node to *out*. Finally, it reports back to the problem solver all the changes regarding the beliefs involved in the process.

Belief revision occurs when the responsible node for the contradiction is identified and its label is changed, that is, when an assumption from the set of assumptions that supports the contradiction node is selected for culprit. This behavior is intrinsic to the JTMS.

Belief Revision Supported by ATMS

A belief revision system that relies on an ATMS typically determines and keeps the full set of consequents that are consistent with the represented assumptions/propositions—multiple belief contexts. Because the set of represented propositions is intrinsically dynamic, these systems usually implement a forward-chaining inference mechanism as well as specific knowledge representation (which include bit sets and efficient pattern matching algorithms). The inference rules are ordered according to their respective level of dependency/depth. The deeper the rule is, the greater is its dependency on other rules. A rule with depth D should be executed only after all rules with depth $D-1, \ldots, 1$ have been executed, and rules with equal depth should be executed according to the number of assumptions its antecedent/precondition nodes depend on, starting with those that depend on fewer assumptions.

The problem solver scrolls the depth-ordered rule list and, for each rule, it queries the ATMS about the statuses of the antecedent/precondition nodes. Whenever they are all believed, the problem solver fires the rule and sends the new justification of the consequent/conclusion node to the ATMS. De Kleer (17) calls these instantiated rules consumers because, once fired, they cease to exist and are converted into justifications of the consequent/conclusion node. The ordered set of rules ready to be fired is established through an appropriate scheduling algorithm (17) that intends to find efficiently the most generic context of each node and the most specific version of a contradiction/inconsistency. Simultaneously, the ATMS is constantly checking the consistency between the already represented and the newly received data.

The problem solver has specific knowledge to detect contradictions/inconsistencies. This knowledge is represented as consistency maintenance rules (or inconsistency detection rules). Whenever the problem solver explores a new space/time search point, the consistency maintenance mechanism is automatically triggered to ensure the consistency of all contexts under evaluation. As soon as an inconsistency is detected, it is immediately reported to the ATMS. The ATMS registers the contradictory/inconsistent set of assumptions or *nogood* and removes it from the labels of all represented nodes.

The detection of a contradiction/inconsistency leads to belief revision: (*1*) registration of the contradictory/inconsistent set of assumptions as a nogood, (*2*) removal of the contradictory/inconsistent set of assumptions from the labels of all represented nodes, (*3*) identification of the culprits, and (*4*) removal of the culprits. Whereas the first two stages are intrinsic to the ATMS operation, the identification of the culprit assumptions is external to the ATMS and depends on the existence of specific knowledge on the problem solver side. The culprit assumptions are abandoned, that is, they become disbelieved propositions.

Multiple Belief Reasoner

The MBR of (9) is a BRS system that handles multiple belief contexts simultaneously. It was developed on top of a logic system that keeps track of the dependencies among propositions and knows how to propagate them. The logic system used is the SWM of Shapiro, Wand, and Martins, which is based on relevance logic (18).

The SWM system associates each proposition with one or more supporting triple. Each triple is of the form <*OT, OS, RS*> where *OT* is the *origin tag*, *OS* represents the *origin set*, and *RS* the *restriction set*. The *OT* identifies how the proposition was created (*{hypothesis, derived, extended}*); *OS* holds the set of hypothesis that was actually used to derive the proposition; *RS* contains all known sets that are inconsistent with the *OS*. A proposition derived from multiple inferences will have multiple supporting triples. Only the *RS* field of a triple may change with time to accommodate new identified contradictions; the *OT* and *OS* fields, once created, remain unchanged throughout the system's operation.

The propositions are added to the knowledge base according to the inference rules of SWM together with its supporting triples. MBR uses the notion of context or set of hypotheses. Each context defines a belief space, which holds the context's set of hypotheses as well as the set of all the propositions that are exclusively derived from this context. At each moment, there is one active context, and all knowledge base operations are defined over the belief space of the current context.

When a contradiction is detected, the origin sets of the contradictory propositions are inspected, and their union becomes a known inconsistent set of hypothesis. All propositions with origin sets that contain the recently identified inconsistent set of hypothesis must update their restriction set as to include it. Finally, in the case of MBR, belief revision is based on the preferences established between the represented beliefs, that is, MBR selects from the set of assumptions involved in the contradiction the least-preferred assumptions and blames them for the contradiction.

CONCLUSIONS

Beliefs, which are volatile by nature, require a rational and justified endorsement. The foundations-based belief-revision systems allow the representation of beliefs by storing and maintaining the reasons behind their representation. These reasons form a dependency network between the represented beliefs, ensuring that, whenever a revision occurs, all repercussions will be correctly propagated. According to Doyle (19), these systems allow the representation and modification of beliefs, the storage of the inference relations between beliefs as well as restrict all changes to minimal changes. Reason maintenance systems, which are also known as truth maintenance systems, are external modules specialized in these tasks.

The presented approaches are intended for scenarios where the information is dynamic, distributed, incomplete, or even eventually, incorrect. Their main goal is to maintain, in a rational and justified manner, a dynamic set of beliefs according to perceived observations (belief update), the identified contradictions (consistency maintenance), and the specified belief preferences (belief revision). The reason maintenance/truth maintenance capabilities can be provided either by an external module—JTMS, LTMS, or ATMS—or be internal to the system—MBR.

WEB INTELLIGENCE (WI)

INTRODUCTION

The study of Web intelligence (WI) was first introduced in several papers and books [see Refs. (1–19)]. Broadly speaking, WI is a new direction for scientific research and development that explores the fundamental roles as well as practical impacts of artificial intelligence (AI) in the context of the Web,[1] such as knowledge representation, planning, knowledge discovery and data mining, intelligent agents, and social network intelligence, as well as advanced information technology (IT), such as wireless networks; ubiquitous devices; social networks; and data/knowledge grids; and the next generation of Web-empowered products, systems, services, and activities.

On one hand, WI applies results from existing disciplines to a totally new domain. On the other hand, WI introduces new problems and challenges to the established disciplines. WI may be considered as an enhancement or an extension of AI and IT (4). The WI technologies revolutionize the way in which information is gathered, stored, processed, presented, shared, and used through electoronization, virtualization, globalization, standardization, personalization, and portals.

The challenges of Internet computing research and development in the next decade will be WI centric, focusing on how we can intelligently make the best use of the widely available Web connectivity. The new WI technologies will be determined precisely by *human needs in a post-industrial era*; namely (2):

- *information* empowerment,
- *knowledge* sharing,
- virtual *social* communities,
- *service* enrichment, and
- practical *wisdom* development.

We observed that one of the most promising paradigm shifts in the Web will be driven by the notion of *wisdom*, and developing the World Wide Wisdom Web (the *Wisdom Web*, or W4) will become a tangible goal for WI research (1,3,7). The new generation of the WWW will enable humans to gain wisdom of living, working, and playing in addition to information search and knowledge queries.

Great potential exits for WI to make useful contributions to e-business (including e-commerce and e-finance), e-science, e-learning, e-government, e-community, and so on. Many specific applications and systems have been proposed and studied. In particular, the e-business activity that involves the end user is undergoing a significant revolution (10). The ability to track users' browsing behavior down to individual mouse clicks has brought the vendor and end customer closer than ever before. It is now possible for a vendor to personalize his product message for individual customers at a massive scale, which is called *targeted marketing* (or direct marketing) (11–13). Web mining and Web usage analysis play an important role in e-business for customer relationship management (CRM) and targeted marketing. Web mining is the use of data mining techniques to discover automatically and extract information from Web documents and services (10,14,15). A challenge is to explore the connection between Web mining and the related agent paradigm, such as Web farming, that is the systematic refining of information resources on the Web for business intelligence (16).

This article investigates various ways to study WI and potential applications. The next section describes what is the Wisdom Web, which includes ten capabilities of the Wisdom Web, and conceptual levels of WI for developing the Wisdom Web. The section after that discusses how to develop various Web-based portals, in particular, intelligent enterprise portals for e-business intelligence, by using WI technologies. Furthermore, based on the discussion, an intelligent Web-based portals-centric schematic diagram of WI-related topics is provided in this section. The section entitled Advanced topics for studying WI describes various ways for studying WI, which include the semantics in the Web and the Web as social networks, as well as proposes new approaches for developing semantic social networks. Based on the above preparation, the section on WI-Based Targeted Marketing shows how to offer advanced features that enable e-business intelligence such as targeted marketing, which is a new business model by an interactive one-to-one communication between marketer and customer, as well as deal with the scalability and complexity of the real world, efficiently and effectively, by using the knowledge grid middleware as a new infrastructure and platform. The final section provides concluding remarks.

THE WORLD WIDE WISDOM WEB (W4)

What is the Wisdom Web?

In the movie *Star Wars: Episode II*, an interesting scene is when Obi Wan Kenobi failed to locate any relevant information about a mysterious planet (where later he discovered the clone manufacturing ground), he turned to his friend for advice. His friend, who apparently knew more than the Jedi's academy knowledge banks combined, gave the following reply: Other people seek *knowledge*, but you my friend know *wisdom*.

The reply in the above scene also provides an answer to the question: What will be the next paradigm shift in the Web and the Internet? The next paradigm shift lies in the notion of *wisdom*. The goal of the new generation WI is to enable users to gain new *wisdom* of living, working,

[1] Here, the term of AI includes classic AI, computational intelligence, and soft computing.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

playing, and learning, in addition to *information* search and *knowledge* queries. Here, the word of *wisdom*, according to the Webster Dictionary (Page: 1658) (17), implies the following meanings (emphasis added):

1. The quality of being wise; knowledge, and *the capacity to make due use of it*; *knowledge of the best ends and the best means*; *discernment and judgment*; discretion; sagacity; skill; dexterity.
2. The results of wise judgments; scientific or practical truth; acquired knowledge; erudition.

In the Web context, the manifestation of wisdom can best be illustrated with a minimalist Wisdom Web example.

When the Web Offers Practical Wisdom

Imagine that you are taking your first trip to the city of Montreal. You would like to find a really nice place to spend your evening. So, you walk into a Cyber Cafe on Sherbrook Street (the only street that you can recognize), and decide to get some *practical wisdom* from a public *Wisdom Web* outlet. You log in with a user name, "Spiderman," and ask:

> What is the best night life in Montreal during this season of the year?

The Wisdom Web *thinks* for about a second or two and then responds:

> Spiderman, the hockey games are on during this season of the year. Would you like to go?

You reply:

> Yes.

Then the Wisdom Web suggests:

> As far as I know, there are still some tickets left and you may purchase some at the Montreal Forum. It is easy to get there by taking Metro to the Atwater station.
>
> Now you decide that this could be an interesting evening for you. . .

One hour later, you arrive at the ticket office by Metro, but surprisingly find that the tickets left are all for the day after tomorrow when you will be traveling in Quebec City.

As you are a bit disappointed, you notice that there is a free Wisdom Web Kiosk right beside the ticket office. Well, that is convenient. So, without too much hesitation, you log on to the Wisdom Web, again as "Spiderman." The Wisdom Web still remembers your conversations an hour ago. As soon as it recognizes that you are "Spiderman," it says to you:

> Hello Spiderman, you were in such a hurry last time that I couldn't have a chance to tell you that all tickets available here are only for the day after tomorrow. They are quite expensive too. . .

Ten Capabilities of the Wisdom Web

To make the above Wisdom Web scenario a reality, the following 10 fundamental capabilities have to be incorporated and standardized (2):

1. *Self-organizing servers.* The Wisdom Web will regulate automatically the functions and cooperations of related websites and application services available. A Wisdom Web server self-nominates automatically to other services its functional *roles* as well as corresponding spatial or temporal *constraints* and operational *settings*.
2. *Specialization.* A Wisdom Web server is an *agent* by itself, which is specialized in performing some roles in a certain service. The *association* of its roles with any service will be measured and updated dynamically, for instance, the association may be forgotten if it is not used for some time.
3. *Growth.* The population of *Wisdom Agents* will change dynamically, as new agents are self-reproduced by their parent agents to become more specialized or as aged agents and are deactivated.
4. *Autocatalysis.* As various roles of wisdom agents are created through specialization and are activated by the *Wisdom Search* requests, their associations with some services and among themselves must be aggregated autocatalytically. In this respect, the autocatalysis of associations is similar to the pheromone laying for positive feedback in an ant colony.
5. *Problem Solver Markup Language (PSML).* PSML is necessary for wisdom agents to specify their roles and settings as well as relationships with any other services.
6. *Semantics.* The Wisdom Web needs to understand what are meant by "Montreal," "season," "year," and "night life," and what is the right judgment of "best," by understanding the granularities of their corresponding subjects and the whereabouts of their ontology definitions.
7. *Metaknowledge.* Besides semantic knowledge extracted and manipulated in the *Wisdom Search*, it is also essential for wisdom agents to incorporate a dynamically created source of metaknowledge that deals with the relationships between concepts and the spatial or temporal constraint knowledge in planning and executing services. It allows agents to self-resolve their conflict of interests.
8. *Planning.* In the above example, the goal is to find a function or an event that may sound attractive to a visitor. The constraint is that they must be happening during this season. Two associated subgoals are involved: To have an access to the recommended function or event, one needs a ticket. Furthermore, to go to get the ticket, one can travel by metro. In the Wisdom Web, ontology alone will *not* be sufficient.
9. *Personalization.* The Wisdom Web remembers the recent encounters and relates different episodes together, according to (1) "Spiderman," (2) time,

and (3) attainability of (sub)goals. In addition, it may identify other goals as well as courses of action for this user as their conversation continues.

10. *A sense of humor.* Although the Wisdom Web does not tell a funny story explicitly, it adds some punch lines to the situation or anxiety that "Spiderman" is presently in when he/she logs on for the second time, which will make "Spiderman" feel absurd.

Levels of WI

To develop a Wisdom Web to benefit from the information infrastructure that the Web has empowered, we have witnessed the fast development as well as applications of many WI techniques and technologies, which cover the following four conceptual levels at least:

1. *Internet-level communication, infrastructure, and security protocols*. The Web is regarded as a *computer-network system*. WI techniques for this level include Web data prefetching systems built upon Web surfing patterns to resolve the issue of Web latency. The intelligence of the Web prefetching comes from an adaptive learning process based on the observation and characterization of user surfing behavior (18,19).
2. *Interface-level multimedia presentation standards*. The Web is regarded as an *interface* for human–Internet interaction. WI techniques for this level are used to develop intelligent Web interfaces in which the capabilities of adaptive cross-language processing, personalized multimedia representation, and multimodal data processing are required.
3. *Knowledge-level information processing and management tools*. The Web is regarded as a *distributed data/knowledge base*. We need to develop semantic markup languages to represent the semantic contents of the Web available in machine-understandable formats for agent-based autonomic computing, such as searching, aggregation, classification, filtering, managing, mining, and discovery on the Web (20).
4. *Application-level ubiquitous computing and social intelligence environments*. The Web is regarded as a *basis for establishing social networks* that contain communities of people (or organizations or other social entities) connected by social relationships, such as friendship, coworking, or information exchange with common interests. They are Web-supported social networks or virtual communities. The study of WI concerns the important issues central to social network intelligence (social intelligence for short) (21). Furthermore, the multimedia contents on the Web are accessible not only from stationary platforms, but also increasingly from mobile platforms (22). Ubiquitous Web access and computing from various wireless devices needs adaptive personalization for which WI techniques are used to construct models of user interests by inferring implicitly from user behavior and actions (23,24).

In particular, the social intelligence approach presents excellent opportunities and challenges for the research and development of WI, as well as a Web-supported social network that needs to be supported by all levels of WI as mentioned above. This approach is based on the observation that the Web is now becoming an integral part of our society, and that scientists should be aware of it and take much care about handling social issues (25). Study in this area must receive as much attention as Web mining, Web agents, ontologies, and related topics.

Wisdom-Oriented Computing

Wisdom-oriented computing is a new computing paradigm aimed at providing not only a medium for seamless information exchange and knowledge sharing (20) but also a type of *man-made resources for sustainable knowledge creation, and scientific and social evolution*(2,3). The Wisdom Web, i.e., the Web that empowers wisdom-oriented computing, will reply on *grid-like service agencies* that self-organize, learn, and evolve their courses of actions to perform service tasks as well as their identities and interrelationships in Web communities. They will cooperate and compete among themselves to optimize their's as well as others, resources and utilities.

Self-organizing learning agents are computational entities that are capable of self-improving their performance in dynamically changing and unpredictable task environments. In Ref. (26), Liu has provided a comprehensive overview of several studies in the field of *autonomy oriented computing*, with in-depth discussions on self-organizing and with adaptive techniques for developing various embodiments of agent based systems, such as autonomous robots, collective vision and motion, autonomous animation, and search and segmentation agents. The core of those techniques is the notion of synthetic or emergent autonomy based on behavioral self-organization.

Developing the Wisdom Web will become a tangible goal for WI researchers and practitioners. The Wisdom Web will enable us to use the global connectivity optimally, as offered by the Web infrastructure, and most importantly, to gain the practical wisdoms of living, working, and playing, in addition to information search and knowledge queries.

To develop the new generation WI systems effectively, we need to define *benchmark* applications, i.e., a new *Turing Test*, that will capture and demonstrate the Wisdom Web capabilities (2).

Take the wisdom-oriented computing benchmark as an example. We can use a service task of compiling and generating a market report on an existing product or *a potential market report on a new product*. To get such service jobs done, an information agent on the Wisdom Web will mine and integrate available Web information, which will in turn be passed onto a market analysis agent. Market analysis will involve the quantitative simulations of customer behavior in a marketplace, instantaneously handled by other service agencies, involving a large number of semantic or computational grid agents (e.g. Ref. 27). Because the number of variables concerned may be in the order of hundreds or thousands, it can easily cost a single system years to generate one predication.

DEVELOPING INTELLIGENT PORTALS BY USING WI TECHNOLOGIES

What is a Portal?

A portal enables a company, an organization, or a community to create a *virtual organization* (or a virtual community) on the Web where key production/information steps are outsourced to partners and customers. In other words, a portal is a single gateway to personalized information needed to enable informed interdisciplinary research, services, and/or business activities. Developing intelligent portals is one of the most sophisticated applications on the Web.

Although specific features of various portals need to be considered, the common requirements of the portals for e-business, e-science, e-government, e-learning, among others, are such that

- they need a unique website (a single gateway) in which all of the contents related to the virtual organization can be accessed although such organization information is geographically distributed in multisite, multi data repositories, and multi-institution, and
- they need to have easy access to expensive remote facilities, computing resources, and share information acquired from different subjects using different techniques and stored in dedicated knowledge-data bases.

Many organizations are implementing a corporate portal first and are then growing this solution into more of an *intelligent* B2B portal. By using a portal to tie in back-end enterprise systems, a company can manage the complex interactions of the virtual enterprise partners through all phases of the value and supply chain.

Here we would like to mention two typical types of enterprises, as examples,

- transnational corporations that have operations, subsidiaries, investments, or branches worldwide, and
- communities with many mid-sized/small-scale companies in a region,

that need such enterprise portals for supporting their e-business and e-commerce activities.

The Virtual Industry Park: An Example of Enterprise Portals

As an example for developing enterprise portals by using WI technologies, here we discuss how to construct an intelligent virtual industry park (VIP) that has been developing in our group. The VIP portal is a website in which all of the contents related to the small/medium-sized companies in Maebashi city, Japan can be accessed.

The construction process can be divided into three phases. We first constructed a basic system including the fundamental functions such as the interface for dynamically registering/updating enterprise information, the database for storing the enterprise information, automatic generation and modification of enterprise homepages, and the domain-specific, keyword-based search engine. When designing the basic system, we also started by analyzing customer performance: each customer what has bought, over time, total volumes, trends, and so on.

Although the basic system can work as a whole one, we now need to know not only past performance on the business front, but also how the customer or prospect enters our VIP portal to target products and to manage promotions and marketing campaigns. To the already demanding requirement to capture transaction data for additional analysis, we now also need to use the Web usage mining techniques to capture the clicks of the mouse that define where the visitor has been on our website. What pages has he or she visited? What is the semantic association between the pages he or she visited? Is the visitor familiar with the Web structure? Or is he or she a new user or a random one? Is the visitor a Web robot or other users? In search for the holy grail of "stickiness," we know that a prime factor is *personalization* for:

- making a dynamic recommendation to a Web user based on the user profile and usage behavior.
- automatic modification of a website's contents and organization.
- combining Web usage data with marketing data to give information about how visitors used a website for marketers.

Hence, we need to extend the basic VIP system by adding more advanced functions such as Web mining, an ontologies-based search engine, as well as automatic e-mail filtering and management.

Finally, a portal for e-business-intelligence can be implemented by adding e-business-related application functions such as targeted marketing and CRM, electronic data interchange, as well as security solution.

An Intelligent Enterprise Portal Centric Schematic Diagram of WI Technologies

From the example stated in the above subsection, we can see that developing an intelligent enterprise portal needs to apply results from existing disciplines of AI and IT to a

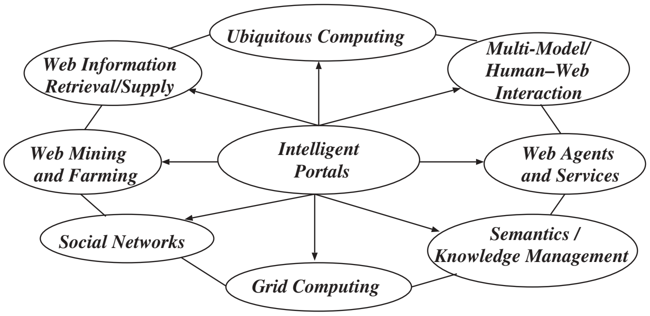

Figure 1. An intelligent enterprise portals centric schematic diagram of WI technologies.

totally new domain. On the other hand, the WI technologies are also expected to introduce new problems and challenges to the established disciplines on the new platform of the Web and the Internet. That is, WI is an enhancement or an extension of AI and IT.

To study advanced WI technologies systematically, and to develop advanced Web-based intelligent enterprise portals and information systems, we provide a schematic diagram of WI technologies from a Web-based, intelligent enterprise portals centric perspective in Fig. 1. In Fig. 1, directed lines denote that the development of intelligent enterprise portals needs to be supported by various WI related techniques, and undirected lines denote that the components of WI techniques are relevant each other.

Web Mining and Farming

The enterprise portal-based e-business activity that involves the end user is undergoing a significant revolution(10). The ability to track users' browsing behavior down to individual mouse clicks has brought the vendor and end customer closer than ever before. It is now possible for a vendor to personalize his product message for individual customers at a massive scale, which is called *targeted marketing* (or *direct marketing*) (11,13). Web mining and Web usage analysis play an important role in e-business for CRM and targeted marketing.

Web mining is the use of data mining techniques to discover and to extract information automatically from large Web data repositories such as Web documents and services (10,12,14,28). Web mining research is at the crossroads of research from several research communities, such as database, information retrieval, artificial intelligence, and especially the subareas of machine learning and natural language processing. Web mining can be divided into four classes of data available on the Web:

- *Web content*: the data that constitutes the Web pages and conveys information to the users, i.e., html, graphical, video, audio files of a Web page.
- *Web structure*: the data that formulates the hyper-link structure of a website and the Web, i.e., various HTML tags used to link one page to another and one website to another website.
- *Web usage*: the data that reflects the usages of Web resources, i.e., entries in Web browser's history and Internet temporary files, proxy server, and Web server logs.
- *Web user profile*: the data that provides demographic information about users of the website, i.e., users' registration data and customers' profile information.

Furthermore, Web content, structure, and usage information, in many cases, are copresent in the same data file. For instance, the file names appeared in the log files and Web structure data contain useful content information. One may safely assume that a file named "WebLogMining.html" must contain information about web log mining. Similarly, the categories of web mining cannot be considered exclusive or isolated from each other. Web content mining sometimes must use Web structure data to classify a web page. In the same way, Web usage mining sometimes has to make use of Web content data and of Web structure information.

A challenge is to explore the connection between Web mining and the related agent paradigm such as Web farming that is the systematic refining of information resources on the Web for business intelligence (16). Web farming extends Web mining into an evolving breed of information analysis in a whole process of Web-based information management including seeding, breeding, gathering, harvesting, refining, and so on.

ADVANCED TOPICS FOR STUDYING WI

With respect to different levels of WI as mentioned in the section entitled "Levels of WI," the Web can be studied in several ways.

Studying the Semantics in the Web

One of the fundamental WI issues is to study the *semantics* in the Web, called the semantic Web, that is, modeling semantics of Web information to

- allow more of the Web content (not just form) to become machine readable and processible.
- allow for recognition of the semantic context in which Web materials are used.
- allow for the reconciliation of terminological differences between diverse user communities.

Thus, information will be machine-processible in ways that support intelligent network services such as information brokers and search agents (20,29).

Main Components of the Semantic Web. The semantic Web is a step toward intelligence of the Web. It is based on languages that make more semantic content of the page available in machine-readable formats for agent-based computing. The main components of semantic Web techniques include:

- a unifying data model such as RDF (Resource Description Framework).
- languages with defined semantics, built on RDF, such as OWL.
- ontologies of standardized terminology to mark up Web resources, used by semantically rich, service-level descriptions (such as OWL-S, the OWL-based Web Service Ontology), and to support tools that assist the generation and processing of semantic markup.

Ontologies and agent technology can play a crucial role in Web intelligence by enabling Web-based knowledge processing, sharing, and reuse between applications. Generally defined as shared formal conceptualizations of particular domains, ontologies provide a common understanding of topics that can be communicated between people and agent-based systems.

An ontology is a formal, explicit specification of a shared conceptualization (30). It provides a vocabulary of terms and relations to model the domain and specifies how you view the target world. An ontology can be very high-level, consisting of concepts that organize the upper parts of a knowledge base, or it can be domain-specific such as a chemical ontology. We here suggest three categories of ontologies: *domain-specific*, *task*, and *universal*.

A domain-specific ontology describes a well-defined technical or business domain.

A task ontology might either be domain-specific, or might be a set of ontologies with respect to several domains (or their reconstruction for that task), in which relations between ontologies are described for meeting the requirement of that task.

A universal ontology describes knowledge at higher levels of generality. It is a more general-purpose ontology (or called a common ontology) that is generated from several domain-specific ontologies. It can serve as a bridge for communication among several domains or tasks.

Roles of Ontologies. Generally speaking, a domain-specific (or task) ontology forms the heart of any knowledge information system for that domain (or task). Ontologies provide a way of capturing a shared understanding of terms that can be used by human and programs to aid in information exchange. Ontologies have been gaining popularity as a method of providing a specification of a controlled vocabulary. Although simple knowledge representation such as Yahoo's taxonomy provides notions of generality and term relations, classic ontologies attempt to capture precise meanings of terms. To specify meanings, an ontology language must be used.

Ontologies will play a major role in supporting information exchange processes in various areas. The roles of ontologies for WI include:

- communication between Web communities.
- agent communication based on semantics.
- knowledge-based Web retrieval.
- understanding Web contents in a semantic way.
- social network and Web community discovery.

More specifically, new requirements for any exchange format on the Web are:

- *Universal expressive power*. A Web-based exchange format must be able to express any form of data.
- *Syntactic interoperability*. Applications must be able to read the data and get a representation that can be exploited.
- *Semantic interoperability*. One important requirement for an exchange format is that data must be understandable. It is about defining mappings between terms within the data, which requires content analysis.

The semantic Web requires interoperability standards that address not only the syntactic form of documents, but also the semantic content. Ontologies serve as metadata schemes for the semantic Web, providing a controlled vocabulary of concepts, each with explicitly defined and machine-processible semantics.

A semantic Web also lets agents use all (meta) data on all Web pages, allowing it to gain knowledge from one site and apply it to logical mappings on other sites for ontology-based Web retrieval and e-business intelligence. For instance, ontologies can be used in e-commerce to enable machine-based communication between buyers and sellers, vertical integration of markets, and description reuse between different marketplaces. Web-search agents use ontologies to find pages with words that are different syntactically but similar semantically.

Although ontology engineering has been studied over the last decade, few (semi) automatic methods for comprehensive ontology construction have been developed. Manual ontology construction remains a tedious, cumbersome task that can easily result in a bottleneck for WI. Learning and construction of domain-specific ontology from Web contents is an important task in both text mining and WI (31–34).

Studying the Web as Social Networks

The study of the Web as a network has resulted in a better understanding of the sociology of Web content creation; it has improved the search engines on the Web dramatically and has created more effective algorithms for community mining and for knowledge management.

We can view the Web as a directed network in which each node is a static web page to another. Thus, the Web can be studied as a *graph* that connects a set of people (or organizations or other social entities) connected by a set of social relationships, such as friendship, coworking or information exchange with common interests (21,35,36).

Social Network Analysis. In his keynote talk at WI '01, Raghavan stated that the main questions about the Web graph include:

- How big is the graph?
- Can we browse from any page to any other?
- Can we exploit the structure of the Web?
- What does the Web graph reveal about social dynamics?
- How to discover and manage the Web communities?

Modern social network theory is built on the work of Stanley Milgram (37). Milgram found so-called the *small-world phenomenon*, that is, typical paths took only six hops to arrive. Ravi Kumar et al. (35) observed there is a strong structural similarity between the Web as a network and social networks. The small-world phenomenon constitutes a basic property of the Web, which is not only interesting, but also useful.

In Ref. 21, it is suggested that the Web graph has several billion nodes (pages of content) and an average degree of about 7. A recurrent observation on the Web graph is the prevalence of power laws: The degree of nodes are distributed according to inverse polynomial distribution (18,19,38–40).

The Web captures automatically a rich interplay between hundreds of millions of people and billions of pages of content. In essence, these interactions embody a *social network* involving people, the pages they create and view, and even the Web pages themselves. These relationships have a bearing on the way in which we create, share, and manage knowledge and information. It is our hope that exploiting these similarities will lead to progress in knowledge management and business intelligence.

The *broader* social network is a self-organizing structure of users, information, and communities of expertise (21,23). Such social networks can play a crucial role in implementing next-generation enterprise portals with functions such as data mining and knowledge management for discovery, analysis, and management of social network knowledge.

The social network is placed at the top of a four-level WI infrastructure as described in the section on "levels of WI" and is supported by functions, provided in all Levels of WI, including security, prefetching, adaptive cross-language processing, personalized multimedia representation, semantic searching, aggregation, classification, filtering, managing, mining, and discovery.

Semantic Social Networks for Intelligent Portals. One of the most sophisticated applications on the Web today is *enterprise information portals* operating with state-of-the-art markup languages to search, retrieve, and repackage data. The enterprise portals are being developed into an even more powerful center based on component-based applications called Web Services (21,23).

WI researchers must study both centralized and distributed information structures. Information on the Web can be either globally distributed throughout the Web within multilayer over the infrastructure of Web protocols, or located locally, centralized on an intelligent portal providing Web services (i.e., the intelligent service provider) that is integrated to its own cluster of specialized intelligent applications. However, each approach has a serious flaw. As pointed out by Alesso and Smith (23), the intelligent portal approach limits uniformity and access, whereas the global semantic Web approach faces combinatory complexity limitations.

A way to solve the above issue is to develop and use the Problem Solver Markup Language (PSML), for collecting globally distributed contents and knowledge from Web-supported, semantic social networks and incorporating them with locally operational knowledge/databases in an enterprise or community for local centralized, adaptable Web intelligent services.

The core of PSML is distributed inference engines that can perform automatic reasoning on the Web by incorporating contents and meta-knowledge autonomically collected and transformed from the semantic Web with locally operational knowledge-data bases. A feasible way as the first step to implement such a PSML is to use existing Prolog-like logic language with agent technologies. In our current experiments, KAUS is used for representation of local information sources and for inference and reasoning. KAUS is a knowledge management system developed in our group that involves data/knowledge bases on the basis of an extended first-order predicate logic and relational data model (41,42). KAUS enables representation of knowledge and data in the first-order logic with data structure in multi-level and can be easily used for inference and reasoning as well as transforming and managing both knowledge and data.

By using this information transformation approach, the dynamic, global information sources on the Web can be combined with the local information sources in an enterprise portal for decision making and e-business intelligence.

Soft Computing for WI

Another challenging problem in WI is how to deal with uncertainty of information on the wired and wireless Web. Adapting existing soft computing solutions, when appropriate for WI applications, must incorporate a robust notion of learning that will scale to the Web, adapt to individual user requirements, and personalize interfaces. Ongoing efforts exist to integrate logic (including nonclassical logic), artificial neural networks, probabilistic and statistical reasoning, fuzzy sets, rough sets, granular computing, genetic algorithm, and other methodologies in the soft computing paradigm, to construct a hybrid approach/system for Web intelligence.

WI-BASED TARGETED MARKETING

An enterprise portal for business intelligence needs the function of WI-based targeted marketing, which is integrated with WI related capabilities such as Web mining, the ontologies-based search engine, personalized recommendation, as well as automatic e-mail filtering and management (8).

Targeted marketing aims at obtaining and maintaining direct relationships between suppliers and buyers within one or more product/market combinations. Targeted marketing becomes more and more popular because of the increased competition and the cost problem.

Furthermore, the scope of targeted marketing can be expanded from considering only how products are distributed, to include enhancing the relationships between an organization and its customers (43) because the strategic importance of long-term relationships with customers. In other words, once customers are acquired, customer retention becomes the target. Retention through customer satisfaction and loyalty can be improved greatly by acquiring and exploiting knowledge about these customers and their needs. Such targeted marketing is called "targeted relationship marketing" or "CRM" (44).

The Market Value Function (MVF) Model

In addition to WI related capabilities, targeted marketing is an important area of applications for data mining and for data warehousing (4,45). Although standard data mining methods may be applied for the purpose of targeted marketing, many specific algorithms need to be developed and applied for direct marketer to make decisions effectively.

Let us consider now a typical problem of targeted marketing. Suppose a health club needs to expand its operation by attracting more members. Assume that each existing member is described by a finite set of attributes. It is natural to examine existing members to identify their common features. Information about the health club may be sent to nonmembers who share the same features of members or similar to members. Other examples include promotion of special types of phone services and marketing of different classes of credit cards. In this case, we explore the relationships (similarities) between people (objects) based on their attribute values. The underlying assumption is that *similar type of people tend to make similar decisions and to choose similar services*. Techniques for mining association rules may not be applicable directly to this type of targeted marketing. One may produce too many or too few rules. The selection of a good set of rules may not be an easy task. Furthermore, the use of the derived rules may produce too many or too few potential new members.

To address this issue, we proposed a new model for targeted marketing by focusing on the issues of knowledge representation and computation of market values (4,12). More specifically, we assume that each object is represented by its values on a finite set of attributes. Also, we assume that market values of objects can be computed using a linear market value function. Thus, we may consider the proposed model to be a *linear* model, which is related to, but is different from, the linear model for information retrieval.

Let U be a finite universe of objects. Elements of U may be customers or products we are interested in market oriented decision making. The universe U is divided into three pair-wise disjoint classes, i.e., $U = P \cup N \cup D$. The sets P, N, and D are called *positive*, *negative*, and *don't know* instances, respectively. Take the earlier health club example, P is the set of current members, N is the set of people who had refused to join the club previously, and D is the set of the rest. The set N may be empty. A targeted marketing problem may be defined as finding elements from D, and possibly from N, that are similar to elements in P, and possibly dissimilar to elements in N. In other words, we want to identify elements from D and N that are more likely to become new members of P. We are interested in finding a market value function so that elements of D can be ranked accordingly.

Information about objects in a finite universe is given by an information table (46,47). The rows of the table correspond to objects of the universe, the columns correspond to attributes, and each cell is the value of an object with respect to an attribute. Formally, an information table is a quadruple:

$$S = (U, At, \{V_a | a \in At\}, \{I_a | a \in At\})$$

where U is a finite nonemptyset of objects, At is a finite nonempty set of attributes, V_a is a nonempty set of values for $a \in At$, $I_a : U \rightarrow V_a$ is an information function for $a \in At$. Each information function I_a is a total function that maps an object of U to exactly one value in V_a. An information table represents all available information and knowledge. Objects are only perceived, observed, or measured by using a finite number of properties (46).

A market value function (MVF) is a real-valued function from the universe to the set of real numbers, $r : U \rightarrow \Re$. In the context of information retrieval, the values of r represent the potential usefulness or relevance of documents with respect to a query. According to the values of r, documents are ranked. For the targeted marketing problem, a market value function ranks objects according to their potential market values. For the health club example, a market value function ranks people according to their likelihood of becoming a member of the health club. The likelihood may be estimated based on its similarity to a typical member of P.

We studied the simplest form of market value functions, i.e., the linear discriminant functions. Let $u_a : V_a \rightarrow \Re$ be a utility function defined on V_a for an attribute $a \in At$. The utility $u_a(\cdot)$ may be positive, negative, or zero. For $v \in V_a$, if $u_a(v) > 0$ and $I_a(x) = v$, i.e., $u_a(I_a(x)) > 0$, then attribute a has a positive contribution to the overall market value of x. If $u_a(I_a(x)) < 0$, then a has a negative contribution. If $u_a(I_a(x)) = 0$, then a has no contribution. The pool of contributions from all attributes is computed by a linear market value function of the following form:

$$r(x) = \sum_{a \in At} w_a u_a(I_a(x)) \tag{1}$$

where w_a is the weight of attribute a. Similarly, the weight w_a may be positive, negative, or zero. Attributes with larger weights (absolute value) are more important, and attributes with weights close to zero are not important. The overall market value of x is a weighted combination of utilities of all attributes. By using a linear market value function, we have implicitly assumed that contributions made by individual attributes are independent. Such an assumption is known as utility independence assumption commonly. Implications of utility independence assumption can be found in literature of multi-criteria decision making (48).

The market value model proposes a linear model to solve the target selection problem of targeted marketing by drawing and extending result from information retrieval (4,12). It is assumed that each object is represented by values of a finite set of attributes. A market value function is a linear combination of utility functions on attribute values, which depends on two parts: *utility function* and *attribute weighting*.

The market value function has some advantages. First, it can rank individuals according to their market value instead of classifying; second, the market value functions is interpretable; and last, the system of the market value function can perform without expertise.

Multi-Aspect Analysis in Multiple Data Sources

Generally speaking, customer data can be obtained from multiple customer touchpoints. In response, multiple data sources that are obtained from multiple customer touchpoints, including the Web, wireless, call centers, and brick-and-mortar store data, need to be integrated into a distributed data warehouse that provides a multi faceted view of their customers, their preferences, interests, and expectations for multi aspect analysis. Hence, a multi strategy and multi agent data mining framework is required (6,49).

One of main reasons for developing a multi agent data mining system is that we cannot expect to develop a single data mining algorithm that can be used to solve all targeted marketing problems because of the complexity of real-world applications. Hence, various data mining agents need to be used cooperatively in the multi step data mining process for performing multi aspect analysis as well as multi level conceptual abstraction and learning.

The other reason for developing a multi agent data mining system is that when performing multi aspect analysis for complex targeted marketing problems, a data mining task needs to be decomposed into subtasks. Thus, these sub tasks can be solved by using one or more data mining agents that are distributed over different computers and multi data repositories on the Internet. The decomposition problem leads us to the problem of distributed cooperative system design.

In the VIP stated in the section on the virtaul Industry Park for instance, mainly three kinds of data sources are considered, namely, customer database, products database, and Web farming database. Furthermore, in addition to the MVF based data mining method (12) mentioned in the section on the MVF model, we have developed various data mining methods, such as the GDT-RS inductive learning system for discovering classification rules (50), the LOI (learning with ordered information) for discovering important features (51,52), as well as the POM (peculiarity oriented mining) for finding peculiarity data/rules (53), to deal with each of such data sources, separately, for various services oriented multi aspect data analysis.

However, when we try to integrate the three kinds of data sources together into the advanced VIP system, we must know how to interact with each of those sources to extract the useful pieces of information, which then have to be combined for building the expected answer to the initial request. Hence, the core question is how to manage, represent, integrate, and use the information coming from huge, distributed, multiple-data sources.

Here, we would like to emphasize that how to manage, analyze, and use the information intelligently from different data sources is a problem that not exists only in the e-business field, but also in e-science, e-learning, e-government, as well as all WI systems and services (54,55). The development of enterprise portals and e-business intelligence is a good example for trying to solve such problem.

Building a Data Mining Grid

To implement an enterprise portal (e.g., the VIP discussed previously) for Web-based targeted marketing and business intelligence, a new infrastructure and platform as the *middleware* is required to deal with large, distributed data sources for multi aspect analysis. One methodology is to create a grid-based, organized society of data mining agents, called a *Data Mining Grid* on the grid computing platform (e.g., the Globus toolkit) (27,55–59). A data mining and must do the following:

- Develop various data mining agents, as mentioned in the section on the MVP model, for various services, oriented multiaspect data analysis;
- Organize the data mining agents into a multi layer grid, such as a data-grid, mining-grid, or knowledge-grid, under the Open Grid Services Architecture that aligns firmly with service-oriented architecture and Web services and understands the user's questions, transforms them to data mining issues, discovers the resources and information about the issues, and obtains a composite answer or solution.
- Use a conceptual model with three level workflows, namely data flow, mining flow, and knowledge flow, with respect to the data grid, the mining grid, and the knowledge grid, respectively, for managing the grid of data mining agents for multi aspect analysis in distributed, multiple-data sources and for organizing the dynamic, status-based business processes.

That is, the data mining grid is made of many smaller components that are called *data mining agents*. Each agent by itself can only do one simple thing. Yet when we join these agents in a *grid*, this implements more complex targeted marketing and business intelligence tasks.

Furthermore, ontologies are also used for description and for integration of multi data source and grid-based data mining agents in data mining process planning (6,7,28), which will provide the following:

- a formal, explicit specification for integrated use of multiple data sources in a semantic way.
- a conceptual representation about the sorts and properties of data/knowledge and data mining agents, as well as relations between data/knowledge and data mining agents.
- a vocabulary of terms and relations to model the domain, and specifying how to view the data sources and how to use data mining agents.
- a common understanding of multiple data sources that can be communicated between grid-based data mining agents.

CONCLUDING REMARKS

WI has been recognized as one of the most important as well as the fastest-growing IT research fields in the era of the World Wide Web, knowledge Web, grid computing, intelligent agent technology, and ubiquitous social computing. WI technologies will continue to produce the new tools and the infrastructure components necessary for creating intelligent enterprise portals that can serve users *wisely*.

To meet the strong demands for participation and the growing interests in WI, the Web Intelligence Consortium (WIC) was formed in spring 2002. The WIC (http://wi-consortium.org/) is an international non-profit organization dedicated to advancing world-wide scientific research and industrial development in the field of WI. It promotes collaborations among world wide WI research centers and organizational members, technology showcases at WI related conferences and workshops, WIC official book and journal publications, WIC newsletters, and WIC official releases of new industrial solutions and standards.

In addition to major WI related conferences/workshops, such as IEEE/WIC/ACM International Joint Conference on Web Intelligence and Intelligent Agent Technology, and numerous special issues in international journals/magazines, such as IEEE Computer, a WI-focused scientific journal, *Web Intelligence and Agent Systems: An International Journal* (refer to the WIC homepage), has been providing a standard international forum for disseminating results of advanced research and development in the field of WI.

The interest in WI is growing very fast. We would like to invite everyone, who are interested in the WI related research and development activities, to join the WI community. Your input and participation will determine the future of WI.

ACKNOWLEDGMENTS

We are very grateful to people who have joined or supported the WI community, members of the WIC advisory board, WIC technical committee, and WIC research centers, as well as keynote/invited speakers of WI-IAT conferences, in particular, J. Bradshaw, W. Buntine, N. Cercone, P. Doherty, B. B. Faltings, D. Fensel, E. A. Feigenbaum, I. Foster, G. Gottlob, F. Harmelen, J. Hendler, N. Jennings, W. L. Johnson, C. Kesselman, P. Langley, H. Lieberman, V. Lesser, J. McCarthy, R. Mizhouchi, T. M. Mitchell, T. Nishida, S. Ohsuga, P. Raghavan, Z. W. Ras, P. Schuster, A. Skowron, K. Sycara, B. Wah, M. Wooldridge, X. Wu, P. S. Yu, and L. A. Zadeh. We thank them for their strong support.

ROUGH SET THEORY

INTRODUCTION

Rough set theory is a new mathematical approach to imperfect knowledge. The problem of imperfect knowledge has been tackled for a long time by philosophers, logicians, and mathematicians. Recently, it has also became a crucial issue for computer scientists, particularly in the area of artificial intelligence (AI). There are many approaches to the problem of how to understand and manipulate imperfect knowledge. The most successful one is, no doubt, the fuzzy set theory proposed by Zadeh (1).

Rough set theory (2) presents still another attempt to this problem. This theory has attracted attention of many researchers and practitioners all over the world, who have contributed essentially to its development and applications. Rough set theory overlaps with many other theories, despite which rough set theory may be considered as an independent discipline in its own right. The rough set approach seems to be of fundamental importance to AI and cognitive sciences, especially in the areas of machine learning, knowledge acquisition, decision analysis, knowledge discovery from databases, expert systems, inductive reasoning, and pattern recognition. The main advantage of rough set theory in data analysis is that it does not need any preliminary or additional information about data like probability distributions in statistics, basic probability assignments in Dempster–Shafer theory, a grade of membership, or the value of possibility in fuzzy set theory. One can observe the following about the rough sets approach:

– introduction of efficient algorithms for finding hidden patterns in data,
– determination of minimal sets of data (data reduction),
– evaluation of the significance of data,
– generation of sets of decision rules from data,
– easy-to-understand formulation,
– straightforward interpretation of obtained results, and
– suitability of many of its algorithms for parallel processing.

One of the issues discussed in connection with the notion of a set is vagueness. Mathematics requires that all mathematical notions (including set) must be exact (Gottlob Frege (3)). However, philosophers and, recently, computer scientists have become interested in vague (imprecise) concepts. For example, in contrast to odd numbers, the notion of a beautiful painting is vague, because we are unable to classify uniquely all paintings into two classes: beautiful and not beautiful. Sometimes it is not possible to decide whether some paintings are beautiful or not and thus they remain in the doubtful area. Thus, beauty is not a precise but a vague concept. Almost all concepts we are using in natural language are vague. Therefore, common-sense reasoning based on natural language must be based on vague concepts and not on classic logic, which is why vagueness is important for philosophers and recently also for computer scientists. Vagueness is usually associated with the boundary region approach (i.e., existence of objects that cannot be uniquely classified to the set or its complement), which was first formulated in 1893 by the father of modern logic Gottlob Frege (3), who wrote:

> *"Der Begriff muss scharf begrenzt sein. Einem unscharf begrenzten Begriff würde ein Bezirk ensprechen, der nicht überall ein scharfe Grentzlinie hätte, sondern stellenweise gantz verschwimmend in die Umgebung übergine. Das wäre eigentlich gar kein Bezirk; und so wird ein unscharf definirter Begriff mit Unrecht Begriff gennant. Solche begriffsartige Bildungen kann die Logik nicht als Begriffe anerkennen; es is unmäglich, von ihnen genaue Gesetze auszustellen. Das Gesetz des ausgeschlossenen Drititten ist ja eigentlich nur in anderer Form die Forderung, dass der Begriff scharf begrentz sei. Ein beliebiger Gegenstand x fällt entwerder unter der Begriff y, oder er fällt nich unter ihn: tertium non datur."*

Thus, according to Frege, the concept must have a sharp boundary. To the concept without a sharp boundary, there would correspond an area that would not have any sharp boundary-line all around. It means that mathematics must use crisp, not vague concepts, otherwise it would be impossible to reason precisely.

Lotfi Zadeh (1) introduced a very successful approach to vagueness. In this approach, sets are defined by partial membership, in contrast to crisp membership used in the classic definition of a set. Rough set theory (2) expresses vagueness, not by means of membership, but by employing the boundary region of the set. If the boundary region of the set is empty, it means that the set is crisp, otherwise the set is rough (inexact). The nonempty boundary region of the set means that our knowledge about the set is not sufficient to define the set precisely. Discussion on vagueness in the context of fuzzy sets and rough sets can be found in Ref. 4. Basic ideas of rough set theory and its extensions, as well as many interesting applications can be found in books (see Refs. 2, 5–17), special issues of journals (see Refs. 18–25), proceedings of international conferences (see Refs. 26–36), and on the Internet (see, e.g.,www. roughsets.org, logic.mimuw.edu.pl, rsds.wsiz.rzeszow.pl).

Recent years are witness to a rapid grow of interest in rough set theory and its applications worldwide. Many international workshops, conferences, and seminars have included rough sets in their programs. A large number of high-quality papers on various aspects of rough sets and their applications have been published in recent years. In this article, we present the basic concepts of rough set theory and outline some research directions on rough sets.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

BASIC PHILOSOPHY

The rough set philosophy is founded on the assumption that with every object of the universe of discourse we associate some information (data, knowledge). For example, if objects are patients suffering from a certain disease, symptoms of the disease form information about patients. Objects characterized by the same information are indiscernible (similar) in view of the available information about them. The indiscernibility relation generated in this way is the mathematical basis of rough set theory. This understanding of indiscernibility is based on the idea of Gottfried Wilhelm Leibniz that objects are indiscernible if and only if all available functionals take on identical values (Leibnizian indiscernibility). Any set of all indiscernible (similar) objects is called an elementary set, and forms a basic granule (atom) of knowledge about the universe. Any union of some elementary sets is referred to as crisp (precise) set, otherwise the set is rough (imprecise, vague).

Consequently, each rough set has boundary–line cases (i.e. objects that cannot with certainty be classified either as members of the set or of its complement). Obviously, crisp sets have no boundary-line elements at all, which means that boundary-line cases cannot be properly classified by employing the available knowledge.

Thus, the assumption that objects can be "seen" only through the information available about them leads to the view that knowledge has granular structure. Due to the granularity of knowledge, some objects of interest cannot be discerned and appear the same (or similar). As a consequence, vague concepts, in contrast to precise concepts, cannot be characterized in terms of information about their elements. Therefore, in the proposed approach, we assume that any vague concept is replaced by a pair of precise concepts—called the lower and the upper approximation of the vague concept. The lower approximation consists of all objects that surely belong to the concept and the upper approximation contains all objects that possibly belong to the concept. The difference between the upper and the lower approximation constitutes the boundary region of the vague concept. Approximations are two basic operations in rough set theory.

APPROXIMATIONS AND ROUGH SETS

As mentioned, the starting point of rough set theory is the indiscernibility relation, generated by information about objects of interest. The indiscernibility relation expresses the fact that, because of the lack of knowledge, we are unable to discern some objects employing available information, which means that, in general, we are unable to deal with each particular object but we have to consider granules (clusters) of indiscernible objects, as fundamental concepts of our theory.

Now we present the basic concepts more formally.

Suppose we are given two finite, non-empty sets U and A, where U is the *universe of objects* and A is a set of *attributes*. The pair (U, A) is called an *information table*. With every attribute $a \in A$, we associate a set V_a, of its *values*, called the *domain* of a. Any subset B of A determines a binary relation $I(B)$ on U, called an *indiscernibility relation*, defined by

$$xI(B)y \text{ if and only if } a(x) = a(y) \text{ for every } a \in B \qquad (1)$$

where $a(x)$ denotes the value of attribute a for object x.

Obviously, $I(B)$ is an equivalence relation. The family of all equivalence classes of $I(B)$ (i.e., the partition determined by B,) will be denoted by $U/I(B)$, or simply U/B; an equivalence class of $I(B)$ (i.e., the block of the partition U/B) containing x will be denoted by $B(x)$.

If $(x, y) \in I(B)$, we will say that x and y are *B-indiscernible*. Equivalence classes of the relation $I(B)$ (or blocks of the partition U/B) are referred to as *B-elementary sets*. In the rough set approach, the elementary sets are the basic building blocks (concepts) of our knowledge about reality. The unions of *B-elementary sets* are called *B-definable sets*.

The indiscernibility relation will be further used to define basic concepts of rough set theory. Let us define now the following two operations on sets:

$$B_*(X) = \{x \in U : B(x) \subseteq X\} \qquad (2)$$

$$B^*(X) = \{x \in U : B(x) \cap X \neq \emptyset\} \qquad (3)$$

assigning to every subset X of the universe U two sets $B_*(X)$ and $B^*(X)$ called the *B-lower* and the *B-upper approximation* of X, respectively. The set

$$BN_B(X) = B^*(X) - B_*(X) \qquad (4)$$

will be referred to as the *B-boundary region* of X.

If the boundary region of X is the empty set (i.e., $BN_B(X) = \emptyset$), then the set X is *crisp* (*exact*) with respect to B; in the opposite case (i.e., if $BN_B(X) \neq \emptyset$), the set X is referred to as *rough* (*inexact*) with respect to B.

A rough set can also be characterized numerically by the following coefficient:

$$\alpha_B(X) = \frac{|B_*(X)|}{|B^*(X)|} \qquad (5)$$

called the *accuracy of approximation*, where $|X|$ denotes the cardinality of $X \neq \emptyset$. Obviously, $0 \leq \alpha_B(X) \leq 1$. If $\alpha_B(X) = 1$, then X is *crisp* with respect to B (X is *precise* with respect to B), and otherwise, if $\alpha_B(X) < 1$, then X is *rough* with respect to B (X is *vague* with respect to B).

Several generalizations of the classic rough set approach based on approximation spaces defined as pairs of the form (U, R), where R is the equivalence relation (called indiscernibility relation) on the set U, have been reported in the literature. Let us mention two of them.

A generalized approximation space can be defined by a tuple $AS = (U, I, \nu)$, where I is the *uncertainty function* defined on U with values in the powerset $P(U)$ of $U(I(x)$ is the *neighboorhood* of x) and ν is the *inclusion function* defined on the Cartesian product $P(U) \times P(U)$ with values in the interval [0, 1] measuring the degree of inclusion of sets. The lower AS_* and upper AS^* approximation operations can be defined in AS by

$$AS_*(X) = \{x \in U : \nu(I(x), X) = 1\} \tag{6}$$

$$AS^*(X) = \{x \in U : \nu(I(x), X) > 0\} \tag{7}$$

In the standard case, $I(x)$ is equal to the equivalence class $B(x)$ of the indiscernibility relation $I(B)$; in case of tolerance (similarity) relation $\tau \subseteq U \times U$, we take $I(x) = \{y \in U : x\tau y\}$ (i.e., $I(x)$ is equal to the tolerance class of τ defined by x). The standard inclusion relation is defined for X, $Y \subseteq U$ by

$$\nu(X, Y) = \begin{cases} \dfrac{|X \cap Y|}{|X|} & \text{if } X \quad \text{is non-empty} \\ 1 & \text{otherwise} \end{cases} \tag{8}$$

For applications, it is important to have some constructive definitions of I and ν.

One can consider another way to define $I(x)$. Usually, together with AS we consider some set F of formulas describing sets of objects in the universe U of AS defined by semantics $\|\cdot\|_{AS}$, i.e., $\|\alpha\|_{AS} \subseteq U$ for any $\alpha \in F$. Now, one can take the set

$$N_F(x) = \{\alpha \in F : x \in \|\alpha\|_{AS}\} \tag{9}$$

and $I(x) = \{\|\alpha\|_{AS} : \alpha \in N_F(x)\}$. Hence, more general uncertainty functions having values in $P(P(U))$ can be defined. Usually, there are considered families of approximation spaces with approximation spaces labeled by some parameters. By tuning such parameters according to chosen criteria (e.g., minimal description length), one can search for the optimal approximation space for concept description.

The approach based on inclusion functions has been generalized to the *rough mereological approach* (8,12,17,37). The inclusion relation $x\mu_r y$ with the intended meaning *x is a part of y to a degree at least r* has been taken as the basic notion of the rough mereology being a generalization of the Leśniewski mereology (38,39). Research on rough mereology has shown importance of another notion, namely *closeness* of complex objects (e.g., concepts), which can be defined by $xcl_{r,r'}y$ if and only if $x\mu_r y$ and $y\mu_{r'}x$.

Rough mereology offers a methodology for synthesis and analysis of objects in distributed environment of intelligent agents, in particular, for synthesis of objects satisfying a given specification to a satisfactory degree or for control in such complex environments. Moreover, rough mereology has been recently used for developing foundations of the *information granule calculi*, aiming at formalization of the Computing with Words paradigm, recently formulated by Lotfi Zadeh (40). More complex information granules are defined recursively using already defined information granules and their measures of inclusion and closeness. Information granules can have complex structures like classifiers or approximation spaces. Computations on information granules are performed to discover relevant information granules (e.g., patterns or approximation spaces for complex concept approximations).

ROUGH SETS AND MEMBERSHIP FUNCTIONS

Rough sets can be also introduced using a *rough membership function*, defined by

$$\mu_X^B(x) = \frac{|X \cap B(x)|}{|B(x)|} \tag{10}$$

Obviously, $0 \leq \mu_X^B(x) \leq 1$. The membership function $\mu_X(x)$ is a kind of conditional probability and its value can be interpreted as a degree of *certainty* to which x belongs to X.

The rough membership function can be used to define approximations and the boundary region of a set, as shown below:

$$B_*(X) = \{x \in U : \mu_X^B(x) = 1\} \tag{11}$$

$$B^*(X) = \{x \in U : \mu_X^B(x) > 0\} \tag{12}$$

$$BN_B(X) = \{x \in U : 0 < \mu_X^B(x) < 1\} \tag{13}$$

One of the consequences of perceiving objects by information about them is that for some objects one cannot decide if they belong to a given set or not. However, one can estimate the degree to which objects belong to sets, which is a crucial observation in building foundations for approximate reasoning. Dealing with imperfect knowledge implies that one can only characterize satisfiability of relations between objects to a degree, not precisely. One of the fundamental relations on objects is a rough inclusion relation describing that objects are parts of other objects to a degree. Rough mereological approach (8,12,17,37) based on such relation is an extension of the Leśniewski mereology (38).

DECISION TABLES AND DECISION RULES

Sometimes we distinguish in an information table (U, A) a partition of A into two classes C, $D \subseteq A$ of attributes, called *condition* and *decision* (*action*) attributes, respectively. The tuple $\mathcal{A} = (U, C, D)$ is called a *decision table*.

Let $V = \bigcup\{V_a | a \in C\} \cup V_d$. Atomic formulas over $B \subseteq C \cup D$ and V are expressions $a = v$ called *descriptors (selectors)* over B and V, where $a \in B$ and $v \in V_a$. The set $\mathcal{F}(B, V)$ of formulas over B and V is the least set containing all atomic formulas over B and V and closed with respect to the propositional connectives $\wedge$ (conjunction), $\vee$ (disjunction), and $\neg$ (negation).

By $\|\varphi\|_{\mathcal{A}}$, we denote the meaning of $\varphi \in \mathcal{F}(B, V)$ in the decision table $\mathcal{A}$, which is the set of all objects in U with the property φ. These sets are defined by $\|a = v\|_{\mathcal{A}} = \{x \in U | a(x) = v\}$, $\|\varphi \wedge \varphi'\|_{\mathcal{A}} = \|\varphi\|_{\mathcal{A}} \cap \|\varphi'\|_{\mathcal{A}}$; $\|\varphi \vee \varphi'\|_{\mathcal{A}} = \|\varphi\|_{\mathcal{A}} \cup \|\varphi'\|_{\mathcal{A}}$; $\|\neg\varphi\|_{\mathcal{A}} = U - \|\varphi\|_{\mathcal{A}}$. The formulas from $\mathcal{F}(C, V)$, $\mathcal{F}(D, V)$ are called *condition formulas of $\mathcal{A}$* and *decision formulas of $\mathcal{A}$*, respectively.

Any object $x \in U$ belongs to a *decision class* $\| \bigwedge_{a \in D} a = a(x)\|_{\mathcal{A}}$ of $\mathcal{A}$.

All decision classes of $\mathcal{A}$ create a partition of the universe U.

A *decision rule* for $\mathcal{A}$ is any expression of the form $\varphi \Rightarrow \psi$, where $\varphi \in \mathcal{F}(C, V)$, $\psi \in \mathcal{F}(D, V)$, and $\|\varphi\|_{\mathcal{A}} \neq \emptyset$.

Formulas φ and ψ are referred to as the *predecessor* and the *successor* of decision rule $\varphi \Rightarrow \psi$. Decision rules are often called "*IF* ... *THEN* ... " rules.

Decision rule $\varphi \Rightarrow \psi$ is *true* in $\mathcal{A}$ if and only if $\|\varphi\|_{\mathcal{A}} \subseteq \|\psi\|_{\mathcal{A}}$. Otherwise, one can measure its *truth degree* by introducing some inclusion measure of $\|\varphi\|_{\mathcal{A}}$ in $\|\psi\|_{\mathcal{A}}$. It is important to note that an inclusion measure expressed by the confidence, widely used in data mining (41), has been considered by Lukasiewicz (42) a long time ago in studies on assigning fractional truth values to logical formulas. Given two unary predicate formulas $\alpha(x)$, $\beta(x)$, where x runs over a finite set U, Lukasiewicz proposes to assign to $\alpha(x)$ the value $\frac{|\|\alpha(x)\||}{|U|}$, where $\|\alpha(x)\| = \{x \in U : x \, \text{satisfies} \, \alpha\}$. The fractional value assigned to the implication $\alpha(x) \Rightarrow \beta(x)$ is then $\frac{|\|\alpha(x) \wedge \beta(x)\||}{|\|\alpha(x)\||}$ under the assumption that $\|\alpha(x)\| \neq \emptyset$.

Each object x of a decision table determines a *decision rule* $\bigwedge_{a \in C} a = a(x) \Rightarrow \bigwedge_{a \in D} a = a(x)$.

Decision rules corresponding to some objects can have the same condition parts but different decision parts. Such rules are called *inconsistent (nondeterministic, conflicting, possible)*; otherwise, the rules are referred to as *consistent* (*certain*, *sure*, *deterministic*, *nonconflicting*) rules. Decision tables containing inconsistent decision rules are called *inconsistent* (*nondeterministic*, *conflicting*); otherwise, the table is *consistent* (*deterministic*, *nonconflicting*).

Numerous methods have been developed for different decision rule generation that the reader can find in the literature on rough sets. Usually, one is searching for decision rules (semi) optimal with respect to some optimization criteria describing quality of decision rules in concept approximations.

In case of searching for concept approximation in an extension of a given universe of objects (sample), typical steps are the following. When a set of rules have been induced from a decision table containing a set of training examples, they can be inspected to see if they reveal any novel relationships between attributes that are worth pursuing for further research. Furthermore, the rules can be applied to a set of unseen cases in order to estimate their classificatory power. For a systematic overview of rule application methods, the reader is referred to literature.

DEPENDENCY OF ATTRIBUTES

Another important issue in data analysis is discovering dependencies between attributes. Intuitively, a set of attributes D depends totally on a set of attributes C, denoted $C \Rightarrow D$, if the values of attributes from C uniquely determine the values of attributes from D. In other words, D depends totally on C, if there exists a functional dependency between values of C and D. Formally dependency can be defined in the following way. Let D and C be subsets of A.

We will say that D *depends on* C in a *degree* $k (0 \leq k \leq 1)$, denoted $C \Rightarrow_k D$, if

$$k = \gamma(C, D) = \frac{|POS_C(D)|}{|U|} \tag{14}$$

where

$$POS_C(D) = \bigcup_{X \in U/D} C_*(X) \tag{15}$$

called a *positive region* of the partition U/D with respect to C, is the set of all elements of U that can be uniquely classified to blocks of the partition U/D, by means of C.

If $k = 1$, we say that D *depends totally* on C, and if $k < 1$, we say that D *depends partially* (to *degree* k) on C.

The coefficient k expresses the ratio of all elements of the universe, which can be properly classified to blocks of the partition U/D, employing attributes C and will be called the *degree of the dependency*.

It can be easily seen that if D depends totally on C, then $I(C) \subseteq I(D)$,which means that the partition generated by C is finer than the partition generated by D. Notice that the concept of dependency discussed above corresponds to that considered in relational databases.

In summation D is *totally* (*partially*) dependent on C if *all* (*some*) elements of the universe U can be uniquely classified to blocks of the partition U/D, employing C.

REDUCTION OF ATTRIBUTES

We often face a question whether we can remove some data from a data table preserving its basic properties, that is, whether a table contains some superfluous data.

Let us express this idea more precisely.

Let $C, D \subseteq A$ be sets of condition and decision attributes, respectively.

We will say that $C' \subseteq C$ is a *D-reduct* (reduct with *respect* to *D*) of C if C' is a minimal subset of C such that

$$\gamma(C, D) = \gamma(C', D) \tag{16}$$

The intersection of all D-reducts is called a *D-core* (core with *respect* to D). As the core is the intersection of all reducts, it is included in every reduct (i.e., each element of the core belongs to some reduct). Thus, in a sense, the core is the most important subset of attributes, because none of its elements can be removed without affecting the classification power of attributes.

Many other kinds of reducts and their approximations are discussed in the literature. It turns out that they can be efficiently computed using heuristics based on Boolean reasoning approach.

DISCERNIBILITY AND BOOLEAN REASONING

Tasks collected under labels of data mining, knowledge discovery, decision support, pattern classification, and approximate reasoning require tools aimed at discovering in data of *templates* (*patterns*) and classifying them into certain *decision classes*. Templates are, in many cases, most frequent sequences of events, most probable events, regular configurations of objects, the decision rules of high-quality, standard reasoning schemes. Tools for discovering and classifying of templates are based on *reasoning* *schemes* rooted in various paradigms (43). Such patterns can be extracted from data by means of methods based on Boolean reasoning and discernibility.

The discernibility relation is closely related to indiscernibility and is one of the most important relations considered in rough set theory.

The ability to discern between perceived objects is important for constructing many entities like reducts, decision rules, or decision algorithms. In the classic rough set approach, the discernibility relation $DIS(B) \subseteq U \times U$ is defined by $xDIS(B)y$ if and only if $non(xI(B)y)$, which, however, is in general not the case for the generalized approximation spaces (one can define indiscernibility by $x \in I(y)$ and discernibility by $I(x) \cap I(y) = \emptyset$ for any objects x, y).

The idea of Boolean reasoning is based on construction for a given problem P of a corresponding Boolean function f_P with the following property: The solutions for the problem P can be decoded from prime implicants of the Boolean function f_P . Let us mention that to solve real-life problems, it is necessary to deal with Boolean functions having large number of variables.

A successful methodology based on the discernibility of objects and Boolean reasoning has been developed for computing of many important for applications entities like reducts and their approximations, decision rules, association rules, discretization of real value attributes, symbolic value grouping, searching for new features defined by oblique hyperplanes or higher-order surfaces, pattern extraction from data, as well as conflict resolution or negotiation.

Most of the problems related to generation of the above-mentioned entities are NP-complete or NP-hard. However, it was possible to develop efficient heuristics returning suboptimal solutions of the problems. The results of experiments on many datasets are very promising. They show very good quality of solutions generated by the heuristics in comparison with other methods reported in literature (e.g., with respect to the classification quality of unseen objects). Moreover, they are very efficient from the point of view of time necessary for computing of the solution. It is important to note that the methodology makes it possible to construct heuristics having a very important *approximation property*, which can be formulated as follows: Expressions generated by heuristics (i.e., implicants) *close* to prime implicants define approximate solutions for the problem.

CONCEPT APPROXIMATION

In this section, we consider the problem of approximation of concepts over a universe U^{∞}(concepts that are subsets of U^{∞}). We assume that the concepts are perceived only through some subsets of U^{∞}, called samples, which is a typical situation in the machine learning, pattern recognition, or data mining approaches (41,44). In this section, we explain the rough set approach to induction of concept approximations using the generalized approximation spaces of the form $AS = (U, I, \nu)$ defined earlier.

Let $U \subseteq U^{\infty}$ be a finite sample. By Π_{U}, we denote a perception function from $P(U^{\infty})$ into $P(U)$ defined by $\Pi_U(C) = C \cap U$ for any concept $C \subseteq U^{\infty}$. Let $AS = (U, I, \nu)$ be an approximation space over the sample U.

The problem we consider is how to extend the approximations of $\Pi_U(C)$ defined by AS to approximation of C over U^{∞}. We show that the problem can be described as searching for an extension $AS_C = (U^{\infty}, I_C, \nu_C)$ of the approximation space AS, relevant for approximation of C, which requires to show how to extend the inclusion function ν from subsets of U to subsets of U^{∞}that are relevant for the approximation of C. Observe that, for the approximation of C, it is enough to induce the necessary values of the inclusion function ν_C without knowing the exact value of $I_C(x) \subseteq U^{\infty}$ for $x \in U^{\infty}$.

Let AS be a given approximation space for $\Pi_U(C)$ and let us consider a language L in which the neighborhood $I(x) \subseteq U$ is expressible by a formula $pat(x)$, for any $x \in U$. It means that $I(x) = \|pat(x)\|_U \subseteq U$, where $\|pat(x)\|_U$ denotes the meaning of $pat(x)$ restricted to the sample U. In case of rule-based classifiers, patterns of the form $pat(x)$ are defined by feature value vectors.

We assume that for any new object $x \in U^{\infty} \backslash U$ we can obtain (e.g., as a result of sensor measurement) a pattern $pat(x) \in L$ with semantics $\|pat(x)\|_{U^{\infty}} \subseteq U^{\infty}$. However, the relationships between information granules over U^{∞} like-sets $\|pat(x)\|_{U^{\infty}}$ and $\|pat(y)\|_{U^{\infty}}$, for different x, $y \in U^{\infty}$, are, in general, known only if they can be expressed by relationships between the restrictions of these sets to the sample U [i.e., between sets $\Pi_U(\|pat(x)\|_{U^{\infty}})$ and $\Pi_U(\|pat(y)\|_{U^{\infty}})$].

The set of patterns $\{pat(x) : x \in U\}$ is usually not relevant for approximation of the concept $C \subseteq U^{\infty}$. Such patterns are too specific or not enough general and can directly be applied only to a very limited number of new objects. However, by using some generalization strategies, one can search, in a family of patterns definable from $\{pat(x) : x \in U\}$ in L, for such new patterns that are relevant for approximation of concepts over U^{∞}. Let us consider a subset $PATTERNS(AS, L, C) \subseteq L$ chosen as a set of pattern candidates for relevant approximation of a given concept C. For example, in case of a rule-based classifier, one can search for such candidate patterns among sets definable by subsequences of feature value vectors corresponding to objects from the sample U. The set *PATTERNS(AS,L,C)* can be selected by using some quality measures checked on meanings (semantics) of its elements restricted to the sample U (like the number of examples from the concept $\Pi_U(C)$ and its complement that support a given pattern). Then, on the basis of properties of sets definable by these patterns over U, we induce approximate values of the inclusion function ν_C on subsets of U^{∞}definable by any of such pattern and the concept C.

Next, we induce the value of ν_C on pairs (*X,Y*), where $X \subseteq U^{\infty}$ is definable by a pattern from $\{pat(x) : x \in U^{\infty}\}$ and $Y \subseteq U^{\infty}$ is definable by a pattern from *PATTERNS* (*AS,L,C*).

Finally, for any object $x \in U^{\infty} \backslash U$, we induce the approximation of the degree $\nu_C(\|pat(x)\|_{U^{\infty}}, C)$ applying a conflict resolution strategy *Conflict_res* (a voting strategy, in case of rule-based classifiers) to two families of degrees:

$$\{\nu_C(\|pat(x)\|_{U^\infty}, \|pat\|_{U^\infty}) : pat \in PATTERNS\,(AS, L, C)\} \tag{17}$$

$$\{\nu_C(\|pat\|_{U^\infty}, C)\ :\ pat \in PATTERNS\,(AS, L, C)\} \tag{18}$$

Values of the inclusion function for the remaining subsets of U^∞ can be chosen in any way—they do not have any impact on the approximations of C. Moreover, observe that, for the approximation of C, we do not need to know the exact values of uncertainty function I_C—it is enough to induce the values of the inclusion function ν_C. Observe that the defined extension ν_C of ν to some subsets of U^∞ makes it possible to define an approximation of the concept C in a new approximation space AS_C .

In this way, the rough set approach to induction of concept approximations can be explained as a process of inducing a relevant approximation space.

MEREOLOGY AND ROUGH MEREOLOGY

Exact and rough concepts can be characterized by a new notion of an element, alien to naive set theory in which this theory has been coded until now. For an information system $\mathcal{A} = (U, A)$ and a set B of attributes, the mereological element $el_B^{\mathcal{A}}$ is defined by letting

$$x el_B^{\mathcal{A}} X \text{ if and only if } B(x) \subseteq X \tag{19}$$

Then, a concept X is B-exact if and only if either $x el_B^{\mathcal{A}} X$ or $x el_B^{\mathcal{A}}\, U \backslash X$ for each $x \in U$, and the concept X is B–rough if and only if for some $x \in U$ neither $x el_B^{\mathcal{A}} X$ or $x el_B^{\mathcal{A}}\, U \backslash X$.

Thus, the characterization of the dychotomy exact–rough cannot be done by means of the element notion of naive set theory, but it requires the notion of containment ($\subseteq$)(i.e., a notion of mereological element).

The Leśniewski Mereology (theory of parts) is based on the notion of a part (38,39). The relation π of part on the collection U of objects satisfies,

1. if $x\pi y$ then not $y\pi x$,
2. if $x\pi y$ and $y\pi z$ then $x\pi z$.

The notion of mereological element el_π is introduced as,

$$x el_\pi y \text{ if and only if } x\pi y \text{ or } x = y \tag{20}$$

In particular, the relation of proper inclusion $\subset$ is a part relation π on any non-empty collection of sets, with the element relation $el_\pi = \subseteq$.

Formulas expressing rough membership, quality of decision rule, quality of approximations, and so on can be traced back to a common root (i.e., $\mu(X,Y)$ defined by Equation (8). The value $\mu(X,Y)$ defines the degree of *partial containment* of X into Y and naturally refers to the Leśniewski Mereology. An abstract formulation of this idea in Ref. 37 connects the mereological notion of element el_π with this idea of partial inclusion in the idea of a *rough inclusion* as a relation $\mu \subseteq U \times U \times [0, 1]$ on a collection of pairs of objects in U endowed with part π relation, and such that

1. $\mu(x, y, 1)$ if and only if $x el_\pi y$,
2. if $\mu(x, y, 1)$ then (if $\mu(z, x, r)$ then $\mu(z, y, r)$),
3. if $\mu(z, x, r)$ and $s < r$ then $\mu(z, x, s)$.

Implementation of this idea in information systems can be based on *archimedean* t–norms (37); each such norm T is represented as $T(r, s) = g(f(r) + f(s))$ with f, g pseudo–inverses to each other, continuous and decreasing on [0, 1]. Letting for (U, A) and $x, y \in U$,

$$DIS(x, y) = \{a \in A : a(x) \neq a(y)\} \tag{21}$$

and

$$\mu(x, y, r) \text{ if and only if } g\left(\frac{|DIS(x, y)|}{|A|}\right) \geq r \tag{22}$$

defines a rough inclusion that satisfies additionally the transitivity rule

$$\frac{\mu(x, y, r), \mu(y, z, s)}{\mu(x, z, T(r, s))} \tag{23}$$

Simple examples here are as follows: The Menger rough inclusion in the case $f(r) = -lnr$, $g(s) = e^{-s}$ yields $\mu(x,y,r)$ if and only if $e^{-\frac{|DIS\,(x,y)|}{|A|}} \geq r$ and it satisfies the transitivity rule

$$\frac{\mu(x, y, r), \mu(y, z, s)}{\mu(x, y, r \cdot s)} \tag{24}$$

where the t–norm T is the Menger (product) t–norm $r \cdot s$, and the Lukasiewicz rough inclusion with $f(x) = 1 - x = g(x)$ yielding $\mu(x,y,r)$ if and only if $1 - \frac{|DIS(x,y)|}{|A|} \geq r$ with the transitivity rule

$$\frac{\mu(x, y, r), \mu(y, z, s)}{\mu(x, y, max\{0, r + s - 1\})} \tag{25}$$

with the Lukasiewicz t–norm.

Rough inclusions (37) can be used in *granulation of knowledge* (40). Granules of knowledge are constructed as aggregates of indiscernibility classes close enough with respect to a chosen measure of closeness. In a nutshell, a granule $g_r(x)$ about x of radius r can be defined as the aggregate of all y with $\mu(y, x, r)$. The aggregating mechanism can be based on class operator of mereology (like in rough mereology (37)) or on set theoretic operations of union.

Rough mereology (37) combines rough inclusions with methods of mereology. It employs the operator of mereological class that makes collections of objects into objects. The class operator Cls satisfies the requirements, with any non–empty collection M of objects made into the object

$Cls(M)$,

$$\text{if } x \in M, \text{ then } x el_{\pi} Cls(M) \quad (26)$$

$$\text{if } x el_{\pi}\, Cls\,(M), \text{then there exist } y, z \text{ such that } y el_{\pi} x,\ y el_{\pi} z, z \in M \quad (27)$$

In case of the part relation $\subset$ on a collection of sets, the class *Cls(M)* of a non–empty collection M is the union $\bigcup M$.

Granulation by means of the class operator *Cls* consists in forming the granule *$g_r(x)$* as the class $Cls(y : \mu(y, x, r))$. One obtains a granule family with regular properties (see Ref. 36).

RESEARCH DIRECTIONS IN ROUGH SET THEORY

In this section, we present a list of research directions on the rough set foundations and the rough set-based methods. For more details, the reader is referred to the bibliography on rough sets.

List of research directions on rough sets

- Boolean reasoning and approximate Boolean reasoning strategies as the basis for efficient heuristics for rough set methods.
- Tolerance (similarity)-based rough set approach.
- Rough set-based approach based on neighborhood (uncertainty) functions and inclusion relation, in particular, variable precision rough set model.
- Rough sets in multi-criteria decision analysis and preference modeling.
- Recurrent rough sets.
- Rough sets and nondeterministic information systems.
- Rough set-based clustering.
- Rough sets and incomplete information systems, in particular, missing value problems.
- Rough sets and noisy data.
- Rough sets and relational databases.
- Rough sets and inductive reasoning.
- Rough sets in modeling of decision systems and analysis of complex systems, in particular, rough sets and layered (hierarchical) learning.
- Rough sets as a tool for approximate reasoning in distributed systems, by autonomous agents, and in multiagent systems.
- Rough mereology foundations, in particular, rough mereological approach to synthesis and analysis of complex objects.
- Rough sets and rough mereology in granular computing. In particular:

- Rough sets and formal concept analysis.

A CHALLENGE FOR RESEARCH ON ROUGH SETS

There are many real-life problems that are still hard to solve using the existing methodologies and technologies. Among such problems are, for examples, classification of medical images, control of autonomous systems like unmanned aerial vehicles or robots, or problems related to monitoring or rescue tasks in multiagent systems. All these problems are closely related to intelligent systems that are more and more widely applied in different real-life projects.

One of the main challenges in developing of intelligent systems are methods for approximate reasoning from measurements to perception (i.e., from concepts close to sensor measurements to concepts expressed in natural language by human beings that are the perception results).

Today, new emerging computing paradigms are investigated attempting to make progress in solving problems related to this challenge. Further progress depends on a successful cooperation of specialists from different scientific disciplines such as mathematics, computer science, artificial intelligence, biology, physics, chemistry, bioinformatics, medicine, neuroscience, linguistics, psychology, and sociology. In particular, different aspects of reasoning from measurements to perception are investigated in psychology (45,46), neuroscience (47), layered learning (48), mathematics of learning (47), machine learning, pattern recognition (44), data mining (41), and also by researchers working on recently emerged computing paradigms, like computing with words and perception (40), granular computing (17), rough sets, rough-mereology, and rough-neural computing (17).

One of the main problems investigated in machine learning, pattern recognition (44), and data mining (41) is concept approximation. It is necessary to induce approximations of concepts (models of concepts) from available experimental data. The data models developed so far in such areas like statistical learning, machine learning, and pattern recognition are not satisfactory for approximation of complex concepts resulting in the perception process. Researchers from the different areas have recognized the necessity to work on new methods for concept approximation (see Refs. 49 and 50). The main reason is that these complex concepts are, in a sense, too far from measurements, which makes the searching for relevant (for their approximation) features infeasible in a huge space. There are several research directions aiming at overcoming this difficulty, one of which is based on the interdisciplinary research where the results concerning perception in psychology or neuroscience are used to help to deal with complex concepts (see Ref. 44). There is a great effort in neuroscience toward understanding the hierarchical structures of neural networks in living organisms (47,51). Also, mathematicians are recognizing problems of learning as the main problem of the current century (47).

The problems discussed so far are also closely related to complex system modeling. In such systems, the problem of concept approximation and reasoning about perceptions using concept approximations is one of the main challenges. One should take into account that modeling complex phenomena entails the use of local models (captured by local agents, if one would like to use the multiagent terminology (52)) that next should be fused. This process involves the negotiations between agents (52) to resolve contradictions and conflicts in local modeling. This kind of modeling will become more and more important in solving complex real-life problems that we are unable to model using traditional analytical approaches. The latter approaches lead to exact models. However, the necessary assumptions used to develop these models are causing the resulting solutions to be too far from reality to be accepted. New methods or even a new science should be developed for such modeling (53). One of the possible solutions in searching for methods for complex concept approximations is the layered learning idea (48). Inducing concept approximation should be developed hierarchically starting from concepts close to sensor measurements to complex target concepts related to perception. This general idea can be realized using an additional domain knowledge represented in natural language. For example, one can use principles of behavior on the roads, expressed in natural language, trying to estimate, from recordings (made, e.g., by camera and other sensors) of situations on the road, whether the current situation on the road is safe. To solve such a problem, one should develop methods for concept approximations together with methods aiming at approximation of reasoning schemes (over such concepts) expressed in natural language. Foundations of such approach are based on rough set theory (2) and its extension rough mereology (8,12,17,37), both discovered in Poland.

Objects we are dealing with are information granules. Such granules are obtained as the result of information granulation (40). Information granulation can be viewed as a human way of achieving data compression, and it plays a key role in implementation of the strategy of divide-and-conquer in human problem solving.

Computing with Words and Perception "derives from the fact that it opens the door to computation and reasoning with information which is perception-rather than measurement-based. Perceptions play a key role in human cognition, and underlie the remarkable human capability to perform a wide variety of physical and mental tasks without any measurements and any computations. Everyday examples of such tasks are driving a car in city traffic, playing tennis and summarizing a story" (40). The rough mereological approach (8,12,17,37) is based on calculi of information granules for constructing complex concept approximations. Constructions of information granules should be robust with respect to their input information granule deviations. In this way, a granulation of information granule constructions is considered. As a result, we obtain the so-called AR schemes (AR networks) (8,12,17,37). AR schemes can be interpreted as complex patterns (41). Searching methods for such patterns relevant for a given target concept have been developed (17). Methods for deriving relevant AR schemes are of high computational complexity. The complexity can be substantially reduced by using domain knowledge. In such a case, AR schemes are derived along reasoning schemes in natural language that are retrieved from domain knowledge. Developing methods for deriving such AR schemes is one of the main goals of our projects.

The outlined research directions create foundations toward understanding the nature of reasoning from measurements to perception is a challenge and crucial for constructing intelligent systems for many real-life projects.

CONCLUSIONS

In this article, basic concepts of rough set theory are presented. It has turned out, however, that the "basic model" of rough sets—presented here—has not been sufficient for many applications and is in need of some extensions. Besides, theoretical inquiry into the rough set concept also has led to its various generalizations. Some of them have been mentioned in the article.

A variety of methods for decision rules generation, reducts computation, and continuous variable discretization are very important issues not discussed here. We have only emphasized the developed powerful methodology based on discernibility and Boolean reasoning for efficient computation of different entities including reducts and decision rules. Also, the relationship of rough set theory to many other theories has been extensively investigated. In particular, its relationships to fuzzy set theory, the theory of evidence, Boolean reasoning methods, statistical methods, and decision theory have been clarified and seem now to be thoroughly understood.

There are reports on many hybrid methods obtained by combining the rough set approach with other approaches such as fuzzy sets, neural networks, genetic algorithms, principal component analysis, and singular value decomposition.

Recently, it has been shown that the rough set approach can be used for synthesis and analysis of concept approximations in the distributed environment of intelligent agents. We outlined the rough mereological approach and its applications in information granules calculi for synthesis of information granules satisfying a given specification to a satisfactory degree.

Readers interested in the above issues are advised to consult the enclosed references.

Many important research topics in rough set theory such as various logics related to rough sets and many advanced algebraic properties of rough sets were only mentioned in the article. The reader can find details in the cited books, articles, and journals.

Finally, we have outlined a challenge for research on rough sets related to approximate reasoning from measurements to perception.

AD HOC AND SENSOR NETWORKS

INTRODUCTION

In a wireless ad hoc network, each node is equipped with one or more wireless radio transceivers. A node can communicate with nodes in its radio range directly (called *single-hop* wireless); otherwise, it relies on the intermediate nodes to relay its message to a non-neighbor node. The latter mechanism is called *multi-hop* wireless communication. In contrast, infrastructure-based networks such as wireless local area networks (WLANs) and cellular networks use only single-hop wireless communication. Moreover, a wireless ad hoc network usually does not have special-purpose relay nodes similar to routers in conventional networks — every node is a potential router (that can relay the data of other nodes). Furthermore, the network topology of a wireless ad hoc network is usually much more dynamic than that of a conventional network, because of node failures and/or node mobility.

A wireless ad hoc network has several benefits over wired infrastructure-based networks, which make it a compelling choice for networking in certain application scenarios. We discuss some of these benefits here:

- **Quick to Deploy**: A wireless ad hoc network, by definition, does not require an existing infrastructure, such as wall power or wiring. This quality significantly reduces the time to deploy a wireless ad hoc network and have it up and running. Sometimes, the time to deploy may be minutes or seconds as opposed to days or weeks for an infrastructure-based network.
- **Suitable for a Wider Range of Environment**: A wireless ad hoc network can be deployed easily in remote places such as in forests, under water (e.g., rivers, oceans, etc.), on mountain tops, on moving troops in a battlefield, in toxic areas, or on other planets.
- **More Resilient to Failures**: Wireless ad hoc networks typically are more resilient to failures than infrastructure-based networks. This resihence is because communication among nodes can be over multiple hops using intermediate nodes (each of which can act as a router) and because the protocols developed do not assume any existence of infrastructure. Most ad hoc network protocols are/can be designed to reconfigure quickly upon failure; therefore, communication among surviving nodes is possible even if several or the majority of nodes have failed (as in a battlefield scenario).
- **Offers Freedom of Mobility**: Because no wiring exists among nodes, the nodes in a wireless ad hoc network can move freely and still maintain communication with other nodes in the network. The protocols also are designed to adapt quickly to mobility (which may cause frequent changes in the set of neighbors). This characteristic makes ad hoc networks especially useful in mobile applications such as among a group of moving soldiers, a fleet of moving vehicles, and a fleet of aircrafts flying together, as well as in disaster locations.
- **Economical**: Because of its low set-up overhead (e.g., no wiring and labor), deploying a wireless ad hoc network is more economical compared with its wired counterpart in several application scenarios.

Although wireless ad hoc networks have several advantages over infrastructure-based networks, they have their own limitations. For example, the nodes usually have limited lifetime because they typically run on batteries. Moreover, it is often more challenging to develop efficient protocols for the wireless ad hoc networks, because of the mobility and the limitations of the wireless communication medium.

wireless ad hoc networks can be classified into several categories. Below are three major categories of ad hoc networks, each of which has become a fertile research area in its own right:

1. **Mobile Ad Hoc Network (MANET)**: A MANET is a network of mobile computing devices, such as laptops and PDAs. The purpose of forming a MANET is to facilitate communication among mobile host devices that make up this network.
2. **Wireless Sensor Network (WSN)**: WSNs are composed of small wireless sensors, such as motes (2) that can monitor their surrounding physical environment by using various on-board sensors. The purpose of a WSN is to monitor the environment in which it is embedded either to collect data of interest or to detect events of interest, such as monitoring its surrounding for illegal intrusion activity.
3. **Wireless Mesh Networks**: A wireless mesh network consists of wireless devices mainly used as routers to provide a wireless infrastructure to other devices. A wireless mesh network can provide Internet access to computational devices, such as laptops and PDAs, without having to deploy a wired infrastructure.

Each of the above categories can be classified additionally based on the devices and communication technology it employs. For example, the mobile devices in a MANET can be laptops, PDAs, or even cell phones, and the communication technology used by these devices can be 802.11, Bluetooth, ZigBee, and so forth.

Our focus in this article is on the first two categories–MANETs and WSNs (see Ref. (3) for a survey of wireless mesh networks). MANETs and WSNs share several key characteristics; both of them rely on the wireless medium for communication and use multi-hop wireless routing. However, they have important differences as well because

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

of the intrinsic differences in their potential applications. For example, typical applications of MANETs include communication on a battlefield and during disaster recovery; therefore, research on MANETs has been focusing on supporting human communication in the face of unconstrained mobility. Alternately, WSNs are used to monitor the physical environment, such as natural habitats and volcanoes, as well as to detect intrusions in a highly secure area. The sensor nodes usually are stationary and need to last months without human intervention, so energy-efficiency is a critical issue for WSNs, whereas ensuring connectivity despite user-induced (and hence uncontrolled) mobility has not been a major focus of WSN research.

In the remainder of this article, we first discuss the common issues in MANETs and WSNs, all of which are important for wireless mesh networks, as well. Then, we describe differences between MANETs and WSNs. Finally, we conclude the article.

COMMON ISSUES IN WIRELESS AD HOC NETWORKS

The Issue of Connectivity

A wireless ad hoc network, by its very definition, does not have a preplanned network topology. At the same time, the network needs to facilitate communication among different nodes. For this to be possible, the network needs to have some form of connectivity. Depending on the particular network, we may want all the nodes in the network to form a connected graph, most of the nodes to form a connected graph, or the network to provide delay-tolerant connectivity (4). Sometimes, for fault tolerance or to balance the routing load among nodes, k-connectivity in the network may be desired such that k node-disjoint paths exist between every pair of nodes.

Connectivity (or k-connectivity) can be made possible by increasing the density of nodes, by adjusting the transmission range of individual nodes, or by moving (controlled or uncontrolled) the nodes. If the nodes are mostly static and their location distribution can be approximated by a Poisson process or a random uniform process, then a critical relation exists between the transmission range and node density (5,6). Given one of these two parameters, the other can be derived. If the density is given, then the required transmission is called critical, and vice versa. The term critical (in say transmission range) intuitively means that if the transmission range is less than the critical value, then the network is disconnected with high probability. However, if the transmission range is higher than the critical value, then the network is connected with high probability. The connectivity of the network is said to have a phase transition (from disconnected to connected) at this critical value.

When nodes are mobile, similar results exist for the critical relation between the transmission range and density (7). These results assume that node movements can be approximated by certain mobility models.

Although critical density provides a guidance as to what behavior can be expected from a randomly deployed network in terms of connectivity, the results are not directly usable by a practitioner who would like to have a guarantee on connectivity for finite deployment regions. This situation is because the results derived for critical density are asymptotic, by definition. Recently, a new technique has been proposed to derive density estimates for random deployments that are quite reliable for finite deployment regions (8). Such work bridges the gap between theory and practice in the area of connectivity because theoretical results now can be readily used in practice.

Another area of research that has received considerable attention is called “Delay-tolerant connectivity.” It means that the network may not be connected at every instant in time, but movement of nodes may facilitate occasional communication among pairs of disconnected nodes. In the extreme case, data mules (9) may be deployed whose sole purpose is to ferry data between source–destination pairs. In other scenarios, nodes that have data packets destined to another node may wait till they come in direct contact with each other or pass the message to one of their current neighbors, who repeats the process until the data reaches its destination or until its time to live runs out, in which case it is dropped. Figuring out a good approach for message delivery in a mobile network that is not always connected currently is a highly active area of research.

Distributed Medium Access Control

Because the wireless medium is broadcast in nature, collision can occur when two nodes within the transmission range of each other send packets at the same time. In an infrastructure-based wireless network, such as a cell phone network, the access point (or base station) can allocate a different frequency band or a different transmission slot to each node in the same cell. However, in an ad hoc network, no centralized controller exists. Therefore, the first issue that needs to be addressed in any wireless ad hoc network is how to coordinate the transmissions of different nodes without using a centralized controller. The major objectives are to avoid collision (that may lead to loss of all colliding messages and hence loss of bandwidth) in a distributed manner, make efficient use of scarce wireless bandwidth, ensure fairness among the nodes, provide real-time guarantees to high-priority packets, and achieve all these tasks with a mechanism that scales to large network sizes. A protocol that achieves these objectives (or a subset of these) in a distributed manner is called a Distributed Medium Access Control (MAC) protocol. [1]

Several distributed MAC protocols have been proposed. Most of them can be classified in two categories:

- **Competitive Protocols**: These protocols subscribe to the philosophy that each node should compete for access to the common wireless channel by itself. Each node makes a local decision on whether to transmit its packets at a given time instant or not. These decisions are based on rules that are expected to maximize the chances of a successful transmission. One

[1] Some infrastructure networks such as wireless LANs also may use distributed MAC protocols to avoid collision.

common technique is to sense the channel for idleness before starting a new transmission, which is referred to as Carrier Sense Multiple Access with Collision Avoidance (CSMA-CA). The main advantage of these protocols is simplicity and, hence, scalability. The main disadvantage is inefficient use of the wireless channel, especially when the number of nodes competing for the channel is high. Examples of such protocols include Multiple Access Collision Avoidance for Wireless LANs (MACAW), Floor Acquisition Multiple Access Protocol (FAMA), Busy Tone Multiple Access (BTMA), Dual BTMA (DBTMA), Receiver Initiated BTMA(RI-BTMA), Multiple Access Collision Avoidance by Invitation (MACA-BI), and Media Access with Reduced Handshake (MARCH).

- **Cooperative Protocols**: These protocols follow a different approach; they are based on the philosophy that nodes should cooperate on deciding a schedule, for example, who has the right to use the channel at a particular time. In most of these protocols, time is divided in slots and nodes work together on deciding which slots are assigned to which nodes. The main advantage of these protocols is efficient use when most nodes have continuous data to send. Another advantage is the guarantee of an upper bound on the delay that any node will experience in sending its packets. The major disadvantage is its complexity, which arises from its core philosophy of requiring cooperation among nodes. Examples of such protocols include Distributed Packet Reservation Multiple Access (D-PRMA), Collision Avoidance Time Allocation (CATA), Hop Reservation Multiple Access (HRMA), Soft Reservation Multiple Access with Priority Assignment (SRMA/PA), and Five Phase Reservation Protocol (FPRP).

Some protocols use a combination of the two philosophies, for example, use reservation for real-time traffic that needs a delay guarantee and use competitive access for regular traffic. An example of such a protocol is MACA with Piggy-Backed Reservation (MACA/PR).

We refer the reader to chapter 6 in Ref. 10 for a description of all the MAC protocols listed above. Some issues that are unique to a MAC protocol in WSN are described in the section “Energy Efficiency” below.

Neighbor Discovery and Multi-Hop Routing

Because nodes in a wireless ad hoc network depend on their neighbors to relay packets for them, each node needs first to discover its neighbors after initial deployment (“neighbor discovery”) and needs to update this information as neighboring nodes fail or move out of its transmission range. Moreover, each node needs to figure out to which neighbor a particular packet should be forwarded so that the packet can reach its destination most efficiently. This task is accomplished using a distributed ad hoc routing protocol, which typically takes into consideration the unique characteristics of wireless ad hoc networks, for example, frequent topology changes, limited power source, and low bandwidth resources.

Numerous ad hoc routing protocols have been proposed to date (see Ref. 11 and chapter 7 in Ref. 10) [2]. These protocols perform either flat or hierarchical routing. In flat routing, a node potentially can obtain a route to all the other nodes in the network. In hierarchical routing, the network usually is divided into many non overlapping clusters. Each cluster has a clusterhead that handles inter cluster routing, whereas other nodes only need to discover routes to nodes within their own cluster. Hierarchical routing protocols usually are more suitable for large networks. Below, we focus our discussion on flat routing protocols. Readers are referred to Ref. 11 for more discussion of hierarchical routing protocols. Issues that are unique to a routing protocol in WSN are described in the “Typical Traffic Pattern” section below.

Flat routing protocols can be classified into one of the following three categories, based on when the routes are discovered:

- A *proactive* routing protocol always maintains a route to every destination in a network, regardless of whether such a route will be used. The routes usually are computed using a distance vector algorithm or a link state algorithm. The protocols in this category are closest to traditional routing protocols, but they typically include optimizations that reduce bandwidth and processing overhead. They also are able to detect obsolete routes faster, for example, by adding more information in routing messages. Examples of proactive ad hoc routing protocols include DSDV [Destination-Sequenced Distance Vector (12)], OLSR [Optimized Link State Routing Protocol (13)], TBRPF [Topology Dissemination-based on Reverse-Path Forwarding (14)], and WRP [Wireless Routing Protocol (15)].
- A *reactive* routing protocol performs route discovery only when a node receives a packet to a particular destination that has no associated route in the routing table of the node. In other words, routing overhead will not be incurred for destinations that have no traffic destined to them. Therefore, reactive protocols usually have a lower processing, storage, and bandwidth overhead than proactive protocols. The reactive approach is especially suitable for networks with highly dynamic nodes, as the costs of maintaining routes to the dynamic destinations are extremely high. However, the overhead reduction also depends heavily on the traffic pattern in the network. If traffic is evenly distributed among all the destinations, the overhead saving may not be significant. Moreover, because route discovery takes time to complete, networks using reactive routing protocols may have a longer delay in packet delivery. Examples of reactive ad hoc routing protocols include AODV [Ad-hoc On-demand Distance Vector (16)], DSR [Dynamic Source Routing (17)], and DYMO [DYnamic Manet On-demand Routing (18)].

[2] Several of these protocols are being standardized by the Internet Engineering Task Force (IETF) MANET working group (http://www.ietf.org/html.charters/manet-charter.html).

- A *hybrid* routing protocol maintains pre computed routes to some destinations and performs on-demand route discovery for the other destinations. This type of protocol is designed for large networks, where a pure proactive protocol may incur too much control traffic and a pure reactive approach may have too high a packet delay and/or too much control traffic. One example of hybrid routing protocols is ZRP [Zone Routing Protocol (19)].

We now briefly describe DSR and ZRP as an illustration of how ad hoc routing protocols work.

Dynamic Source Routing. Each node in Dynamic source routing (DSR) (17) maintains a cache of discovered routes. When a sender needs to communicate with a new destination, it broadcasts a Route Request (RREQ) message to its neighbors. Each neighbor checks its cache to see if a route to the destination has been discovered before. If not, the node appends its address to the RREQ message and broadcasts this message to its neighbors. This process continues until at least one node identifies a route to the destination in its cache. This node then sends a Route Reply (RREP) message to the original sender of the RREQ message with the entire path in the reply. If no intermediate nodes have a path to the destination, the destination eventually will receive the RREQ message and send a RREP to the sender.

DSR uses source routing in packet delivery, for example, the sender of a packet specifies the entire path in the header of each data packet. Source routing allows a node to use multiple paths to reach the same destination while avoiding packet loops. However, it incurs more message overhead as each packet needs to carry the entire path in its header. Another downside is that the source route may become obsolete when a packet is still–route to its destination, especially when the nodes are highly mobile.

Zone Routing Protocol. In Zone Routing Protocol (ZRP) (11), each node maintains routes proactively to all the nodes within a certain number of hops. This set of nodes is called a *zone* for the node, and the number of hops is called a *zone radius*. If a node needs to deliver a packet to a destination outside its zone, it just sends a route request message to the nodes on the boundary of its zone. Those nodes, in turn, forward the message to the nodes on their zone boundary until a node can locate the destination in its own zone. Because the zone radius determines the routing traffic both within a zone and between zones, the main research issue is how to determine the appropriate zone radius to minimize the overall routing traffic.

Reliable Data Delivery

The wireless medium typically has a higher error and loss rate than the wired medium because of path loss, multi path fading, and interference. Path loss means that the signal strength weakens after the wireless signal travels for some distance. The remaining signal strength usually is a function of the distance. Multi path fading occurs when the wireless signal propagates in different directions and finally all the signals arrive at the same destination. These different versions of the original signal may have different phases and strength, so the combination of them may look very different from the original signal. Interference is caused by signals transmitted at frequencies close to each other. It can be reduced to a certain extent by using guard bands between frequency bands and minimizing the transmission range of each node (as described in “The Issue of Connectivity” section).

Given the higher error and loss rate of the wireless medium, how to ensure the reliable data delivery without negatively impacting end-to-end throughput becomes a key issue in wireless ad hoc networks. First, unlike wired networks that can rely solely on end-to-end recovery, wireless ad hoc networks also need hop-by-hop link-level error recovery to minimize delay, improve throughput, and reduce unnecessary retransmissions by end nodes. Second, the transport layer needs to distinguish losses caused by errors from those caused by congestion. The most popular reliable transport layer protocol is Transmission Control Protocol (TCP). It was designed for wired networks in which most of the losses are caused by congestion, so a TCP sender reduces its speed drastically whenever a loss is detected. This reaction is considered inappropriate for error-triggered losses as the sender should probably be as aggressive as before. As a result, the TCP performance in a wireless network could be problematic. Several extensions to TCP and alternative protocols have been proposed to address these problems. We refer the reader to Ref. 10 chapter 9 for details. A new trend in this research area is for the lower layer to expose more information to the transport layer so that the overall system will be more efficient and effective. Such *cross layer optimization* has been proposed for solving other problems in wireless ad hoc networks as well.

Security

Securing wireless ad hoc networks is especially challenging (20,21). First, privacy and integrity are more difficult to ensure in a wireless network than in a wired network because it is easy for an attacker to snoop on a wireless channel and modify ongoing transmission. Second, because of the infrastructureless nature of wireless ad hoc networks, authenticity is difficult to establish; no trusted central authority exists. Third, because the wireless nodes are more portable than computers in a traditional network, they may be easier to lose and be used later by attackers to inject false information. Furthermore, conventional security mechanisms usually have high computational and storage demands that may make their implementation difficult on wireless nodes.

WHAT SETS MANETS AND WSNS APART?

Although discussions of wireless ad hoc networks (which mostly refers to MANETs) often include wireless sensor networks (WSN) as a special case, these two areas each have blossomed into exciting research areas in their own right. The reason for this is because these two networks possess several unique characteristics that set them apart. Below we discuss some major characteristics that are unique to each of these networks.

Typical Usage

MANETs are used mostly for communication between human-operated devices, such as laptops, PDAs, or cellular phones, whereas wireless sensor networks are deployed mostly for data collection and event monitoring. We now discuss some representative applications of each network.

We first describe two applications of MANETs.

- **Facilitating Communication Among a Troop of Soldiers**: Each soldier carries a computing device with ad hoc networking ability. The devices hosted on the soldiers form an ad hoc network as soon as they are turned on. This network allows messages from any node to reach any other node even though the soldiers are allowed to move freely to achieve their operational goals (their movements are not constrained to maintain a connected network). Therefore, the network of devices needs to take care of maintaining connectivity.
- **Facilitating Communication in Remote Locations**: Cellular phone towers do not cover remote areas (such as mountains and forests). If mobile phones are equipped with ad hoc networking capability (as is being planned), then an ad hoc network among the various mobile phones can be formed. This ad hoc network will enable data and possibly voice communication among users even if no cellular phone towers are in the neighborhood to provide regular coverage.

Now we describe two applications of WSNs.

- **Detecting Illegal Crossing on an International Border**: Wireless sensor nodes are sprayed from an aircraft on the international border. Once these sensors land on ground, they form a multi-hop wireless network. They start monitoring for people or vehicles crossing the border. As soon as such an event is detected by one or more sensors, a detection message is dispatched to a manned station for possible action. The message takes less than a couple of seconds to reach a manned station that may be situated several miles from the point of occurrence of the intrusion event. This system has the potential to improve significantly the border surveillance at a low cost. With this system, the entire border can be monitored continuously instead of the spotty surveillance that is done today.
- **Monitoring a Fabrication Plant to Prevent Downtime**: Wireless sensors can be deployed in a fabrication plant to monitor the vibration and acoustic signatures of critical equipments. If the signature matches some specific patterns that typically precede failures, a message is immediately dispatched to a manned station and preventive actions are taken to ensure no downtime occurs. This system has the potential to save millions of dollars by preventing downtime of critical equipment.

As illustrated by the above-mentioned applications, the purpose of deploying a MANET is very distinct from that of deploying a WSN. The implication is that new research issues emerge in a WSN that had not been so critical in a MANET, such as the issues of coverage (i.e., ensuring that a WSN provides the desired quality of monitoring), tolerance to new types of faults, focus on energy efficiency, and so forth. Even those issues that are common to both networks, such as the design of medium access control, routing, and other protocols (discussed in the “Common Issues in wireless Ad Hoc Networks” section), need to be revisited for WSNs. Below, we elaborate on these and other differences between MANETs and WSNs.

Typical Traffic Pattern

Because the typical uses of the two networks are distinct, their typical traffic patterns are quite distinct as well. In a MANET, traffic pattern usually is point to point or point to multipoint. In other words, traffic originating from one node may be destined to one particular subset of nodes at a given instant, whereas traffic originating from another node or from the same node but at a different instant may be destined to a different subset of nodes.

In a wireless sensor network, however, data traffic either flows from sensor nodes to one or a set of base stations, called source to sink, or from the base station(s) to some or all nodes, called sink to source. Examples of source-to-sink traffic are event detection messages from sensors or sensor data about the environmental variations. Examples of sink-to-source traffic are the dissemination of a new program to all (or a subset of) sensors or the dissemination of a new value of some parameters to all (or a subset of) sensors. Base stations sometimes are referred to as *sinks* to emphasize this traffic pattern.

Because the traffic pattern in a WSN is so distinct from that in a MANET, the routing protocol used in these two networks is different as well. As mentioned in the previous paragraph, two types of traffic need to be supported by a WSN, information from sensors to sink(s) and from sink(s) to sensors. Traffic from sensors to sink(s) is referred to as *data gathering*, and that from sink(s) to sensors is referred to as *data dissemination*. The major issues that need to be addressed in a routing protocol to support each of these traffic patterns are very distinct, and hence two different categories of routing protocols have been developed to cater to these two traffic types. MintRoute (22) is an example of a data gathering routing protocol, and Deluge (23) is an example of a data dissemination routing protocol.

Attended Versus Unattended—Implications for Fault-Tolerance

MANETs typically consist of human-operated devices and therefore are attended mostly by a human being. Several types of faults easily may be detected and repaired (by resetting the device). Battery exhaustion also is not a major concern as the human operator may recharge the device when needed.

A wireless sensor network typically is deployed outdoors and may remain unattended for long periods of time. This unattended nature has several fault-tolerance implications. First, sensor nodes are subject to new types of faults that may come from outdoor environmental conditions such as wind, rain, excessive heat or cold, physical tampering, and so forth. Excessive heat or cold or excessive battery depletion may cause other types of failures that qualify as byzantine failures (24). Second, node failures are more frequent in a wireless sensor network. Further, node failures may not be detected immediately and sometimes and not be detected at all (for example, if message from a healthy sensor node cannot reach the base station). Third, physically repairing or replacing individual nodes may not be feasible (e.g., if the sensors are deployed in inhospitable terrain or in enemy territory), and, hence, only remote repair of failures is feasible. Fourth, battery recharging may not be feasible (especially if the nodes are not equipped with energy scavenging mechanisms as in solar cells).

Consequently, the protocols developed for wireless sensor network needs to be adaptive to these new types of failures. These failure types are not prevalent in a MANET.

Resource Constraints

The computational capacity, memory size, buffer capacity, and network bandwidth available to a sensor node is an order of magnitude lower than that available to a node in a typical MANET. See Table 1 for a comparison of the hardware specification of a typical WSN device with that of a typical MANET device. Observe that the processor is at least 50 times slower in a WSN and that RAM size is at least 6,400 times lower. This implies that the protocols and algorithms developed for a WSN need to be considerably simpler than that developed for a typical MANET.

Energy Efficiency

Sensor nodes, being deployed outdoors and unattended, run on batteries that may not be replaced. Hence, the issue of energy efficiency and network longevity are high-priority considerations, whereas this problem is less severe in MANETs that mostly consist of personal digital devices that can be recharged. As a result, every protocol or algorithm developed for wireless sensor network should be designed with a consideration of energy efficiency. For example, the MAC protocols proposed for MANETs are not very appropriate for use in a WSN because energy efficiency is not as critical in a MANET. In a WSN, even keeping the radio in listening mode for an extended period of time can drain significant energy. Hence, the radio may be completely turned off to save energy and turned on only periodically or when needed to receive or transmit data. If the radio is not always in the listening mode, communication (especially of real-time data like the detection of an intruder) becomes nontrivial. Several MAC protocols to ensure timely communication while ensuring energy-efficiency have been proposed. An example of such a protocol is B-MAC (25).

Table 1. Comparison of the key hardware properties of a typical WSN device (telosb mote), a pocket PC (HP iPAQ), and a typical laptop

Property	WSN Device	Pocket PC	Laptop
Processor speed	8 MHZ	400 MHZ	1.8 GHZ
RAM size	10 KB	64 MB	1 GB
Persistent storage	1 MB	64 MB	60 GB
Radio data rate	250 kbps	11 mbps	54 mbps

The issue of energy efficiency also is critical in the process of deployment. If redundant sensors are deployed, then the redundant sensor nodes are put to sleep, taking turns, to maximize the lifetime of the sensors (as discussed in “The Issue of Coverage” section).

Mobility

The nodes in a typical MANET are assumed to be frequently mobile. The nodes in a WSN, however, are mostly static, unless moved by wind or other external phenomenon. In the future, some sensor networks may consist of mobile nodes, (26). In these cases, however, the motion of sensors will be dictated by the network requirement [such as to facilitate data collection from a sensor node disconnected from the base station (9) or to provide temporary coverage in place of a failed sensor node (26)] as opposed to a user-induced motion as in a typical ad hoc network. This difference in the mobility pattern affects how the protocols for the two networks are designed.

Security Threats

New types of security threats are possible in a sensor network because of outdoor and unattended deployment, such as physical capture and physical destruction. Because sensor nodes have the ability to receive new program code to replace the currently active program code via a wireless channel, an adversary may inject malicious program onto sensor nodes. False sensory data or bogus events also can be injected in the network. Communication can be jammed by accompanying a malicious target (that the network is supposed to detect) with a jammer device. Because the sensors have limited energy reserve, attacks can be played to deplete sensors of their energy, such as by sending too many messages (from a more powerful device) or by causing too many event detections. Designing protocols to mitigate these and other security threats in a WSN currently is an active area of research.

The Issue of Coverage

Because the main purpose of a WSN is data collection and event monitoring, the issue of coverage becomes a key issue in the deployment and maintenance of sensor networks. The issue of coverage is that of determining methods of initial deployment and subsequent maintenance of the network topology (over time) to ensure that a WSN provides the desired quality of monitoring (27,28). This issue does not arise in MANETs because their main purpose is not to monitor events.

When a sensor network is to be deployed, several critical deployment issues arise, such as how many sensors should be deployed and in what pattern. Determining how many sensors to deploy becomes more challenging when sensors cannot be deployed at desired locations, as when spraying them from an aircraft. Once sensors have been deployed, mechanisms are needed to detect whether the network continues to provide the desired quality of monitoring, as some sensors may fail unexpectedly because of environmental factors. In the event that the network can no longer provide the desired quality of monitoring, additional sensors may need to be deployed, or if the sensors have movement ability, then some sensors may need to be repositioned to repair the network. Designing efficient methods of redeployment or reconfiguration continues to be an active area of research.

To tolerate unanticipated sensor failures, some redundant sensors may be deployed. In such a case, mechanisms are needed to determine a sleeping schedule (29) for the redundant sensors such that the batteries of the active nodes get depleted at a slower rate, ensur which a longer life for the network.

Localization

Because the main purpose of a wireless sensor network is to monitor events or collect information about the environment, it often is critical to associate location information with the data collected by a sensor node. For example, if a sensor network is deployed to detect fire, then it is not sufficient to learn that fire has erupted. Location of the fire eruption is a critical part of the information. Additionally, because installing GPS at every sensor node is prohibitively expensive and energy consuming, the process of localization needs to be performed in a sensor network such that each sensor node knows its absolute location. Either the process of localization is not so critical in a typical MANET, or installing a GPS unit on each device is within the budget.

Various mechanisms have been proposed to perform localization. For example, a mobile unit with GPS mounted on it can traverse through the network broadcasting its location (30). Sensors can localize themselves using this broadcast. Alternatively, some anchor nodes who know their location (possibly using a GPS) can be placed in the network. These nodes then help other nodes determine their locations by using a localization algorithm. Some mechanisms for localization use the time difference of arrivals of radio or acoustic signals (31), whereas others use radio interferometric techniques where radio signals are transmitted to cause interference (and hence phase difference) at the receivers (32). Localization in a WSN still is an active area of research.

Time Synchronization

Because the main purpose of a WSN is to monitor events or collect information about the environment, often it is critical to associate time information with the data collected by a sensor node. For example, if a sensor network is deployed to track the trajectory of a moving target, then the time of detection of the target at a specific sensor is necessary to chart the trajectory of the target movement.

Time synchronization also is useful in MANETs (especially for implementing some cooperative MAC protocols). However, the clocks of MANET nodes usually are more accurate than that of sensor networks. Also, in MANET devices such as cell phones, time synchronization is provided by a centralized infrastructure. Consequently, the problem of time synchronization is more critical in a WSN than in a MANET and requires a nontrivial solution.

Several protocols exist for time synchronization in a WSN. They can be classified in two categories: *proactive* and *reactive*(33). In proactive protocols, a virtual global reference time across the entire network is established and maintained via the exchange of messages. Reference Broadcast Synchronization (RBS) (34) and Flooding Time Synchronization Protocol (FTSP) (35) are examples of proactive protocols. In reactive protocols, time is not synchronized at all. Packets are time-stamped using local unsynchronized times. Synchronization is done after the detection of events. An example of such a protocol is Routing Integrated Time Synchronization (RITS) protocol (36,33).

CONCLUSION

Wireless ad hoc networks have revolutionized the world of communication by enabling quick and infrastructureless communication at the point of need, whether it is in a battlefield, on a mountain, under water, or on a different planet. Wireless sensor networks, alternately, are revolutionizing many disciplines by providing the unprecedented ability to observe our environment. By enabling the unobtrusive collection and accessibility of real-time data from the environment, new research capability now is available in several scientific disciplines, such as biology, geology, oceanology, medicine, and elderly care. Also, by enabling real-time and continuous monitoring of the environment, new capabilities in surveillance have become possible such as efficient and comprehensive border surveillance. Both of these disciplines, wireless ad hoc network and wireless sensor network, are relatively young disciplines with highly active research communities. As new applications emerge and as the technologies mature, these two technologies potentially can have a greater impact on our lives than personal computers and the Internet have.

COMMUNICATION-INDUCED CHECKPOINTING PROTOCOLS AND ROLLBACK-DEPENDENCY TRACKABILITY: A SURVEY

INTRODUCTION

A *checkpoint* is a snapshot of the current state of a process, saved on nonvolatile storage. A process periodically takes a checkpoint so that it can reduce the amount of lost work upon a failure. To survive a failure, the process reloads the state recorded in the latest checkpoint into volatile memory and restarts from that checkpoint. Such a procedure is called *rollback recovery*.

A distributed computation is composed of multiple processes connected by a communication network. Processes communicate and synchronize only by exchanging messages via the network. The execution of each process produces a sequence of events, and all the events produced by a distributed computation can be modeled as a partially ordered set with the well-known Lamport's *happened-before* relation (1). In a distributed computation, the states of all involved processes and those of the underlying communication channels constitute the system state. Upon a failure, lost process states may create *orphan* messages that result in an *inconsistent* state, i.e., a state that is impossible to reach via any failure-free distributed execution. A message is called *orphan* with regard to an ordered pair of checkpoints if the receiving event of such a message happens before the latter checkpoint in the pair but its sending event occurs after the former one. Hence, an ordered pair of checkpoints is *consistent* if there are no orphan messages with respect to this pair. Furthermore, a *global checkpoint* is a set of checkpoints, one from each process. A global checkpoint is consistent if all pairs of its component checkpoints are consistent (2). In particular, the consistent global checkpoint that can minimize the total rollback distance upon a failure is called the *recovery line*. Computing a consistent global checkpoint, preferably the recovery line, is fundamental to any rollback-recovery protocol after inconsistencies happen due to failures.

If checkpoints are taken independently, it is possible that cascading rollback propagation, which is required to eliminate all orphan messages, may occur during the course of finding the recovery line. In the worst case, no consistent global checkpoints can be found (except for the set of all initial checkpoints), and this is the well-known *domino effect* problem (3). Many checkpointing protocols have been proposed to selectively take checkpoints to avoid this problem. For more details, see the survey paper (4). Among them, *coordinated checkpointing*(2,5) avoids the domino effect by synchronizing the checkpointing actions of all processes through explicit control messages. In contrast, *communication-induced checkpointing (CIC)*(6) accomplishes coordination by piggybacking control information on application messages. Specifically, in addition to taking application-specific *basic* checkpoints, each process can also be directed by the protocol to take extra *forced* checkpoints according to certain checkpoint-inducing conditions, to ensure the progression of the recovery line. Such conditions typically predicate on information piggybacked on messages as well as on local control variables.

CIC protocols can also be used to achieve a stronger property, called *rollback-dependency trackability* (RDT) (7). Besides the inconsistencies resulting from causal dependency, two checkpoints can have a noncausal, *zigzag* dependency that makes it impossible for them to belong to the same consistent global checkpoint (8). A CIC protocol satisfies RDT if all such hidden dependencies are guaranteed to be online trackable through a simple transitive dependency vector. The RDT property can both eliminate the domino effect and ensure that any set of checkpoints that are not causally related pairwise can be extended to form a consistent global checkpoint. Moreover, it allows efficient decentralized calculation of the recovery line (7).

PRELIMINARIES

In this section, we define terms that are essential for understanding the CIC protocols. Associated with a distributed computation, the set of messages and the set of local checkpoints constitute the *checkpoint and communication pattern*. In a pattern, $C_{i,x}$ represents the xth checkpoint of process P_i. The sequence of events occurring at P_i between $C_{i,x-1}$ and $C_{i,x}$ $(x > 0)$ constitute a *checkpoint interval* (or *interval* for short), which is denoted by $I_{i,x}$.

A *Z-path* is defined as a sequence of messages in which the sending event of every message except for the first one happens in the same or a later interval than the receiving event of the preceding message (9). Furthermore, a Z-path is from checkpoint $C_{i,x}$ to $C_{j,y}$ if its first message is sent after $C_{i,x}$ and its last message is received before $C_{j,y}$. A Z-path denotes that its terminating checkpoint has a rollback dependency on its starting one. More specifically, with a Z-path from $C_{i,x}$ to $C_{j,y}$, if process P_i rolls back to $C_{i,x}$ upon a failure, process P_j also needs to rollback to $C_{j,y-1}$ in order to eliminate inconsistency. Hence, a Z-path from a checkpoint $C_{i,x}$ to itself, which is also called *Z-cycle*, is the cause of the domino effect since it will induce recursive, cascading rollback propagation. The checkpoint $C_{i,x}$ involved in this Z-cycle is thus unable to belong to any consistent global checkpoint (8) and considered *useless* in Ref. 10. Intuitively, the ultimate goal of a CIC protocol is to eliminate all Z-cycles from a checkpoint and communication pattern. A protocol can take an additional forced checkpoint prior to a condition representing a Z-cycle to remove this Z-cycle. Such a forced checkpoint is also consistent with the involved useless checkpoint. One major challenge is that not all Z-cycles are on-the-fly detectable. Consequently, CIC protocols employ various techniques to discover suspect conditions that may result in a Z-cycle.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

A Z-path is *causal* if the receiving event of each message aside from the last one precedes the sending event of the next message in the sequence. A causal Z-path is sometimes referred to as a *causal path*. A Z-path is *noncausal* if it is not causal. A causal path means that the information in its starting checkpoint can be online transmitted to its terminating one through the piggybacking technique. In addition, a noncausal Z-path sent in interval $I_{i,x}$ and arriving in $I_{j,y}$ is *causally doubled* if a causal path exists from $I_{i,x'}$ to $I_{j,y'}$ such that $x \leq x'$ and $y' \leq y(9)$. The idea of *causal doubling* is that for this noncausal Z-path, the information in its starting checkpoint can still be online forwarded to its terminating one via the doubling causal path. Hence, if all Z-paths in a checkpoint and communication pattern are either causal or causally doubled, all rollback dependencies between checkpoints can be on-the-fly trackable with a transitive dependency vector and the pattern, by definition, satisfies RDT. Moreover, because a Z-cycle can never be causally doubled, RDT protocols suppress the formation of Z-cycles altogether (11).

The most extreme method to prevent the domino effect by enforcing RDT is to direct a process to take a forced checkpoint whenever a message is received. A better way to this end is to force a checkpoint before every message-receiving event with a preceding message-sending event in the same interval (12). In doing so, the two protocols can ensure that all message-receiving events precede all message-sending events within every interval to prevent noncausal Z-paths from being formed. In the next two sections, we will introduce several more sophisticated CIC protocols and RDT protocols, respectively.

CIC PROTOCOLS

CIC protocols can be divided into two distinct categories: *index-based* and *model-based*(4). An index-based protocol associates every checkpoint with a sequence number similar to the Lamport's logical clock (1). In contrast, a model-based protocol does not use a time-stamping mechanism; rather, it prevents the formation of certain checkpoint and communication patterns during the execution.

Index-based CIC protocols have been extensively studied in the literature (10,13–17). A common technique among them is to guarantee that sequence numbers of checkpoints always *increase* along a Z-path (14,18). Doing this technique can eliminate all Z-cycles since the sequence number of a checkpoint cannot be larger than itself. Furthermore, checkpoints with the same sequence number from different processes are consistent because a Z-path will never be formed from one checkpoint to another with the same sequence number. Such a consistent global checkpoint can thus be used for recovery upon a failure. For example, the checkpoint-inducing condition of the protocol, introduced in Ref. 13, is expressed as "$m.sn > sn_i$", where sn_i represents the current sequence number of a process P_i and $m.sn$ the sequence number carried on a message m received by P_i. The intuition behind this condition is that when a process P_i receives a message m with $m.sn > sni$, it will take a forced checkpoint with the sequence number set to $m.sn$ prior to delivering m so that P_i can contribute a checkpoint to the construction of the new consistent global checkpoint with sequence number $m.sn$.

Because forcing extra checkpoints incurs runtime overhead, it is desirable to take as few forced checkpoints as possible while avoiding the domino effect. To this end, one fundamental principle of improved CIC protocols is to reuse existing checkpoints as much as possible as part of a coming consistent global checkpoint with a higher sequence number to avoid the requirement of some forced checkpoints. For instance, a protocol proposed in Ref. 10 will direct a process to force a checkpoint only when the "$m.sn > sn_i$" condition is encountered after at least one message-sending event in the same interval. If there is not any message-sending event between the last checkpoint of process P_i and the receiving event of message m, it is impossible to have a Z-path from the last checkpoint of P_i to a checkpoint of other processes prior to delivering m. Therefore, despite receiving one message with a larger sequence number, P_i can still employ its last checkpoint as part of the coming consistent global checkpoint corresponding to $m.sn$. In addition, by subtly collecting as much information as it can from the causal past, another protocol in Ref. 10 achieved an even more restrictive checkpoint-inducing condition, at the expense of piggybacking much more control variables on messages than just a single sequence number. In practice, much of the causal information is too obsolete to be helpful to checkpointing decisions. Accordingly, the protocol presented in Ref. 15 discarded some obsolete information from the causal past to reduce the size of piggybacked information to a small constant, while achieving nearly as good performance as the previous protocol, especially on a tree-shaped communication network (15).

Another way to reuse existing checkpoints is to adopt a different indexing strategy from the classic one. The sequence number of the underlying indexing strategy used in Refs. 10, and 13–15 is maintained in the classic way of Ref. 1 in that it is increased by one each time a basic checkpoint is taken. Hence, if a process takes basic checkpoints at a higher rate than other processes and consequently has a larger sequence number, forced checkpoints may be induced when other processes receive messages from this process. To deal with this asymmetry, the *lazy indexing* strategy is presented in Ref. 16. With such a strategy, if one process P_i has only received messages with sequence numbers smaller than its own in the current interval, it is unnecessary for P_i to increase the sequence number when the next basic checkpoint is taken. The reason is that, in such a situation, the new checkpoint of P_i can still be consistent with existing checkpoints of other processes that are originally consistent with its preceding one so that it does not need to belong to another consistent global checkpoint with a higher sequence number. Furthermore, a more sophisticated lazy indexing strategy is proposed in Ref. 17. This strategy precisely traces orphan messages to allow the consistent global checkpoint corresponding to the current sequence number to gradually progress to succeeding checkpoints as best it can. Such an improved strategy can increase the sequence number at a lower speed than the previous lazy indexing scheme.

Next, model-based CIC protocols, like those introduced in Refs. 19 and 20, are more complex protocols that track the the checkpoint and communication pattern to prevent particular patterns that can potentially result in a Z-cycle. In general, a model-based protocol needs more control information carried on a message than an index-based protocol. Moreover, simulation experiments showed that the former is more eager to remove a suspect Z-cycle than the latter, which results in many more forced checkpoints (21).

Finally, a common intuition about CIC protocols is if a protocol forces a checkpoint only at a stronger condition, then it must take at most as many forced checkpoints as a protocol based on a weaker condition. It has been proved that such an intuition is in fact false because any forced checkpoint may affect subsequent condition testings (22). This result implies that the usual approach of sharpening the checkpoint-inducing condition by piggybacking more information on each message may not always yield a more efficient protocol. But interestingly, comparisons of some existing protocols can indeed be based solely on comparing their conditions (22). The analysis also led to an impossibility result: An optimal online CIC protocol cannot exist that always takes fewer forced checkpoints than any other protocol (22).

RDT PROTOCOLS

Given a checkpoint and communication pattern, a CIC protocol does not need to examine that every noncausal Z-path is causally doubled to ensure the RDT property. Causally doubling a certain subset of noncausal Z-paths is sufficient. Such a subset is called an *RDT characterization* in Ref. 11. Important RDT characterizations are all derived from the notion of *prime* causal paths. A causal path from a checkpoint $C_{i,x}$ to a process P_j is *prime* if it arrives at P_j the first among all causal paths from $C_{i,x}$ to P_j. Intuitively, such a causal path is the first causal path causing P_j to have a dependency on $C_{i,x}$.

The first RDT characterization is the *PCM-path*, which is a noncausal Z-path formed by concatenating a prime causal path and a single message (11). A PCM-path is the first Z-path that cannot transmit to its arriving process the information about the rollback dependency on the starting checkpoint, if it is not causally doubled. Hence, a safe strategy to satisfy RDT is to *break* any non-causally doubled PCM-path with a forced checkpoint prior to meeting the involved prime causal path. Moreover, for an online protocol, the information of being causally doubled must be contained in the causal past of a process at the moment it detects a PCM-path for the checkpointing decision. This concept is called *visible doubling*(23). An online protocol can achieve RDT if it breaks all PCM-paths that are not visibly doubled. Several protocols based on the PCM-paths are derived in Ref. 11, where each protocol breaks a certain subset of PCM-paths, containing at least all non-visibly doubled PCM-paths. Among them, a protocol with a stronger condition generally needs more control information carried on a message. A comprehensive comparison of their performance can be found in Ref. 24.

A more constrained RDT characterization, called the *EPSCM-path*, is proposed in Ref. 11 as well. An EPSCM-path is a PCM-path such that the component prime path is both *elementary* and *simple*. A causal path is *elementary* if it merely traverses a process once, whereas a causal path is *simple* if it does not include any checkpoints. This characterization is the minimal subset of non causal Z-paths that have to be *causally doubled* to satisfy the RDT property. A few protocols based on EPSCM-paths are also presented in Ref. 11.

Recently, it was proved in Ref. 25 that *visibly doubling* all *PMM-paths* in a pattern suffices to satisfy RDT, where a PMM-path is a noncausal Z-path composed of just two messages with the first being prime. So it is the minimal noncausal Z-path allowed in the computation model. Several RDT protocols can be derived from PMM-paths as well. Interestingly, it has been demonstrated in Ref. 26 that for an RDT protocol, the last elementary and simple part of every prime causal path it encounters online is still prime and so is the last message. Thus, RDT protocols will always encounter a PCM-path, an EPSCM-path, and a PMM-path simultaneously. Moreover, several protocols derived from these three kinds of Z-paths, respectively, have the same behavior for all patterns (26).

The most important benefit of the RDT property is that it allows us to find the recovery line in an efficient, distributed manner because all checkpoint dependencies are online trackable. But an RDT protocol typically needs more forced checkpoints and requires more control information piggybacked on a message. Such protocols can be classified into the model-based category because it prohibits some particular patterns from occurring. Finally, an impossibility result was presented in Ref. 27, stating that it is not possible to design a *scalar, clock-based* CIC protocol that carries only one integer on a message, while satisfying RDT.

CONCLUSIONS

CIC protocols allow each process to take its basic checkpoints autonomously. No special coordination messages are exchanged to ensure consistency among all processes. Furthermore, the calculation of a consistent global checkpoint upon a failure can be accomplished in an efficient and decentralized manner. But every application message needs to carry extra control information. More importantly, the behavior of taking forced checkpoints highly depends on the number of processes and on the communication pattern. Also, the number of checkpoints induced by a protocol may be a considerable burden. Therefore, the main challenge for CIC protocols is to control the unpredictable checkpointing behavior and to reduce the number of forced checkpoints while preserving the desirable properties.

COORDINATION AND SYNCHRONIZATION: DESIGNING PRACTICAL DETECTORS FOR LARGE-SCALE DISTRIBUTED SYSTEMS

INTRODUCTION

Large-scale distributed systems such as PlanetLab (1), peer-to-peer systems (e.g., (2–4)) , Grid networks (5), and so on, have exploded in popularity in the past few years. It is well known that such systems are failure-prone, for example, "nodes" (client machines or computer hosts) can join and leave the system at will (a phenomenon called churn), and messages can be dropped by the underlying network.

Several distributed applications have began to run atop such clusters, for example, distributed computations, cooperative file sharing, multimedia and content streaming, resource discovery, and application-level DNS. To enable coordination and synchronization, in each of these distributed applications, the application must keep track of the behavior of each node involved in the application. Intuitively, each node has individual "personalities" from the viewpoint of its cooperativeness or willingness to contribute to the overall good of the system. Thus, it is important to keep track of the individual characteristics of these nodes in a distributed fashion.

On the one hand, at the most basic level, simple node-level failures must be detected. For instance, when a node fails (or joins the system), some other nodes that are currently in the system need to be made aware of the change in the *membership*. Similarly, some nodes may be modifying messages maliciously or deviating from the core protocols specified as a part of the system—it is important to detect (and then perhaps punish) such nodes.

At the other extreme, several applications must detect system-wide properties. We consider one interesting class of detectors that fall at this end of the spectrum—one requires nodes to be aware of the approximate size of the system, that is, the number of non-faulty nodes present in the system currently. In between these two extremes, some applications track the individual availability history of nodes, which includes, their up/down characteristics. This availability of information can then be used to place replicas (of files or services) so as to maximize the availability of the service being replicated, to ensure that the multicast reliability at recipient nodes varies as a function of the node's availability, and so on.

We broadly call the above problems of measuring node-specific or aggregated, system-wide properties as the problem of *detection.* A variety of detectors for distributed systems exist, and it is possible that a book-length article could be written to cover these various detectors! To maintain brevity, this article focuses on a "sliver" of detectors from across the spectrum of node-level to system-wide detectors.

Specifically, we will focus only on the failure-, Byzantine-, and availability-related classes of detectors . We will mention, at appropriate places, other detector classes that are not covered here and that the reader may be interested in researching. The reader should use this article as a beginning step to understand more about the topic.

Notice that the latter extreme of detection is related to "statistics collection" and aggregation (6,7), but we are interested only in the actual availability-related or behavior-related characteristics of nodes, and not in collecting statistics that are specific to a particular application. In other words, most solutions to the detection problems we will discuss can be used by a wide variety of distributed applications. Furthermore, we hope this article will motivate the reader to read existing literature on other problems such as termination, deadlock detection, snapshots, and reputation mechanisms.

We focus on practical solutions with the two following characteristics: (1) they have been implemented and validated in experimental evaluation or practice and (2) they are based on novel ideas and on strong theory. Our goal here is to enable and to enhance the understanding of such viable and practical solutions for practitioners to use in real systems.

Thus, this article considers four main classes of detection problems.

1. *Crash Failure Detectors:* When the given node in the system crashes, other nodes that knew about it should be informed that it crashed.
2. *Byzantine Failure Detectors:* When the given node deviates from the specified application protocol behavior, other nodes that are non-Byzantine must be informed.
3. *Availability Detectors:* The system (or a small set of nodes) maintains information about the availability history of each node.
4. *System Size Estimators:* An initiator node (or all nodes in the system) must know about the approximate number of non-faulty nodes present as a part of its distributed group. This group could be either a one-shot or a continuous estimation problem.

Two points must be noted here. First, we are interested primarily in *fully distributed solutions* to these problems. That is, protocols that operate in a peer-to-peer fashion, without requiring a central server, are of the most interest to us. Second, we will discuss rarely the action taken by the application when such a detection is triggered. In some of the referenced papers, such reactive application behavior may be discussed. However, our discussion in this article presents detectors in a modular fashion so they can be used in a plug-and-play manner with a variety of applications.

Although the main goal of this article is to make the reader aware of practicalities of detection problems and solutions, we do highlight relevant theoretical results that form the context or indicate the difficulties of a problem.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

CRASH FAILURE DETECTORS

Here, we consider the failure detection of nodes under the *fail-stop* failure model. Under this model, either a node is non-faulty (or correct) or it has crashed. Any node can crash, and once it has done so it never executes any more instructions (i.e., it never recovers).

Crash failure detection is the core of all peer-to-peer systems and distributed systems that attempt to operate in a non-centralized manner.

Before solving any problem (such as that of crash failure detection), it is important to discuss under what *system model* (i.e., assumptions) the problem must to be solved. Primarily, two types of system models exist for distributed systems:

1. *Synchronous System Model:* Each non-faulty node has a maximum known time bound on the time taken to execute any instruction. Furthermore, a maximum known time bound on the delay is faced by a message sent by one non-faulty process to another non-faulty process. An example of a system that follows this model are multiprocessor systems such as supercomputers. Notice that nodes are still allowed to fail in this model.
2. *Asynchronous System Model:* Unlike the above model, the asynchronous model imposes no limits on either the time taken by a non-faulty node to execute any instruction nor the message delays. In other words, messages can be delayed an arbitrarily long time, and nodes can be arbitrarily slow without being faulty. Most practical networks follow the asynchronous system model, for example, Internet, wireless networks, and sensor networks.

Fail-Stop failure detectors are interested in two properties:

- Completeness: The percentage of failures that are detected eventually by all concerned non-faulty nodes.
- Accuracy: The percentage of detections that correspond to a failed node.

Notice that it is easy to guarantee trivially either 100% completeness (each node always consider all other nodes as crashed all the time) or 100% accuracy (each node never considers any other node as crashed at any point of time).

Chandra and Toueg (8) showed that it is impossible to guarantee both 100% completeness and 100% accuracy in an asynchronous system model. In the synchronous system model, however, implementing a complete and accurate failure detector is straightforward—any one of the following detectors for asynchronous systems can be used, along with timeouts that are decided based on the message delay and the instruction processing bounds.

In view of the above impossibility, most distributed applications have come to expect 100% completeness (and thus probabilistic accuracy) from the underlying crash failure detector. Each crash of a node in a distributed application must be followed by a repair or recovery operation in that application—thus, it is important to detect each failure, but it is alright to have mistaken detections. All algorithms we discuss below guarantee 100% completeness.

Chandra and Toueg (8) were the first to present failure detectors with a view for solving the problem of consensus for a bit, in a process group. Specifically, they provide a taxonomy of detectors in Ref. (8), which includes the weakest failure detector to solve consensus. Substantial work has occurred in the theoretical community since then on failure detectors for a variety of system models, e.g., see Ref. (9). However, we preclude such papers (even though classic) because either they do not scale to large distributed systems with thousands of nodes or they have not been validated in practice.

For asynchronous systems, practical failure detectors for fail-stop failures tend to be of two types: (1) heartbeating based, and (2) ping-based.

Heartbeating-Based Failure Detectors

Each node *n* sends an “I am alive” (heartbeat) message periodically (once every *hb* seconds) to a subset of other nodes in the system. Successive heartbeat messages are numbered with monotonically increasing sequence numbers to be distinguishable. Each other node that is aware of node *n* maintains the time since the last heartbeat was received from node *n*. When this time crosses a timeout threshold *(timeout* seconds), the node *n* is marked as failed.

First, this satisfies 100% completeness—once node *n* fails, it will stop sending heartbeats, and because *timeout* is finite, all previously sent heartbeats by *n* will be received and the timeout will expire eventually (at any given recipient node). In practice, the value of *timeout* is typically much larger than message transmission delays; hence, the actual detection time is *timeout* seconds.

However, this algorithm does not guarantee accuracy, especially in an asynchronous network where heartbeat messages can be delayed for an arbitrarily long time. This delay can cause another message to timeout while waiting for heartbeats from a (correct) node *n*, and consequently mark *n* as crashed mistakenly. Notice that the larger the value of *timeout* is compared with message delays, the more is the accuracy of the protocol, that is, the smaller is the false-positive rate. However, larger *timeouts* also entail longer detection times; hence, the value of *timeout* will trade off between detection time and accuracy.

Heartbeat transmission can be implemented in one of two ways—*explicit* or *implicit.* Explicit heartbeat creates separate messages for heartbeats, whereas implicit heartbeat either piggybacks heartbeat messages, atop application messages or, in some cases, uses application messages themselves as heartbeat messages.[1] For the rest of our discussion, we will assume explicit heartbeating; however, our discussion applies to the implicit variety too.

Several variants of heartbeat-based failure detectors exist—the difference between these detectors is based on which is the “subset” of nodes that receive the heartbeats

[1] We will ignore this last option mentioned because our goal in this section is to focus on application-independent protocols.

from the given node *n*. This choice is decided based on the *overlay*, or the *membership graph* (i.e., the graph defined by a node's neighbors). Below, we describe several different types of such overlays, along with the associated heartbeat-based protocol.

Simple Overlays. The classical approach was a *ring-based* overlay, with nodes arranged in a virtual ring (with no necessary correlation to their actual locations). Each node merely sent heartbeats to its clockwise neighbor (in addition, the anticlockwise neighbor was also used to increase the fault-tolerance), and these neighbors would be the only ones to detect failure of this node. In a system with N nodes, the overhead of this scheme is $O(N)$ since every node sends heartbeats periodically. The drawback of this scheme was that multiple simultaneous failures could cause an unnecessarily long delay for detecting failures, especially if a sequence of nodes in the ring failed in succession. Because the likelihood of this occurrence increases as the total number of nodes increased, the ring-based algorithm was not scalable.

A different, simpler alternative is to send the heartbeat to *all* other nodes in the system. Although this is clearly more fault-tolerant than the ring, this scheme has a very high overhead ($O(N^2)$ messages) and could have lower accuracy. Any slow node could mark a very large set of other nodes as faulty because it did not receive several heartbeat messages in a timely manner.

Gossip-style Heartbeating. Van Renesse et al. (10) made the above all-to-all heartbeating model more accurate by not having each node send its heartbeats directly to every other node, but instead *gossip* the latest heartbeat counters for several other nodes. At any node *n*, gossiping selecting entails periodically selecting a few other random nodes and sending them the array of the latest heartbeat counters (from other nodes) known at node *n*.

Van Renesse et al. (10) showed that if all heartbeats could be included in each gossip message, and each node gossiped with a constant other randomly selected gossip targets every second (on average), it took $O(\log(N))$ seconds for any node's updated heartbeat information to spread to all other nodes with high probability. Here, N is the number of nodes in the system. Thus, the timeouts could be set in this range (if one knew an upper bound on the value of N). Thus, the failure detection times are small—because $\log(N)$ is a small number, and it grows very slowly, even for values of N up to 2^{32} (the number of possible IPv4 addresses), the value of $\log_2(N) = 32$.

Distributed Hash Table-based Overlays (or Structured Overlays). Distributed hash tables (DHTs), also known as structured overlays,[2] are overlays that follow a specific structure. For instance, the Pastry p2p overlay follows a hypercube-type structure, with nodes that maintain overlay "neighbors" based on prefix matches of id's assigned to nodes, these id's are assigned by hashing the node's IP address (e.g., by using SHA-1 or MD-5), but that fact is orthogonal to our discussion here. In turn, each node sent heartbeats to its neighbors in this overlay.

Similarly, in other DHTs such as Chord, a heartbeat-style strategy was used to detect failures. Information about a node failure would propagate to its immediate neighbors and might cause these nodes to select other, "better" neighbors that were non-faulty.

Random Partial Membership Graphs. Although DHTs such as Pastry and Chord follow a specific pattern of "neighbor" selection of nodes, to make resource discovery and file insertion operations very efficient, a separate class of overlays have been designed for other applications that do not use the resource-discovery functionality primarily. For instance, publish-subscribe and multicast applications often rely on the presence of a connected overlay graph among the nodes. Yet, the protocol attempts to achieve this by having each node maintain only a *small random subset* of other nodes in the system as its neighbors.

Below, we discuss the core design of one such random partial membership graph system briefly. The reader is encouraged to research other algorithms in this class, such as T-Man (11).

Scamp. Scamp (12, 13) attempts to maintain a *uniform random* overlay graph among nodes, with each node maintaining $O(\log(N))$ neighbors in this graph. This is achieved by the following mechanisms: (*1*) Each node *n* maintains a list of neighbors in the overlay, denoted as Neighbor Set(*n*), as well as the list of other nodes than point to them (the in-neighbor list), (*2*) [Node Join] When a new node joins the system, it obtains at least *c* contacts (*c* is a fixed parameter), and forwards its subscription (joining) information to *c* of these nodes. A node *n* that receives a new joining node's information will include it in with probability $1/(1 + |\text{Neighbor Set}(n)|)$; otherwise, it forwards this subscription to one of its neighbors, selected at random. (*3*) [Node Departure] A voluntarily leaving node *n* asks the highest-id *c* neighbors of itself to delete *n* from their neighbor lists. Every in-neighbor of *n* is asked to point to another of the previous neighbors of *n* (which excludes the *c* selected above)—duplicate selections may be allowed.

Although the basic SCAMP assumes voluntary departures only, each node sends heartbeats periodically to all of its neighbors. This avoids a node from being partitioned (isolated) out from the network—when a node has not received *any heartbeats* from any other node, it knows that it is partitioned.[3]

The authors show in Ref. (12) that this protocol causes each node to have an expected $(c+1)\log(N)$ neighbors, and that the distribution of neighbor selection is random (i.e., the probability distribution of the number of in-neighbors at a node has a small standard deviation).

It is easy to see how SCAMP can be extended to handle fail-stop failures—all neighbors of a given node would time

[2] To be more precise, a structured overlay is the actual underlying overlay, whereas a DHT is layered atop this overlay and provides get- and put-style functionalities to an application. However, today, the two terms are often used as synonyms by several sections of the distributed computing community, and hence we treat "DHT" and "structured overlays" as synonyms in this article.

[3] Note that this does not avoid a large subgraph from being partitioned out of the overlay!

out waiting for a heartbeat and then execute actions similar to the voluntary unsubscriptions described above. However, it is not clear whether this would continue to maintain the uniform randomness of the overlay. Furthermore, false positives could occur—any node that misses a heartbeat would propagate a failure notification, and a suspected node would be forced to leave the group. This problem is addressed in the SWIM system discussed in the next section.

Ping-Based Failure Detectors

Unlike heartbeat-based failure detectors, ping-based failure detectors do not use any kind of heartbeat messages. Instead, each node n is pinged periodically by a subset of other nodes in the system. If the node is unresponsive, the pinging nodes could retry the pinging. If several retries do not lead to a response, the node n is marked as crashed. Below, we describe two such ping-based failure detectors: SWIM and CYCLON.

Swim. The SWIM system (14) by Das et al. has each node periodically (once every T seconds) select *one* other node (say n) uniformly at random from across the system and ping this remote node. If the remote node is unresponsive (T is assumed to be larger than the typical round-trip time in the system), then the pinging node may ask up to K (value fixed) other nodes to ping the node n indirectly and return replies (if any). If either the direct or any one of the the indirect pings results in a positive reply from n, the pinging node takes no additional action. However, in the absence of a response, the pinging node marks node n as crashed.

Clearly, this protocol satisfies 100% completeness—a crashed node will be picked eventually as a ping target by some node in the system, and be detected as failed. Furthermore, the authors showed that this protocol has a constant failure detection time *on expectation*, for examples, for $K = 0$, the expected time between failure of node n and the *first* other node that detects this failure is $\frac{T}{1 - e^{-1}}$ seconds. It is important to note that this time does not depend on the size of the system, this is a desirable and scalable property, especially in a really large distributed system. Furthermore, the authors show how to tune the value of K to obtain a tradeoff between the detection time, the false positive rate (the inaccuracy rate), and the overhead (messages per second per node). The reader is referred to Ref. (14) for more details.

Cyclon. CYCLON (15) is another membership protocol that attempts to maintain a uniform, random membership graph while having each node maintain only a small number of neighbors. Briefly, each node maintains an *age* for each of its neighbors, which denotes the time since that neighbor entry was created at node n. Each node does the following two actions periodically—eliminate the neighbor with the maximum age and exchange neighbor lists with this oldest aged neighbor. CYCLON then describes a specific way to update the neighbor lists to maintain the uniform randomness of the overlay graph. However, notice that this selection of the oldest age neighbor is *implicit failure detection*, but in the heartbeat style. If this oldest neighbor does not respond, it is deleted. Thus, failed nodes disappear eventually from neighbor lists. If the size of neighbor lists is $O(\log(N))$, then the failure detection time is also $O(\log(N))$, which is small!

BYZANTINE FAILURE DETECTORS

Unlike the fail-stop failure model discussed in the previous section, the *Byzantine* failure model specifies that nodes can behave in any arbitrary and perhaps malicious manner, that is, a Byzantine-faulty node could deviate from the protocol specified by the application in arbitrary ways. For instance, it could execute instructions that are unauthorized or do not result from the applying the specified protocol on its received messages, it could send messages with malicious intent or junk content, or claim to have received messages that it never received. In short, the Byzantine model is the most general of all models of failure. Clearly, it encompasses the fail-stop failure model.

Yet, the Byzantine model is a very realistic model. Hosts whose security has been compromised, by viruses, worms, or human hackers, as well as a process based on buggy program code, all follow the Byzantine model.

The traditional approach to handling Byzantine failures has, until very recently, been to *mask*, rather than to detect, these types of failures. Most protocols for Byzantine fault tolerance are replicated state machines with a focus on solving problems such as atomic commit and consensus (8, 16–19), that is, where all nodes must agree on the value of a variable. These protocols assume that at most f faulty nodes exist in the system, and at least $3f + 1$ total nodes exist in the system (faulty or not). Several such protocols have been specified in theory (20,21) and in practice (22,23). These protocols are designed to allow the non-faulty nodes to solve the agreement problem in the presence of up to f Byzantine nodes among them. The reader would be interested to know that it has been proved (24) that one cannot implement Byzantine fault-tolerant consensus when more than one-third of the nodes are faulty, hence these protocols have "optimal" tolerance.

Although these protocols [especially Castro and Liskov's (22)] are highly practical and perform well in real systems, they are unable to tolerate more than f failures. If one used a Byzantine failure detector instead, the following advantages could be obtained (25):

- More than f failures could be detected (and tolerated, if the application is equipped with mechanisms to respond to detected failures). In fact, no upper bound exists on the number of Byzantine nodes in the system.
- The common case (where all nodes are non-Byzantine) becomes very efficient w.r.t. performance metrics such as throughput, latency, and scalability. Simplicity of design is preserved because typically detectors are designed to fit in very modularly with the rest of the application.
- Many applications do not need to solve the consensus problem, and Byzantine failures are interested in other problems that are not related to consensus.

For these problems, applications require information about the nodes that might be faulty. We remind the reader that one cannot implement Byzantine fault-tolerant consensus when more than one-third the nodes are faulty (24).

The same properties of completeness and accuracy apply to Byzantine failure detectors (thus no failure detector can achieve both properties with a 100% guarantee). Below, we briefly describe two systems—LOCKSS and PeerReview—that provide some semblance of Byzantine failure detectors. Besides these two systems, other systems exist that come close to providing a detector, but do not provide one that is fully specified. Aiyer et al. (25) provide a mechanism to monitor quorum systems so that an alarm is raised when failure assumptions are about to be violated. Intrusion detection systems work at the level of a single node. Reputation systems (see, e.g., Ref. 27) monitor the behavior of nodes in a p2p system but do not provide a notion of detection of Byzantine failure.

Before we discuss these systems, we note an important point—a Byzantine failure detector depends, to some extent, on the application itself, for example, what is considered to be unacceptable behavior by a node. Yet, the LOCKSS system is generic enough to be applicable to any distributed storage solution, whereas PeerReview applies modularly to any distributed application that allows auditing actions on application logs.

LOCKSS (Lots Of Copies Keeps Stuff Safe). The LOCKSS system by Maniatis et al. (28) provides a protocol to maintain a consistency of replicas—LOCKSS is implemented in the context of a digital library archive, where archival units (AUs) are the basic blocks that are replicated across multiple nodes. The challenge is that even though the AUs are immutable, attacks by either adversaries or bit-rot may cause some of the replicas of the AU to become corrupted as time progresses. The goal of the LOCKSS system is to (*1*) maintain the correctness and consistency of these replicas and (*2*) enable detection of an ongoing attack, especially when a large number of replicas are in disagreement with one another.

LOCKSS meets the above challenges by (*1*) building a continuously-changing (churned) overlay among nodes and (*2*) using this overlay to execute periodic polling on the replicas of the AU (to check for and correct their consistency). We do not describe here the intricate details of the protocol, viz., or the actual quotas on how much of the list is churned for each of the above actions. The reader is encouraged to read Ref. (28) for all details and adversary attacks on the protocol.

In brief, the protocol works in the following manner. Each node n:

1. Maintains two types of neighbors—inner circle neighbors (more trusted) and outer circle (less trusted) neighbors. At any time, the inner circle consists of a random subset of other nodes that have agreed with the recent *votes* of this node n. In addition to these two circles, node n maintains a list of *friends*—other nodes on whom it places a very high level of trust.
2. Initiates a *Voting procedure* periodically. This procedure is done by querying the inner circle neighbors, each of which in turn nominates a few nodes for n's outer circle. Then n chooses a small random subset from each nomination and asks these nodes to vote. Each vote is classified as either "agreeing" or "disagreeing" with n's own vote. This calculation is based on the hash of the replica of the AU in question, that is, the entire contents of the AU replica are hashed to generate a signature and this signature is matched. (In addition, the LOCKSS protocol marks each vote as either valid or invalid based on a proof of computational effort. For our purposes, an invalid vote will result in the offending voter being ignored and removed from the neighbors lists at n.) Finally, if V total votes were requested and received, then three cases may arise: *(1)* if the number of agreeing votes is at least $V-D$, the poll was successful and n retains its replica, (*2*) if the number of agreeing votes was no more than D, the poll was a failure and n repairs its replica (from a random disagreeing neighbor), and (*3*) if the number of agreeing votes is between D and $V-D$, n raises an *alarm* (the effects of an alarm are described below). D is a configurable parameter.
3. *Churns* its neighbor lists. After each vote, the inner circle neighbors who have disagreed or who have not voted for awhile are eliminated. A random subset of the remaining nodes is left in, a few random recently agreeing nodes (no voting) from the outer circle are brought in, and finally a few random friends are brought in. The goal of this churning of neighbors is to ensure that malicious nodes do not gain a foothold on the neighbor list of a node n for too long.

The authors of the LOCKSS system show that under a variety of adversary attacks, if most of the replicas of the AU are good (resp. bad), then most polls will end successfully (resp., in failure). However, and most importantly, it takes a very long time for an AU with predominantly good replicas to transition to a state with predominantly bad replicas. Hence, the *alarm* condition raised in the specification above will have enough time (and enough alarms) to detect this shift. In the authors' words—"The rate at which at an attack can make progress is limited by the smaller of the adversary's efforts and the efforts of the victims." Put another way, LOCKSS slows down the conversion of good replicas into bad replicas (which occurs because of the presence of malicious nodes) so much that victims (i.e., good nodes) are able to fix the bad replicas. Thus, even a delayed and slow human response to such an alarm would restore the correctness of the system because the adversaries are slowed down considerably by LOCKSS.

Notice that even though the above protocol does not *detect* Byzantine nodes explicitly in the system, but it is able to detect *disagreeing* votes. In the case of alarms raised for the AU, compromised nodes can be detected easily (via their proposed hashes for the AU) and thus repaired. Logs of the votes obtained can be used to detect faulty nodes (albeit perhaps with human involvement), and if a particular group of nodes is raising alarms, a local spoofing alarm could be raised to audit local nodes.

PeerReview. The PeerReview system (25) shares some common design characteristics with the LOCKSS system designed above. However, unlike it, PeerReview provides for explicit Byzantine failure detection with interesting completeness and accuracy properties (see below). Specifically, PeerReview ensures that a correct node will never be declared as being faulty (assuming that the node is indeed responsive). *This is a major difference from the fail-stop failure detectors of Crash failure Detectors*.

The PeerReview protocol has each node monitor application protocol-compliance of all other nodes in the group. It is potentially expensive and inefficient (it involves $O(N^2)$ messages in the system), however it is a good first-cut at this difficult problem. Among the several assumptions made by PeerReview, the most important ones are: (*1*) Messages sent by correct nodes are eventually received by the recipient (if it is correct) and (*2*) the application protocol for which compliance must be checked is a replicated state machine (29).

First, each node *n* maintains a log of all its previous protocol actions and uses this to sign messages. Top-level hashes of the log are taken periodically and on-demand—such *authenticators* are piggybacked on top of all messages sent out by *n*. In other words the log is maintained as a hash chain. All messages must be acknowledged (acknowledgment messages also carry authenticators). Besides the authenticator, each message sent by *n* also contains a short *proof* that the latest message is the latest action in the local log. Finally, node *n* periodically forwards to other nodes the authenticators it knows for other nodes; this ensures eventual dissemination of any authenticator.

Second, each node *n* is *audited* periodically by other nodes *j*. Node *j* can show that *n* is faulty if either (*1*) it has an authenticator and a log both from *n*, both signed by *n*, but disagreeing with each other or (*2*) a signed log segment from *n* that fails a conformance check. During the audit phase, node *j* can begin to *suspect n* if the latter is either unresponsive or noncompliant. Otherwise, node *j* performs a consistency check to see if the log matches the recent authenticators it has for *n* (this is for rule (*1*) above). Then, node *j* extracts all authenticators from the log segment and forwards them to all other nodes—this ensures eventual dissemination of these authenticators to all other correct nodes. Finally, *j* performs a conformance check for step (*2*) above. This phase is perhaps the most computationally expensive operation in the protocol. node *j* instantiates a local copy of the application state machine i.e., algorithm replays all inputs form the log, and checks whether outputs match the ones in the log.

Notice that any deviation based on the above checks can be forwarded to other interested nodes, who can then verify for themselves whether node *n* is faulty, either by repeating the checks for itself or by contacting node *n* directly to re-do the checks.

This helps PeerReview to ensure a nice variant of the Accuracy property—*no non-faulty node will be suspected or detected by another non-faulty node.* The completeness property is not guaranteed either, but an interesting variant of it is guaranteed. Although it is possible that a faulty node may in fact escape detection forever, it is true that if many faulty nodes exist in the system, at least one node will be detected eventually. Thus, a finite number of bad nodes can affect the good nodes for only so long.

PeerReview has been implemented and found to perform well in practice—readers are referred to Ref. (25) for more details. However, at the time of writing this article, it remains to be seen what alternative Byzantine failure detectors can be designed. Furthermore, whether this detector class can be made scalable at all remains a million dollar question!

AVAILABILITY DETECTORS

After having discussed detectors for *online* individual node-level characteristics (crash and Byzantine), we transition to the problem of *availability detection.* The failure model considered here is the *crash-recovery* model, where a node can leave or fail away from the system and rejoin the system later with the same node identifier.

The availability detection problem is to estimate the *short-term* or *long-term* up/down characteristics of each node *n*. The earlier detectors informed other nodes of the immediately recent failure of a node *n*—that is not our goal here; instead, tracking the up/down characteristics of *n* is our goal.

Availability detection is an absolutely essential component in the design of many peer to peer storage systems, e.g., see Refs (30) and (31). In these systems, the availability histories of nodes are used to select the best set of nodes to hold replicas for a given object to increase the system-wide availability of the object. In these systems, availability detection is sometimes tied to an *availability predictor*, which predicts the future availability of node *n* based on its history.

Availability detection is also useful in trying to satisfy reliability predicates, where the reliability of an application protocol (e.g., multicast) at a recipient node is tied to the availability of that node, e.g., see Ref. (32).

Below, we describe different types of availability detection schemes. Notice that detection schemes typically have two subcomponents: *who monitors node n*, and *how the availability history of n is maintained at other monitoring nodes*. We discuss both these issues below. Furthermore, in cases where availability prediction is possible, it is described briefly, as well.

Group-Based Master Detectors

The Total Recall system (30) uses a *master node* in a group (of replica-holding nodes) to detect the availability of the nodes that hold replicas, and to maintain availability history, as well as to predict availability. It uses this to select the best set of replicas. The master node is selected on a per-object basis, and it is responsible to monitor (via pings or heartbeats) the availability of two types of nodes: *inode storage nodes* and *data storage nodes*. Higher-granularity availability information is maintained for the former set of nodes (and those lost replicas repaired eagerly by the master), whereas the latter set has lower-granularity availability detection (and those lost replicas are repaired lazily).

Group-Based Distributed Detectors

Carbonite (31) and HBHC (33) each use more distributed schemes than group-based master detectors, but once again, these schemes work within small groups of nodes (holding replicas of a given object).

Carbonite's availability detection works by creating a spanning tree [of height $O(\log(N))$] rooted at each node in the group, which contains other nodes at its leaves. The spanning tree is created using the routing algorithm of the underlying p2p DHT (distributed hash table). Each node sends out heartbeat messages to its children periodically, and the heartbeat is propagated down the tree to its leaves. If a heartbeat is missed, the monitoring node triggers a repair for every object stored on the node detected as down. In a manner, this scheme is a crash-recovery protocol, but we include it in this section because it is used by Carbonite to measure the availability history of individual nodes.

HBHC (33) is another system for replica maintenance. The availability monitoring in HBHC is also fully distributed within the replica group. In brief, each node pings each other node in the group periodically, that is, it is an all-to-all pinging scheme. This information is also disseminated periodically to all other nodes in the group using a gossip-style (epidemic-style) dissemination (34).

System-Based Detectors

AVCast (32) is a system that links the multicast reliability at recipient nodes to their availability. The availability monitoring occurs on a system-wide basis, without assuming replica groups. Thus, it is a general scheme. To start, availability monitoring can be done either by having each node report its own availability individually or by using the overlay structure itself to decide which nodes monitor the availability of a given node n. The former approach is infeasible because nodes can lie about their own availability, whereas the latter scheme does not generalize easily because in power-law overlays [e.g., Gnutella (2)], higher-degree nodes would have a higher monitoring overhead.

Instead, AVCast's detector says that a node m will monitor another node n if the condition $\text{Hash}(m, n) < K/N$, where Hash is a consistent hashing function with range [0,1], m and n are id's of the nodes, K is a small fixed constant, and N is the approximate system size (a fixed quantity at all nodes). If the actual system size stays within a constant factor of N, each node will have an expected $O(K)$ other *random* nodes that monitor its availability via ping and reply messages. Besides ensuring load balance, this scheme is *verifiable*; any third node can verify (using the hash condition above) if two nodes m and n are in fact related by a monitoring relationship. Thus, it is very difficult for a node n to cheat others either by reporting a higher availability for itself or by colluding with other nodes. Reference (32) describes additional optimizations in the algorithm, where the value of K is changed adaptively—the reader is encouraged to read the paper for details.

Types of Availability History

Although the detectors of the previous sections merely maintained a straightforward history of the availability of a given node n, and calculated its availability as the average of all previous availability-test points (i.e., times at which the availability of the node was explicitly measured), other approaches to *maintaining history* are possible. References (32) and (35) discuss some of these approaches very well in the context of the goal of *availability prediction*, and we describe some below. Notice that most of these history-maintenance schemes can be used orthogonally along with the availability monitoring schemes above. However, we do not discuss integration issues here.

RightNow. This is just the current up/down status of the node.

Aged. Reference (32) uses an aged detector, where the last k availability tests on a node are weighed in an aged manner, with more recent availability tests weighed exponentially heavily compared with older tests. This aged equation is used to estimate the availability probability of node n. This aging rule is similar to the aging-based prediction of run times of tasks in operating systems.

SatCount. In this scheme (35), the availability of a node is marked as one of 4 values (using a 2-bit counter), based on its history. These values are -2 (strongly offline), -1 (weakly offline), $+1$ (weakly online), $+2$ (strongly online). This categorization is based on the results of the past k availability-testing points for node n.

de Bruijn Graph-Based. For each node, the last k points of availability testing are maintained, with the most recent tests being in the lowest significant bits. A left-shift operation is done with each new test. Using this as a basis, a state machine based on a de Bruijn graph can be set up among the 2^k possible availability states for node n (for the *k-bit* availability history). In a de Bruijn graph, each of the 2^k states leads into the two other states obtained by left-shifting it. Reference (35) describes how to predict availability of a node n based on this—either by following the most likely path from the current availability state, or by following multiple paths, or by using a linear predictor (this works best for short-term-stable availability behavior). These techniques are based on digital signal processing approaches. Finally, a hybrid detector combines all the above using an adaptive tournament scheme. Readers are encouraged to read Ref. (35) for more details. Using availability traces collected from two different clusters, the authors showed that in practice, the hybrid detector and predictor work very well for home and office clusters and moderately well for geographically distributed clusters like PlanetLab.

SYSTEM SIZE ESTIMATORS

Finally, we discuss how to detect system-wide properties related to failures. Specifically, we discuss different approaches to solving the *System Size Estimation* problem in large-scale distributed systems. Informally, the problem involves finding the "current" (at initiation time) number of non-faulty processes present in a distributed system, since nodes can join and leave at any point of time. First, notice that an accurate estimate is impossible to achieve—messages have non-zero latencies, and departure or failure of even a single node, immediately after its last message with respect to the estimation protocol, will lead to an inaccurate estimate (and this is very likely to occur in large-scale distributed systems).

Such estimation protocols are extremely useful in many distributed systems, which includes p2p overlays whose design depends on the value of system size N(36,37), nodeID assignment schemes (36), for estimating the latency of lookups in some log(N)—p2p overlays (3,4). Finally, estimated system sizes can be used to monitor and to audit performance of distributed applications, (e.g., on PlanetLab), as well as for dynamic partitioning of Grid applications.

Like our prior detection protocols, we desire our estimation protocols to be scalable, efficient, fault-tolerant, and practical. In addition, increasing the (probabilistic) accuracy is an important goal. The estimation problem comes in two flavors—*one-shot* detection involves a one-time estimation of system size, whereas *continuous* detection involves estimating the system size continuously. Accuracy can be defined as either the root mean square of the error between the estimated system size and the current system size or as the standard deviation of these errors. The former metric measures how *close* the estimate is to the actual size; the latter metric measures how *consistently* the estimated size shadows the actual size.

Protocols for system size estimation come in two varieties—*active protocols* and *passive protocols*. Active protocols must be initiated by a single node and they involve passing messages around inside the group until the initiator receives enough responses or information to draw an estimate. This style of protocol is a one-shot solution, but it can be repeated for a continuous implementation.

Passive protocols, on the other hand, do not involve exchanging any estimation messages actively. Instead, these protocols attempt to *snoop* on messages sent by the application or by a membership protocol (such as the ones discussed in Crash Failure Detectors) to obtain an estimate. By nature, they are continuous estimators.

Below, we discuss a small subset of active and passive estimation protocols. Following the theme of this paper, we choose only protocols that are the most practical, are implemented easily and have the least assumptions to hinder their transition into practice.

Active Estimation Protocols

Bawa et al. and Sample & Collide. Both Bawa et al. (39) and Massoulie et al's Sample and Collide scheme (40) use the birthday paradox to estimate the system size. These protocols initiate a random walk within the distributed system—each node uses its neighbor information (provided by any of the group membership protocols such as the ones discussed in Crash Failure Detectors). If the number of nodes in the system is N, it takes an expected number of $\sqrt{2N}$ steps to get back to a node that was already traversed by the random walk. Based on this, the system size is estimated.

Aggregation-Based Protocols. Several aggregation protocols have been proposed for the distributed system. These protocols calculate the sum, average, min, and max, of a set of values provided by the nodes in the system. Jelasity et al. (41) use one such aggregation protocol to derive an estimation protocol. Basically, once the protocol is initiated, each node keeps an estimate of the current size of the system. At node n, this value is initialized to 1 when the initiating message is received. Periodically, node n exchanges its value with one neighbor chosen at random and replaces its current estimate with the average of these two estimates. The authors of Ref. (41) then show that the estimate converges in time that is logarithmic in the group size. Several other aggregation protocols such as those by Kempe et al. (42) could also be used potentially to derive a system size estimate similarly.

Hops Sampling. This scheme (43,44) involves disseminating a *gossip* message (also called *epidemic* message) into the group and measuring the average latency of the receipt times of this gossip. Because the dissemination latency of a gossip varies logarithmically with the system size, an estimate for the latter can be derived. The basic gossiping model works as follows: when a gossip message is received at node n, this node (once every T seconds) selects a fixed constant number of gossip targets (nodes) periodically at random and sends them copies of the gossip. In addition, the Hops Sampling approach carries the *hopcount* variable (initialized to 0 by the initiating node); when a node n first receives the initiating message, it notes the hopcount, increments it by 1, and then starts to gossip the initiating message with the new hopcount piggybacked on top of it. Finally, after $O(\log(N))$ rounds, the initiating node queries a small subset of nodes in the system to sample their hopcounts, relates this to log(N), and obtains a system size estimate. The latency of this protocol is also logarithmic in the system size.

Comparing the Above Three Approaches. Le Merrer et al. have compared the above three active approaches quantitatively via simulations (45). They found that using aggregation (with estimates over last 50 rounds) provides the best accuracy, whereas Hops Sampling (with the estimate averaged over last 10 runs) provides lower accuracy comparatively. Admittedly, this particular comparison lacks a common baseline across the algorithms (e.g., the number of messages exchanged), but it is clear that Hops Sampling uses significantly fewer messages than aggregation, whereas Sample&Collide uses the least messages and has somewhat middling accuracy. Overall, the comparison does show that these different active protocols define an overhead-accuracy trade-off. This opens the door for the design of adaptive estimation protocols (e.g., try to achieve a given level of accuracy while trying to stay within an overhead budget).

Other Active Estimators. Awerbuch and Scheideler (46) assign special id's to nodes and organize them in a hierarchy to enable estimation. Malkhi and Horowitz (47) use a ring-based algorithm for estimation, however unlike the above schemes this scheme could have a very high error. Finally, several systems have been proposed to estimate the size of p2p overlays [e.g., Stutzbach and Rejaie's crawler-based approach (48)].

Passive Estimation Protocols

Passive protocols for size estimation do not initiate one-shot runs of the protocol. Instead, they snoop on application or membership protocol messages to estimate the system size. Furthermore, this class of protocols enables *each and every node* in the system to have an estimate without restricting this knowledge to a privileged initiating node.

The Interval Density Scheme (44) is one such passive estimation protocol that works by snooping on the messages passed along by a gossip-style membership protocol such as the one by van Renesse et al. (10) (discussed in Crash Failure Detectors). Basically, given a membership protocol (such as Ref. (10)) that enables each node n in the system to eventually (and perhaps quickly) learn information about the id or IP address of each other node joining into, or failing or departing from the system, the node n can estimate the system size *by only remembering a small fraction of these node ids*.

Each node uses a consistent hash function (e.g., one based on SHA-1 or MD-5) to hash a heard-of node IP address into the real interval [0,1]. In a nutshell, node n is interested only in those other nodes whose IP addresses hash into a sub-interval I of the interval [0,1]. If I is of size $O(K/N)$, where K is a constant, and N is the (approximate) system size, then the memory use at node n because of this estimation protocol is merely $O(K)$. Furthermore, using snooping on the gossip-style membership protocol, it turns out that the time for a node join or failure to reflect at the estimate at all other nodes is $O(\log(N))$. Finally, the inventors of this scheme showed that it suffices for K to be $O(\log(N))$ to derive an accuracy of the protocol that goes to 1 as the actual system size increases toward infinity.

Reference (44) describes several ways to adjust both the size and the centerpoint of the interval I at node n so as to obtain an accurate detection—the reader is encouraged to read the referenced paper for more details.

Active vs. Passive Approach. The active Hops Sampling approach was compared with the passive Interval Density scheme in Ref. (43). Both these algorithms are available as part of an open-source software called *Peer-Counter*(44). Overall, if the group size is more or less static, the passive approach yields a better accuracy. If the group size is highly dynamic, the algorithms perform comparably when one considers the root mean square error. However, the passive scheme has better performance w.r.t. the standard deviation of these errors (i.e., it is able to shadow the variation of system size better).

SUMMARY

In this article, we have discussed online detectors for several types of problems in large-scale distributed systems. We have seen (*1*) heartbeat- and ping-based detectors for crash failures, (*2*) implicit and explicit Byzantine failure detectors, (*3*) master-based, group-based and fully distributed availability monitors, and (*4*) active and passive system size estimation schemes. Our focus was on approaches that were practical yet novel at their core. This continues to be a flourishing area of research, which implements ideas in a variety of real systems.

DISTRIBUTED DATABASES

INTRODUCTION

The development of network and data communication technology has resulted in a trend of decentralized processing in modern computer applications, which includes distributed database management. Naturally, the decentralized approach reflects the distributed organizational structure, allows the improved availability and reliability of data, and allows improved performance and easier system expansion.

We can define a *distributed database*(1,2) as a collection of data that belong logically to a single database but are stored physically in several databases over the sites of a network. Two important aspects in the definition of a distributed database exist. First, a distributed database is distributed physically within several databases called *local databases* on different sites of a network; this aspect distinguishes a distributed database from a centralized database. Second, a user may have an illusion that a distributed database is a single database (i.e., a virtual database called a *global database*); this aspect distinguishes a distributed database from a set of networked databases.

The fact that a distributed database is spread physically over several local databases, yet it is viewed logically as a whole brings challenging tasks for a distributed database management system (DDBMS), a software that is used to manage distributed databases. A distributed database system (DDBS) consists of a DDBMS and the distributed databases that it manages. The key issue of a DDBS is the support of *transparency*. With transparency, users may access and update a distributed database through a single *global schema* by using an ordinary query language such as SQL in the same way as they do to a centralized database. Three fundamental tasks must be supported by a DDBS: distributed database design, distributed query processing, and distributed transaction management.

Apart from data distribution, heterogeneity and autonomy are two other aspects of a DDBS. In terms of heterogeneity, a DDBS may be classified as homogeneous or heterogeneous. A *homogeneous DDBS* has identical local DBMSs on all sites, whereas a *heterogeneous DDBS* allows differences in their local DBMSs. Sometimes, local DBMSs of a heterogeneous DDBMS may be of different types: relational, hierarchical, network, and object-oriented. In terms of autonomy, a DDBMS with high autonomy of local DBMSs is called a *federated* DBS (FDBS) or a *mutidatabase* system (3).

Date (4) has listed twelve rules for a DDBMS. They are as follows:

1. Local autonomy. The sites in a distributed system should be autonomous. In this context, autonomy indicates that local data is locally owned, local operations remain purely local, and all operations at a given site are controlled by that site.
2. No reliance on a central site. There should be no single site without which the system cannot operate.
3. Continuous operation. Ideally, a need should never exist for a planned system shutdown.
4. Location independence. The user should be able to access all data from any site as if it were stored at the user's site, regardless of where it is stored physically.
5. Fragmentation independence. The user should be able to access the data, regardless of how it is fragmented.
6. Replication independence. The user should be unaware that data has been replicated. Thus, the user should not be able to access a particular copy of a data item directly, nor should the user have to update all copies of a data item.
7. Distributed query processing. The system should be capable of processing queries that reference data at more than one site.
8. Distributed transaction processing. The system ensures that both transactions at local and global levels conform to ACID properties (i.e., atomicity, consistency, isolation, and durability).
9. Hardware independence. It should be possible to run the DDBMS on a variety of hardware platforms.
10. Operating system independence. It should be possible to run the DDBMS on a variety of operating systems.
11. Network independence. It should be possible to run the DDBMS on a variety of disparate communication networks.
12. Database independence. It should be possible to have a DDBMS that consists of different local DBMSs. In other words, the system should support heterogeneity.

Recently, we have observed the rapid development of Internet technology and the use of XML as a standard for data formatting and exchange on the Internet. The effective management and integration of huge amounts of XML data resources on the Internet brings new topics for distributed database management.

The rest of this paper is organized as follows: Three fundamental tasks of a DDBMS (i.e., distributed database design, distributed query processing, and distributed transaction management) are introduced in the first 3 Sections, respectively. In the next Section, we discuss the problems in FDBSs. In the final Section, we discuss distributed database related research topics on the Web and XML.

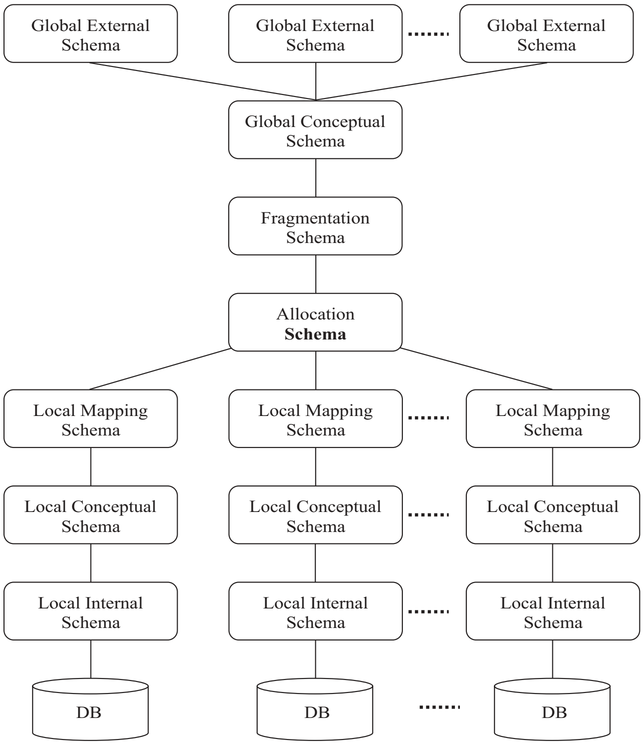

Figure 1. Distributed database architecture.

DISTRIBUTED DATABASE ARCHITECTURE AND DESIGN

The ANSI/SPARC three-level architecture provides a reference architecture for a centralized database. This architecture can be extended for a distributed database as shown in Fig. 1(5). Given that the global virtual database of a distributed database is used by end users, whereas local databases of the distributed database are actually used to store and to manage real data, the architecture only has global external schemas and local internal schemas. The task of distributed database design is to map a global conceptual schema into a set of local conceptual schema. Three steps can be followed, which result in three schemas, fragmentation schema, allocation schema, and local mapping schema. The fragmentation schema describes how global relations are partitioned into subrelations called *fragments*. The allocation schema describes on which site(s) a fragment is placed, which takes into account any replication. The local mapping schema maps fragments of allocation schema into relations in local conceptual schema. The local conceptual schema at each site defines the entire local database at the site, and the local internal schema is a physical level representation of a local database.

Fragmentation

Two types of fragmentation exist: *horizontal* and *vertical*. A horizontal fragment is a subset of tuples, and a vertical fragment is a subset of attributes of a global relation. Two rules must be followed during fragmentation: *completeness*—all the data of a global relation must be mapped into the fragments and *reconstruction*—a global relation must be able to construct from its fragments. For horizontal fragmentation, an additional rule must be followed, which is *disjointness*—no overlapping exits between any two fragments. For vertical fragmentation, the disjointness rule is allowed to be violated because a replicated attribute is required to reconstruct the global relation. The following is global schema with three global relations:

```
SALESPERSON(sid, name, commission, branch)
CUSTOMER(cid, name, address)
ORDER(oid, orddate, totamt, cid, sid)
```

A global relation can be fragmented horizontally into fragments by using a *selection* operation σ and be reconstructed from its fragments by a *union* operation ∪. For example, assume that every salesperson works in either Sydney or Melbourne but not in both branches, then we have the following:

$$\mathrm{SALESPERSON}_{\mathrm{SYD}} = \sigma_{\mathrm{branch}=\text{`SYD'}}\ \mathrm{SALESPERSON}$$
$$\mathrm{SALESPERSON}_{\mathrm{MEL}} = \sigma_{\mathrm{branch}=\text{`MEL'}}\ \mathrm{SALESPERSON}$$
$$\mathrm{SALESPERSON} = \mathrm{SALESPERSON}_{\mathrm{SYD}} \cup \mathrm{SALESPERSON}_{\mathrm{MEL}}$$
$$\mathrm{SALESPERSON}_{\mathrm{SYD}} \cap \mathrm{SALESPERSON}_{\mathrm{MEL}} = \varnothing$$

A global relation can also be fragmented horizonally into fragments that depend on the horizontal fragmentation of another global relation (derived horizontal fragmentation) by using a *semi-join* operation **SJ**. For example,

$\mathrm{ORDER}_{\mathrm{SYD}} = \mathrm{ORDER}\ \mathbf{SJ}\ \mathrm{SALESPERSON}_{\mathrm{SYD}}$
$\mathrm{ORDER}_{\mathrm{MEL}} = \mathrm{ORDER}\ \mathbf{SJ}\ \mathrm{SALESPERSON}_{\mathrm{MEL}}$
$\mathrm{ORDER} = \mathrm{ORDER}_{\mathrm{SYD}} \cup \mathrm{ORDER}_{\mathrm{MEL}}$
$\mathrm{ORDER}_{\mathrm{SYD}} \cap \mathrm{ORDER}_{\mathrm{MEL}} = \varnothing$

A global relation can be fragmented vertically into fragments by using a projection operation π and be reconstructed from its fragments by a natural join operation **NJ**.

$\mathrm{SALESPERSON}_{\mathrm{COMM}} = \pi_{\mathrm{sid,\ commision}}\ \mathrm{SALESPERSON}$
$\mathrm{SALESPERSON}_{\mathrm{DETAIL}} = \pi_{\mathrm{sid,\ name,\ branch}}\ \mathrm{SALESPERSON}$
$\mathrm{SALESPERSON} = \mathrm{SALESPERSON}_{\mathrm{COMM}}\ \mathbf{NJ}$
$\quad \mathrm{SALESPERSON}_{\mathrm{DETAIL}}$

Mixed horizontal and vertical fragmentations may be used for a global relation. Sometimes, a global relation may not need to be fragmented.

Allocation

After the fragmentation step, we have a set of fragments. The problem of allocation is how to distribute this set of fragments to the set of sites such that the distribution is optimal to a predefined set of dominant applications, which can be modeled as a set of retrieval and update references to fragments. Two basic alternatives to allocate fragments exist: *nonredundant* or *redundant*. The former places each fragment into a single site, whereas the latter may place a fragment into multiple sites. The general allocation problem is NP-hard (6). Therefore, the proposed solutions are based on heuristics.

Levels of Transparencies

From Fig. 1, a DDBMS may provide transparencies at different levels, which depend on users' requirement. The highest level of transparency is the fragmentation transparency. At this level, users do not need to know that global relations are fragmented and where the fragments are placed. Therefore, global schema is used for any retrieval and update requests. The middle level of transparency is the location transparency. At this level, users must use fragments specified in the fragmentation schema for any retrieval and update requests. However, users do not need to know the locations of these fragments and how many copies of these fragments exist. The local mapping transparency is the lowest level of transparency. At this level, users must use the allocation schema to specify not only the fragment, but also which copy of the fragment on a given site. The only thing users may not know is how the fragment is represented in the local conceptual schema.

DISTRIBUTED QUERY PROCESSING AND OPTIMIZATION

In a distributed database, a global query is expressed as references to global relations defined in the global schema. A DDBMS must transform this global query into several subqueries; each subquery executes on a local database and then combines the results of subqueries to form the result of the global query (7). The set of subqueries, the queries for combining results of subqueries, and the order for executing these queries constitute a *distributed query execution plan*. For a global query, many such query execution plans exist. The task of the distributed query optimization is to find an optimal plan such that either minimum total cost or minimum response time for executing a global query is achieved. Unfortunately, finding such an optimal plan has been proved a NP-hard problem; therefore, most of the proposed solutions are based on heuristics.

Distributed query optimization is much more complicated than its centralized counterpart. For centralized systems, the primary factor for the cost of a particular execution plan is the cost of local processing. In a distributed system, more factors must be considered.

1. The distribution of data. As global relations are fragmented and allocated, possibly with more than one copy, to several sites as local relations. Much space exists to choose which copy of a fragment to use for a global query. This process is called *materialization*.
2. Communication cost. As data is spread over different sites of a network, data transmission between sites is inevitable. For wide area networks, the speed of data transmission is much slower than that of disk access. As such, communication cost becomes a dominant factor toward the measurement of cost of a global query.
3. Potential parallelism. As subqueries are executed by local DBMSs, it is possible to parallelize the processing of these subqueries, provided they are not dependant in the execution order. As such, performance gain can be achieved by parallelism. Exploring parallelism is especially important if minimum response time is selected as the criterion of optimization.

In addition, accurate database profiles are important to estimate the cost of operations and the size of intermediate relations. A database profile contains statistic information of the databases, such as the size of relations and attributes, the data distribution information, the selectivity of operations such as selection and join, and so on.

Several optimization strategies have been used for distributed query optimization. These strategies include transformation, semi-join based, and join based strategies.

Query Transformation

Rules are available that can be applied to a query (as a expression of relational algebra) to rewrite it into an equivalent expression, (1,8). Let U and B stand for unary and binary algebraic operations, respectively. We may have the following algebraic laws for some relational algebraic operations where R, S, and T are relations.

- Commutativity: $U_1\ U_2\ R \leftrightarrow U_2\ U_1\ R$, $R\ B\ S \leftrightarrow S\ B\ R$.
- Associativity: $R\ B\ (S\ B\ T) \leftrightarrow (R\ B\ S)\ B\ T$.
- Idempotence: $U\ R \leftrightarrow U_1\ U_2\ R$.

- Distributivity: U (R B S) → U(R) B U(S).
- Factorization: U(R) B U(S) → U(R B S).

A query can be represented as an operator tree where the leaf nodes of the tree are relations and nonleaf nodes are operators. Obviously, the operators closest to leaf nodes will be executed first, and the root operator will be executed the last. The objective of query optimization based on equivalent transformation is to find an operator tree with the minimum cost for execution. In centralized databases, heuristics can be used for better performance of queries (e.g., use idempotence of selection and projection to generate appropriate selections and projections for each relation, push selections and projections down in the tree as far as possible).

In distributed databases, a global relation may be fragmented horizontally and/or vertically into fragments, and real data is stored in local relations that represent physical copies of those fragments. Therefore, a global relation in a global query must be replaced as union (horizontal fragmentation) and/or natural join (vertical fragmentation) of fragments. It is always beneficial to reduce the size of fragments before they are transmitted to other sites. Sometimes, while pushing selection down the tree to union of horizontal fragments, a contradictory qualification may be achieved for some fragments, which means no result will be obtained from those fragments. Consequently, those fragments can be removed from the query. Similarly, while pushing projection down the tree to join of vertical fragments, those fragments that do not contain the projected attributes can be removed from the query. To distribute joins that appear in the global query, unions that represent collections of fragments must be pushed up beyond the joins that we want to distribute. Although a join between two global relations with one horizontally fragmented depends the other, only joins between correspondent fragments are needed.

Semi-Join Strategy

A join operation is even more expensive in distributed databases than in centralized ones when data transmission cost is the dominant factor for query optimization. To reduce the cost of a join across sites, it is ideal to reduce the size of operand relations fully. A semi-join operator can be a reducer in most cases. The theory of semi-joins is well defined by Bernstein and Chiu (9).

Let R and S be two relations, in which A and B are the join attributes that belong to R and S, respectively, and **SJ** stand for semi-join, then R $\mathbf{SJ}_{A=B}$ S is a subset of tuples of R, constituted by those tuples that give a contribution to the join of R with S. The benefit of this is that the tuples that are not concerned with join will be filtered out before the real join operation.

A semi-join program for a join between R and S can be done by one of the following strategies:

1. R $\mathrm{JN}_{A=B}$ (S $\mathrm{SJ}_{B=A}$ π_A R).
2. S $\mathrm{JN}_{B=A}$ (R $\mathrm{SJ}_{A=B}$ π_B S).
3. (R $\mathrm{SJ}_{A=B}$ π_B S) $\mathrm{JN}_{A=B}$ (S $\mathrm{SJ}_{B=A}$ π_A R).

If R and S are from different sites and we take the first strategy, then the following program can be used to implement R $\mathrm{JN}_{A=B}$ S.

1. Send π_A R to the site of S.
2. Compute S' = S $\mathrm{SJ}_{B=A}$ π_A R at the site of S.
3. Send S' to the site of R.
4. Compute R $\mathrm{JN}_{A=B}$ S' at the site of R.

The cost of the above semi-join program is the cost of step 1 and step 3, whereas the cost of a join-based algorithm is that of transferring relation S. The semi-join approach is better if size(π_A R) + size(S $\mathrm{SJ}_{B=A}$ π_A R) < size(S), i.e.,

$$\mathrm{size}(\pi_A R) < \mathrm{size}(S) - \mathrm{size}(S\,\mathrm{SJ}_{B=A}\pi_A R)$$

Notice that the right side of the above inequity is the reduced tuples of S. The semi-join approach is better if the semi-join acts as a sufficient reducer (i.e., if a few tuples of S participate in the join). The join approach is better if most of the tuples of S participate in the join, because the step 1 of semi-join requires additional cost.

The semi-join can be useful to reduce the size of the operand relations involved in a multiple-join query. The size of an operand relation may be reduced by more than one semi-join. For example, R in a multiple join query of operand relations R, S, and T can be reduced by R' = R SJ (S SJ T). Such a sequence of semi-joins is called a semi-join program for R. For an operand relation, several potential semi-join programs exist. One of these programs is optimal and it is called the full reducer. Given that the number of semi-join programs is exponential in the number of operand relations, the cost of the full reducer program is sometimes greater than the benefit. In the DDBMS prototype SDD-1, a semi-join based algorithm has been proposed (10) based on a hill-climbing algorithm for centralized query optimization.

Join-Based Strategy

In a DDBS in which data transmission cost is much more expensive than local processing cost, the use of semi-joins can improve the performance of a query significantly. If we also consider the cost of local processing to evaluate alternative execution plans, then the direct use of joins as a query processing tactic is often more convenient than the use of semi-joins. For example, R* query optimization algorithm (11) uses joins rather than semi-joins. It uses a compilation approach in which an exhaustive search of all alternative execution plans is performed to choose one with the least cost. Both data transmission and local processing costs are considered in Ref. 11.

DISTRIBUTED TRANSACTION MANAGEMENT

The objectives of distributed transaction management are the same as those of centralized transaction management [i.e., the guarantee of ACID properties (12–14)]:

Atomicity requires that either all or none of the transaction's operations be performed. In other words, if a transaction fails to commit, its partial results cannot remain in the database.

Consistency requires that a transaction to be correct. In other words, if a transaction is executed alone, it takes the database from one consistent state to another. When more than one transaction is executed concurrently, the database management system must ensure the consistency of the database.

Isolation requires that an incomplete transaction cannot reveal its results to other transactions before its commitment. This function can avoid the problem of cascading abort (i.e., the necessity to abort all the transactions that observed the partial results of a transaction that was later aborted).

Durability means that once a transaction has been committed, all the changes made by this transaction must not be lost even in the presence of system failures.

Two types of transactions we need to consider in a distributed database system are *local* and *global* transactions. A local transaction may access and update data in only one local database, whereas a global transaction may access and update data in several local databases. Thus, a global transaction consists of a set of *subtransactions*, each of which involves data residing on one site. A *transaction manager* at each site ensures ACID properties of local transactions as well as subtransactions at that site. For global transactions, the task is much more complicated, because several sites may be participating in execution. The concurrent global transactions must be serializable and recoverable in the distributed database system. In consequence, each subtransaction of a global transaction must be either performed in its entirety or not performed at all.

Serializability in a Distributed Database

It is well understood that the maintenance of the consistency of each single database does not guarantee the consistency of the entire distributed database. It follows, for example, from the fact that serializability of executions of the subtransactions on each single site is only a necessary (but not sufficient) condition for the serializability of the global transactions. To ensure the serializability of distributed transactions, a condition stronger than the serializability of single schedule for individual sites is required.

In the case of distributed databases, it is relatively easy to formulate a general requirement for correctness of global transactions. The behavior of a distributed database system is the same as a centralized system but with distributed resources. The execution of the distributed transactions is correct if their schedule is serializable in the whole system. The equivalent conditions are as follows:

- Each local schedule is serializable.
- The subtransactions of a global transaction must have a compatible serializable order at all participating sites.

The last condition indicates that for any two global transactions G_i and G_j, their subtransactions must be scheduled in the same order at all the sites on which these subtransactions have conflicting operations. Precisely, if G_{ik} and G_{jk} belong to G_i and G_j, respectively, and the local serializable order is G_{ik} precedes G_{jk} at site k, then all the subtransactions of G_i must precede the subtransactions of G_j at all sites where they are in conflict.

Various concurrency control algorithms such as two phase locking (2PL) (15,16) and timestamp ordering approaches (17,18) have been extended to distributed database systems. Because the transaction management in a distributed database system is implemented by several identical local transaction managers, the local transaction managers cooperate with each other for the synchronization of global transactions. If the timestamp ordering technique is used, a global timestamp is assigned to each subtransaction and the order of timestamps is used as the serialization order of global transactions. If a 2PL algorithm is used in the distributed database system, the locks of a global transaction cannot be released at all local sites until all the required locks are granted. In distributed systems, the data item might be replicated. The updates to replicas must be atomic (i.e., the replicas must be consistent at different sites). The following rules may be used to lock with n replicas:

- Writers need to lock all n replicas, readers need to lock one replica.
- Writers need to lock all m replicas ($m > n/2$), readers need to lock $n - m + 1$ replicas.
- All updates directed first to a primary copy replica (one copy has been selected as the primary copy for updates first and then the updates will be propagated to other copies).

Any one of the above rules will guarantee consistency among the duplicates.

Atomicity of Distributed Transactions

In a centralized system, transactions can either be processed successfully or be aborted with no effects left on the database in the case of failures. Normally, the failures cause loss of volatile or nonvolatile storage data. In a distributed system, however, additional types of failure may occur.

For example, network failures or communication failures may cause network partition, and the messages sent from one site may not reach the destination site. If a partial execution of a global transaction at a partitioned site existed in a network; it would not be easy to implement the atomicity of a distributed transaction. To achieve an atomic commitment of a global transaction, it must be ensured that all of its subtransactions at different sites are capable and available to commit. Thus, an agreement protocol must be used among the distributed sites. The most popular atomic commitment protocol is the two phase commitment (2PC) protocol.

In the basic 2PC, the site where a global transaction is issued serves as a *coordinator*. The participating sites that execute the subtransactions must commit or abort the transaction unanimously. The coordinator is responsible to make the final decision to terminate each subtransaction. The first phase of 2PC is to request from all *participants* the information on the execution state of subtransactions. The participants report to the coordinator, who collects the answers and makes the decision. In the second phase, that decision is sent to all participants. In detail, the 2PC protocol proceeds in two phases for a global transaction T_i (1).

Phase 1. Obtaining a Decision.

1. Coordinator asks all participants to prepare to commit transaction T_i:
   a. add [prepare T_i] record to the log
   b. send [prepare T_i] message to each participant
2. When a participant receives [prepare T_i] message it determines if it can commit the transaction:
   a. if T_i has failed locally, respond with [abort T_i]
   b. if T_i can be committed, send [ready T_i] message to the coordinator.
3. Coordinator collects responses:
   a. all respond *ready*, decision is commit
   b. at least one response is *abort*, decision is abort
   c. at least one fails to respond within time-out period, decision is abort.

Phase 2. Recording the Decision in the Database.

1. Coordinator adds a decision record ([abort T_i] or [commit T_i]) in its log.
2. Coordinator sends a message to each participant informing it of the decision (commit or abort).
3. Participant takes appropriate action locally and replies *done* to the coordinator.

The first phase is that the coordinator initiates the protocol by sending a *prepare-to-commit* request to all participating sites. The *prepare* state is recorded in the log and the coordinator is waiting for the answers. A participant will reply with a *ready-to-commit* message and record the *ready* state at the local site if it has finished the operations of the subtransaction successfully. Otherwise, an *abort* message will be sent to the coordinator and the subtransaction will be rolled back accordingly.

The second phase is that the coordinator decides whether to commit or abort the global transaction based on the answers from the participants. If all sites answered *ready-to-commit*, then the global transaction is to be committed. The final *decision-to-commit* is issued to all participants. If any site replies with an *abort* message to the coordinator, the global transaction must be aborted at all the sites. The final *decision-to-abort* is sent to all the participants who voted the *ready* message. The global transaction information can be removed from the log when the coordinator has received the *completed* message from all the participants.

The basic idea of 2PC is to make an agreement among all the participants with respect to committing or aborting all the subtransactions. The atomic property of global transaction is then preserved in a distributed environment.

The 2PC protocol is subject to the blocking problem in the presence of site or communication failures. For example, suppose that a failure occurs after a site has reported *ready-to-commit* for a transaction, and a global commitment message has not yet reached this site. This site would not be able to decide whether the transaction should be committed or aborted after the site is recovered from the failure. Three phase commitment (3PC) protocol (19) has later been introduced to avoid the blocking problem. But, 3PC is too expensive.

The 2PC protocol is used not only in distributed databases, but also in parallel databases for transactions, which contain subtransactions to be executed in different partitions of a parallel database (20).

FEDERATED DATABASE SYSTEMS

A *federated database system* (FDBS) is a collection of cooperating but autonomous database systems called *component DBSs* that are integrated to various degrees (3). The software that provides controlled and coordinated manipulation of the component DBSs is called a *federated database management system* (FDBMS). A component DBS in an FDBS can participate in more than one federation. A *multidatabase system* (MDBS) differs from an FDBS in that only a single federation schema is defined for a multidatabase. The DBMS of a component DBS, or component DBMS, can be a centralized or distributed DBMS or another FDBMS. Several significant aspects of an FDBS are as follows:

1. Local autonomy. Component DBSs are often under separate and independent control. Those who control a database are often willing to let others share the data only if they retain control. A component DBS can continue its local operations and can participate in a federation at the same time. Normally, no difference to a component DBS exists between a local applications or a global applications at federated levels.
2. Heterogeneity. Usually, component DBMSs are different; they can differ in such aspects as data models, query languages, and transaction management capabilities.
3. Pre-existing distribution. Usually, multiple component DBSs are built before an FDBS is built. Therefore, discrepancy in semantics and conflicts may exist among those component databases.

Schema Architecture and Design

Figure 2 shows a five-level schema architecture of a FDBS proposed by Sheth (3).

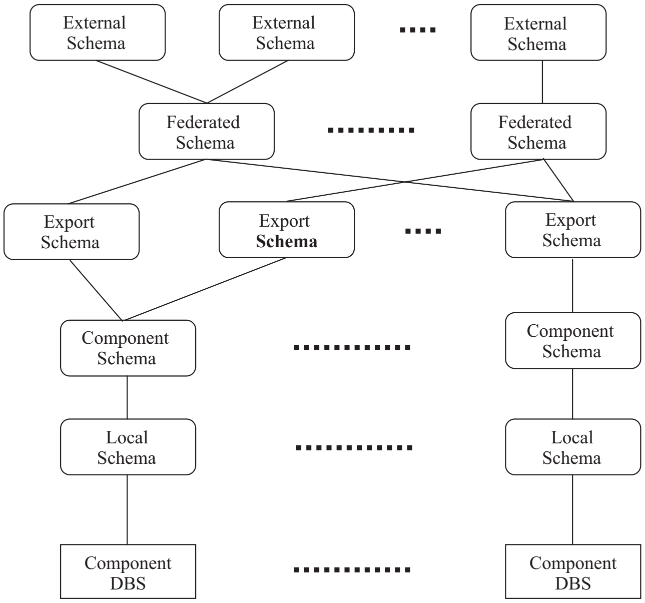

Figure 2. Five-level schema architecture of an FDBS.

- Local Schema. A local schema is the conceptual schema of a component DBS. A local schema is expressed in the native data model of the component DBMS; and hence, different local schemas may be expressed in different data models.
- Component Schema: A component schema is derived by translating local schemas into a data model called the canonical or common data model (CDM) of the FDBS. Two reasons for defining component schemas in a CDM are 1) they describe the divergent local schemas using a single representation and 2) semantics that are missing in a local schema can be added to its component schema.
- Export Schema. Not all data of a component DBS may be available to the federation and its users. An export schema represents a subset of a component schema that is available to the FDBS. It may include access control information regarding its use by specific federation users. The purpose of defining export schemas is to facilitate control and management of association autonomy.
- Federated Schema. A federated schema is an integration of multiple export schemas. A federated schema also includes the information on data distribution that is generated when integrating export schemas. Some systems use a separate schema called a distribution schema or an allocation schema to contain this information. Multiple federated schemas may exist in an FDBS, one for each class of federation users. A class of federation users is a group of users and/or applications who perform a related set of activities.
- External Schema. A subschema or a view defined over a federated schema primarily for a pragmatic reason of not having to define too many federated schemas or to tailor a federated schema for smaller groups of federation users than that of a federated schema.

As component databases normally pre-exist in a FDBS, we can take a bottom-up design approach for federated databases. This approach is in contrast to the top-down design approach discussed in a previous section. The major tasks of the bottom-up design are schema translation and schema integration.

Schema Translation. As local schemas of different component databases may be defined in different data models, the specification of a CDM for defining federated schemas is required. Relational data model and object-oriented data model are often chosen as a CDM. Mapping rules must be studied between data models (e.g., relational model, DBTG or network model, hierarchical model, object-oriented model, and more recently XML data model).

Schema Integration. After schema translation, component schemas are generated for component databases. After that, export schemas are generated from component schemas for integration to different federated schemas. Four steps can be followed for schema integration.

- Pre-Integration. Pre-integration is required to establish the *rules* of the integration process before actual integration occurs. For example, candidate keys in each schema must be identified; equivalent domains of attributes must be described in terms of mappings from one representation to another.
- Comparison. During this phase, both the naming and the structural conflicts are identified. Naming conflicts include *synonym* (two identical entities or attributes with different names) and *homonym* (two different entities or attributes with the same name). Structural

conflicts include 1) *type conflicts*: the same object is represented by an attribute in one schema and by an entity in another, 2) *dependency conflicts*: different relationship types are used to represent the same thing in different schemas (1:m vs m:n), 3) *key conflicts*: different candidate keys are available and different primary keys are selected in different schemas, and 4) *behavioral conflicts* are implied by the modeling mechanism (e.g., deletion of the last employee causes the dissolution of the department).

- Conformation. Conformation is the resolution of the conflicts that are determined at the comparison phase.
- Merging and Restructuring. All schemas must be merged into a single database schema and then restructured to create the best federated schema.

Global Query Processing and Optimization

In a loosely coupled FDBS, the FDBMS can support little or no query optimization. In a tightly coupled FDBS, the FDBMS can perform extensive query optimization. Query processing involves converting a query against a federated schema into several queries against the export schemas and executing these queries. Query processing in an FDBMS is similar to that in a distributed DBMS. In an FDBMS, however, several additional complexities may be introduced because of heterogeneity and autonomy. The cost of performing an operation may be different in different component DBSs. The component DBMSs may differ in their abilities to perform local query optimizations. The system and database operations provided by each of the component DBMSs and the FDBMSs may be different. Landers and Rosenberg (21) discuss optimization problems and solutions adopted for some of the above issues in Multibase.

Global Transaction Management

Supporting global transaction management in an environment with multiple heterogeneous and autonomous component DBSs is very difficult. The challenge is to permit concurrently global updates to the underlying databases without violating their autonomy. Two types of transactions to be managed exist: *global transactions* submitted to the FDBMS by federation users and *local transactions* submitted directly to a component DBMS by local users. The basic problem in supporting global concurrency control is that the FDBMS does not know about local transactions because a component DBMS is autonomous. That is, local wait-for relationships are known only to the transaction manager of the component DBMS. Without knowledge about local as well as global transactions, it is highly unlikely that efficient global concurrency control can be provided. Because of the existence of local transactions, it is very difficult to recognize when the execution order differs from the serialization order at any site (22). Additional complications occur when different component DBMSs and the FDBMS support different concurrency control mechanisms (23). Georgakopoulos et al. (24) proposed to incorporate additional data manipulation operations on *tickets* in the subtransactions of each global transaction and show that if these operations create direct conflicts between substransactions at each participating component DBS, indirect conflicts can be resolved even if the FDBS is not aware of their existence. However, all the published solutions often make unrealistic and pessimistic assumptions, or support a low level of concurrency or sacrifice autonomy to obtain higher concurrency. It is unlikely that a theoretically elegant solution exists that provides conflict serializability without sacrificing performance (i.e., concurrency and/or response time) and availability.

Work on weaker consistency criteria (25) and advanced transaction models (26) provide techniques to specify and to execute transactions that provide ACID properties selectively. A concept of *S-Transactions* (27) is proposed for semantic transactions suited for a banking environment that consists of a network of highly autonomous systems. It may be desirable to devise solutions that do not meet the conflict serializability criteria but that are practical and meet a desired level of consistency. Du and Elmagarmid (22) propose a weaker consistency criterion called *Quasi Serializability* that works if no value dependencies (e.g., referential integrity constraints) exist across databases. Garcia-Molina and Salem (28) propose a concept of *Sagas* that provides semantic atomicity but does not serialize execution of global transactions.

THE WEB AND DISTRIBUTED DATABASES

The last decade has seen the emergence of the Web as the central forum for data storage and exchange. More recently, XML has been proposed as a standard for data exchange and storage. Compared with the relational data model, the de facto standard for database systems and its structural primitives for building trees of elements with attributes offer much more flexibility in data organization and format. The Web and XML provide many avenues for database researchers. The Web bears a similarity to a bottom-up designed federated database in terms of intergrating structured data sources from different websites; however, the Web is much more loosely coupled. In the following, we address two areas that are relevant to distributed databases.

Information Integration on the Web

Data integration is a pervasive challenge faced in applications that need to query across multiple autonomous and heterogeneous data sources (29). Data integration is crucial in large enterprises that own a multitude of data sources. Integrating information from data resources over the Internet requires creating some form of integrated view to allow for distributed querying. The context of the Internet raises several issues for information integration that are far more difficult than those of multidatabase systems (3). First, the number of data sources may be very high, which makes view integration and conflict resolution a problem. Second, the space of data resources is very dynamic, so adding or dropping a data source should be done with minimal impact on the integrated view. Third, the data sources may have different computing capabilities, which range from full-featured

DBMS to simple files. This feature is unlike multidatabase systems, which assume data sources with an SQL-like interface. Finally, data sources may be unstructured or semi-structured, which provides virtually no information for view integration. To address these problems, the database research community has revisited the multidatabase architecture (i.e., the architecture of a FDBS with a single federation schema) with data source wrappers and mediators. For each data source, a wrapper exports some information about its source schema, data, and query capabilities (30). For the whole integration system, a mediator centralizes the information provided by the wrappers in a unified global view of all available data, decomposes global queries into subqueries executable by wrappers on data sources, and gathers the partial results and computes the answer to the global queries. This wrapper–mediator architecture differs from a data warehouse in that integrated global view is not materialized.

Two basic approaches exist in data integration, GAV and LAV (31–33). These two approaches have also been used in the context of data integration on the Web. GAV (Global As View) defines a global schema as a view over a set of source schemas, whereas LAV (Local As View) defines source schemas as views over the global schema. GAV has been used in FDBSs and multidatabase systems, in which the quality depends on how well we have compiled the sources into the global schema through mapping. Whenever a source changes or a new source is added, the global schema must be reconsidered. Query processing can be based on some sort of rewriting. Each element in the user's query corresponds to a substitution rule just as each element in the global schema corresponds to a query over the source. Query processing is simply expanding the subgoals of the user's query according to the rule specified in the mediator, and thus the resulting query is likely to be equivalent. LAV has high modularity and reusability. Once the global schema is well designed, changes on a source only affect the definition of the source. The quality depends on how well we have characterized the sources. In LAV systems, queries undergo a more radical process of rewriting because a mediator does not exist. The integration system must execute a search over the space of possible queries to find the best rewrite. The resulting rewrite may not be an equivalent query but maximally contained, and the resulting tuples may be incomplete.

Recently, *Semantic Web* (34) has attracted great attentions from both research communities and standard organizations. Semantic Web is supposed to be an extension of the Web where the semantics of data is available to and processable by machines. At the core of this new technology are the languages that are used to describe the semantics of XML documents and ontology, such as RDF, DAML+OIL, and OWL. Ontology can be used to define global schemas, which makes information integration on the Web easy.

Publishing Relational Data on the Web

Although XML is emerging as the universal format to publish and to exchange data on the Web, most business data is still stored and maintained in relational database systems. As a result, an increasing need exists to publish relational data efficiently as XML documents for Internet-based applications. One approach to publish relational data is to create XML views of the underlying relational data. Through the XML views, users may access the relational databases as though they were accessing XML documents. Once XML views are created over a relational database, queries in an XML query language like XML-QL or XQuery can be issued against these XML views for the purpose of accessing relational databases. SilkRoute (35) is one of the systems that takes this approach. In SilkRoute, XML views of a relational database are defined using a relational to XML transformation language called RXL, and then XML-QL queries are issued against these views. The queries and views are combined together by a query composer and the combined RXL queries are then translated into the 1corresponding SQL queries. XPERANTO (36) takes a similar approach which uses XQuery for user queries. DTD directed publishing is introduced in Ref. 37 where an attribute translation grammar (ATG) is designed to creating XML views of relational databases. Another approach (38) to publish relational data is to provide virtual XML documents for relational data via an XML schema that is transformed from the underlying relational database schema such that users can access the relational database through the XML schema. In this approach, the process of XML schema generation preserves integrity constraints of the underlying relational schema, which makes a difference compared with the view approach taken by SilkRoute.

DISTRIBUTED FILE SYSTEMS

INTRODUCTION

A distributed file system, also known as a network file system, is a means for to access data transparently across a network. A user should not have to know whether a file actually resides locally or on a remote server. In the typical distributed file system architecture in Fig. 1(a), a client uses the same standard file system calls that are translated into network requests at runtime. If the access to remote data is not transparent, a client might have to retrieve explicitly a file locally, make modifications, and then move explicitly the file back to the server as in Fig. 1(b).

Distributed file systems are a broad topic in computer science. We have organized our discussion into four distinct areas. We begin by focusing on high availability techniques that improve uptime and provide support for mobile or disconnected operation. Then, we closely examine closely several protocol standards for compatibility and implementation-independent optimizations. The next section describes several distributed file systems that are tuned for high-performance computing (HPC) applications. Finally, we discuss several distributed file systems that have application-specific features.

HIGH AVAILABILITY

Users who need reliable and distributed access to files across various networks (i.e., university campuses and large companies) use “highly available” distributed file systems. Distributed file systems with high availability can be characterized generally by a fair degree of fault tolerance: addressing client, network, and server failures. Files must be accessible easily to users from multiple locations, and although concurrent, or near concurrent, writing to shared files is rare, reading shared files is vital for collaboration. Data availability is critical to virtually every organization. Typical techniques include both replication and logs. Industry demand for highly available distributed file systems has resulted in a plethora of proprietary solutions.

The serverless approach to highly available storage bears a striking resemblance to peer-to-peer systems. Although high availability may be the most high profile goal, any production read-write file system must address security.

The Network File System (NFS) and Common Internet File System (CIFS) are described in the next section from a design and protocol perspective. The file systems themselves do not address high availability explicitly. Availability is left to proficient system administration and fault tolerant storage techniques.

In this section, we focus on the Andrew file system (AFS), Coda, and a few serverless file systems.

Andrew File System

The Andrew File System (AFS) (1,2) was started at Carnegie Mellon University as part of the Andrew distributed computing environment. It has gone through three iterations: AFS-1, AFS-2, and AFS-3. The primary focus of AFS is scalability: namely across many client workstations in a large institution. In AFS, a pool of trusted file servers are known collectively as *Vice*. Clients, who each run a *Venus* process, are untrusted and must have local disks. The benefit of this security model is that administrators need to worry about only a small percentage of the entire system. Users are aware of only directory structure, and not of physical location of files. This transparency is not only important to interactive users, but to user applications as well.

AFS-1 was a pilot vehicle for the basic AFS architecture, and it was used for only about a year. Local caching is done at the file granularity, and client-side cache coherence is handled in a very simplistic but inefficient manner. Before any locally cached version of a file can be used, the client first verifies its validity with Vice. Although cached copies of files can be read and written, updates to cached directories go to the servers directly.

AFS-2 is built on the lessons learned with the deployment of AFS-1 as well as additional performance evaluations. Notable changes were made to cache management, the global name space, and the server design.

Effectively, caching entire files is a prefetching technique, and it is proved beneficial, if not vital, to performance. AFS-2 introduced the *callback*, an explicit agreement made between a client and server when a client first caches some given data. A callback allows servers to notify actively the appropriate clients when their cached data becomes invalid. Until then, a client will assume that the particular cached data is still safe. In AFS-2, callbacks reduce the validation traffic significantly. Updated data is passed to the servers on file close.

AFS-2 also adopted the notion of *volumes*. Volumes consist of a set of files that form partial subtrees in Vice. Collectively, all the volumes in Vice form the entire file system name space. The typical division of volumes is about one volume per user. Volumes can be archived easily and migrated to different servers.

AFS-3 is focused on administrative improvements, but it is worth noting that Venus was moved into kernel space, which allows it to cache data 64KB at a time. Caching data at a finer grain than entire files improves latency and allows operation on very large files that do not otherwise fit on the client disk. The task of administering AFS-3 is decentralized using *cells*. Cells are composed of servers, clients, system administrators, and users. Multiple cells can coordinate to aid collaboration between sites.

AFS-3 was adopted for commercialization by Transarc, and they were bought subsequently by IBM. IBM then branched and opened the code as OpenAFS. The AFS-2 design became the starting point for the Coda file system.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

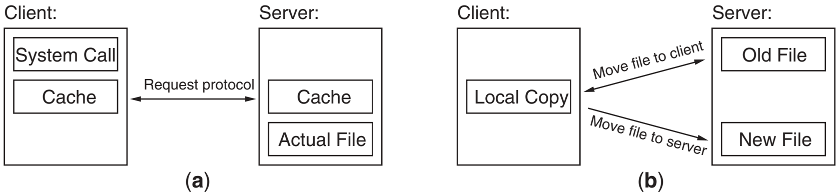

Figure 1. (a) Typical distributed file system access. (b) Explicit remote file access (for example, through FTP).

Coda

Coda (3,4) is based on the AFS-2 design with several major differences. This close relationship is clear in Table 1. AFS-2 was subject to debilitating failures if any server crashed. Coda addresses server failure with server replication. Disconnected operation in Coda is treated as a temporary state, but it can be tolerated for an extended period of time.

In Coda, a volume is replicated on multiple servers that compose a *volume storage group* (VSG). Reads are done from a single replica, and updates are performed on all copies. The subset of servers in the VSG that is accessible makes up the accessible VSG (AVSG). On a cache miss, all the servers in the AVSG are contacted, and the most recent data from one of the servers is cached. Any servers with stale data are also notified.

Two contexts exist for disconnections: brief temporary failures and extended disconnections. Because Coda already caches entire files on the client, disconnected operations are relatively easy: One just needs to ensure that the appropriate files are cached before they are remove from the network. During disconnected operations, any cache miss cannot be resolved. For brief, unintentional disconnections, the regular LRU cache policy may suffice and cache misses may be avoided. Extended disconnections may be the result of more severe failures in either the network or the servers, or it may also be the result of a mobile device that is disconnected intentionally. For longer disconnections, the LRU policy will not likely be sufficient to avoid cache misses. To this end, Coda provides the user with a mechanism to prioritize files and directories for caching.

Disconnected operation in a distributed system entails implicitly some mechanism for reconnection. As soon as the AVSG is available again, updates are pushed upstream. If no conflicts exist because of modifications by other clients, this process is completely transparent. Any files and directories without conflicts are simply updated, and Coda provides tools for users to resolve and to update conflicts.

Intermezzo (5) later sought to replicate the benefits and useful features of Coda with a simpler ground-up implementation.

Serverless File Systems

Serverless file systems make no distinction between client and server nodes. Separate client and server processes may exist, but no real technical restrictions exist on what machines they might run on. Because of this, the security and administrative models are different from those of AFS and its derivatives. Some common trends in serverless file systems are leveraging routing/storage systems as well as using versioning or logs to store immutable file modifications. This basic design is illustrated in Fig. 2. The separate routing and storage systems can be optimized independently to exploit locality, load balancing, and other low-level aspects involved with storage. Salient characteristics of several serverless file systems are compiled in Table 2.

OceanStore (6,7) is an ambitious wide-area storage system built on fundamentally untrusted servers. The OceanStore prototype, Pond features "location-independent routing, Byzantine update commitment, push-based update of cached copies though an overlay multicast network, and continuous archiving to erasure-coded form (8)." Nodes in OceanStore are not symmetric, but they are tiered. The unit of storage in OceanStore is the *data object*; this corresponds to a file in Pond. Data objects are versioned completely, so data is never modified in-place or deleted. The stream of versions for a particular object is called an *active global unique identifier* and each version is called a *version global unique identifier* (VGUID). Only the "delta blocks," or changes, of subsequent VGUIDs are stored. Versioning allows atomic updates, simpler replication, and easy rollback to earlier versions of data. The *inner ring*, a small group of coordinated servers, manages updates to data objects and has the final say on the *primary replica* for an object. Although the inner ring need not be trusted explicitly and it is designed to be fault tolerant to a

Table 1. A comparison of AFS-3 and Coda

Category	AFS-3	Coda
Dedicated servers	Yes	Yes
Consistency semantics	Session	Transactional

Caching	Client disk chunked	Client disk file-level
Fault tolerance	Local disk cache	Local disk cache /Hoarding
Replication	Manual	ROWA volume replication
Security	Needham-Schroeder	Needham-Schroeder

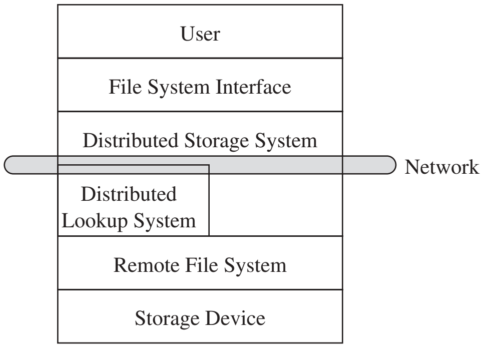

Figure 2. Typically, are serverless file systems composed of a file system interface, a distributed storage system, and a distributed lookup system.

degree, it should be composed of fairly reliable, well-connected servers. The underlying blocks are stored as cryptographically-secure hashes. Object location and routing is handled by a scalable overlay network called Tapestry (9). Unlike distributed hash tables, Tapestry can store data blocks anywhere because hosts publish the GUIDs of their resources. With this flexibility, Tapestry can shuffle data for better locality and lookup performance. OceanStore uses replication primarily for performance purposes. For archiving, OceanStore uses erasure codes to store blocks. New blocks are erasure-coded and distributed across OceanStore servers. Because reconstructing data from erasure-coded blocks can be expensive, frequently used whole-blocks are cached. User applications can access secondary replicas of data, but updates are also sent directly to the primary replica as well as a few random secondary replicas. The secondary replicas then propagate the updates amongst themselves epidemically. When the inner ring commits the update, the commit signal is multicasted to the appropriate secondary replicas.

The Cooperative File System (CFS) (10) is a peer-based read only file system built on the Chord (11) distributed hash system and Self-certifying File System (SFS). File blocks are distributed and balanced across clients using Chord to maintain their locations. For increased availability, CFS uses block-level replication across nodes.

Ivy (12) was designed subsequently with read and write capabilities. Writes are log based, and each client updates its own log records. The log records themselves are distributed using Chord. File modifications become visible at least upon closing the file. Reads are done from all clients' logs. To aid performance, clients cache recent copies of the file system state. Essentially, the clients' combined logs for a particular file make up the file. A special *view* block maintains the appropriate log-heads globally for each client that is part of the entire file system. The view itself cannot change once the participating nodes have been established for an Ivy file system. To add or remove a node, the nodes must coordinate explicitly to create a new Ivy file system. If nodes become partitioned, operations continue without any consistency guarantees. Ivy relies on the replication mechanisms within Chord for availability. Upon reconnection, Ivy retains all updates because of its intrinsic log design, but the user or application must use the provided tools to detect and resolve any atomicity issues.

Like Ivy, Frangipani (13) is also built over a distributed storage system, in this case, Petal (14). Also similar to Ivy, Frangipani derives features such as scalability and fault tolerance from Petal. Frangipani itself is intended to run within a single administrative umbrella; consequently, implicit trust exists between nodes. The Petal interface provides a distributed virtual disk image that is actually made up of some number of Petal servers, each of which may contain multiple disks. Petal allows for easy addition and removal/crashes of Petal servers, which makes these events transparent to Frangipani. Petal servers need not be dedicated machines, and they can be run on users' machines. Although Petal provides a disk-like interface, Frangipani hides Petal with a more user-friendly file system interface. User programs access Frangipani files through a virtual file system mechanism and a locally running Frangipani file server module. Alternatively, a Frangipani server process can be described as a local daemon on the "client" machine that only provides services to the local user. The "server," in the sense that it is across the network, is the Petal virtual disk. Frangipani accesses file data directly on Petal, but each Frangipani server maintains its own log of pending metadata changes also on the Petal disk. If a Frangipani server crashes, its log can be used by another Frangipani server to recover. Frangipani itself, however, does not log file updates, only metadata updates. By design, Frangipani servers do not communicate directly with each other, which makes additions, removals, and tolerance more simple.

Table 2. A comparison of serverless high-availability file systems

Category	OceanStore	Ivy	Frangipani	Pastis
Dedicated servers	No	No	No	No
Consistency semantics	POSIX	Close-to-open	Metadata	Close-to-open
Consistency enforcement	Single *primary replica*/Inner ring	Versioning	Locking/leases	Global timestamp
Caching	Client disk (Shared) block-level	Client memory Block-level	Client memory Sector-aligned chunks	Client disk file-level
Fault tolerance	Erasure-coded versioning	DHash - temporary partitioning	Automatic recovery	Pastry - node addition & failure
Replication	Two-level block	DHash	Petal option	*k* copies
Security	Cryptographically-secure hash	Self-certifying	Trusted hosts	Smartcard

The Pastis (15) file system is layered very similarly to Ivy. It is built on the PAST (16) peer-to-peer storage service, which in turn uses Pastry (17), a fault tolerant and self-organizing routing system based on a distributed hash table. PAST itself ensures high availability through replication. Pastis is structured internally similar to traditional file systems, and it uses its own *inodes* stored in PAST. Like Frangipani, Pastis operates on a block abstraction. File updates in Pastis are also nondestructive because PAST blocks are immutable.

PROTOCOL STANDARDS AND RELATED OPTIMIZATIONS

Several distributed file system protocols have been established to ensure vendor and enterprise interoperability. A partial list of distributed file system protocols includes the Common Internet File System, the Apple Filing Protocol, the NetWare Core Protocol (NCP), and the Network File System (NFS). We direct our discussion towards the two most pervasive protocols in use today: NFS and CIFS.

Network File System

NFS was developed by Sun Microsystems to provide transparent file access in a networked, distributed environment. Since 1989, NFS has been an internet engineering task force standard protocol (18–22). The most popular revision currently in use is NFS version 3. It is implemented on a variety of operating systems and provides file sharing among a collection of heterogeneous computers. To improve performance in the broader Internet environment, a major revision of NFS, version 4, has been defined to integrate several new or improved features, such as file locking, security, operation coalescing, and file delegation (23–25).

NFS consists of two components, namely client-side and server-side systems. Figure 3 demonstrates how NFS components interact. The client-side systems process local user requests for files stored at a remote server. All client–server communication is handled with remote procedure calls (RPCs). RPCs allow programs on a local machine to initiate procedures on remote machines. When a local process calls a procedure on a remote machine, the calling process is suspended, and instructions to run the procedure are sent over the network to the remote machine where the procedure is executed. The execution results are transported back over the network to the caller process. The client-side system uses RPCs to transmit user requests to remote NFS servers. The server is responsible to carry out the requested file operations and to send the results back to the client to conclude the RPC call. NFS version 4 introduces compound RPC procedures that enable the encapsulation of related operations into a single RPC, which creates new opportunities for better I/O (input-output) performance.

File System Model. In the NFS model, files and directories are organized as a hierarchical tree graph in which internal nodes and leaves represent directories and files, respectively. An NFS server makes a local directory available to clients by *exporting* that directory. Directories from different locally mounted file systems can be exported. An NFS client mounts the exported directories to its local file system so that user processes on the client machine can access the NFS mounted directories as if they are part of the local file system. To access a file, a client must first look up the filename and obtain the associated file handle from the server. A file handle is unique to all file systems exported by the same server. Each file contains the attributes *fsid* and *fileid* to identify a file system uniquely on a server and the file/directory within that file system. Other attributes include permission modes, owner ID, group ID, file size, last access time, and last modification time, last metadata modification time.

Client Caching and File Locking. In NFS version 3, servers are not required to preserve any client file access state. The stateless approach eliminates the need to recover client state after a server crash. An NFS version 3 server does not need to record which clients have open files. When a client accesses a file, the RPC request provides all the necessary information such as file ID and the current offset for the server to function correctly. This stateless approach has been abandoned in version 4 to adapt to the modern wide-area network environment. In particular, the new client-side caching and file locking protocols enable more effective use of cached data and efficient cache consistency control. Although client-side file caching is left out of the NFS version 3 protocol, many implementations make extensive use of caching to improve performance. Because version 3 is stateless, caching is performed independently on the clients, and servers retain no clients' caching state. Data cached on clients can be stale without the server knowing. Some implementations allow cached data to be stale for up to 30 seconds. Cache coherence is left to application developers to enforce. The most common approach uses a separate lock manager, such as the network lock manager protocol (NLM), to provide advisory locks. Unlike mandatory locks, an advisory lock does not block other applica-

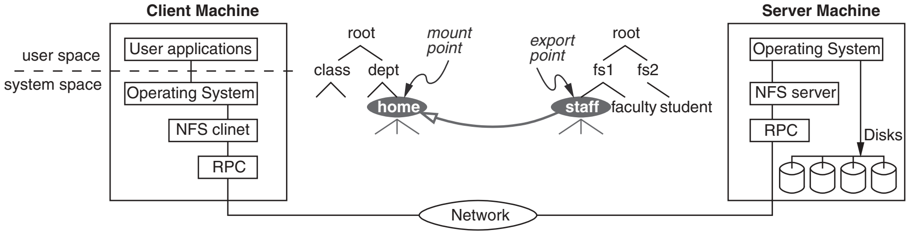

Figure 3. An illustration of the general NFS components and their interaction.

tions forcibly from accessing a locked file region. Advisory locks are only useful between cooperating processes.

NFS version 4 integrates a caching protocol and supports weak coherence. Because data can be cached in client memory and/or a server's local disk cache, the new cache protocol requires that dirty data is flushed to the server when the file is closed. The cached file data can remain in the client's memory after the close, but it must be revalidated if the file is opened again by any process on the particular machine. This close-to-open consistency is sufficient for many applications and users. A new open delegation protocol is designed to address the common situation where a file is accessed by a single client. *Delegations* allow the server to shift responsibility for a file's opens, closes, and locking operations to a client. This action eliminates the server validation costs for operations on a file from different processes that reside on the same client. The delegation state of a file is recorded on the server. When a process on a different client machine requests access rights to the same file, the server must either deny the request or recall the delegation. The revocation is accomplished with an RPC callback to the client. Callbacks are another difference between version 4 and version 3 in that RPCs are only initiated by clients in version 3. The NFS version 4 locking protocol is similar to NLM, but it introduces leases for lock management. During a lease time interval, the server denies the lock requests from other applications. To prevent the removal of a granted lock, a client must renew its lease before it expires.

Fault Tolerance. In NFS version 3, recovering from a server crash is very simple because no state exists to lose. A client is not aware of a server crash and will retry its request until the server responds. In version 4, however, it is essential to recover the state stored at the server after a system reboot because clients rely on the stateful locking protocol to access safely cached data locally. A grace period equal in duration to the lease period is executed at the server after reboot to allow clients to reclaim locks. During the grace period, the server must reject read, write, and nonreclaiming locking requests. Lock recovery from a client crash is simpler. Because a lock is leased with a time constraint, the server removes the lock when it is expired. After reboot, a client needs to request the lock again. Although important, lock recovery is different from data recovery. If a file has been delegated to a client and that client crashes with dirty data, the data is lost.

NFS version 4 handles RPC recovery from a network partition by introducing a duplicate request cache at the server. A client inserts a unique transaction ID in each RPC request and the server caches the ID to identify duplicate requests from a client during retry requests after a time out. The results of a file operation are also stored in the cache in case the server response was lost. Thus, the server can retrieve the cached results for retransmission without duplicating the requested actions.

Security. NFS version 3 only covers the user authentication and file access permission check. Because NFS is built on top of the RPC protocol, authentication is established on two RPC authentication parameters: a credential and a verifier. If an NFS implementation chooses not to implement authentication, these two parameters are ignored. The protocol defines three types of authentication, and a server may support several different flavors of authentication at once. The first is UNIX-style authentication in which a client passes the user ID, group ID, and groups to the server and the server checks the permission rights for file access. This method relies simply on the security at the client machine, because it assumes all users have passed the client security check. The second uses DES-encrypted host names and session keys exchanged between clients and servers via a public key scheme. The third also uses the DES-encrypted method, but it functions instead with Kerberos secret keys.

One of the NFS version 4 goals is to use a strong security protocol for a wide-area network environment. It supports not only authentication, but also message confidentiality through cryptography. NFS version 4 employs the RPCSEC_GSS security framework, which is based on the Generic Security Service API. This framework allows for the use of various security mechanisms at the RPC layer. RPCSEC_GSS can perform integrity checksums and encrypt the entire RPC request and response. NFS version 4 also requires RPCSEC_GSS to support Kerberos version 5 and LIPKEY public-key mechanisms.

Common Internet File Systems

Since the 1990s, use of the Internet and the World Wide Web can be characterized primarily by read-only access. The most popular examples are the web browsing in HTTP and document transfer in FTP. As the Internet continues to increase in bandwidth and in availability, the demand to share files with both read/write permissions increases. The Common Internet File System (CIFS) proposed by Microsoft, defines a distributed file system protocol to enable document sharing over a wide-area network (26). Although CIFS is based on the file system developed for Windows operating systems, the protocol is platform-independent. CIFS is derived from the standard server message block (SMB) protocol (27), an Open Group standard for personal computers and UNIX interoperability since 1992.

CIFS uses TCP/IP for client–server communication and the Internet domain name service (DNS) to resolve server IP addresses. A uniform resource locator address is used to identify a file at a remote server. Clients parse the URL character string to separate the server host name and the file location within that server. The SMB message format is used to communicate between clients and servers. An SMB message header contains the command code, error code, directory ID, caller process ID, user ID, command parameters, and data buffer.

Security. The CIFS protocol requires server authentication for users before file accesses are allowed, and each server authenticates its own users. A client system must send authentication information to the server to gain access to its resources. A CIFS server keeps an encrypted form of a client's password using DES encryption in block mode. Two methods are defined and can be selected by the server for security: share level and user level.

Table 3. A comparison of NFS and CIFS file systems

Category	NFS v3	NFS v4	CIFS
Dedicated servers	Yes	Yes	Yes
Consistency semantics	Close-to-open	Close-to-open	POSIX
Consistency enforcement	NLM	Leased lock protocol	Opportunistic lock protocol
Caching	—	Client memory	Client memory
Fault tolerance	Stateless servers	Grace period at reboot	Grace period at reboot
Replication	—	Alternative locations	—
Security	RPC authentication	RPCSEC_GSS	DES encryption

At the share level, an optional password may be required to gain access to an available resource at the server. To access the resource, a user must know the name of the server, the location of the resource on that server, and the password. Share level security servers may use different passwords for different levels of access.

A user-level server requires clients to provide a user name and a corresponding user password to gain access to the resource. Hence, different levels of access for the same resource can be set for different users. When a client's authentication is validated, the server will generate and return an identifier to represent that authenticated instance to the client in the user ID field of the response SMB message. This user ID must be included in all additional requests made on behalf of the user from that client. In contrast, a share level server does not set the user ID field in the returning SMB message.

Client Caching and File Locking. A CIFS implementation is expected to use client-side file caching to enhance network performance. The protocol supports both read-ahead and write-behind file caching. Three types of opportunistic locks are defined for cache coherence control. An exclusive lock allows a client to open a file for exclusive access, a batch lock allows a client to keep a file open on the server even if the local user on the client machine has closed the file; and a level II lock indicates that there are multiple readers of a file and no writers. When a client opens a file, it makes a request to the server for a particular type of lock on the file. The response from the server indicates the type of lock granted to the client. The client uses the granted lock type to adjust its caching policy.

An exclusive lock is intended for single client access to a file. It provides optimized file access by allowing the client to work on a local copy of the file. When a second client requests to open the same file, the server will break the lock granted to the first client. In breaking an exclusive lock, the former lock possessor must flush its dirty data to the server and purge read-ahead data.

Batch locks are useful particularly in a slow network environment. For a sequence of commands that involve repeated open and close operations to the same file, batch locks allow the client to skip the extraneous open and close requests. If the server receives either a rename or a delete request for the file that has a batch lock, it must inform the client who has possession of the lock that it will be broken. The client can then switch to a mode where the file will be opened and closed. When a batch lock is broken, the client must flush its dirty data and synchronize with the server. Most of the time, this process involves closing the file. Once the file is closed, the open request from the initiating client may be completed.

Level II locks are used to protect shared files for read-only operations even though the files are opened in read-write access mode. Multiple clients can be granted level II locks to the same file if no client writes to the file. When a client holds an exclusive lock on a file and another client opens subsequently the same file, the exclusive lock held by the first client is broken and downgraded to a level II lock. After the first client synchronizes its cached data with the server, a level II lock is granted to the second client. The level II lock may be broken if any of the clients write to the file. Once the level II lock is broken, all file requests must be executed on the server across the network.

CIFS opportunistic locks are somewhat similar to the NFS file delegation. NFS delegations differ from opportunistic locks in that a delegation is initiated by the NFS server and opportunistic locks are requested by the CIFS clients. Table 3 summarizes the features of the two file systems.

HIGH-PERFORMANCE COMPUTING

Large-scale scientific simulations, which include those in astrophysics, computational chemistry, bioinformatics, nuclear testing, energy and petroleum, finance, and many others, dominate the field of high-performance computing (HPC). The TOP500 list, maintained by Hans Meuer, Erich Strohmaier, Horst Simon, and Jack Dongarra, describes the top supercomputers in the world, and they are classified architecturally as clusters, massively parallel processing machines, and constellations. Typically, applications in the HPC domain are optimized heavily for performance and scalability.

Most of these applications use the message passing interface (MPI) (28), the most commonly used portable, parallel API in the HPC community. Its portability allows scientists to run their applications on a variety of supercomputing platforms with minimal effort. In 1997, the MPI-2 standard was created by the MPI Forum to address parallel I/O (MPI-IO) as well as add other useful new features for portable parallel computing. ROMIO (29) is the reference MPI-IO implementation distributed with Argonne National Laboratory's MPICH library. Other MPI distributions, such as OpenMPI and LAM, often use ROMIO directly or as the basis for their own MPI-IO implementations. Frequently, higher-level libraries (for example, netCDF and HDF5) are built on top of MPI-IO to leverage its portability across different I/O systems and

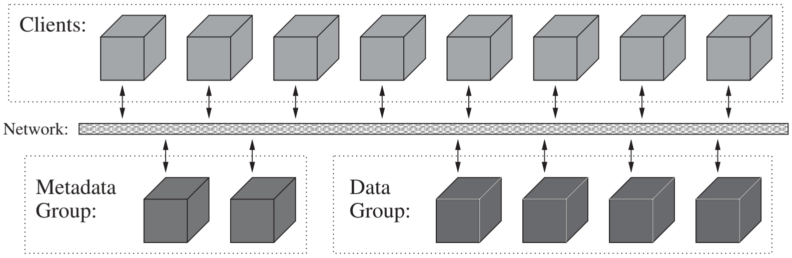

Figure 4. Typical parallel file system configuration. Clients have parallel access to components within the metadata and data groups.

to provide features specific to particular user communities. As the gap between processor and hard disk technologies continues to widen, I/O becomes an increasingly severe performance bottleneck. Parallel file systems, as shown in Fig. 4, help to narrow that gap by scaling up the number of hard disks to increase aggregate I/O bandwidth.

The HPC file system domain can be divided into production file systems and research file systems. Typically, production file systems are stable commercial products used in production machines. Some examples of production file systems include Lustre (30), Panasas (31), GPFS (32), SGI's CXFS, IBRIX FusionFS (33), and GFS (34). Research file systems are used primarily for trying out new ideas that may one day make it into production if appropriate. Several research file systems exist, which include PVFS (35,36), Clusterfile (37), Ceph (38), LWFS (39), Galley (40), Sorrento (41), and many more. We have chosen to focus our discussion on the three most used HPC production file systems: (Table 4), Lustre, Panasas, and GPFS, in the following three sections. We also describe three prominent HPC research file systems (PVFS, LWFS, and Ceph) in the sections that follow (Table 5).

Lustre

Lustre (30), from Cluster File Systems, gets its name from a portmanteau of the terms "Linux" and "cluster." As of the June 2006 TOP500 list, over 70 of the 500 supercomputers use Lustre technology, which includes the number one computer (Lawrence Livermore National Laboratory's BlueGene/L machine). The Lustre architecture consists of clients, metadata servers (MDSs), and object-storage targets (OSTs). MDSs maintain a transactional record of high-level file system changes, such as the location of related objects and stripe sizes. They are protected from failure through MDS replication and failover techniques. OSTs are responsible for actual file data and locking. Clients make requests to objects on the OSTs, in which an object is simply a container of data that may have attributes associated with it. In the future, object-based disks (OBDs) may be able to offload the work necessary to translate file system requests into physical storage requests. Currently, Lustre uses OBD device drivers to implement OBD functionality on top of ext3 or other Linux file systems. Failure of an OST is handled by failover techniques. If a failover OST is unavailable, clients will get errors when trying to access the failed OST and new file create operations will avoid the failed OST.

Lustre uses a distributed lock manager (DLM) to ensure POSIX compliance. The DLM helps Lustre to maintain its globally coherent collaborative cache. Although locks for an arbitrary byte-range may be requested, OSTs round the granted locks to file system block boundaries. Metadata operations use "intent based" locks (lock requests combined with data requests) for efficient atomic operations that do not require lock revocations. Additionally, Lustre provides snapshots, rollback, and copy-on-write semantics. Lustre uses secure network attached disk features for authentication, authorization, and encryption. A preliminary Lustre driver for the ROMIO MPI-IO implementation has not yet been integrated into the ROMIO distribution.

Panasas

Panasas (31,42) is used on many TOP500 supercomputers and was chosen to be deployed on the Los Alamos National Laboratory's new Roadrunner petascale supercomputer. Many application domains, which include energy research, high energy physics, atmospheric science and weather prediction, seismic data analysis, automotive design and simulation, as well as many others, have chosen Panasas as their storage solution. Panasas's main product is the ActiveScale Storage cluster, which uses the Panasas ActiveScale File System (PanFS). The core PanFS architecture is based on the decoupling of the datapath from the control path and the *object* abstraction of file data, similar to

Table 4. A comparison of HPC production file systems

Category	Lustre	Panasas	GPFS

Lustre. The PanFS client module accepts POSIX file system commands from the operating system and addresses and stripes the objects across multiple OSDs. The OSD component in PanFS manages data storage, handles storage-side caching and prefetching, and contains the metadata associated with its objects. Using OSDs instead of the typical block-based storage interface shifts some of the burden of fine-grain layout information to the OSDs. The PanFS metadata server (MDS) coordinates the layout of a file across OSDs, helps maintain RAID integrity, manages file and directory access, and keeps client caches coherent with file locks.

PanFS uses client-side data caching in the Linux buffer/page caches to complement the caching done by the OSDs. It aggregates writes on the client for more efficient I/O operation and also supports prefetching. The MDS handles client cache coherency with a single writer/shared readers protocol with invalidation and flushing. PanFS allows files to use different RAID levels individually across objects. To limit *incast* behavior and too many senders overflowing the network buffers, a two level striping layout is used to limit simultaneous accesses to the number of OSDs in a parity stripe. Therefore, files are striped across all the OSDs for maximum bandwidth, and the OSDs are broken up into RAID parity groups whenever appropriate (with a maximum of 13 objects per parity group). Panasas OSDs each have two SATA disk drives, a processor, RAM, and a Gigabit Ethernet network interface. An OSD battery-backed RAM cache allows data to be committed even if a power failure occurs.

General Parallel File System (GPFS)

IBM has designed many of the world's top supercomputers, which include the recent BlueGene/L architecture. Its flagship file system, GPFS (32), is available for its AIX and Linux clusters, and most recently on the BlueGene/L architecture as of December 2005. Although GPFS is designed primarily for high-performance computing, it is also used in industries such as media and entertainment, ISPs, finance, telecommunications, electronics, and retail. GPFS uses a shared-disk architecture, in which file system nodes have access to all disks through the network fabric. The disks are assumed to use the conventional block I/O interface (as opposed to the object based interfaces used by Lustre and Panasas). GPFS clients communicate directly with file system nodes, which perform I/O on their behalf. GPFS guarantees single-node equivalent POSIX semantics for file system operations across all nodes through the use of distributed locking. The only exception to POSIX compliance is that access time updates are not visible on all nodes immediately. The metanodes that handle metadata in GPFS are allocated dynamically with the help of the global lock manager.

The GPFS DLM is composed of a centralized global lock manager and the local lock managers on each file system node. Lock tokens are passed out by the global lock manager to the local lock managers that grant locks. A lock token is revoked only when another node requests conflicting lock operations to the same object. As with Lustre and Panasas, lock tokens play a large role to maintain cache consistency between nodes. Locks are acquired with byte-range granularity in GPFS and are rounded to block boundaries. The first node to write a file will receive a byte-range lock from zero to infinity. When the second node begins to write to the same file, the first node will relinquish part of its byte-range lock token until the offset of the second node's write. As more nodes write to the file, the byte-range lock tokens are further divided. In this way, GPFS attempts to keep locks as large as possible to avoid the increasing overhead of a plethora of locks.

Parallel Virtual File System (PVFS)

The first generation of PVFS (35) began at Clemson University to serve as a research-oriented open source parallel file system for Linux clusters. Since its inception, it has grown tremendously in popularity. A second generation version of PVFS (36) was released initially in late 2003 and has stabilized during the last couple years. This second generation of PVFS is intended to serve as a production file system as well as to quickly incorporate novel research ideas because of its highly modular architecture. The Argonne Leadership Computing Facility (ALCF) has selected PVFS as its storage solution. In this section, we describe the second generation PVFS storage system.

The PVFS architecture has clients and I/O servers. The I/O servers may manage metadata, data, or both. Clients communicate directly with I/O servers to access file metadata, file distribution information, and file data, similar to other parallel file systems. Modularity has been introduced in the networking subsystem through the buffered messaging interface to abstract access to various underlying networking technologies. Similarly, the trove storage interface provides APIs for various storage implementations. PVFS was redesigned, in part, to handle noncontiguous data access efficiently through its request system. PVFS requests understand and process derived datatypes built on basic datatypes such as contigs, vectors, and structs, similar to MPI derived datatypes. In addition, PVFS has a highly optimized MPI-IO device driver that can, in most cases, make a one-to-one mapping between MPI-IO calls and PVFS system calls. To improve fault-tolerance, PVFS has stateless clients and servers to minimize the impact of failing components. Failover high-availability solutions can be used by PVFS if multiple machines have access to shared storage.

Light Weight File System (LWFS)

Catamount, a lightweight operating system for Red Storm (currently number two in the TOP500 as of November 2006) at Sandia National Laboratories (SNL), implements only the required underlying services while avoiding functionality that could compromise application scalability. In the same spirit, the LWFS (39) project is a joint collaboration between SNL and the University of New Mexico to investigate the viability of a "lightweight" approach to I/O. The LWFS core only implements a thin layer of software above the hardware, which includes infrastructure to provide controlled access to distributed data across multiple storage severs, to expose the parallelism of multiple storage servers, and to allow the client implementation to create additional functionality. Because many more compute nodes exist than I/O nodes, LWFS servers determine when to move data. LWFS clients make asynchronous RPCs and servers either "pull" data for writes or "push" data for reads (43). All data movement is performed over the Portals message passing interface that supports one-sided operations.

In accordance with U.S. Department of Energy security requirements, LWFS provide scalable mechanisms for authentication, authorization, and "immediate" revocation of access permissions when policies change. LWFS has coarse-grain access control to *containers* of objects, in which every object belongs to a single container. All objects in the same container are subject to the same access control policy. Higher-level libraries are responsible to organize objects in containers as LWFS does not manage the relationship of objects in a container. To enable scalable security, LWFS uses fully transferable credentials and capabilities. To support "immediate" revocation, LWFS invalidates cached entries on each of the storage servers.

Ceph

Ceph (38) is a research-oriented file system from the University of California at Santa Cruz. It has three major components: clients that export a near-POSIX file system interface; a cluster of OSDs that collectively store all metadata and data; and a metadata cluster responsible to manage the namespace and coordinating security, consistency, and coherence. As with the other object-based file systems, Ceph separates file metadata management from data storage. Ceph uses its reliable autonomic distributed object store (RADOS) to protect against OSD failures. Primary OSDs forward updates to their replicas in an asynchronous manner for better performance, and reads are only serviced by the primary OSD to reduce synchronization costs.

In the metadata cluster, Ceph employs dynamic distributed metadata management that is based on dynamic subtree partitioning. In essence, dynamic distributed metadata maps subtrees of the directory hierarchy to metadata servers based on their workload. Individual directories are hashed across multiple nodes only if they become hot spots.

For data distribution, Ceph uses the controlled replication under scalable hashing (CRUSH) algorithm (44). CRUSH relies heavily on a suitably strong multi-input integer hash function. Using the hash function, CRUSH can locate any object with a placement group and an OSD cluster map. Placement rules help CRUSH map the placement groups onto OSDs based on the desired level of replication as well as other constraints. CRUSH also helps Ceph adapt to the addition and removal of storage devices with low overhead.

APPLICATION-SPECIFIC

In distributed file systems, design decisions are made to balance performance, scalability, reliability, usability, and security. Ideally, all these aspects would be maximized, but some desirable traits conflict inevitably with each other, which leads to tradeoffs. For example, achieving a usability characteristic like strong consistency typically hinders performance and scalability, and the converse is also true. Typically, general purpose distributed file systems attempt to provide reasonable support for most of the above features. A file system that has been designed for a specific application, however, can relax certain restrictions (based on the requirements of the application) to improve certain behaviors. For example, search engines store very large files that rarely are deleted or overwritten, as most of the requests involve appending or reading files in bulk. In this particular case, a relaxed consistency model is acceptable for scalability and efficiency reasons.

We will discuss three such special purpose file system areas. In the next section, we consider web application optimizations on the Google file system that supports the Google search engine. In the section after that, we examine security optimizations for the self-certifying file system (SFS). Last, we discuss how distributed file systems are used for virtualized storage. The characteristics of all file systems in this section are shown in Tables 6 and 7.

Table 6. A comparison of GFS and SFS file systems

Category	Google FS	SFS
Dedicated servers	Yes	Yes
Consistency semantics	Application-specific	N/A
Consistency enforcement	MDS	NLM
Caching	Metadata caching at client	N/A
Fault tolerance	Shadow masters, logging, checksum	Stateless servers
Replication	Three copies (default)	N/A
Security	Capability	Separate key management

Table 7. A comparison of virtual machine distributed file systems

Category	VMFS	VxFS
Dedicated servers	Optional	Optional
Consistency semantics	Guest OS	Guest OS
Consistency enforcement	On-disk locks	I/O fencing
Caching	OS-dependent	OS-dependent
Fault tolerance	Journal-based recovery	VCS backup
Replication	Unknown	FlashSnap
Security	SAN	SAN

Google File System

The Google file system (GFS) (45) is a scalable, distributed file system designed for Linux platforms. GFS evolved out of BigFiles (46), which was developed at Stanford in the early days of the Google search engine. At that time, BigFiles existed primarily to store multi-Gigabyte files efficiently. Today, GFS runs on hundreds or thousands of commodity Linux machines and is tailored for high-performance data-intensive applications as well as storing a few million very large files. Because multi-Gigabyte files are common, the overall system should be optimized for large files. Small file access is also supported, but not optimized. The largest of the current GFS clusters is 1000 nodes with a 300 TB storage capacity. It is accessed concurrently by hundreds of clients (45). These machines, both cheap and unreliable, often fail. On average, at least one machine will fail everyday at Google, so it can be assumed that not all of them will be working at any given time (47). Some challenges for GFS are fault tolerance and fast recovery support. GFS runs a persistent monitoring mechanism that helps make it fault tolerant and automatically recoverable.

Because GFS was designed to support a search engine, architectural decisions are based on several domain-specific characteristics: files are rarely deleted, overwritten, or shrunk; most of the workload involves large contiguous writes when files are being appended; small writes are supported but are not optimized to keep high efficiency for large writes; high sustained bandwidth is preferable when compared with low latency for individual reads or writes; and autonomy with minimal synchronization overhead is essential to allow multiple clients the ability to append to the same file concurrently.

Architecture. The GFS architecture consists of a single *master*, multiple *chunkservers*, and the client library, as illustrated in Fig. 5. GFS employs commodity Linux machines with user-level server processes that run on each of them. Files are divided into fixed size (default 64 MB) chunks, each of which is identified using a unique 64-bit chunk handler. Chunks are stored on local disks as Linux files. For fault tolerance and recovery, each chunk is replicated on at least three chunkservers. The master maintains the metadata for the entire file system: mostly namespace and access control information, the mapping from file to chunks, and the current locations of every chunk. The master communicates with chunkservers through *HeartBeat* messages to give instructions and to collect states.

Because of the single master architecture, larger file systems can be supported on the master at the cost of adding extra memory to handle the additional metadata load. The master does not keep a consistent record of which chunkservers have replicas on a per-chunk granularity. During startup, the chunkserver provides this information to the master, and subsequently the master keeps itself updated with HeartBeat messages. This protocol avoids consistency issues when a chunkserver crashes. The GFS client library is linked with each application and it reads and it writes on behalf of the linked applications. A client interacts with the master to acquire metadata, but all data

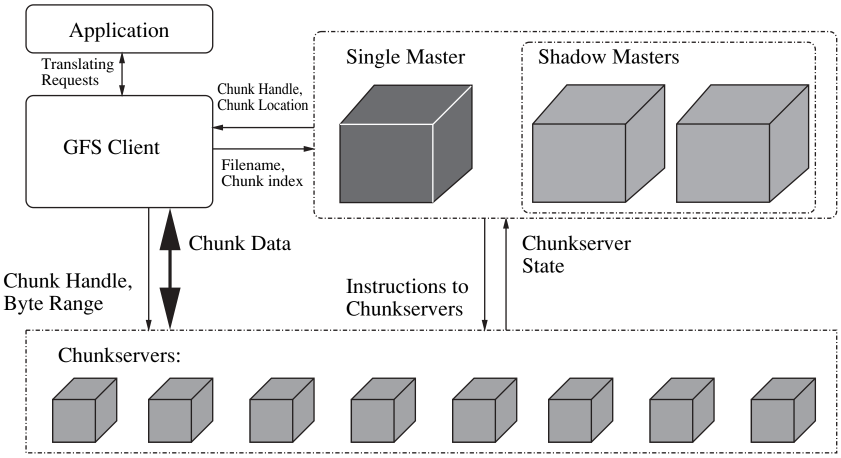

Figure 5. The Google File System architecture.

communication is handled strictly between a client and the chunkservers. The client does not cache data because most of the Google applications stream through huge files; however, they do cache metadata to avoid repeated access to the master. Chunkservers cache frequently accessed data in the Linux buffer cache because chunks are stored as local files on Linux machines.

Record Append and Consistency. GFS has a relaxed, simple, and efficient consistency model. Most of the target applications for GFS involve large sequential writes and large streaming reads. Small random reads or writes at arbitrary positions are also supported, but need not be highly efficient. A unique result of the GFS design is that appending to a file is more efficient than overwriting it. A write causes data to be written at an application specified offset. A record append, on the other hand, appends a record atomically at most once even in the presence of concurrent mutations at an offset decided by GFS. The client only specifies the data, and the offset returned to the client is the beginning of the record region. GFS may insert padding or record duplicates between appended records. The reader may deal with occasional padding and duplicates using checksums, or can remove duplicates by using unique identifiers in records.

Fault Tolerance. The master and the chunkservers are designed to restore their state seconds after a failure. As already mentioned, every chunk is replicated on at least three different chunkservers. If a chunkserver goes down or corrupted data is detected through checksum calculations, then other replicas of this chunk are used to recover the correct data. The master state is also replicated for reliability. Operation logs and checkpoints are replicated on multiple machines. A mutation is considered committed only after its log record has been flushed to disk. The master is in charge of all mutations as well as garbage collection. If it fails, it must be restarted immediately. A new master can be created by using replicas of the operation log. There are also *shadow masters* that provide read-only access to the file system while the actual master is unavailable (Fig. 5). Shadow masters are not mirrors; they lag behind the master by fractions of a second. GFS generates many operation logs to record significant events. These files can be deleted right away but are kept as long as space exists. RPC logs contain requests and responses, but not data. These logs can serve for load testing and for later analysis.

Self-Certifying File System

In almost any system, file system or other, often a tradeoff occurs between security and performance. In the case of distributed file systems, an additional tradeoff is scalability. To ensure secure and transparent transfers we need remote file transfer protocols to operate securely between physically dispersed workstation environments. These protocols should also be able to provide confidentiality, authentication, and data integrity. Some applications of secure file systems are financial transactions, multimedia streaming, medical records, and devices that use digital rights management.

Replicas are used commonly in distributed file systems for better locality as well as fault tolerance. Secure file systems can either store unencrypted replicas on trusted servers or encrypted replicas on untrusted servers. A built-in key management system may be required to ensure security.

Most file systems come with a key management system; some examples include Kerberos (48) and SSL (49). Internet file sharing deals with such wide diversity that managing encryption keys becomes very cumbersome, and establishing a secure web server with SSL can take a significant amount of time. The Self-certifying File System (SFS) tries to solve the above mentioned problems of security, key management, and extensibility.

Related Work. Before we discuss SFS, it is appropriate to understand some of the security mechanisms present in other distributed file systems. The Andrew File System (AFS) (1,2,50) is one of the earliest and most successful secure distributed file systems. It uses a message authentication code to protect the integrity between client and server. AFS uses password authentication to guarantee the integrity of remote files. After logging into an AFS client machine, a user is able to obtain a key shared by the file server. If malicious users gain access to a session key, they can pollute the client disk cache, buffer cache, and name cache for parts of the file system that they supposedly should not have permission. If multiple users log on the same AFS client machine, they must either trust each other or the operating system (OS) must maintain separate secure caches for each user.

SFS Design. SFS claims to provide better security and extensibility without key management. SFS (51) is a secure distributed file system that removes key management from the file system entirely. Like AFS, it also provides a shared namespace, but it introduces self-certifying pathnames (filenames) that effectively contain the appropriate remote server's public key. It makes sharing of files over the Internet secure by allowing the local area network to gain control of a remote file by using self-certifying pathnames. Because pathnames already specify the public key, SFS doesn't need a separate key management mechanism to communicate with file servers. By moving the key management scheme out of the file system, many key management policies can coexist in the same file system. This makes SFS extensible while securely working over the untrusted Internet.

The overall security of SFS can be divided in two parts: file system security and key management. SFS provides only file system security, so a malicious user can't read or change the file system without permission. SFS ensures that an attacker can do no worse than delay the file system's operation, and any data that a client receives can be verified as authentic. Clients and read-write servers always communicate over a secure channel that guarantees secrecy and data integrity. Although self-certifying pathnames solve the problem of authenticating file servers to a user, SFS must also authenticate users to servers. When a user first accesses an SFS file system, the client delays the access and notifies its authentication agent of this event. The agent can then authenticate the user to the remote server before file access begins. A server-side authentication server program performs user authentication. The agent and authentication server pass messages to each other through SFS using a protocol opaque to file system. Security, extensibility and portability are achieved at a performance cost attributed mostly to the underlying encryption overhead in SFS.

SFS Read-Only. For a read-write secure file system, expensive encryption/decryption becomes the critical path and performance does not scale with the number of processes. The SFS read-only file system (52) is a distributed file system that allows a high number of clients to access public read-only data securely with acceptable performance. The data of the file is stored in a database and is signed off-line with the private key of a system stored in a database to replicate on many untrusted machines. In online certificate authorities, frequent disk accesses are avoided by having copious amounts of memory. The SFS read-only server performs better than the SFS read-write server because no online cryptography operation exists. Public key decryption is a performance bottleneck for a SFS read-write server. The SFS read-only server pushes the cost of cryptographic operations from the server to the clients, which allows the server to support a large number of clients.

Virtual Machine Distributed Storage

In the enterprise domain, virtualization has become an important technology that aids high availability, server consolidation, and reduced testing complexity. Typically, the concept of virtualization revolves around the idea of a virtual machine, or hardware virtualization, that is based on adding a virtualization layer between the hardware and the OS. This virtualization layer allows multiple virtual machines to run concurrently on a single actual machine that shares its physical resources among them. Some example virtualization vendors include VMware, Xen, Qemu, Parallels, and Innotek.

Virtualized storage refers to the abstraction of logical storage from physical storage. Although an OS may believe that it has a single, SATA-connected hard drive, in reality, the physical storage device may be network-based, storage device-based, or host-based (typically, distributed file systems). Several virtualization vendors use distributed file systems to support virtual storage for their virtual machines. A virtual disk may be as simple as a file on a remote server that allows any client with connectivity to the server to resume the virtual machine. Distributed file systems that support virtualized storage efficiently include VMware's VMFS and Symantec's VxFS. In 2003, Red Hat purchased Sistina to use the global file system for its upcoming virtualization platform; however, a product is yet to be released. These distributed file systems are corporate products, which makes it difficult to find detailed information.

VMFS. VMware provides several virtualization products for both desktops and servers. Their storage virtualization solution that is optimized for virtual machines is the Virtual Machine File System (VMFS). VMFS was designed to allow virtual machine state to be stored in a centralized repository. VMFS-3 is the latest revision that addresses manageability, availability, scalability, and performance issues and can use a wide range of Fibre Channel and iSCSI SAN equipment.

Several VMFS features improve manageability and availability. Distributed journaling and journal-based recovery allow for faster recovery during server failure. An exhaustive file system check would take a long time before the server could come back online. VMFS can hot add virtual disks to running virtual machines to handle increased application requirements or provide backup capability. Logical unit numbers are discovered automatically and are mapped to VMFS volumes. VMFS-3 now supports many files using techniques similar to other file systems rather than the flat address space in VMFS-2. On-disk locking ensures that operations are atomic across shared virtual storage.

To support its performance and scalability goals, VMFS has several optimizations. Block sizes are adaptive and can adjust for both max file size limits and better backend resource use. Because backend storage devices are disks, increasing the access sizes has a lot of potential to improve performance and to reduce network traffic. Caching is used for nonvirtual disk-based files because guest OSs expect syncing the disk to push data to the storage devices. Changes in the on-disk locking protocol allow better scalability with respect to the number of files open in a virtual machine. Older versions of VMFS stored on-disk locks per file in different (noncontiguous) sectors, on disk. VMFS-3 now stores all locks in a single sector that supports the same number of open files as other VMware products.

VxFS. Recently, Symantec acquired Veritas in 2004 to consolidate its enterprise operations. Instead of writing its own core virtualization software, Symantec makes virtualization products, such as the Veritas Cluster Server (VCS), based on VMware and Xen technology. Symantec also provides virtualized storage solutions based on its Veritas Storage Foundation Cluster File System, which includes the Veritas File System (VxFS) and the Veritas Volume Manager (VxVM). VxVM volumes are used as boot disks for guest OSs to enable easy cloning. VxFS is used in the guest OS for better reliability and performance.

VCS improves administrator efficiency through reduced management. The cluster nodes share a single set of configuration and data files, which requires the administrator to "manage" only a single node regardless of the number of nodes in the cluster. VxFS also enables VCS backup/recovery operations by means of shared access and FlashSnap, a point-in-time copy of production information. If file systems are checkpointed, the file system can be "rolled back" to a consistent point in time. VxFS is an integral part of VCS's ability to handle both application and node failures. If a node fails, the application will be migrated dynamically to an available node in the cluster. Additionally, because storage resources are consolidated and abstracted from the virtual machines, maintenance costs are reduced.

From a performance point of view, VxFS provides *Dynamic Storage Tiering*, a technology that moves unimportant or out-of-date files transparently to less expensive storage hardware. The policies can be dynamically set, are centrally managed, and work on heterogeneous server and storage infrastructure. RAID support provides performance and reliability as per user needs. To ensure data integrity, VxFS uses I/O fencing through the SCSI-3 persistent group reservation technology. VxFS can remove access from "errant" nodes using I/O fencing. Automatic performance tuning helps the system adjust to dynamically changing workloads.

ELECTRONIC DATA INTERCHANGE

INTRODUCTION

Electronic data interchange (EDI) is the process by which a business organization exchanges business transactions between application systems in electronically processable forms. In this process, an automated business application system originates the transaction, the value-added network (VAN) transmits it to the receiver, and an automated business application system at the receiver adequately responds to the transaction. For example, at a store, the bar code scanner at the cash register can update the inventory of each item sold. If the inventory falls below some predetermined number, the bar code scanner system triggers an ordering system. The ordering system creates an order and hands it over to the EDI system. The EDI translator translates the purchase order into a standardized transaction set according to ANSI ASC X12.850 standards and electronically sends the purchase over to a vendor's mailbox using an EDI VAN. Human intervention is not needed in any step of the whole process. It is clear from the above example that for EDI to be successful, integration must exist among various business application systems and the EDI software. The EDI system should support the seamless location, transfer, and integration of business information in a secure and reliable manner.

EDI uses computers to transmit business transactions and, in the process, eliminates paperwork significantly. With this paperless transfer of data, one does not have to rekey the information at the receiving end. Therefore, errors, time, and cost incurred in the rekeying of data are saved. This automatic creation and transfer of business transactions enables organizations to improve accuracy of business data, better serve their customers, improve relationships with suppliers, and effectively compete in the global market. For example, just-in-time (JIT) inventory control practices that have significantly cut inventory costs will be difficult to implement without EDI.

In addition to the above-mentioned direct benefits, EDI provides many indirect benefits. EDI standardizes business transactions for the whole industry, as participants in EDI must agree in advance on what data are to be exchanged, in what order, and what format needs to be used. This standardization helps in streamlining the transaction process, as parties do not have to go back and forth asking for clarifications or missing data. The federal government as well as major companies expect their suppliers to use EDI. For example, the U.S. Department of Defense will not transact business with a vendor any other way except through EDI. So a vendor has no choice but to have EDI capabilities. This article details EDI system components and processes needed to implement EDI.

EDI SYSTEMS AND PROCESSES

To automate transactions processing among different business partners, a successful EDI system has the integrated components shown in Fig. 1 (1,2).

STANDARDS

Every industry has a set of transactions. Different terms have specific meaning and usage in a specific industry. Standards are needed so that transactions are formatted in a structure that can be processed by the transaction processing systems of the industry. Standards provide the framework for formatting any specific transaction. ANSI ASC X12 and EDIFACT are the two predominant standards.

ANSI ASC X12

The American National Standards Institute (ANSI) is the national body that coordinates the development of standards in all areas of business. ANSI created the Accredited Standards Committee (ASC) X12 and gave it a charter to develop a set of standards for electronic exchange of business transactions. ANSI ASC X 12 standards define the data structures and the rules for encoding business transactions. Following; are the structures used in ANSI ASC X12 standards:

Data Element

A data element is the very basic or elementary unit of information, for example, item number, quantity, item description, and so on. The characteristics of each data element are defined. A group of simple data elements that represents a single named item is known as a composite data element. For example, if a piece of metal has to undergo seven different machining processes, then 1c234de represents those seven machining processes.

Data Segments

A data segment consists of a group of related data elements. These logically related data elements are arranged in a predefined sequence to generate a data segment. For example, an address segment consists of a group of data segments, that is, company name, city, state, and zip code. A segment contains some data elements that are essential, whereas other data elements may be optional. Some of the optional data elements may not be applicable for a business; therefore, they are omitted in the transaction. When a data element is omitted, the data element separator should

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

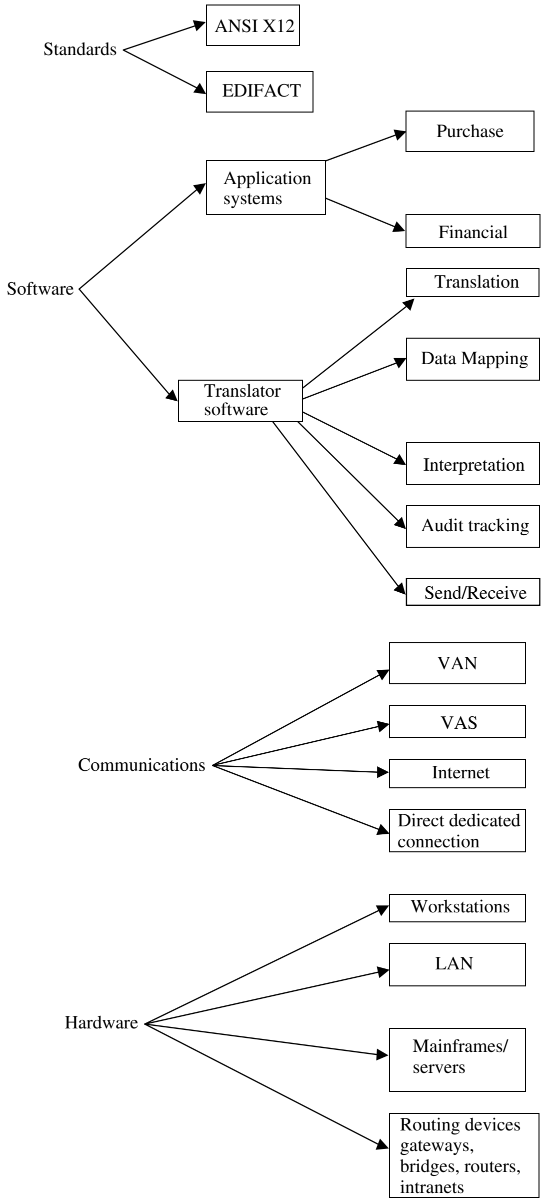

Figure 1. EDI system and processes.

explicitly indicate such an omission. For example, a purchase order can be sent as follows:

PO1**100*EA50.00**VC*P123

*	Element separator
PO1	Purchase order1
100	Quantity
EA	Each
**	Omitted data element
50.00	Price
VC	Vendor catalog
P123	Part number P123

Quantity: 100
Unit: Each
Description: Part No 123
Unit Price: 50.00
Total: 5,000.00

Transaction Set

A transaction consists of a group of related data segments that must be present to provide information for a viable business transaction. For example, transaction set X12 840 is a request for quotation (RFQ). This transaction set X12 840 provides the information about different data segments and data elements that are required to make RFQ a meaningful transaction. Similarly, X12 850 is a purchase order and X12 855 is a purchase order acknowledgement. To create a format for a transaction, one has to define the following:

- segments to be used,
- the structure of each segment,
- data elements to be used in each segment, and
- the characteristics of each data element.

Functional Group

A functional group consists of a group of similar transaction sets. For example, if there are three RFQs for three different items to be sent to the same trading partner, the EDI software will create one interchange with one RFQ functional group. This RFQ functional group will contain three different transaction sets, one each for three different items. Some EDI translators allow several different functional groups to be included in one interchange. For example, if two responses for RFQs and five purchase orders are being sent to the same trading partner, the EDI translation software will create one interchange that contains two functional groups, that is, one RFQ response functional group and one order functional group.

Envelope

An EDI envelope is a specialized segment that contains (1) routing information; that is, it provides addresses of both the sender and the receiver of the transmission. The address segment marks the beginning of the transmission, (2) the date and timings of the EDI interchange; (3) the unique control number used for tracking the transaction; (4) the authorization and security information; (5) the EDI standards and version of the interchange; and (6) the number of functional groups in the interchange. Figure 2 explains the structure of EDI envelope, arrangement of functional groups, and transaction sets (1,2).

EDIFACT

For international trade, the United Nations rules for EDI for administration, commerce, and transport (EDIFACT) provide a set of standards, directories, and guidelines that

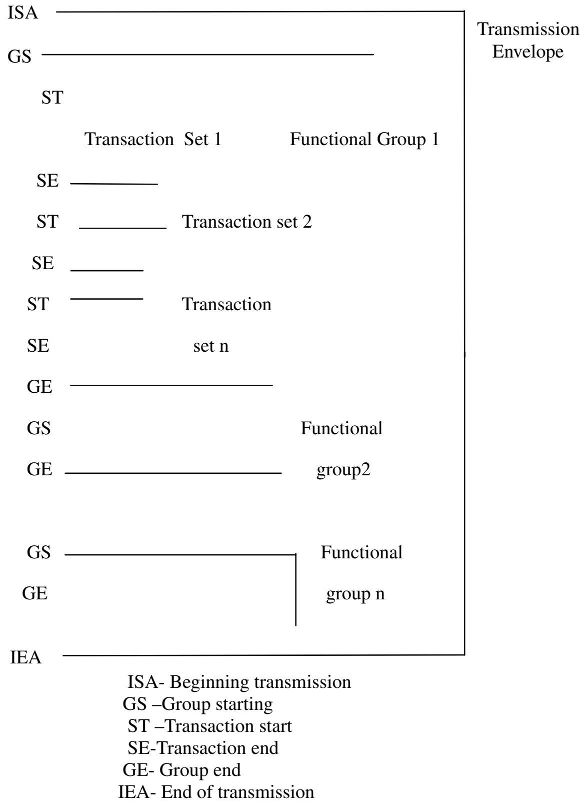

Figure 2. EDI envelope and group mapping.

have been internationally agreed upon for electronic exchange of structured business transactions. EDIFACT is a global attempt to standardize such information exchanges so all computers involved are speaking the same language, which will create an open system that anyone can join at any point. EDIFACT is designed to be independent of software, hardware, or communication media, thus accomplishing universal connectivity. The International Organization for Standardization (ISO) adopted the EDIFACT syntax in 1987.

To achieve global open EDI, one can use EDIFACT document syntax rules, X.400 message handling systems, and X.500 directory services. X.500 directory services can be used to store product information so that purchase managers can order electronically. These X.500 directory services are a powerful tool that allows EDI to take place between organizations without prior EDI agreements.

Both ANSI ASC X12 and EDIFACT standards perform the same functions. ANSI ASC X12 is an older standard and provides many more functions than EDIFACT. The EDIFACT organization is trying to develop additional functions. The two standards have different syntax and therefore it is difficult to convert transactions from one system to the other. In January 1995, the ANSI ASC X12 development body decided to follow the syntax and standards of EDIFACT so that full compatibility is achieved. EDIFACT can be used for both domestic and international interchanges, whereas ANSI ASC X12 is mainly for domestic interchanges. One can obtain a complete listing of both these standards from the Data Interchange Standards Association.

EDI SOFTWARE

An organization may have automated applications in the area of finance, marketing, accounting, production and operations, and human resources management. Data are entered into these application systems and transactions are generated that may have to be communicated to business partners. These business information systems call on EDI software to establish and maintain standards and handshaking rules for communicating among business partners. EDI software defines the methods, timing, and routines for receiving, transmitting, storing, and updating transactions among application systems (see Fig. 3). EDI software makes the exchange transparent; that is, it hides the complexity of the underlying communication protocols from the end user. A good integrated EDI software package provides the following functions:

- an application interface,
- translation, and
- data communication.

Application Interface Software

As the term indicates, the application interface software is the software bridge that facilitates the interface between the business application system and the EDI standards translation software. This software enables transparent flow of transactions between business partners. After the required data have been entered in the application software and the transaction is ready to be transmitted to the receiver, this software retrieves transaction data from the application database and places them into a flat file for subsequent conversion into EDI-formatted data before to transmission to trading partners. Flat files are used to pass transaction data between an application system and the EDI translation software. System interface software is important for both outgoing and incoming transactions, as it either reads or writes flat files of transaction data. For incoming transactions, this software retrieves data from a flat file and prepares them for acceptance by the application system. Some transaction software packages may not use a flat file because they exchange data directly with the application system database, thereby eliminating the need for interface software.

Standard Translation Software

A business organization transacts business with many trading partners. Some degree of flexibility is needed to support communication with the various trading partners because a need may exist to modify a trading partner's data to ensure compliance with the standards or to facilitate integration with the user's application system. EDI translation software allows for both the semantic translation and the syntax translation of the data element. A summary of

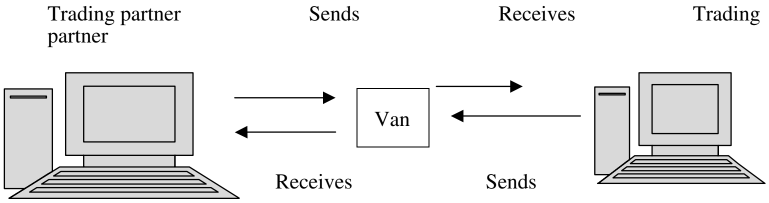

Figure 3. EDI process.

the characteristics of the standard translation software listed by the National Institute of Standards and Technology is as follows:

Transaction Set Mapping. Translation software translates data retrieved from an application database into a standard EDI format before it is transmitted to trading partners. It also converts EDI-formatted data, for example, in ANSI ASC X12 format, received from trading partners into a file format that the application system recognizes. Before the translator can translate data, it must know the location of the data to be translated. Some translators require some users to create a separate flat file formatted as an ASCII text file. Such a flat file helps in the standardization of data from various files and different formats. Some translators have a utility called "transaction set mapper." The transaction set mapper cross-references the contents of the flat file with an EDI standard set and subsequently translates the flat-file information into the desired transaction set. Mapping from/to the standards to/from the application formats is one of the key functions of translation software. The mapper reduces the amount of programming for application system interface. Data manipulators map internal data fields to applications according to an ANSI ASC X12 transaction set, which enables different trading partners to exchange transactions.

Character Set Convention. If business applications of the trading partners use different character sets (ASCII and EBCDIC), the need may exist to convert one to the other. Sometimes EDI software may do the conversion or, if VAN is used, it will do the required set conversion.

Code Conversion. Codes used in a vendor's application program might be different from the EDI codes. For example, the X12 ID Qualifier for serial number is SN, whereas the user application might use the code SRNUM to identify a serial number. The EDI software converts the standard codes to and from the user's code to facilitate integration between the user's application and EDI software.

Automatic Compliance Correction. For both inbound and outbound data, EDI software verifies the identity of trading partners, the syntax of the data, and whether it complies with the EDI standards and version being used. To accomplish this verification, EDI software references its tables of EDI standards at the user's trading partner profiles. Some simple errors are automatically corrected by adjusting the data to make them comply with the standards.

Manual Compliance Correction. Some compliance verification errors may be so severe that EDI software cannot automatically correct them. In such circumstances, the software suspends the processing so that the end user can review the transaction, correct the errors, and submit the transaction for reprocessing.

Duplicated Number Detection. Some EDI software tracks the use of business document numbers, such as purchase order numbers. If a number is duplicated, the software identifies the duplication and can take several different actions. It can either display or log error messages or it can suspend processing of the transactions until the end user can correct the duplication.

Functional Acknowledgement. Senders of transactions would like to know if the recipient received the information. The ANSI ASC X12 997 transaction set is known as functional acknowledgement. The recipient uses functional acknowledgement to send the sender an acknowledgement of the EDI transaction. It verifies the acceptance or rejection of a transaction set and reports any syntactical errors. Generally, EDI translators are so configured as to automatically return functional acknowledgement.

Document Type Sequencing. Control numbers are used to identify functional groups in an exchange. There may be several different kinds of document types within the multiple functional groups. These document types are also identified using control numbers. Each trading partner may have a set of functional group and document control numbers sequentially. It is easy to find a missing document from transmission by viewing the lapses in document control numbers.

Multiple Functional Groups. Some EDI translators permit multiple functional groups in one interchange. For example, if three invoices (ANSI ASC X12 810) and two RFQ (ANSI ASC X12 840) responses are being sent to the same trading partner, the EDI software creates one interchange containing two functional groups, that is, one functional group for invoices and the other for RFQ responses. If the software does not support multiple functional groups, then two interchanges would be needed, one for each functional group. The second interchange would cause increased overhead in terms of double transmission costs and greater storage requirements.

DATA COMMUNICATION SOFTWARE

The communication software establishes the communication link between the sender and the receiver. One can use a general-purpose data communication software for modem dialing and connecting to VANs. To complete this job, the communication software has to perform several tasks.

Protocol(s) Support

Communications software must support the required protocol(s). Some EDI software include: asynchronous transmission; others provide bisynchronous transmission. These programs would provide seamless transmission if they were fully integrated with simple mail transfer protocol (SMTP) or X.435.

VAN Script Files

For communicating with the VAN, the sender initiates a session. The session is governed by a predefined set of commands called "VAN script," which are specific to the VAN's host computer. The functions of a VAN's script are as follows: (1) It dials into the VAN, (2) it recognizes the login name and password for allowing access, (3) it deposits EDI messages to be delivered to trading partners, and (4) it retrieves EDI messages from the mailbox.

Unfortunately, there is not a standardized set of commands for communicating with VANs. Different VANs may have different VAN scripts. Therefore, when purchasing EDI software, the user should make sure that it has the VAN script that enables the user to communicate with the available VAN services. VAN providers know this difficulty and therefore generally provide the VAN subscribers the software required for communicating with the application systems. A software vendor that offers scripts for several different EDI VANs is a desired choice for purchasing EDI software.

Multiple VAN Support

Trading partners of an EDI user may subscribe to many different VANs. Therefore, the communications software must be flexible so that it can connect to many different VANs.

Direct Trading Partner

Some trading partners may use VAN services whereas others may not. Those who are not using VAN services must be connected directly by the EDI software. For receiving messages from these direct trading partners, a dedicated computer system is required, as no VAN exists to provide storage or message-forwarding capabilities.

Script Building Tool

In some cases, a trading partner may have to connect to a VAN or to a mainframe computer for which no communication script is available. EDI software that has capabilities of building scripts can help in such situations by creating custom scripts for connecting to other VANs or directly to mainframes.

Communication Audit Trails

Communication audit trails can be used for verification that a transaction was communicated among trading partners. An audit trail may include the following:

- times and dates of communication,
- identifiers,
- acknowledgements, and
- errors encountered, if any, and others.

Viewing Utility

Large amounts of information are generated in EDI processes such as audit trails, configuration data, functional acknowledgements, and others. Manually viewing or editing all these data may be cumbersome. Viewing utilities help in viewing various aspects of communication data.

Installation, Maintenance and Support

Several of the following functions are essential to install and maintain EDI software. Automated installation routines make it easier to install EDI software and to update periodically. EDI software has to keep pace with the changes in standards and versions. Tracing facilities in the software provide a trace or show the way a transaction is processed. It helps in debugging translator software. Logging functions provide the ability to maintain a computerized log of all data interchanges and, therefore, provide an audit trail. Need may exist to permanently store some data interchanges among trading partners for a long period of time. The archiving function helps in this long-term storage of data, either in regular format or compressed format. Over a period of time, a lot of data from interchanges may accumulate. Automated purging utilities provide the ability to automatically purge data based on some criteria such as starting and ending dates, particular partner, specific item, and others. As a result of power failure or other reasons, the EDI process may fail during transaction interchange. Data recovery and restart utilities automatically recover the data and retransmit transactions that were not completed beacuse of the earlier failure.

EDI COMMUNICATION NETWORK

EDI needs a communication network that will transmit, receive, and store EDI messages and transactions so that the entire communication process is fully automated. These networks can be classified as follows: (1) VANs and value-added services (VASs), (2) Internet, and (3) direct dedicated communications.

VAN

VAN is a store-and-forward mechanism for exchanging business transactions. VAN performs EDI requirements as VAN acts as the communication facilitator that provides the function of transmitting, receiving, and storing messages (see Fig. 4). The easiest way to start communicating

Business Information Systems
Application interface software

Figure 4. Commercial and value-added network.

with the trading partners is to subscribe to a VAN. A VAN operator provides the EDI communication expertise and equipment necessary for electronic communication. VAN providers also provide VASs such as consulting and training in the mapping of EDI transactions, coding VAN communication script, on-site EDI software and hardware installation, and others.

VANs are the most widely used communication networks for EDI communication. Increased competition among the VAN providers has resulted in low prices for VAN services, which has facilitated organizations to outsource the delivery of data and message services. In an increasingly competitive marketplace that demands fast responses to customer needs, an organization may ask the following question: Why struggle single-handedly trying to support national and international voice and data traffic when VAN service providers are ready to assume those responsibilities at very competitive prices? VAN services provide the current technology, economies of scale, customer service fault management, and so on. VAN provides a single communications access point, 24-hour access and support, control reports on EDI traffic, and reliability of services. Advantages of VANs are as follows (1–3):

- VAN is generally available throughout the day, 24 hours a day.
- Any trading partner is just a call away to VAN.
- VAN provides a mailbox capability; that is, messages are routed, stored, and forwarded any time of the day.
- VAN capabilities are available irrespective of geographical location or time.
- VANs support different speeds and protocols.
- VANs provide reliable connectivity to trading partners.
- VANs provide security for transactions.

Users can schedule when the VAN scripts is executed. Execution of VAN scripts can be automated or manual. Automated execution is the preferred way. In a manual system, the communications process will have to be started manually whenever desired. With manual control, the communications errors can be noted and corrected in real-time.

There are several requirements that a VAN must fulfill before it can be used (1–3):

1. A VAN must support the protocol (asynchronous or bisynchronous) being used by the communication software. Some VANs may not support the X.25 protocol.
2. A VAN must support the standards such as ANSI ASC X12, UN/EDIFACT, or industry-specific TDCC, VICS, and so on.
3. No conflict should exist in the data segment and data element delimiters used by the trading partners and the VAN.
4. A VAN should support the access method desired by the user, such as dial-up lines, leased lines, and so forth.
5. Data backup and recovery functions must be available.
6. Data security features should provide transmission status reports and usage accounting data.
7. Transmission timing should be short.
8. Additional VASs must be provided.

Support by VAN Service Providers

Support is essential for someone who has just bought EDI software. Users need guidance in installation, maintenance, and use of any new EDI software. Such user support can be provided both by the software and the vendors. For example:

- user documentation provides narrative text concerning the daily use of the EDI software,
- technical documentation,
- help success,
- online tutorial,
- vendor services,

- training, and
- user groups.

Internet

The Internet provides the retailers and other businesses with the ability to communicate business documents electronically. The Internet provides a more convenient form of business communication. These online business transactions are more efficient and flexible. As no intermediary is involved, the cost of business transactions using the Internet is lower compared with VAN-assisted electronic commerce. With the growth in Internet and related services, it has become possible for retailers to access a worldwide network of customers. VANs, as compared with the Internet's worldwide connectivity, have very limited connectivity to only a few thousand other paying subscribers. The Internet also provides interactive capabilities rather than just store-and-forward functions provided by VANs. These interactive functions provide browsing abilities to users and help retailers to market their products to a much larger audience. One major problem with the Internet is security, which is discussed in a later section.

Direct Dedicated Connections

There are many transmission and switching mechanisms that can make it feasible to have direct dedicated connection. Synchronous digital hierarchy, frame relays, and asynchronous transfer mode provide the potential for direct partner interface, mainly from LAN to LAN.

HARDWARE REQUIREMENTS

For operating the EDI software, communication software, and application systems, a business needs workstations, servers, and mainframe computers. For communicating with other organizations, LAN, WAN, intranets, Internets, and other networks are needed. Routing devices such as gateways, bridges, routers, brouters, and others are needed for packet, message, or circuit switching. The detailed explanation of these hardware devices, network management devices, switching mechanisms, and communication protocols are beyond the scope of this article.

SECURITY

EDI demands that an organization become a part of the network. Once an organization becomes a part of a network, it faces challenges from unauthorized intruders and hackers. A list of control activities is provided to ensure that interchange of data takes place while maintaining the integrity of the computer systems.

Access Control

Access controls are required at initiation, transmission, and destination. These controls can be achieved by using password, user ID, storage lockout, and different levels of storage and function access.

Data Integrity

Authentication, acknowledgement protocol, computerized log, digital signatures, and edit checks can be used for detecting errors during the process of input or transmission. Authentication, integrity, confidentiality, and nonrepudiation can be achieved through public key cryptosystems that employ digital signature, encryption, and key exchange technologies. Nonrepudiation can be accomplished through the use of certification authority. Upon user authentication, traditional access control or role-based access control methods can be employed to define access rights. For security, many competing algorithms exist and may give rise to interoperability problems.

Digital certificates, electronic forms that encrypt and authenticate both ends of the same transaction, are crucial in enabling EDI over the Internet. They provide the level of security EDI users are accustomed to with existing VAN service providers. Digital certificates exist that are compatible with the standard ANSI ASC X12 data types. The Internet could prove to be a much simpler and cheaper transmission medium for EDI than VANs if adequate security is developed.

Transaction Completeness

To avoid loss or duplication of a transaction during transmission, one can use batch totaling, sequential numbering, and one-to-one checking against the control file.

Availability

Viruses, Trojan horses, programming errors, and hardware and software errors may interrupt the availability of EDI systems. One can use anti-virus packages to prevent viruses. By planning, developing, installing, and operating error-free software, one can eliminate the problems of Trojan horses, viruses, and other software errors that lead to interruption of services. Fault-tolerant systems including off-site backup, redundant arrays of independent disks (RAID), disk mirroring, tandem computers, and other techniques help in avoiding interruption because of sabotage or natural causes.

SUMMARY

EDI is being used for accelerating the flow of business transactions among business partners. Advances in computer and communication technologies have made it possible to create transactions in a few minutes and transmit them to trading partners in seconds. Standardization must exist among transaction formats for computerized communication to take place between application systems of different organizations. ANSI ASC X12 and EDIFACT are two dominant formats for domestic and international interchanges, respectively. The output of the sender's application system is sent to the receiver's application system with the help of application interface, standard translation software, and communication software. Understanding of the different components and their integration requirements helps in the successful implementation of EDI. Such a successful implementation reduces transaction costs, provides flexibility, and improves the competitive advantage.

ACKNOWLEDGMENTS

This article is based on the fundamental concepts explained in Guidelines for the Evaluation of Electronic Data Interchange Products and Electronic Data Interchange (1,2). The framework of this article and many details are repeated from these documents.

FAILURE DETECTORS FOR ASYNCHRONOUS DISTRIBUTED SYSTEMS: AN INTRODUCTION

WHY FAILURE DETECTORS?

To stop waiting or not to stop waiting? That is the question! Asynchronous distributed systems are characterized by the fact that there is no bound on the time it takes for a process to execute a computation step, or for a message to go from its sender to its receiver. This is why these systems are usually called *"time-free"* systems. The major part of the software that addresses non-real-time problems implicitly considers a time-free underlying system. This has several advantages. The main one is "generality." As it is does not require that the underlying system satisfies specific timing assumptions, the software can be safely executed on any system. Moreover, the understanding and the correctness proof are usually easier as they do not rest on particular timing assumptions.

Unfortunately, the previous advantage can become useless as soon as there are failures. Assuming there is a process per node (processor), let us consider the case where a node can crash. The problem is then for a process p to know whether another process q has or has not crashed. The bad news is that the combination of crashes and asynchrony creates a context where p has no safe means to know whether q has or has not crashed. If, thinking q has crashed, p stops waiting from q after some time, it can be wrong as maybe q has not crashed and the message from q to p is only very slow. If, after it stops waiting from q and before it gets q's message, p takes an irrevocable decision (motivated by the fact that it thinks that q has crashed), this decision is wrong (and the safety property of the upper layer application can consequently be violated[1]). On the other side, let us assume that q has crashed. To prevent the bad previous scenario from occurring, p must wait until it gets q's message. It is easy to see that p will wait forever, and the liveness property of the application will never be satisfied. This is one of the main problems we are faced with when designing fault-tolerant distributed algorithms in asynchronous systems prone to failures (2).

Do the same as ancient Greeks did: Ask an oracle! To solve the previous dilemma, Chandra and Toueg have introduced and investigated the notion of failure detectors (3). A failure detector can be seen as a distributed oracle related to the detection of failures.[2] Such oracles do not change the pattern of failures that affect the execution in which they are used. Their essential characteristic is related to the guess they provide about failures. As defined by Chandra and Toueg (3), a failure detector class is basically defined by two properties, namely, a completeness property and an accuracy property. *Completeness* is on the actual detection of failures, while *accuracy* restricts the mistakes a failure detector can make.

Why use failure detectors? There are several good reasons for using a failure detector. One lies in the design approach it favors. More precisely, a failure detector is not defined in terms of a particular implementation (involving network topology, message delays, local clocks, etc.) but in terms of abstract properties (related to the detection of failures) that allow problems to be solved despite process crashes. Thus, the failure detector approach allows a modular decomposition that not only simplifies protocol design but also provides general solutions. More specifically, during a first step, a protocol is designed and proved correct assuming only the properties provided by a failure detector class. So, this protocol is not expressed in terms of low-level parameters, but it depends only on a well-defined set of abstract properties. The implementation of a failure detector *FD* of the assumed class can then be addressed independently. Additional assumptions can be investigated, and the ones that are sufficient to implement *FD* can be added to the underlying distributed system in order to get an augmented system on top of which *FD* can be implemented. In that way, *FD* can be implemented in one way in some context and in another way in another context, according to the particular features of the underlying system. It follows that this layered approach favors the design, the proof, and the portability of protocols.

Another important advantage of failure detectors lies in the approach they promote to address problems that are impossible to solve in time-free asynchronous distributed systems prone to failures. One of the most famous of them is the consensus problem that cannot be solved in asynchronous systems as soon as a process can crash (5).[3] When faced with a problem *Pb* that cannot be solved in an asynchronous system prone to failures, a natural and fundamental question that comes to mind is as follows:

> *Which is the weakest failure detector FD_{min}(Pb) the underlying asynchronous system has to be equipped with in order for the problem Pb to be solved?*

Answering this question is important from both a practical and a theoretical point of view. From a theoretical

[1] A problem can be defined with a *safety* and a *liveness* property. The safety property stipulates that "nothing bad ever happens," while the liveness property stipulates that "something good eventually happens" (1).

[2] Let us notice that the *oracle* notion has first been introduced in language theory. An oracle is a *language* whose words can be recognized in one step from a particular state of a Turing machine (4). The main characteristic of such oracles is to hide in a single "observed" step a sequence of computation steps or the use of an uncomputable function. They have been used to provide hierarchies of problems with respect to complexity or computability.

[3] Failure detectors have initially been introduced to cope with the impossibility to solve consensus in time-free systems prone to process crashes (3).

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

point of view, the properties defining such a weakest failure detector state the necessary and sufficient conditions under which the problem Pb can be solved. This means that $FD_{min}(Pb)$ defines the borderline beyond which Pb cannot be solved. More precisely, Pb can be solved only in asynchronous systems enriched with additional mechanisms able to implement $FD_{min}(Pb)$. This has an immediate practical consequence. To solve Pb, we need a system where the $FD_{min}(Pb)$ properties can be implemented.[4] Of course, if the system we are provided with satisfies stronger properties, Pb can be solved. This means that when a (provably correct) protocol does not work in a system, it is only because the properties assumed by this protocol are not satisfied by the underlying system. (Let us notice that the same argument applies to hierarchies of failure modes (6).)

Failure detectors further a deeper understanding of distributed computing problems in the presence of failures, in the sense that they allow us to know whether a problem Pb_1 is “more difficult” to solve than a problem Pb_2 or whether Pb_1 and Pb_2 require different kinds of assumptions. Pb_1 is said to be more difficult to solve than Pb_2 if it requires that the underlying system satisfies additional assumptions not necessary for solving Pb_2; that is, formally, $FD_{min}(Pb_1) \Rightarrow FD_{min}(Pb_2)$. If we have neither $FD_{min}(Pb_1) \Rightarrow FD_{min}(Pb_2)$ nor $FD_{min}(Pb_2) \Rightarrow FD_{min}(Pb_1)$, Pb_1 and Pb_2 are incomparable, which means that they require underlying systems with different properties in order for them to be solved.

Can failure detectors be implemented? Guided by practical motivations, we only consider failure detectors that cannot guess the future. Those failure detectors have been called *realistic* (7). They actually do correspond to the failure detectors that can be implemented in a synchronous system (i.e., a system with known upper bounds on both message delays and the time it requires for a process to execute a step).

So, a simple way to implement a failure detector is to use an underlying synchronous system as an additional subsystem. This subsystem is only used to implement the required failure detector and is not directly accessible by the processes. They do not ever know the existence of it. They evolve in a computation model defined by an asynchronous system enriched with the appropriate failure detector.

As we will see later, it is possible to solve some problems with *eventually accurate* failure detectors. Those failure detectors are assumed to satisfy their accuracy property (restriction on the mistakes they can make) only after some finite but unknown time. It appears that the use of such failure detectors generally requires a majority of correct processes (this constraint can be seen as the price that has to be paid to cope with *eventual* accuracy).

Interestingly, the use of eventually accurate failure detectors allows the design of *indulgent* algorithms (8), i.e., algorithms that never violate their safety property, whatever the behavior of the failure detector they use. This means that, if the failure detector never meets its accuracy property, these algorithms cannot terminate, but if they terminate, they terminate correctly. Such eventually accurate failure detectors are very interesting for a simple reason. They have best effort implementations in asynchronous systems; namely, these implementations provide failure detector outputs that a priori can only be considered as *approximate* outputs. But, very interestingly, when the underlying system behaves synchronously during a long enough period, the outputs are no longer approximate but become correct. The periods during which the underlying asynchronous system behaves synchronously are usually called *“stable”* periods. An interesting consequence is that, as we can see, the protocols implementing such failure detectors can run concurrently with the application processes on the same asynchronous system. This is practically relevant.

It is important to notice that there is no “magic” behind a failure detector. This means that, if a failure detector allows solving an otherwise impossible problem P in a given computation model M, then that failure detector cannot be implemented in the model M. The impossibility to solve P in the model M is not circumvented; it is only moved “inside” the failure detector.

Due to its inherent modularity, a main advantage of the failure detector approach is the very clean separation between the properties offered by a failure detector and the machine/network-dependent requirements that allow for implementation of it (those encapsulate low-level synchrony requirements that can change from one implementation to another one).

ASYNCHRONOUS SYSTEM MODELS

Process model. We consider a system consisting of a finite set of n processes $\Pi = \{p_1, p_2, \ldots, p_n\}$. A process can fail by crashing, i.e., prematurely halting. It behaves correctly (i.e., according to its specification) until it (possibly) crashes. By definition a process is *correct* (during a run) if it does not crash (during that run); otherwise, it is *faulty*. There is no assumption on the time it takes for a (non-crashed) process to execute a step. In the following, $t \leq n - 1$ denotes the maximum number of processes that can crash, and $f \leq t$ the actual number of process crashes during a given run.

Communication model. Processes communicate and synchronize by exchanging messages through links. Every pair of processes is connected by a link. We consider two types of links.

- The link connecting p_i to p_j is *reliable* if it does not create or duplicate messages, and every message sent by p_i to p_j is eventually received by p_j (if p_j is correct).
- The link connecting p_i to p_j is *fair lossy* if, while it does not create or duplicate messages, it can lose messages, but if p_i sends an infinite number of messages to p_j and p_j executes receive actions infinitely often, then it receives an infinite number of messages from p_i.

A process p_i sends a message m to a process p_j by invoking *“send* (m) *to* p_j*”*; p_j receives it when it terminates the invocation of “*receive*( )”. The *send*( ) and *receive*( ) primitives are provided by the underlying communication

[4] Or (in some cases) approximated, as we will see later.

network. The notation *"broadcast* (m)*"* is used as a shortcut for "**forall** $j \in \{1, \ldots, n\}$ **do** *send* (m) to p_j **enddo**". If p_i crashes while executing "*send* (m) *to* p_j", either m is sent or m is not sent at all (i.e., *send*( ) is atomic, while *broadcast*( ) is not.)

Computation models. In the following we consider two types of asynchronous computation models:

- The FLP computation model that considers crash-prone processes and reliable links.[5]
- The FLL computation model that considers crash-prone processes and fair lossy links.

SOLVING CONSENSUS

The Consensus Problem

The *consensus* problem is a paradigm of agreement problems. It appears, in one form or another, as soon as processes have to agree, e.g., on a common action to execute, on the same decision to take, etc. A well-known example of where consensus appears is *atomic broadcast.* That problem, which appears as a basic software layer in a lot of replication-based, fault-tolerant distributed systems, requires that the correct processes deliver the same set of messages in the same order. So, it is at the same time a communication problem (all the correct processes have to deliver the same set of broadcast messages), and a consensus problem (as they have to deliver them in the same order) (3). So, in the consensus problem, every correct process p_i *proposes* a value v_i and all correct processes have to *decide* on some value v, in relation to the set of proposed values. More precisely, the *consensus problem* is defined by the following three properties (3,5):

- C-Termination: Every correct process eventually decides on some value.
- C-Validity: If a process decides v, then v was proposed by some process.
- C-Agreement: No two correct processes decide differently.

The agreement property applies only to correct processes. So, it is possible that a process decides on a distinct value just before crashing. *Uniform consensus* prevents such a possibility. It has the same Termination and Validity properties plus the following agreement property:

- C-Uniform Agreement: No two processes (correct or not) decide differently.

In the following we consider the uniform consensus problem.

An Eventually Accurate Failure Detector

As indicated in the beginning of the article, the consensus problem cannot be solved in asynchronous systems prone to even a single process failure (5). It is to circumvent this impossibility that Chandra and Toueg proposed the failure detector concept (3). Among the several classes of failure detectors they have proposed, the one denoted $\diamond S$ has been shown to be the weakest to solve consensus (9). Each process p_i is equipped with a local failure detector module that provides it with a set *suspected*$_i$; p_i can only read this set that contains the identities of the processes that are currently suspected to have crashed. Any failure detector module is inherently unreliable. It can make mistakes by not suspecting a crashed process or by erroneously suspecting a correct one. Moreover, suspicions are not necessarily stable. A process p_j can be added to or removed from a set *suspected*$_i$ according to whether p_i's failure detector module currently suspects p_j. We say "process p_i suspects process p_j" at some time, if at that time we have $p_j \in suspected_i$.

To be useful a failure detector class has to satisfy some properties, and those have to be as weak as possible while allowing the problem of interest to be solved. The class $\diamond S$ includes all the failure detectors satisfying the following properties:

- Strong Completeness: Eventually, every process that crashes is permanently suspected by every correct process.
- Eventual Weak Accuracy: There is a time after which some correct process is never suspected by the correct processes.

The implementation of failure detectors of the class $\diamond S$ has been addressed in Refs. 10–14. As noted, all these implementations assume that the underlying system is eventually *stable.* If the stability assumption is satisfied during a long enough period, the sets *suspected*$_i$ satisfy the properties defining $\diamond S$. "Long enough" means here "a duration allowing the protocol using the failure detector to terminate."

A $\diamond S$-based Consensus Protocol

The protocol that follows considers the FLP model. It is indulgent, so it enjoys the nice property of never violating consensus safety (validity and uniform agreement), whatever the sequence of (correct or bad) values read from the *suspected*$_i$ sets; moreover, it terminates (at least) when these sets contain correct values during a long enough period (namely, the period during which the consensus protocol needs the failure detector).

The protocol presented in Fig. 1 is a particular instance of the generic protocol introduced in Ref. 15. It requires a majority of correct processes ($t < n/2$), which has been shown to be a necessary requirement for indulgent protocols (8). Its principles are surprisingly simple. The processes (p_i) proceed by asynchronous consecutive rounds (r_i). Each round r is coordinated by a process p_c such that $c = (r \bmod n) + 1$ (hence, if the round number never stops increasing, each process is ensured to be the coordinator of a future round).

[5] The name "FLP" is coined from the first letters of Fischer, Lynch, and Paterson who proved the impossibility of solving consensus in this system model (5). This abbreviation is of general use in the literature.

```
Function Consensus($v_i$)

Task $T1$:
(1)  $r_i \leftarrow 0$; $est_i \leftarrow v_i$;
(2)  while $true$ do
(3)      $c \leftarrow (r_i \bmod n) + 1$; $r_i \leftarrow r_i + 1$; % $1 \le r_i < +\infty$ %

         ——— Phase 1 of round $r$: from $p_c$ to all ———
(4)      if $(i = c)$ then broadcast PHASE1($r_i$, $est_i$) endif;
(5)      wait until (PHASE1($r_i$, $v$) has been received from $p_c \vee c \in suspected_i$);
(6)      if (PHASE1($r_i$, $v$) received from $p_c$) then $aux_i \leftarrow v$ else $aux_i \leftarrow \perp$ endif;

         ——— Phase 2 of round $r$: from all to all ———
(7)      broadcast PHASE2($r_i$, $aux_i$);
(8)      wait until (PHASE2 ($r_i$, $aux$) msgs have been received from a majority of proc.);
(9)      let $rec_i$ be the set of values received by $p_i$ at line 8;
         % We have $rec_i = \{v\}$, or $rec_i = \{v, \perp\}$, or $rec_i = \{\perp\}$ where $v = est_c$ %
(10)     case $rec_i = \{v\}$       then $est_i \leftarrow v$; broadcast DECISION($est_i$); stop $T1$
(11)          $rec_i = \{v, \perp\}$ then $est_i \leftarrow v$
(12)          $rec_i = \{\perp\}$    then skip
(13)     endcase
(14) endwhile

Task $T2$: when DECISION($est$) is received: broadcast DECISION($est_i$); return($est$)
```

Figure 1. A simple $\diamond S$-based consensus protocol ($t < n/2$) (15).

Let v_i be the value initially proposed by p_i. The local variable est_i represents p_i's estimate of the decision value. During a round r, its coordinator p_c tries to impose its current estimate as the decision value. To attain this goal, a round is made up of two phases. During the first phase, (1) p_c sends est_c to all the processes (line 4), and (2) any process p_i waits until it receives p_c's estimate or suspects it (line 5). According to the result of its waiting, a process p_i sets a local variable aux_i to the received value $v = est_c$, or sets it to a default value $\perp$ (line 6). It is important to notice that due to the completeness property of the underlying failure detector, no process can block forever at line 5.

Then, the processes start the second phase of round r, during which they exchange the values of their aux_i variables (line 7). Let us observe that, due to the "majority of correct processes" assumption, no process can block forever at line 8. Moreover, it is important to notice that only two values can be exchanged: $v = est_c$ or $\perp$. Consequently, the set rec_i of values received by a process p_i can only have the values $\{v\}$, $\{v, \perp\}$, or $\{\perp\}$. Moreover, due to the "majority of correct processes" assumption, it is impossible for two sets rec_i and rec_j to be such that $rec_i = \{v\}$ and $rec_j = \{\perp\}$, so we also have the following invariant (for each pair of processes p_i and p_j, that have not crashed):

$$rec_i = \{v\} \Rightarrow (\forall\, p_j : (rec_j = \{v\}) \vee (rec_j = \{v, \perp\}))$$
$$rec_i = \{\perp\} \Rightarrow (\forall\, p_j : (rec_j = \{\perp\}) \vee (rec_j = \{v, \perp\}))$$

This invariant dictates the behavior of p_i:

- $rec_i = \{v\}$ (line 10). In this case, p_i decides the value v. It can safely do so, since in this case, a process that does not decide adopts v as its new estimate value. Moreover, to prevent possible deadlock situations, p_i broadcasts its decision value.
- $rec_i = \{v, \perp\}$: (line 11). In this case, consistently with the previous item, p_i adopts v as its new estimate value, and proceeds to the next round.
- $rec_i = \{\perp\}$ (line 12). In this case, p_i proceeds to the next round without modifying est_i.

The proof that this $\diamond S$-based consensus protocol is correct is relatively easy. It is left to the reader (who can also find it in Ref. 15). The strong completeness property is used to show that the protocol never blocks. The eventual weak accuracy property is used to ensure termination (there will be a round coordinated by a correct nonsuspected process). The majority of correct processes are used to prove consensus agreement.

Other $\diamond S$-based consensus protocols can be found in Refs. 3,16–18.

Interactive Consistency

This problem has first been introduced in the context of synchronous systems where some processes can behave in a Byzantine way (19). Here we consider the interactive consistency problem in the FLP model.

This problem is harder than consensus in the following sense: The processes have to agree not on a proposed value but on the *vector* of proposed values. So, each process p_i proposes a value v_i and has to decide a vector D_i such that the following properties are satisfied (we consider here the *uniform* version of the problem):

- IC-Termination: Every correct process eventually decides on a vector.
- IC-Validity: Any decided vector D is such that $D[i] \in \{v_i, \perp\}$, and is v_i if p_i does not crash.
- IC-Agreement: No two processes decide differently.

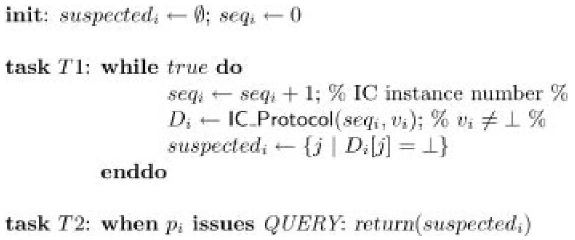
It is shown in Ref. 20 that the weakest failure detector class that allows the interactive consistency problem to be solved in the FLP model is the class of perfect failure detectors. This class, denoted $\mathcal{P}$, contains all the failure detectors that satisfy the following properties (3):

- Strong Completeness: Eventually, every process that crashes is permanently suspected by every correct process.
- Strong Accuracy: No process is suspected before it crashes.

As we can see, a perfect failure detector never makes mistakes. A $\mathcal{P}$-based interactive consistency protocol is described in Ref. 21. Interestingly, this protocol that proceeds by consecutive asynchronous rounds, is as efficient as the "best" synchronous interactive consistency protocol ("best" from a time complexity point of view, i.e., when we count the maximum number of rounds that are required, namely, min($f + 2$, $t + 1$, n)).

While consensus can be solved in the FLP model (with a majority of correct processes) equipped with $\diamond S$, it is not possible, assuming a solution to the consensus problem, to design a protocol building a failure detector of $\diamond S$. On the contrary, we show here that, in the FLP model, the construction of a perfect failure detector and interactive consistency are equivalent problems in the sense that one can solve either of them as soon as we are provided with a solution to the other.

Interactive consistency protocols based on a perfect failure detector are described in Refs. 20 and 21. A protocol



```
init: $suspected_i \leftarrow \emptyset$; $seq_i \leftarrow 0$

task $T1$: while $true$ do
        $seq_i \leftarrow seq_i + 1$; % IC instance number %
        $D_i \leftarrow$ IC_Protocol($seq_i, v_i$); % $v_i \neq \perp$ %
        $suspected_i \leftarrow \{j \mid D_i[j] = \perp\}$
    enddo

task $T2$: when $p_i$ issues $QUERY$: $return(suspected_i)$
```

Figure 2. From interactive consistency to a perfect failure detector (20).

providing the inverse construction is described here (Fig. 2). Assuming a solution to the interactive consistency problem (subroutine protocol called IC_Protocol(x,v)), this protocol implements a perfect failure detector. The protocol consists of two tasks and is very simple.[6] Task $T1$ repeatedly invokes the interactive consistency protocol and suspects a process p_j as soon as the output D_i returned by an invocation is such that $D_i[j] = \perp$. Task $T2$ processes the queries issued by the upper layer. It returns the current value of *suspected*$_i$. The reader can easily check that the sets *suspected*$_i$ satisfy strong completeness and strong accuracy.

SOLVING NON-BLOCKING ATOMIC COMMIT

The Non-Blocking Atomic Commit Problem

Originated from databases, the *non-blocking atomic commit* problem (NBAC) is certainly one of the oldest agreement problems encountered in distributed computing. According to its local state, each process first issues a vote (*yes* or *no*). Then, according to the set of votes and the fact that some processes possibly crashed, the non-crashed processes have to decide on a single value, namely, *commit* or *abort*. More precisely, the problem is defined by the following properties:

- NBAC-Termination: Every correct process eventually decides.
- NBAC-Validity: A decided value is *commit* or *abort*. Moreover:
    —NBAC-Justification: If a process decides *commit,* all processes have voted *yes*.
    —NBAC-Obligation: If all processes vote *yes* and there is no crash, then the decision value is *commit*.
- NBAC-Agreement: No two processes decide differently.

It is easy to see that the justification property relates the *commit* decision to the *yes* votes, while the obligation property eliminates the trivial and useless solution where all processes would always decide *abort*. Actually, this property defines what is a "good" run. It is a run in which all the processes want to commit (they voted *yes)* and the environment behaves correctly (no process crashes). The decision can only be *commit* in good runs.

As the reader can see, a major difference between the specification of consensus and the specification of NBAC lies in the fact that the latter mentions explicitly process crashes occurring during a protocol execution.

An Appropriate Failure Detector

Solving NBAC in the FLP model requires the model to be enriched with appropriate failure detectors. Such failure detectors are studied and investigated in Refs. 22 and 23. We consider here *timeless* failure detectors, i.e., failure detectors that do not provide information on when exactly (in the sense of global time) failures occurred. (Let us notice that $\mathcal{P}$ and $\diamond S$ define classes of timeless failure detectors.)

To address this question, a failure detector class, denoted $?\mathcal{P}$ and called the class of *anonymously perfect* failure detectors, has been proposed in Ref. 23. This class is defined as follows:

- Anonymous completeness: If a crash occurs, eventually every correct process is permanently informed that some crash occurred.
- Anonymous accuracy: No crash is detected unless some process crashed.

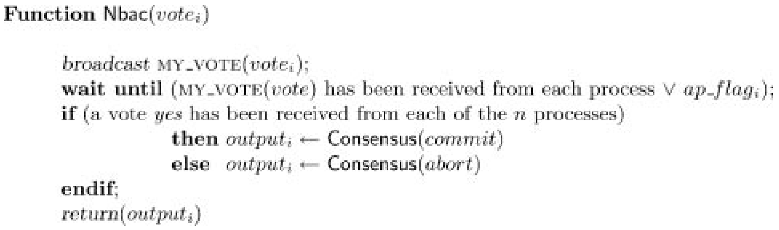
The class of failure detectors denoted $?\mathcal{P}+\diamond S$ includes all the failure detectors that satisfy both $?\mathcal{P}$ and $\diamond S$. In the following, a failure detector module of that class is represented at p_i as a boolean variable *ap_ flag*$_i$ ("approximate flag") that is *true* iff a crash is detected.

Figure 3 describes an NBAC protocol based on a failure detector of $?\mathcal{P} + \diamond S$. This protocol actually reduces NBAC to consensus (which, as we have seen, can be solved in the FLP model enriched with $\diamond S$ when $t < n/2$). The protocol is pretty simple. From a methodological point of view, it is interesting to see how each of $?\mathcal{P}$ and $\diamond S$ are used: the first is for ensuring the validity of NBAC, the second to be able to use the subroutine consensus protocol.

The weakest failure detector to solve the NBAC problem has been investigated and solved in Ref. 22. That failure detector, denoted $(\Psi, ?\mathcal{P})$, has a hierarchical structure. It is made up of two components (ψ and $?\mathcal{P}$), which means that at any time it outputs a pair of values, one related to ψ, the other one related to $?\mathcal{P}$. The failure detector ψ is in turn composed of three failure detector components Ω, Σ (see below), and a new instance of $?\mathcal{P}$. It initially outputs the default value $\perp$, and after some finite time behaves as the pair (Ω, Σ) at all processes, or (only in case a failure has previously occurred) it *may* behave as $?\mathcal{P}$ at all processes. (The switch from $\perp$ to (Ω, Σ) or $?\mathcal{P}$ need not occur simultaneously at all processes, but the same choice is made at all processes. It is important to note that the choice from $\perp$ to $?\mathcal{P}$ is allowable only if a crash has occurred. Moreover, if a failure occurs, any of the switches from $\perp$ to $?\mathcal{P}$ or (Ω, Σ) can occur.[7])

[6] The difficult construction is the other one: solving interactive consistency from a perfect failure detector (20,21).

[7] This means that, after a finite time, $(\Psi, ?\mathcal{P})$ behaves as $(?\mathcal{P}, ?\mathcal{P})$ or as $((\Omega, \Sigma), ?\mathcal{P})$.



```
Function Nbac($vote_i$)

    broadcast MY_VOTE($vote_i$);
    wait until (MY_VOTE($vote$) has been received from each process $\vee$ $ap\_flag_i$);
    if (a vote $yes$ has been received from each of the $n$ processes)
            then $output_i \leftarrow$ Consensus($commit$)
            else $output_i \leftarrow$ Consensus($abort$)
    endif;
    return($output_i$)
```

Figure 3. A simple $?\mathcal{P} + \diamond S$-based NBAC protocol ($t < n/2$) (23).

.

IMPLEMENTING QUIESCENT COMMUNICATION

This section continues our visit with the failure detector concept by considering the problem that consists of implementing *quiescent communication* despite process crashes and fair lossy links, i.e., in the FLL model (24).

The Quiescence Problem

Considering two processes p_i and p_j that do not crash connected by a fair lossy link, a basic communication problem consists in building a reliable link on top of that fair lossy link. This problem is well known, and basic mechanisms such as retransmission and acknowledgments allow it to be solved. Retransmission allows message losses to be tolerated, while acknowledgments allow their retransmission to be eventually stopped. When a receiver receives a message *m,* it sends back *ack*(m), and for each message *m* it wants to send, the sender repeatedly resends it until it gets an *ack*(m). This simple protocol is *quiescent* in the sense that, after some time, no process sends or receives messages related to the transmission of *m.*

Let us now consider the case where the receiver p_j can crash. In this case, it is possible that p_j crashes before receiving *m* and the sender will consequently send copies of *m* forever. The protocol is no longer quiescent. So, the problem is to provide quiescent implementations of communication primitives in the FLL model. This problem is addressed and solved in Ref. 24. This article first shows that the *quiescent communication* problem cannot be solved in a pure FLL model. To solve it, that model has to be appropriately enriched with a failure detector. This is not at all counter-intuitive since, to stop retransmitting a message, the sender has to know—in a way or another—whether the receiver has crashed.

Ref. 24 shows that the weakest class of failure detectors solving the quiescent communication problem is the class of eventually perfect failure detectors, i.e., the failure detectors that, after some unknown but finite time, suspect all the crashed processes and only them. Unfortunately, such a failure detector cannot be implemented in FLL. So, the authors investigated another class of implementable failure detectors capable of providing quiescent communication protocols. They called it the class of *heartbeat* failure detectors.

A Heartbeat Failure Detector

A heartbeat failure detector outputs at each process p_i an array $HB_i[1 \cdots n]$ of non-decreasing counters satisfying the following properties:

- HB-completeness: If p_j crashes, then *HB_i[j]* stops increasing.
- HB-accuracy: If p_j is correct, then *HB_i[j]* never stops increasing.

As we can see, heartbeat failure detectors can be implemented, but their implementation is not quiescent. In that sense these failure detectors allow the non-quiescent part of a communication protocol to be isolated. Moreover, the use of a heartbeat failure detector favors design modularity and eases correctness proofs. Additionally, a single heartbeat failure detector "service" can be used by several upper layer applications.

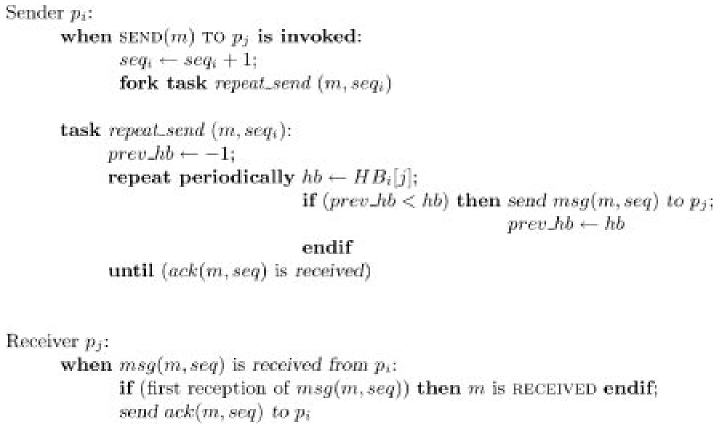
A Quiescent Implementation

Figure 4 presents a quiescent protocol providing a reliable link in an FLL system model equipped with a heartbeat failure detector. The protocol on the sender side provides an implementation of the SEND() primitive invoked by the upper layer application. To that end, it uses the send() primitive provided by the underlying communication layer. Similarly, on the receiver side, RECEIVE() notifies the upper layer that a new message has arrived, while receive() is used to receive a message from the underlying communication layer. The protocol is particularly simple and self-explanatory. The *seq_i* variable (initialized to 0) is used by the sender as a sequence number generator. It is easy to see that, after some unknown but finite time, p_i either receives *ack*(m) (due to the fairness of the underlying channel) or stops retransmitting as *HB_i[j]* no longer increases (when p_j has crashed).

This protocol shows an important difference between a *quiescent* protocol and a *terminating* protocol. The protocol described in Fig. 4 is quiescent as for each message *m* sent by p_i to p_j, there is a time after which no more protocol messages are exchanged. However, this protocol is not terminating. This is because, until it receives *ack*(m), p_i has no means to know whether it has to retransmit *m*. If p_j crashes and all *ack*(m) it sent before are lost, p_i will never terminate the task *repeat_send* (*m, seq_i*). The reader can observe that this is the best that can be done. This important difference is discussed in detail in Ref. 25.

Failure Detectors in Synchronous Systems

While atomic broadcast, consensus, NBAC, etc. cannot be solved in the FLP computation model, they can be solved in synchronous systems, i.e., in systems where there are



```
Sender $p_i$:
    when SEND($m$) TO $p_j$ is invoked:
        $seq_i \leftarrow seq_i + 1$;
        fork task $repeat\_send\ (m, seq_i)$

    task $repeat\_send\ (m, seq_i)$:
        $prev\_hb \leftarrow -1$;
        repeat periodically $hb \leftarrow HB_i[j]$;
                    if $(prev\_hb < hb)$ then $send\ msg(m, seq)\ to\ p_j$;
                                              $prev\_hb \leftarrow hb$
                    endif
        until $(ack(m, seq)$ is $received)$

Receiver $p_j$:
    when $msg(m, seq)$ is $received\ from\ p_i$:
        if (first reception of $msg(m, seq)$) then $m$ is RECEIVED endif;
        $send\ ack(m, seq)\ to\ p_i$
```

Figure 4. A quiescent implementation of a reliable link (24).

bounds on processing time and message transfer delay. So, failure detectors are useless in these systems from a decidability point of view. They add no computational power. Nevertheless, failure detectors suited to synchronous systems have recently been introduced. Their aim is to help design more efficient protocols, i.e., protocols with a "best case" time complexity that cannot be attained in pure synchronous systems. To illustrate this idea, we show here how *fast failure detectors* can be used to expedite consensus in synchronous systems (26).

Synchronous System Model

As previously mentioned, a synchronous systems is characterized by the existence of a bound on the time it takes to receive and process a message, and the fact that this bound is known by the processes. In order to simplify the presentation and without loss of generality, we assume in the following that local computations take no time and transfer delays are upper bounded by D. Thus, a message sent at time t is not received after $t + D$ (D-timeliness). The links are reliable (no creation, duplication, or loss). Moreover, processes have access to a common clock.

The combination of D-timeliness and no-loss properties with the possibility of process crashes makes possible the following behaviors when, at time t, a process p_i sends a message m to processes p_j and p_k. If p_i does not crash at time t, both p_j and p_k receive m by time $t + D$. However, if p crashes at time t, different scenarios are possible. Namely, it is possible that neither p_j nor p_k receives m, or that only one of them receives m (by time $t + D$) while the other does not receive it, or that both of them receive m (by time $t + D$).

Fast Failure Detectors

Such failure detectors have been introduced in Ref. 26. A *fast perfect* failure detector provides the processes p_i with sets $suspected_i$ that satisfy the following properties (where $d < D$):

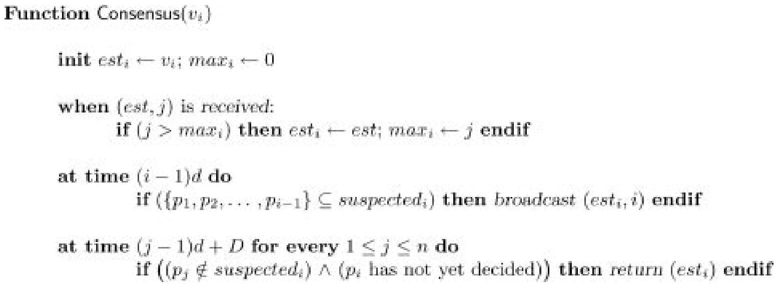
- d-Timely completeness. If a process p_j crashes at time t, then, by time $t + d$, every alive process suspects it permanently.
- Strong accuracy. No process is suspected before it crashes.

Let us observe that, if a process crashes between times t and $t + d$, then some, but not necessarily all, processes may suspect it at $t + d$.

As indicated in Ref. 26, fast failure detectors can be implemented with specialized hardware (with provides $d << D$). From a user point of view (the one in which we are interested here), they can be used to attain time complexity lower bounds that are better than what can be attained in a pure synchronous system.

To illustrate this, let us consider the fast failure detector-based synchronous consensus protocol described in Fig. 5 (26). This protocol enjoys the following early deciding property. Started at time $T = 0$, it allows the processes to decide by time $D + fd$ (let us remember that f is the actual number of process crashes). Thus, its time complexity is $D + fd$, which is much better than the best that can be done without using failure detectors, namely, $\min(f + 2, t + 1)D$.

Let us now describe in detail the behavior of a process p_i. Let us first observe that, during the time period $[0, (i - 1)d)$, p_i can only receive messages. Then, at time $(i - 1)d$, if p_i suspects all the processes with a smaller id, it sends its current estimate of the decision value (est_i) to all the processes. When a process p_i receives an estimate value *(est),* it updates its own estimate (est_i) only if it is coming from a process whose id is larger than max_i (a local variable initialized to a value smaller than any id). In that way, the successive values of est_i are coming from processes with increasing ids. Finally, at times $(j - 1)d + D$, for $j = 1, \ldots, n$, p_i decides if it trusts the corresponding process p_j. A proof of the protocol can be found in Ref. 26. It is easy to see that the processes decide by D time units when the process p_1 does not crash (in that case they decide the value v_1 proposed by p_1). If p_1 crashes while p_2 does not, they decide by time $d + D$; according to



```
Function Consensus($v_i$)

    init $est_i \leftarrow v_i$; $max_i \leftarrow 0$

    when $(est, j)$ is received:
        if $(j > max_i)$ then $est_i \leftarrow est$; $max_i \leftarrow j$ endif

    at time $(i-1)d$ do
        if $(\{p_1, p_2, \ldots, p_{i-1}\} \subseteq suspected_i)$ then broadcast $(est_i, i)$ endif

    at time $(j-1)d + D$ for every $1 \leq j \leq n$ do
        if $((p_j \notin suspected_i) \wedge (p_i$ has not yet decided$))$ then return $(est_i)$ endif
```

Figure 5. Synchronous consensus with a fast failure detector (26).

the failure pattern, the decided value is the value v_1 proposed by p_1 or the value v_2 proposed by p_2(it is the value v_1 proposed by p_1, if p_1 succeeded in sending v_1 to p_2). Etc.

ADDITIONAL REMARKS

Other problems. In addition to the previous distributed computing problems that we have shortly visited, the failure detector approach has been used to circumvent other impossibility results. We list here two of them.

The first is the construction of a *reliable atomic register* in the FLP model. It has been shown that such a construction is possible if and only if $t < n/2$. Intuitively, the majority of correct processes assumption can be used to ensure that the last value[8] of the register can always be accessed (27). A natural question is then: "Which is the weakest failure detector to implement an atomic register in the FLP model when $n/2 \leq t < n$ (i.e., when any number of processes can crash)?" This question is answered in Ref. 22 with the failure detector denoted Σ, and called the *quorum* failure detector. That failure detector outputs a set $trusted_i$ at each process p_i (the value of each of these sets can change with time). Let $trusted_i^{\tau}$ be the value of $trusted_i$ at time τ. Intuitively, $trusted_i$ contains a set of processes that p_i currently trusts as being alive. More formally, the sets $trusted_i$, $1 \leq i \leq n$, satisfy the following properties:

- Safety: $\forall i, j, \tau, \tau' : trusted_i^{\tau} \cap trusted_i^{\tau'} \neq \theta$.
- Liveness: There is a time after which, for any process p_i that has not crashed, $trusted_i$ contains only correct processes.

So, Σ provides the processes with intersecting sets, and eventually each of these sets contains only correct processes.

Σ-based algorithms building an atomic register are described in Refs. 28 and 29. (Interestingly, Σ can be built in the FLP model when $t < n/2$. This is not at all surprising as the atomic register problem can be solved in the same context without the help of a failure detector.) For the interested reader, let us mention that a protocol solving the consensus problem, despite up to $t \leq n$ crashes, in the FLP model enriched with both Σ and $\diamond S$ is described in Refs. 30.

The second problem we mention here is related to communication, namely the design of a *uniform reliable broadcast* primitive. This primitive allows the processes to broadcast messages, and it ensures that (*1*) at least the messages broadcast by the correct processes are delivered to all the correct processes, and (*2*) if a process (correct or faulty) delivers a message m, then all correct processes deliver m. So, this primitive ensures that no message from a correct process is "lost," and that no message delivered by a process is missed by a correct processes. The correct processes deliver the same set of messages, and a faulty process delivers a subset of it.

As previously mentioned, this problem can be easily solved in the FLP model when $t < n/2$ and requires additional assumptions when $n/2 \leq t < n$. The main difficulty lies in ensuring item (2). The interested reader will find in Ref. 31 an appropriate (optimal) failure detector and a uniform reliable broadcast protocol based on such a failure detector. For the interested reader, a uniform reliable broadcast protocol that additionally satisfies the quiescence property is described in Refs. 14 and 32.

Other failure detectors. Other failure detectors have been proposed. One of the most well known is the *eventual leader* failure detector, denoted Ω (9). That failure detector provides the processes with a function leader satisfying the following properties:

- Validity: Each invocation of leader returns a process name.
- Eventual Leadership: There is a time t and a correct process p such that, after t, every invocation of leader by a correct process returns p.

A failure detector of the class Ω actually provides the processes with an eventual leader election capability. But, let us notice that there is no knowledge of when the leader is elected. This means that several leaders can coexist during an arbitrarily long period of time, and there is no way for the processes to learn when this "confusing" period is over.

Ω-based consensus protocols are described in Refs. 33 and 34. The requirement $t < n/2$ is necessary for such protocols (3). Moreover, it has been shown that Ω and $\diamond S$ have the same computational power (32,35). No one allows the solution of a problem that could be solved without the other.

Consensus is a particular case of a more general problem, namely the k-set agreement problem. In that

[8] "Last" refers here to physical time, as the consistency criterion considered for the register is atomicity.

problem, the processes can decide up to k different (proposed) values. Consensus is consequently a 1-set agreement. The weakest failure detector to solve the k-set agreement problem has been investigated in Ref. 36.

On the methodology. Since the implementation of some failure detectors (e.g., eventually accurate failure detectors such as $\diamond S$) can be only approximate during some periods (when the underlying system is unstable), it is interesting to use a failure detector only in "extreme" cases, which means that the use of a failure detector has to be avoided whenever possible.

Considering the atomic broadcast problem, several articles (37–39) have provided atomic broadcast implementations that use a failure detector-based consensus black box only in extreme cases. Such protocols are said to be *thrifty* (or non-trivial) with respect to the underlying oracle.

A few references. The reader interested in the implementation of failure detectors should consult the following references (9–11, 13, 40–44). Protocols implementing failure detectors of the class Ω can be found in Refs. 12,40,45 and 46. The reader interested in the classification of distributed computing problems in presence of failures can consult Refs. 47–49. The reader interested in the weakest failure detector classes to solve some fundamental distributed computing problems can consult Refs. 9 and 22. A class of failure detectors (and related problems) that can be implemented in asynchronous systems is presented in Ref. 50.

Random oracles have also been investigated to solve distributed computing problems in the presence of crash failures (51,52). A combination of random oracles with failure detectors is addressed in Refs. 53–55.

The condition-based approach to solve agreement problems consists in characterizing the largest set of input vectors for which it is possible to solve the problem (56). As a "trivial" example, we can consider the case where we know that more than a majority of processes do propose the same value. It is easy to solve consensus for such input vectors despite one process crash. Roughly speaking, a condition-based protocol solves the corresponding agreement problem each time the input vector belongs to the condition (or when there are no failures), and it does its best to terminate when the input vector does not belong to the condition and there are failures. Very recently, a new class of failure detectors it has been proposed that allows combining the power of conditions with the information on failures required to solve agreement problems (54).

CONCLUSION

The failure detector approach was introduced by Chandra and Toueg. Initially designed for asynchronous systems, it allows a statement of the weakest assumptions that have to be added to these systems in order to solve problems that otherwise could not be solved. So, in this type of system, they allow the barrier separating impossibility and decidability to be crossed. From a more practical software engineering point of view, they strongly favor a modular approach (they allow hiding the timing assumptions needed to solve problems that are otherwise impossible to solve in pure asynchronous systems). Failure detectors have then been extended to synchronous systems. In these systems, they allow the attainment of time complexity lower bounds that could not be attained in purely synchronous systems.

G

GRADIENT-BASED OPTIMIZATION TECHNIQUES FOR DISCRETE EVENT SYSTEMS SIMULATION

INTRODUCTION

Often, decision makers shy away from system simulation modeling as a tool because of the prohibitive computational cost of generating random realizations. The development, in recent years, of efficient "single-run" approaches, as well as dramatically reduced computer cost through improved hardware, make simulation more attractive. Now that the roadblocks have been eased, a new awareness of the prescriptive simulation modeling applications, such as optimization, goal-seeking, and controlling of the prescribed design input values, is needed. This article brings together the new approaches to prescriptive simulation modeling.

Discrete event systems simulation modeling has been an important and effective technique in describing systems in several areas, such as business and engineering. Simulation modeling is an effective way of pretesting proposed systems, plans, or policies, before developing expensive prototypes, field tests, or actual implementations.

Many human-made systems can be modeled as discrete event systems (DESs); examples are computer systems, communication networks, flexible manufacturing systems, production assembly lines, and traffic transportation systems. DESs evolve with the occurrence of discrete events, such as the arrival of a job or the completion of a task, in contrast with continuous dynamic processes, such as aerospace vehicles, which are primarily represented by differential equations. Because of the complex dynamics that result from *stochastic interactions* of such discrete events over time, the tasks of performance analysis and optimization of DES can be difficult. At the same time, because such systems are becoming more widespread as a result of modern technological advances, it is important to have tools for analyzing and optimizing the parameters of these systems.

Analyzing complex DESs often requires computer simulation. In these systems, the objective function may not be expressible as an explicit function of the input parameters; rather, it involves some performance measures of the system whose values can be found only by running the simulation model or by observing the actual system. However, because of the increasingly large size and inherent complexity of most human-made systems, purely analytical means are often insufficient for optimization. In these cases, simulation is an alternative; its chief advantage is *its generality applicability*, and its primary disadvantage is its cost in terms of *time* and *money*. Although the price for computing resources continues to dramatically decrease, only a statistical estimate as opposed to an exact solution can be obtained. For practical purposes, a statistical estimate derived from a simulation is sufficient.

These human-made DESs are costly, and therefore it is important to operate them as efficiently as possible. These high costs make it necessary to find more efficient means of conducting simulation and optimizing its output. Consider optimizing an objective function with respect to a set of continuous and/or discrete controllable parameters subject to some constraints.

In almost all simulation models, an expected value can express the system's performance. Let

$$J(\theta) = E\{L[X(\theta)]\} \tag{1}$$

be the expected steady-state performance measure of a stochastic system. For the transient period analysis, see Equation (1). In Equation (1), $X(\theta)$ is a random vector with a known joint probability density function (pdf) $f(x;\theta)$, depending on a decision parameter θ which could be a vector $\theta \in \Theta \subseteq R^N$, and $L[X(\theta)]$ is the performance function. For example, in a queuing system, $L[X(\theta)]$ might be the steady-state waiting time in the system, $f(x;\theta)$ the underlying pdf of the service time, and θ the service rate.

Simulation is an option when $L[X(\theta)]$ is either unknown or too complicated to calculate analytically. An estimator of $J(\theta)$ for a given value $\theta=\theta_0$ is obtained by averaging over n independent replications; that is

$$\hat{J}(\theta_0) = \sum_{i=1}^{n} L[X_i(\theta_0)]/n \tag{2}$$

where x_i, $i=1, 2,\ldots, n$ are random vector realizations, and n is the sample size (number of independent replications, regenerative cycle, batches, etc.). This equation is an asymptotically unbiased estimator and converges to $J(\theta)$ by the law of large numbers. The goal is to optimize $J(\theta)$, subject to $\theta \in \Theta$

Figure 1 shows a general scheme to integrate simulation with gradient-based optimization techniques.

The optimizer and simulator modules are closely coupled, with the output of each module directly providing input for the other module. When users specify a performance measure $J(\theta)$ to be optimized, they must also select one or more of the optimization techniques provided in the following sections. The simulation *begins* with the processing of the initial input parameter θ. The *output data*—an estimate based on Equation (1) for $J(\theta)$—are in turn an input to the optimizer. The optimizer then generates output parameter θ, which in turn is a new input parameter for the simulator. This process is performed iteratively until one reaches a satisfactory solution. A general framework for integrating simulation and optimization as shown in Fig. 1 is proposed in Ref. 1. The inputs are subdivided into two categories: controllable inputs and uncontrollable inputs. For example, in a queuing system, the service rate (μ) and arrival rate (λ) are controllable and uncontrollable inputs, respectively; whereas the expected waiting time in the system $J(\lambda, \mu)$ could be the expected system performance measure.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

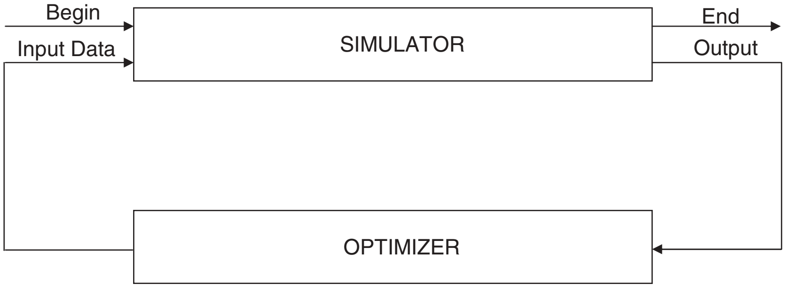

Figure 1. An optimizer support system.

Descriptive analysis includes problem identification, problem formulation, data collection and analysis, computer simulation model development, validation and verification, and output analysis.

Prescriptive analysis includes sensitivity estimation. The traditional approach to obtaining sensitivity information (derivative, Hessian, etc.) combines Crude Monte Carlo estimation with finite "differencing." This approach is impractical when each simulation run takes hours of computer time on even the fastest computers. Methods, which yield enhanced efficiency in estimating sensitivity information at little additional computational not simulation cost, are of great value. In recent years, the first two methods—-infinitesimal perturbation analysis (PA) and score function (SF), also known as likelihood ratio (LR)—have been proposed for estimating sensitivity while simulating the nominal system. Combined with appropriate variance reduction techniques, SF or LR method for sensitivity information could enlarge substantially the class of optimization and goal-seeking problems that can be solved.

Optimization is trying to find the best course of action, for example, optimizing the performance function J over μ. Optimization in simulation has challenged researchers for many years as shown in Fig. 2.

Traditionally, two approaches have been undertaken for optimization of simulation. First, when any part of a simulation can be solved analytically, simulation analysis is combined with analytical modeling. Second, attention is focused on statistical design, such as fractional factorial design and response surface design. Nowadays, the single-run sensitivity estimation is incorporated in the stochastic algorithms, such as Keifer-Wolfowitz, using PA. In using SF or LR sensitivity estimate, because the performance J and the sensitivity are estimated from the *same* sample, they are dependent; moreover, the effect of these correlated errors are usually significant. Therefore, slower procedures, such as the Robbins-Monro (R-M) algorithm, are more satisfactory.

Goal seeking, or targeting the parameter design problem, means trying to solve design problems to meet the target value, that is, to solve the inverse simulation

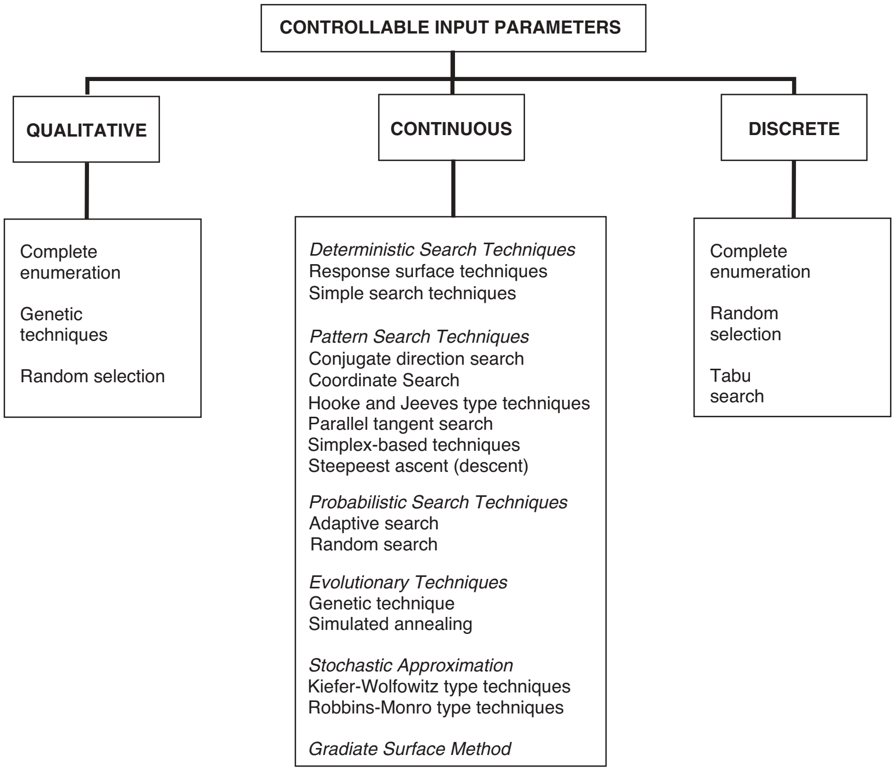

Figure 2. A classification of optimization techniques via simulation.

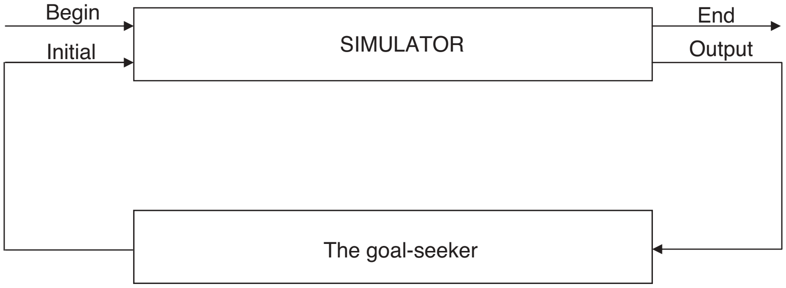

Figure 3. Goal seeking or targeting the parameter design problem.

problem. The "goal-seeking" problem considers the inverse question of descriptive simulation; namely, what must be the controllable input parameter value to achieve a desired output? A simulation-based approach is to estimate the derivative of the performance measure function with respect to the input parameter for a nominal system in a single simulation run, as shown in Fig. 3.

This estimated derivative is used in first-order local approximation of the stochastic version of Newton's root-finding algorithm to estimate the necessary controllable input parameter with a desired statistical confidence.

Postprescriptive analysis includes stability and the what-if analysis. In these analyses, the controllable input parameters are varied to study stability of the solution and to measure the responsiveness of the estimated performance measure to the change in uncontrollable input parameters; that is, to perform the so-called what-if analysis. Simulation models are often subject to serious errors propagated from statistical errors in estimating the parameters of the input distributions. Postprescriptive analysis establishes confidence in the prescriptive results with respect to small changes of parameters in the input distributions. It also provides systematic guidelines for allocating scarce organizational resources to data-collection and data-refinement activities. For example, this estimator requires only one sample path to estimates; any number of small changes in $\mu 1$ are computed simultaneously from a single simulation run while simulating the nominal system.

The remainder of the article is organized as follows. "Gradient Estimation" presents an introduction to gradient estimation. The finite difference (FD), simultaneous perturbation (SP), PA, the SF/LR, and harmonic analysis gradient estimators are presented in the next four sections, respectively. The next section provides a short comparison among these different views of gradient estimators. Then, gradient-based optimization techniques are introduced. Stochastic approximation techniques are presented next, whereas the section that follows is devoted to gradient surface methods. Postoptimality tools are derived in "Postsolution Analysis." Concluding remarks are given last. All techniques are presented in English-like format and therefore can be implemented in a variety of operating systems and machines, which provides unlimited portability.

GRADIENT ESTIMATION

In the design, analysis, and operation of DESs any information about the sensitivity or gradient $dJ(\theta)/d\theta$ is useful to both engineers and managers. The sensitivity $dJ/d\theta$ can be used in conjunction with various optimization algorithms whose function is to adjust θ gradually until a point is reached where $J(\theta)$ is maximized (or minimized). If no other constraints on θ are imposed, then we expect $dJ/d\theta = 0$ at this point. A typical algorithm is the R-M stochastic approximation described by

$$\theta_{n+1} = \theta_n + \eta_n (dJ/d\,\theta)_{\theta=\theta n}\; n = 1, 2, \ldots. \qquad (3)$$

where the parameter is adjusted gradually from some initial value θ_0 until $dJ/d\theta = 0$ for some θ_n. The amount of adjustment is proportional to the value of the derivative evaluated at $\theta = \theta_n$, with properly selected coefficients η_n, $n = 1, 2, \ldots$. These coefficients are referred to as step sizes, scaling factors, or learning rates, which could be any positive sequence of numbers that converge to zero. In our case, the derivative is replaced by its estimate (2–6).

The gradient estimate can be used as a subroutine in a nonlinear programming algorithm, such as the *Augmented Lagrangians* method (7), to obtain the optimal solution of the following stochastic nonlinear program:

Problem P:

$$\min \mathrm{J}(\theta) = \min \mathrm{E}[\mathrm{L}(\mathrm{X}(\theta))]$$

subject to:

$$\begin{aligned} \mathrm{g}_i(\theta) &= \mathrm{E}\,\mathrm{G_i}[(\mathrm{X}(\theta))] \leq 0,\ i = j, \ldots, \mathrm{m} \\ \mathrm{h}_j(\theta) &= \mathrm{E}\,\mathrm{H_j}[(\mathrm{X}(\theta))] = 0,\ \mathrm{j} = \mathrm{I}, \ldots, \mathrm{p} \end{aligned}$$

The objective function and perhaps some constraints are not known analytically, so their functional evaluation and their gradients must be replaced by their estimates via simulation (2, 4, 5).

FINITE DIFFERENCE (FD)

Suppose that we have a system performance parameterized random variable $L(\theta)$ for each θ in some interval, say [a, b]; that is, a stochastic process $\{L(\theta)\text{: } \theta\ \varepsilon[\mathrm{a, b}]\}$. For example, $L(\theta)$ could be the amount of time that a customer waits in the system. The parameter θ could be the mean service rate of the server.

Suppose that the measure of interest is $E[L(\theta)]$ and that the decision maker is interested in the sensitivity of the measure with respect to the parameter value. Also, assume that this measure is differentiable in θ on [a, b]. The brute force FD method consists of the following steps:

Step 1: *Generate* N *sample points*

Generate N sample points ω_1, ω_2, ω_3, …. ω_N, using $\theta - \Delta\theta$ for some small $\Delta\theta$ to generate N realizations. This task is generally done in simulation by generating N sequences of pseudo-random numbers. Then N realizations can be generated for $L(\theta - \Delta\theta)$, namely $L(\theta - \Delta\theta, \omega_1)$, $L(\theta - \Delta\theta, \omega_2)$, $L(\theta - \Delta\theta, \omega_3)$, …. $L(\theta - \Delta\theta, \omega_N)$. In other words, the simulation is performed N times with the parameter set at $\theta - \Delta\theta$.

Step 2: *Perform another* N *simulations*

Typically using the same pseudo-random numbers, that is, using common random variate as a variance reduction technique (VRT), generate N realizations of:

$$L(\theta + \Delta\theta, \omega_1), L(\theta + \Delta\theta, \omega_2), L(\theta + \Delta\theta, \omega_3), \ldots. L(\theta + \Delta\theta, \omega_N).$$

Step 3: *Estimate the derivative*

$$dE[L(\theta)]/d\theta\_[\Sigma L(\theta + \Delta\theta, \omega_i) - \Sigma L(0 - \Delta\theta, \omega_i)]./2N\Delta\theta \quad (4)$$

where the sums are over $i = 1, 2, \ldots, N$. The estimate should get better as N gets larger.

The first fact to notice about this estimate is that it requires $2N$ simulation runs. If θ were a parameter vector and the decision maker were interested in sensitivity analysis with respect to each of the components, then $2N$ simulations would have to be run for each component of θ. This method is inefficient. The second fact to notice about this estimate is that it may have a very poor variance, and it may result in numerical calculation difficulties, because for very small $\Delta\theta$ there is not much statistical difference between $L(\theta + \Delta\theta)$ and $L(\theta - \Delta\theta)$, and we are dividing this difference by a small number. Finally, this estimate is unbiased for each non-zero $\Delta\theta$, because the slope of a secant line is approximating the slope of the tangent line. This result leads to the difficult question of which $\Delta\theta$ to use. To minimize the "secant error," we should use a small $\Delta\theta$, but using such a small value contributes to the variance and numerical difficulties mentioned above. The well-known Kiefer-Wolfowitz stochastic approximation algorithm (8) is based on the FD gradient approximation.

SIMULTANEOUS PERTURBATION (SP)

The SP algorithm introduced by Spall (10, 11) has attracted considerable attention. SP is based on an easily implemented and highly efficient gradient approximation that relies on measurements of the performance function, not on measurements of the gradient of the performance function. The gradient approximation is based on only *two*function measurements, regardless of the dimension of the gradient vector θ. This finding contrasts with the FD approach, which requires several function measurements proportional to the dimension of the gradient vector. The fundamental (and perhaps surprising) theoretical result is that under reasonably general conditions, SP and Kiefer-Wolfowitz FD-based stochastic approximation (for optimization - purposes) achieve the *same* level of statistical accuracy for a given number of iterations, even though SP uses fewer function evaluations than FD.

The step-by-step summary below shows how to produce the gradient estimate.

Step 0: *Initialization and Coefficient Selection*

Set counter index k equal to 0. Pick an initial guess for the non-negative coefficients C and for η in the SP gain sequence

$$C_k = C(k+1)^{-\eta} \quad (5)$$

A practically effective (and theoretically valid) value for η is 0.101; C may be determined based on prior knowledge and/or numerical experimentation. In the latter case, C is approximately equal to the standard deviation (noise) when running the simulation several times with the same input, using different random number streams.

Step 1: *Generation of a simultaneous perturbation vector*

Generate by Monte Carlo a p-dimensional random vector Δ_k where p is the dimension of θ, and each of the p components of Δ_k is independently generated from a Bernoulli $(-1, +1)$ distribution with a probability of 1/2 for each outcome.

Step 2: *Performance measure evaluations*

Obtain two measurements of the performance function J(.) based on N realizations of simultaneous perturbation around θ: $L(\theta + C_k\,\Delta_k)$ and $L(\theta - C_k\,\Delta_k)$ with the C_k and Δ_k from Steps 0 and 1.

Step 3: *Gradient approximation*

Generate the simultaneous perturbation approximation to the (unknown) p-dimensional gradient of $J(\theta)$ by averaging over N:

$$\begin{matrix} \dfrac{J(\theta + C_k\,\Delta_k) - J(\theta - C_k\,\Delta_k)}{2C_k\,\Delta_{k1}} \\ \vdots \\ \dfrac{J(\theta + C_k\,\Delta_k) - J(\theta - C_k\,\Delta_k)}{2C_k\,\Delta_{kp}} \end{matrix} \quad (6)$$

where Δ_{ki} is the ith component on the Δ_k vector (Δ_{ki} may be a Bernoulli random variable, as discussed in Step 1). Note that only the denominators change in the p components of the gradient estimation; the numerators reflect the simultaneous perturbation of all components of θ in contrast to the component-by-component perturbation in the FD gradient approximation.

For SP-based optimization, refer to Ref. 6. SP can be seriously limited by, for example, the stability constraints of the system (traffic intensity must remain less than 1 for steady-state sensitivity estimation).

One-measurement PA analog to Equation (5) is:

$$\begin{matrix} \dfrac{J(\theta + C_k\Delta_k)}{2C_k\,\Delta_{k1}} \\ \vdots \\ \dfrac{J(\theta + C_k\,\Delta_k)}{2C_k\,\Delta_{kp}} \end{matrix} \quad (7)$$

A closely related approach to SP is the random directional SP. Let $d_k \in \mathrm{R}^p$ denote a vector that contains p mutually independent variables generated by the standard normal distribution. Then the kth component of random direction gradient estimate is:

$$[\mathrm{J}(\theta + \mathrm{C}_k \mathrm{d}_k) - \mathrm{J}(\theta - \mathrm{C}_k \mathrm{d}_k)]/2\mathrm{C}_k \tag{8}$$

SP uses two different estimators. A single-run version of SP is given in Ref. 10.

The following approaches avoid any numerical problems associated with taking the difference as an approximation to the gradient; they are based on *a single simulation run*, and the methods have the potential for real-time applications.

PERTURBATION ANALYSIS (PA)

PA computes (roughly) what simulations would have produced had θ been changed to θ + Δθ without actually making this change (11, 15). The intuitive idea behind PA is that a sample path constructed using θ is frequently structurally very similar to the sample path using θ + Δθ. A large amount of information is the same for both of them. It is wasteful to throw this information away and to start the simulation from scratch with θ + Δθ. In PA, moreover, we can let Δθ → 0 to get a derivative estimator without numerical problems.

The effect of a parameter change on the performance measure is important. However, we would like to realize this change by keeping *the order of events exactly the same*. The perturbations will be so small that only the durations, not the order, of the states will be affected. This effect should be observed in three successive stages:

Step 1: How does a change in the value of a parameter vary the sample durations related to that parameter?

Step 2: How does the change in individual sample duration reflect itself as a change in a subsequent particular sample realization?

Step 3: Finally, what is the relationship between the variation of the sample realization and its expected value?

PA calculates the gradient of performance measure for every realization ω. The value of L(θ, ω) is obtained by a simulation run. PA calculates the value of L(θ + Δθ, ω) in parallel. This statement means that PA calculates all derivatives from a single simulation run. Under mild conditions, for every realization ω, a bound Δ(ω) exists, so that the PA estimator equals the exact path derivation of the performance measure for all $|\Delta\theta| \leq \Delta(\omega)$. Averaging the PA estimator over independent replication yields E[dL(θ, ω)/dθ]. PA works by computing a *sample path derivative* from the simulated sample path, which is used as an estimate of E{d[L(θ)]/dθ}. This random variable is the derivative d [L(θ)]/dθ}, which is the derivative of a random variable. If this estimator is statistically unbiased, then

$$\mathrm{E}\{\mathrm{d}[\mathrm{L}(\theta)]/\mathrm{d}\theta\} = \mathrm{d}\,\mathrm{E}[\mathrm{L}(\theta)]/\mathrm{d}\theta \tag{9}$$

This equation says that unbiasedness corresponds to the interchange of the operations of differentiation and expectation. Much theory of PA involves finding conditions that justify this interchange. Now, if the interchangeability holds, then the estimate of dE[L(θ)] / dθ is given by

$$\mathrm{dE}[\mathrm{L}(\theta)]/\mathrm{d}\theta = \mathrm{E}\{\mathrm{dL}(\theta)]/\mathrm{d}\theta\} - \Sigma\, \mathrm{dL}(\theta,\, \omega_i)/\mathrm{N}\mathrm{d}\theta \tag{10}$$

where the sum is over all $i = 1, 2, \ldots, N$, and dL(θ, ω_i) is the random variable dL(θ) / dθ evaluated at the sample point ω_i. The strong law of large numbers implies that

$$\mathrm{dE}[\mathrm{L}(\theta)]/\mathrm{d}\theta = \lim \Sigma\, \mathrm{dL}(\theta,\, \omega_i)]/N\mathrm{d}\theta \quad \text{as}\, N \to \infty \tag{11}$$

where the sum is over all $i = 1, 2, 3, \ldots N$.

Let X(θ) be a parameterized family of random variables with F(x, θ) as its cumulative probability distribution function. Assume F(x, θ) is continuously differentiable in x and θ, and for Δθ > 0, F(x, θ) ≥ F(x, θ + Δθ). We can view X(θ) as the inverse transformation $\mathrm{X}(\theta) = \mathrm{F}^1(\mathrm{U}, \theta)$ where U is uniformly distributed on [0, 1]. The random variable dX(θ)/dθ can now be defined by

$$\begin{aligned}\mathrm{dX}(\theta)/\mathrm{d}\theta &= \lim_{\Delta\theta \to 0} [\mathrm{F}^{-1}(\omega,\, \Delta\theta) - \mathrm{F}^{-1}(\omega,\, \theta)]/\Delta\theta \\ &= \mathrm{dF}^{-1}(\omega,\, \theta/\mathrm{d}\theta)\end{aligned} \tag{12}$$

for each ω ε [0, 1] for which this limit exists. Under differentiability properties of F(x, θ), it can be shown (16) that

$$\mathrm{dX}(\theta)/\mathrm{d}\theta = -\{\partial[\mathrm{F}(\mathrm{X}(\theta), \theta)]/\partial\theta\}/\partial[\mathrm{F}(\mathrm{X}(\theta), \theta)]\}/\partial\mathrm{x} \tag{13}$$

This result is useful because it expresses the derivative of a random variable as a function of the random variable. Note that the denominator of the right side of Equation (13) is the probability density function of X(θ). It is also useful to note that this derivative has the minimum variance among all possible definitions of the sample path derivative (17).

We have already observed that we can view X(θ) as the inverse transformation $\mathrm{X}(\theta) = \mathrm{F}^{-1}(\mathrm{U}, \theta)$ where U is uniformly distributed on [0, 1]. In other words, the expectation may be taken over u ∈ [0, 1] instead of x, with u = F(x, θ); that is,

$$\mathrm{J}(\theta) = \int \mathrm{L}[x(\mathrm{u}, \theta)]\mathrm{du} \tag{14}$$

The interpretation is that the sample path really depends on a uniformly distributed random variable over which the expectation is taken, which specifies another random variable X(U, θ), in turn determines the sample function

L[X(U, θ)]. If we now differentiate Equation (14) with respect to θ, we get

$$\mathrm{dJ}/\mathrm{d}\theta = \int \{\partial \mathrm{L}[x(\mathrm{u}, \theta)]/\partial\theta\}\, \mathrm{du} = \mathrm{E}\{\partial \mathrm{L}[x(\mathrm{u},\, \theta)]/\partial\theta\} \tag{15}$$

If the interchange of expectation and differentiation is allowed, then the sample deviation dL/dθ is an unbiased estimator of the performance derivative dJ/dθ. Note that the sample derivative can be written as follows:

$$\partial L[x(u,\theta)]/\partial\theta = \partial L[x(u,\theta)]/\partial x \quad . \quad \partial x(u,\theta)/\partial\theta \tag{16}$$

This result is useful because it reflects that PA consists of two parts: *perturbation generation* [i.e., how changes in θ introduce changes in X(θ)], and *perturbation propagation* [i.e., how a change in X(θ) ultimately affects the sample function L]. Observe that in this whole process, U (the underlying random number) is kept fixed (16).

Frequently, a PA estimator of d E [L(θ)]/dθ for a performance measure random variable L(θ) will fail to be unbiased or strongly consistent, if it is not the case that L(θ) is a continuous function of θ. When this happens, the treatment involves conditioning on another suitably chosen random variable K(θ). Conditioning tends to "smooth out" discontinuities. Hence, the random variable dE[L(θ) | K(θ)]/dθ can be used as a potential estimator, provided it is a continuous function of θ with probability 1, and if this derivative can be observed from the sample space. Now, *if* this estimator is unbiased, then we have

$$E\{d\,E[L(\theta)|K(\theta)]/d\theta\} = d\,E\{E[L(\theta)|K(\theta)]/d\theta]\} = d\,E[L(\theta)]/d\theta$$

Obviously, PA algorithms cannot be used for discrete parameters. Furthermore, for some systems, the common probability space derivatives do not give relevant information about the derivative of the objective function. For these systems, the finite difference estimator is used. Generally, these algorithms are concerned with calculating:

$$L(\theta+\Delta\theta,\,\omega) = h\,[z_1(\theta+\Delta\theta,\,\omega),\ldots,z_N(\theta+\Delta\theta,\omega)]$$

where a finite ω is given. In this case, the function h is not necessarily the same as the nominal sample path; in fact, it could be different, because a finite perturbation in the parameter value often produces a perturbed sample path that is very different from the nominal sample path. The conclusion is that, except for some limited systems, the information on the nominal sample path cannot be used readily to calculate L(θ + Δθ, ω). Instead, one obtains estimates of E[L(θ)] and E[L(θ + Δθ)], which are to obtained simultaneously by viewing a simulation as a function of the system parameters (including θ) and a sequence of uniform random variables into the performance measure L. Changing the value of θ by a small amount is equivalent to using a slightly different mapping. This method leads to the cut-and-paste concept, which involves making the sample paths obtained from different parameter values behave similarly by appending and cutting pieces of the trajectories appropriately. This result allows for obtaining estimates of the performance measure at different values of the parameter by running parallel simulations.

Related to the cut-and-paste concept is the standard clock method. Under the assumption that the times between events of type i are exponentially distributed with rate λ_i, events are generated at the rate $\Sigma\lambda_i$ which is the maximal rate at which events could possibly occur. Some of these events will be rejected because of perturbations or infeasibility, which allows for many simulations to be run in parallel. Several approximations allow the Markov assumption to be relaxed. The standard clock method is particularly suited for answering "what if" questions in real-time.

SCORE FUNCTION OR LIKELIHOOD RATIO METHOD (SF/LR)

Using S(x, θ) = f(x, θ)/g(x) (the so-called likelihood ratio) and g(x) as the new probability density function, the performance measure can be rewritten as

$$\begin{aligned} J(\theta) &= \int L(x)\,f(x,\,\theta)\,dx = \int L(x)\,S(x,\theta)\,g(x)\,dx \\ &= E_g\{L(x)S(x,\theta)\} \end{aligned} \tag{17}$$

The derivative of the performance measure becomes

$$\begin{aligned} dJ/d\theta &= \int L(x)[\partial S(x,\,\theta)/\partial\theta]\,g(x)\,dx \\ &= E_g[L(x)\,S(x,\,\theta)[\partial \ln f(x,\,\theta)/\partial\theta] \end{aligned} \tag{18}$$

which is the likelihood ratio gradient estimator. The gradient can be estimated simultaneously, at any number of different parameter values, in a single-run simulation. Here L(x) is written instead of L[x(θ)] because L, which is a specific realization of the performance metric, is fixed as θ varies. Thus, this approach is referred to as common realization. The new density function g(x) is usually assumed to be of the form g(x) = f(x, θ_0), where θ_0 is some fixed value of the parameter, which is called the reference parameter. The optimal value of θ_0, to minimize the variance of the gradient estimate, is estimated by simulation (5).

If we set g(x) = f(x, θ), then it is called the score function method of estimating the gradient

$$dJ/d\theta = \int L(x)\,[\partial\,f(x,\,\theta)/\partial\theta]\,dx \tag{19}$$

provided that the interchange of expectation and differentiation in Equation (18) is allowed (18). Moreover, observing that

$$\partial \ln f(x,\,\theta)/\partial\theta = [\partial f(x,\theta)/\partial\,\theta]/f(x,\,\theta)$$

we get, assuming f(x, θ) ≠ 0,

$$\begin{aligned} dJ/d\theta &= \int L(x)\,[\partial \ln f(x,\,\theta)/\partial\,\theta]\,f(x,\,\theta)dx \\ &= E\{L(X)[\partial \ln f(X,\theta)/\partial\,\theta]\} \end{aligned} \tag{20}$$

In this way, an alternative unbiased estimator of dJ/dθ is obtained. This estimator is known as the SF estimator, which is sometimes also referred to as the LR estimator. Again, in this case, the parameter θ is viewed as affecting the probability distribution of values of the sample function but not the particular value observed. This method must be contrasted to the PA approach where we view θ as affecting the sample function itself.

Recent work on the SF or LR approach includes Refs. 19 and 20. The basic idea is that the gradient of the performance measure function, $J'(\theta)$, is expressed as an expectation with respect to the *same* distribution as the performance measure function itself. Therefore, the sensitivity information can be obtained with little computational (not simulation) cost, while estimating the performance measure. For example, a gradient estimate of customer sojourn time in a GI/G/1 queuing system could be

$$\sum_{i=1}^{N} \mathrm{q_i}[\partial \ln \mathrm{f}(x_i,\ \theta)/\partial\theta]/N \tag{21}$$

where q_i is the sojourn time of the ith customer and $\mathrm{f}(x_i, \theta)$ is the pdf of the service time X with service rate θ.

It is well known that the crude form of the SF estimator suffers from the problem of linear growth in its variance as the simulation run increases (19). However, in the steady-state simulation, the variance can be controlled by run length. Furthermore, information about the variance may be incorporated into the simulation algorithm. A recent flurry of activity has attempted to improve the accuracy of the SF estimates. Under regenerative conditions, the estimator can be modified easily to alleviate this problem, yet the magnitude of the variance may be large for queuing systems with heavy traffic intensity. A heuristic decomposition method of estimating the SF-based sensitivity is proposed in Ref. 4. The heuristic idea is to treat each component of the system (e.g., each queue) separately, which synchronously assumes that individual components have "local" regenerative cycles. This approach is promising, because the estimator remains unbiased and efficient although the global regenerative cycle is very long.

Now, look at the general (nonregenerative) case. In this case, any simulation will give a biased estimator of the gradient, as simulations are necessarily finite. If n (the length of the simulation) is large enough, then this bias is negligible. However, as noted earlier, the variance of the SF sensitivity estimator increases with n; so, a crude SF estimator is not even approximately consistent. Many ways can be used to attack this problem. Most variation in an estimator comes *from the score function*. The variation is especially high when all past inputs contribute to the performance and the scores from all are included. When batch means are used, the variation reduces by keeping the length of the batch small.

A second method is to reduce the variance of the score to such an extent that we can use simulations long enough to eliminate the bias effectively. This approach is the most promising. The variance may be reduced further by using standard VRT, such as importance sampling (5). Finally, we can simply use many iid replications of the simulation.

As a way to reduce the amount of simulation, the n observations are divided into k groups, or batches, of m consecutive observations. Batch means are calculated for each of the k batches. However, the batches are not truly independent. The mean-squared error of the resulting sensitivity estimates depends highly on the choice of m, but the optimal value of m is unknown. The estimate of sensitivity is:

$$\sum_{t=1}^{n} \mathrm{L}_i\ \mathrm{S}_t(\theta)/n \tag{22}$$

where $n = km$ and $\mathrm{S}_t(\theta)$ is the score associated with L_t. The batch size used to obtain this sensitivity estimate will depend on the autocorrelation structure of the sequence of the batch performances. The score associated with a particular performance L_t should be calculated from all previous inputs on which the performance depends. The performance will be approximately independent of inputs that occurred in the past. The more L_t depends on past inputs, the more inputs should be used in the calculation of the score and the larger m must be. For example, for an M/M/1 queue, a reasonable batch length is about 10 times the expected length of the busy period. Even this amount leads to large bias for high-traffic intensities. Because m is not infinite, the estimator will be biased. In steady-state estimation, the performance depends mainly on recent inputs, is approximately independent of more remote inputs, and is completely independent of future inputs. In this case, a long simulation is run. However, instead of using the score of all the inputs in the estimate, a weighted score is used:

$$\sum_{t=1}^{n} \mathrm{L}_t \sum_{i=0}^{t-1} \mathrm{a}_i\ \mathrm{S}(x-\mathrm{i};\theta)/\mathrm{n} \tag{23}$$

with the weights decreasing to 0 as i goes to infinity. Two weighing schemes have been examined in Ref. 21. The first is termed the moving batch SF estimate. Its weights are:

$$\begin{aligned} \mathrm{a}_i = 1;\quad & \text{for}\quad i = 0,\ldots,\mathrm{m}-1 \\ \mathrm{a}_i = 0;\quad & \text{for}\quad i = \mathrm{m},\ldots,\mathrm{n}-1 \end{aligned} \tag{24}$$

in other words, only the m most recent inputs are considered in the score. This gives

$$\sum_{t=1}^{n} \mathrm{L_t} \sum_{\mathrm{i}=0}^{\mathrm{m}-1} \mathrm{S}(\mathrm{x_t}-\mathrm{i};\theta)/\mathrm{n} \tag{25}$$

By dropping all but the m most recent inputs, the variance of the resulting sensitivity estimator is reduced. Thus, it makes sense to drop the m terms, because for some terms L_i is independent of future inputs, so these terms have an expectation equal to zero. Moreover, the scores are only approximately independent of the performance, so that the expectation of these scores is approximately zero. This estimate of the gradient is closely related to the batch means. The equations for these estimates for k batches of length m, $n = km$ are:

$$\sum_{j=1}^{k} \sum_{j=(i-1)\mathrm{m}+1}^{im} \mathrm{L}_i \sum_{\mathrm{t}=(i-1)\mathrm{m}+1}^{j} \mathrm{S}(x_t;\theta)/n \tag{26}$$

or

$$\sum_{j=2}^{k+1} \sum_{j=(i-1)\mathrm{m}+1}^{im} \mathrm{L}_i \sum_{\mathrm{t}=(i-2)m+1}^{j} \mathrm{S}(\mathrm{x_t};\theta)/n \tag{27}$$

In each case, only product terms with nonzero expectations are included. However, with the moving batch estimate, each score is calculated from the same number of inputs. The scores for the first estimate are calculated using from t to m terms; those of the second estimate are calculated using from t to $2m$ terms. Some simulation results for these estimators are given in Ref. 21, which shows substantial reduction in variance for both estimators.

A disadvantage of these batch estimates is that they take somewhat longer to compute than a standard batch estimator. As another alternative, exponential weighing may be used weights of the form $a_i = a^i$, for some a <1. Other possible scores for use with a batch estimate are, for $i = 1, \ldots k$, and $(i-1) < t \leq im$:

$$S_{1t}(\theta) = \sum L_i \, \underset{j=(i-1)m+1}{S_j^t(\theta)/n} \tag{28}$$

$$S_{2t}(\theta) = \sum L_i \, \underset{j=(i-2)m+1}{S_j^t(\theta)/n} \tag{29}$$

$$S_{3t}(\theta) = \sum L_i \, \underset{j=(i-1)m+1}{S_j^{im}(\theta)/n} \tag{30}$$

$$S_{4t}(\theta) = \sum L_i \, \underset{j=(i-2)m+1}{S_j^{im}(\theta)/n} \tag{31}$$

In Equation (28), the score is computed from all inputs from the beginning of the batch to the present observation. Equation (29) also includes the total score of the previous batch. The estimate using Equation (30) is the score of the entire batch, which is a crude type of estimator. Equation (31) is the sum of the scores of the present and the last batch, which is also a crude type of estimator. A crude estimate is expected to do more poorly than these efficient estimates. The performance at time t is independent of future inputs. Efficient estimators discard these product terms with expectation zero. The idea behind S_{2t} and S_{4t} is as follows. Adding the score of the previous batch decreases the bias, at the cost of increasing the variance. At moderate to high-traffic intensities, this process will lead to a significant reduction in the mean squared error. At low intensities, the estimates are already approximately unbiased; so, the mean square error will be increased. In the case of the crude estimates, this should do substantially better than merely doubling the batch size. With S_{4t}, all the additional terms in the score are correlated with all the performance estimates in the batch which is not the case when the batch size is doubled. An improvement in the efficient estimates is expected, as the minimum number of terms in the score associated with L_t is $m + 1$ rather than 1. These estimators can be considered as the method of batch means with a "window" of variable width as a function of different estimators using, for example, its own score function in that window, up to that window, or even through the whole process.

Another effective VRT is by *conditioning*. The idea behind conditional expectation is simple. If LS is the output of interest, then E(LS) = E{E{LS | Z)} and Var(LS) = E[Var(LS | Z)] + Var[E(LS | Z) for any random variable Z for which the conditional expectation exists. In other words, Var(LS) $\geq$ Var[E(LS | Z). An estimator based on E(LS) has a variance no larger than one based on LS. The approach is to compute E(LS | Z) analytically and to estimate the expected value of this quantity using Monte Carlo methods. Score function estimates of sensitivity are of the form $L(x)S(\theta)$. Note that

$$E_\theta[L(X)\,S(\theta)] = E_\theta\{E_\theta[L(X)|S(\theta)]S(\theta)\} \tag{32}$$

A new sensitivity estimate can be obtained by estimating the inner expectation, by generating the inputs X conditionally on the value of $S(\theta)$, and then by calculating the outer expectation. Thus, the estimator based on conditioning takes the form

$$\int L(X|S(\theta) = s)\, s\, f_{s(\theta)}(s)\, ds \tag{33}$$

where $f_{S(\theta)}$ (s) is the density of the score function. It may be necessary to evaluate this integral numerically, using the quadrature rule (21, and refs. therein). Other conditioning methods are proposed in Ref. 4.

A *control variate* is another alternative VRT. Consider SF estimates of the gradient of $J(\theta)$. It is natural to consider the efficient score function [Ln(f)]' as the control variate. Under some mild regularity conditions, use $E\{[dLn(f)/d\theta\}] = 0$. Therefore, as another estimator, Equation (20) can also be written as:

$$J'(\theta) = \int \{L(x)\} f'(x;\theta)\, dx = \mathrm{Cov}\,[L(X),\ S] \tag{34}$$

Using the usual estimate for this covariance can lead to large variance reduction (22). Another alternative is:

$$J'(\theta) = E[L(X)\,.\,S] + \alpha\, E[S] \tag{35}$$

where α could be the optimal linear control $\alpha^* = \mathrm{Cov}(L, S)/\mathrm{Var}(S)$, which can be estimated by substituting the usual estimates of variance and covariance for the true values.

Note also that the gradient can be written as

$$\begin{aligned} J'(\theta) &= \int \{L(x)\}\, f'(x;\theta)/f(x;\theta)\, dx \\ &= \int L(x) \frac{f'(x;\theta)}{\varphi(x;\theta), f(x;\theta)} \varphi(x;\theta) dx \end{aligned} \tag{36}$$

The best choice for φ is the one proportional to $L(x).|f'(x;\theta)|$. This function minimizes the variance of $J'(\theta)$, but this optimal φ depends on the performance function $L(x)$ which for most cases is not known in advance. One may use the empirical version of $L(x).|f'(x;\theta)|$.

The inherent variability of the SF makes variance reduction techniques extremely important if SF is to be useful. We have outlined a few of ways to run a simulation to obtain a SF estimate of the gradient of the performance measure. Although the type of simulation being run has a large effect on the precision of the sensitivity estimate, the precision of the estimate of performance, which is obtained at the same time, is insensitive to the type of simulation.

HARMONIC ANALYSIS (HA)

Another strategy for estimating the gradient simulation is based on the frequency domain method, which differs from the time domain experiments in that the input parameters are deterministically varied in sinusoidal patterns during the simulation run, as opposed to being kept fixed as in the time domain runs. The range of possible values for each input factor should be identified. Then the values of each input factor within its defined range should be changed during a run. In time series analysis, t is the time index. In simulation, however, t is not necessarily the simulation clock time. Rather, t is a variable of the model that keeps track of certain statistics during each run. For example, to generate the interarrival times in a queuing simulation, t might be the variable that counts customer arrivals.

In frequency-domain simulation experiments, a separate frequency ω is assigned to each factor. By basing the analysis on Fourier series, ω varies between 0 and 1/2 in multiples of $1/T$, where T is the number of observations. The highest frequency is obtained when ω is chosen to be 1/2, and the lowest frequency is achieved when ω is chosen to be $1/T$. The lowest frequency completes one cycle, whereas the highest frequency completes $T/2$ cycles during each run. The contribution of each frequency to the variability of a time series is measured by a spectrum function. Furthermore, the theory of linear systems indicates that a sinusoidal input to a linear system, in steady state, results in a sinusoidal output at the same frequency. Consequently, the output spectrum and the input factor spectrum are related.

The simulation performance function $L(t\,|\,\theta)$ can be approximated by two different meta-models: a polynomial meta-model and a trigonometric meta-model. The polynomial meta-model is obtained from a Taylor series expansion, whereas the trigonometric meta-model is obtained from a Fourier series expansion. The harmonic gradient estimator is then derived by matching or equating the coefficients of these two meta-models.

Frequency-domain simulation experiments identify the significant terms of the polynomial that approximates the relationship between the simulation output and the inputs. Clearly, the number of simulation runs required to identify the important terms by this approach is much smaller than those of the competing alternatives, and the difference becomes even more conspicuous as the number of parameters increases (23). The implementation steps are as follows:

Step 1: *Initialization*

Assume the input/output relationship for a simulation model can be approximated by a *quadratic dynamic polynomial response surface* meta-model (24). Set the simulation length T (even), the p oscillation frequencies $\{\omega_j\}$, and the p oscillation amplitudes $\{a_j\}$ $(j = 1, 2, \ldots, p)$. The oscillation frequencies are Fourier frequencies of the form $\omega_j = 2\pi h_j/T$, where $h_j \varepsilon \{1, 2, \ldots, T/2\} \subset Z^+$ are from the tables in Ref. 25 to ensure no confounding of any distinct frequencies when gradient components can be estimated. The simulation run length T is set such that $\max\{|\omega_j|\} < \beta$ for some $\beta > 0$ small. The p oscillation amplitudes $\{a_j\}$ are set such that each input parameter remains feasible and $\max\{|a_j|\} < \gamma$ for some $\gamma > 0$,. The value of T and $\{a_j\}$ should also be set based on information in Table 1 in Ref. 25 to allow the interchange of the derivative operator and the expectation operator.

Step 2: *Signal simulation run*

Make a signal simulation run by varying the p input parameters during the run, as follows:

$$\theta_j = \theta_j(0) + a_j \operatorname{Sin}(\omega_j t), j = 1, 2, \ldots, p,\ t = 1, 2, \ldots, T \tag{37}$$

Step 3: *Estimate signal run harmonic coefficients*

Compute

$$A_s(\omega_j) = (2/a_j T) \sum_{t=1}^{T} L_s(t) \operatorname{Sin}(\omega_j t),\ j = 1, 2, \ldots, p \tag{38}$$

Step 4: *Noise control variate simulation run*

Make a second (i.e., noise) simulation run with the p input parameters all held fixed during the run (i.e., $\theta_j = \theta_j(0)$, $j = 1, 2, \ldots, p$, $t = 1, 2, \ldots, T$). Common random number streams should be used for both simulation runs.

Step 5: *Estimate noise-run control-variate harmonic coef ficients*

Compute

$$A_N(\omega_j) = (2/a_j T) \sum_{t=1}^{T} L_s(t) \operatorname{Sin}(\omega_j t),\ j = 1, 2, \ldots, p \tag{39}$$

Step 6: *Set the control variate weighing parameters* $\eta\,(\omega_j)$

Compute

$$\eta(\omega_j) = \sum_{t=1}^{T} L(t|\theta(0) + a \operatorname{Sin}(\omega t) \times (Y(t|\theta(0))/\sum_{t=1}^{T} L^2(t|\theta(0) \tag{40}$$

Step 7: *Compute gradient estimate of the quadratic polynomial response surface*

Compute

$$A_s(\omega_j) - \eta(\omega_j) A_N(\omega_j),\ j = 1, 2, \ldots, p \tag{41}$$

A SHORT COMPARISON

L'Ecuyer (25) showed that PA and SF, (or LR), can be unified. He concluded that PA can be viewed as a (degenerate) special case of SF. Extensive comparison of the PA and SF approaches reveals several interesting differences. Both approaches require an interchange of expectation and differentiation. However, the conditions for this interchange in PA heavily depend on the nature of $L(\theta)$, and they must be verified for each application, which is not the case in SF. Therefore, in general, it is easier to satisfy SF unbiasedness conditions. However, SF requires $f(x,\ \theta) \neq 0$. PA assumes that the order of events in the perturbed path is the same as the order in the nominal path, for a small enough $\Delta\theta$, which allows calculation of $dL/d\theta$, the sensitivity of the sample performance for a particular simulation. For example, if the performance measure is the mean number of customers in a busy period, the PA estimate of the gradient with respect to any parameter is zero! The number of customers per busy period will not change if the order of events does not change.

In terms of the information required to implement these estimators, both approaches require knowledge of the cdf (or pdf) in which θ is as a parameter. SF needs to compute $\partial \ln f(x,\ \theta)/\partial\,\theta$. However, in PA it may be sufficient to know that θ is a scale or location parameter, without full knowledge of the associated event lifetime cdf. In addition, the nature of θ, which can only affect event lifetime distributions in PA, may be more general in the SF approach.

In terms of ease of implementation, PA estimators may require considerable analytical work on the part of algorithm developer, with some ”customization” for each application, whereas SF has the advantage of remaining a general definable algorithm whenever it can be applied. The derivation of the SF estimator, because $L(\theta)$ is directly observed and $\partial \ln f(x,\theta)/\partial\theta$ is readily evaluated; However, the evaluation of $dL/d\theta$ in PA usually requires some analysis and is not immediate. this aspect makes SF attractive. For discrete random variables (r.v.) the comparison is rather interesting. Consider a discrete r.v. that takes the values α_i with probability $p_i (i = 1, 2, \ldots, n)$. A SF algorithm can be developed with respect to the p_i parameters, but not the α_i parameters, whereas PA algorithms can be developed with respect to the α_i but not the p_i parameters.

Perhaps the most important criterion for comparison lies in the question of accuracy of an estimator, which is typically measured through its variance. If an estimator is strongly consistent, its variance is gradually reduced over time and ultimately goes to zero. The speed with which this happens may be extremely important. Because in practice, decisions normally have to be made in a limited time, an estimator whose variance decreases fast is highly desirable. For some simple systems (e.g., $J(\theta) = c$, with c a constant), where it is possible to compute *explicitly* variances of both PA and SF estimators, it can be shown that the variance of a SF estimator is significantly larger than that of its PA counterpart. In general, when PA does provide unbiased estimators, the variance of these estimators is small. PA fully exploits the structure of DESs and their state dynamics by extracting the needed information from the observed sample path, whereas SF requires no knowledge of the system other than the inputs and the outputs. Therefore, when using SF methods, variance reduction is necessary. The question is whether or not the variance can be reduced enough to make the SF estimator useful in all situations to which it can be applied. The answer is certainly yes. Using standard variance reduction techniques can help, but the most dramatic variance reduction occurs using new methods of VR such as conditioning (27), which is shown numerically to have a mean squared error that is essentially the same as that of PA.

It is much easier to extend the SF to higher derivatives, for example,

$$d^2 J(\theta)/d\theta^2 = E[L.S - d^2 \ln f(\theta, x)/d\theta^2] \tag{42}$$

Finally, the PA approach explicitly seeks to exploit the structure of event-driven sample paths in evaluating dL/ dθ. The SF approach does not attempt to do so. In this respect, SF is a general-purpose methodology for obtaining sensitivity of performance metrics of stochastic processes, not necessarily DES.

The SF estimate of the gradient can be related to the FD estimate. Equation (20) can be rewritten as

$$\begin{aligned}&\{\int \{L(x)\} f(x, \theta + \Delta\theta) dx - \int \{L(x)\} f(x, \theta)\, dx\}/\Delta\theta = \\ &\{\int L(x) \frac{f(x, \theta + \Delta\theta)}{f(x, \theta)} f(x, \theta)\, dx - \int \{L(x)\} f(x, \theta)\, dx\}/\Delta\theta \\ &\{E[L(X) \frac{f(X, \theta + \Delta\theta)}{f(X, \theta)}] - E[L(X)]\}/\Delta\theta\end{aligned} \tag{43}$$

However, the SF gradient estimate [Equation (20)] can be rewritten as

$$\begin{aligned}&\int L(x)\,[\partial \ln f(x, \theta)/\partial\theta]\, f(x, \theta) dx = E\{L(x)\,[\partial f(x, \theta)/\partial\theta]/f(x, \theta)\} = \\ &E\{[L(X)/f(X, \theta)]\, \mathrm{Lim}_{\Delta\theta \to 0}[f(X, \theta + \Delta\theta) - f(X, \theta)]/\Delta\theta\} = \\ &\mathrm{Lim}_{\Delta\theta \to 0}\{E[L(X) \frac{f(X, \theta + \Delta\theta)}{f(X, \theta)}] - E[L(X)]\}/\Delta\theta\end{aligned} \tag{44}$$

This shows that the SF estimate is the limit value of the FD as $\Delta\theta \to 0$.

Feuerverger *et al* (28) showed that if the performance depends on an indeterminate, possibly infinite number of inputs, then the SF gradient estimate is $2\pi f(L, S)$, where $f(L, S)$ is the *cross spectral density* of $\{L_i, S_i\}$ where S_i is the score of X_i. The main ideas and interrelationships of the various methods are shown in Fig. 4.

OPTIMIZING SIMULATED SYSTEMS

Simulation is the primary analysis tool for designing complex DESs. However, the simulation must be linked with a mathematical optimization technique to be used effectively for systems design.

Stochastic approximation procedures include Kiefer-Wolfowitz and Robbins-Monro types of techniques. Both types use a gradient estimate. The gradient can be estimated by any of the following approaches: finite difference, simultaneous perturbation, frequency domain, likelihood ratio, or infinitesimal perturbation analysis. Introductory concepts on gradient estimations may be found in Refs. 29–43. In Refs. 44 and 45, theoretical bases are provided.

Gradient surface methods combine the advantages of response surface methodology and efficient derivative esti-

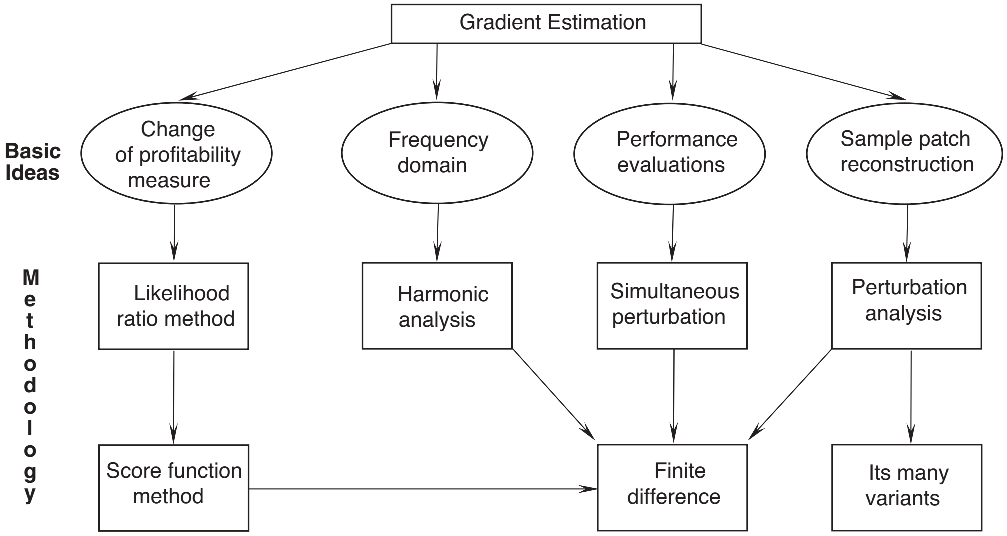

Figure 4. Classification and unification of gradient estimation methods.

mation techniques. Introductory discussions are given in Refs. 46 and 47.

STOCHASTIC APPROXIMATION TECHNIQUES

Two related stochastic approximation techniques have been proposed, one by Robbins and Monro (48) and one by Kiefer and Wolfowitz (8). The first technique was not useful for optimization until an unbiased estimator for the gradient was found. Kiefer and Wolfowitz (8) developed a procedure for optimization using finite differences. Both techniques are useful in the optimization of noisy functions, but they did not receive much attention in the simulation field until recently. Generalization and refinement of stochastic approximation procedures give rise to a weighted average (21), which deals with constraints, nondifferentiable functions, and some classes of nonconvex functions, among other things.

Kiefer-Wolfowitz Type Techniques

Kiefer and Wolfowitz (8) proposed a finite difference approximation to the derivative. One version of the Kiefer-Wolfwitz (K-W) technique uses two-sided finite differences that result in the following recursive procedure:

$$\theta_{n+1} = \theta_n - (\mathrm{a}_n/2\mathrm{b}_n)\,[\mathrm{J}(\theta_n + \mathrm{b}_n) - \mathrm{J}(\theta_n - \mathrm{b}_n)] \tag{45}$$

where the two sequences a_n and b_n satisfy the following conditions:

$$\sum \mathrm{a}_n = \infty \tag{46}$$

$$\lim\,(\mathrm{b}_n) = 0 \tag{47}$$

$$\sum (\mathrm{a}_n/\mathrm{b}_n)^2 < \infty \tag{48}$$

Then the sequence in Equation (45) converges in mean square and with probability 1 to a local optimum of $\mathrm{J}(\theta)$. However, because of the FD approximation for the gradient, the K-W procedure has a slow asymptotic convergence rate, which is typically of order $n^{-1/3}$. In general, any technique that attempts to estimate the gradient via finite differences will converge at a rate slower than $n^{-1/2}$ in the computational efforts (47).

The first fact to notice about the K-W estimate is that it requires $2N$ simulation runs, where N is the dimension of vector parameter θ. If the decision maker is interested in gradient estimation with respect to each of the components of θ, then $2N$ simulations must be run for each component of θ. This method is inefficient. The second fact is that it may have a very poor variance, and it may result in numerical calculation difficulties, because for small b_n, there may not be much statistical difference between estimates of $\mathrm{J}(\theta_n + \mathrm{b}_n)$ and $\mathrm{J}(\theta_n - \mathrm{b}_n)$, and we are dividing this difference by a small number. Finally, this estimate is unbiased for each nonzero b_n, because the slope of a secant line is approximating the slope of the tangent line. This result leads to the difficult question of which b_n to use. To minimize the "secant error," a small b_n should be used; but using such a small value contributes to the variance and numerical difficulties mentioned above.

Robbins-Monro Type Techniques

The original Robbins-Monro (R-M) technique is not an optimization scheme, but rather a root finding procedure for functions whose exact values are observed with noise. Its application to optimization is immediate: Use the procedure to find the root of the gradient of the objective function.

For simplicity, consider a simple parameter; that is, θ is a scalar. Let $\mathrm{H}(\theta)$ be the unknown function. The goal is to find θ^* such that $\mathrm{H}(\theta^*) = 0$. To do this, a sequence of experiments is performed with starting point θ_1 and successive values of θ according to the recursive relation

$$\theta_{n+1} = \theta_n - \mathrm{a}_n.\mathrm{H}(\theta_n) \tag{49}$$

where a_n is one of a sequence of decreasing and divergent positive numbers (such as $1/n$), and $H(\theta_n)$ is the noisy observation obtained from the nth experiment at θ_n. Assuming E $[H(\theta_n) \mid \theta_n = \theta] = H(\theta)$, and some additional mild conditions, the sequence $\{\theta_n\}$ converges to θ^* in mean square error.

Consider the case in which the parameter space is constrained to a bounded set Δ of the form $\Delta = (\theta\colon q_i(\theta) \leq 0, i = 1, \ldots, s)$, where $q_i(\theta)$ are continuously differentiable and Δ is the closure of its interior. Let X_(y) denote any closest point in Δ to y. The projected analog of Equation (16) is

$$\theta_{n+1} = X[\theta_n - a_n H(\theta_n)] \tag{50}$$

Interest was renewed in the R-M technique as a means of optimization, with the development of the perturbation analysis, likelihood ratio also known as score function, and frequency domain estimates of derivatives. Optimization for simulated systems based on the R-M technique is known as a "single-run" technique. These procedures optimize a simulation model in a single run simulation with a run length comparable with that required for a single iteration step in the other methods. This result is achieved essentially by observing the sample values of the objective function and, based on these observations, updating the values of the controllable parameters while the simulation is running (that is, without restarting the simulation). This observing-updating sequence is done repeatedly, which leads to an estimate of the optimum at the end of a single-run simulation. Besides having the potential of large computational savings, this technique can be a powerful tool in real-time optimization and control, where observations are taken as the system is evolving in time.

Generalizing Equation (49) to higher dimension, the Robbins-Monro type technique takes the following form:

$$\theta_{n+1} = \theta_n - a_n D_n \nabla J_n(\theta_n) \tag{51}$$

where a_n is the step size sequence, D_n is a matrix of appropriate dimensions, and $\nabla J_n(\theta_n)$ is the estimate of the gradient $\nabla J(\theta)$ at θ_n. The main idea behind Equation (51) is a trade-off based on the signal-to-noise ratio of the gradient estimate $\nabla J_n(\theta_n)$ to the error of the estimate. Initially, when θ_n is far from the optimal solution θ^*, this ratio is large, and a_n and D_n can be large. As θ^* is approached, notice $\nabla J(\theta) \to 0$, and the expectation of $\nabla J_n(\theta_n)$ is mostly noise. For convergence purposes, a_n should approach zero, but not too fast to avoid being stuck at a nonoptimum. These coefficients are referred to as step sizes, scaling factors, or learning rates. The R-M sequence is asymptotically normal, but it has some problems. It converges slowly when the function is very flat, and it may not converge when the function is steep. For example, solving the following equation $\exp(-3\theta) - 0.9\exp(-4\theta) - 0.1 = 0$, by R-M does not converge to its solution $\theta^* = 0.5073$.

More recently, R-M has been extended to multistep methods to provide the basic optimization technique for reasonable problems by "filtering" past observations. One such step uses *two independent* estimates:

$$\theta_{i+1} = \theta_i - a_n \left\{ \frac{J'_1(\theta_i)}{\min\{\varepsilon, |J^{1}{}_2(\theta_i)|\}} + \frac{J\_2'(\theta_i)}{\min\{\varepsilon, |J'_1(\theta_i)|\}} \right\} \tag{52}$$

where $\varepsilon > 0$ is the scaling factor, and J'_1 and J'_2 are the two independent estimates of J' at θ^i. When unbiased estimators are used, it converges at the rate of $n^{-1/2}$, which is the fastest. The technique is very sensitive to ε; that is, the smaller ε is, the more robust the technique is (29).

A practical concern is how to estimate the gradient $\nabla J_n(\theta_n)$ of the objective function $J(\theta)$, when the function $J(\theta)$ itself has to be estimated from simulation.

GRADIENT SURFACE METHOD

One may combine the gradient-based techniques with the response surface methods (RSMs) for optimization purposes. A response surface is constructed with the aid of n response points and the components of their gradients.

The gradient surface method (GSM) combines the virtue of RSM with that of the single-run, gradient estimation techniques such as perturbation analysis and the score function (or likelihood ratio) techniques. A single simulation experiment with little extra work yields $N + 1$ pieces of information (i.e., one response point and N components of the gradient). This method is in contrast to *crude* simulation, where only one piece of information, the response value, is obtained per experiment. Thus, by taking advantage of the computational efficiency of single-run gradient estimators, in general, N-fold fewer experiments will be needed to fit a global surface compared to the RSM. At each step, instead of using Robbins-Monro techniques to locate the next point locally, a candidate for the next point is determined globally, based on the current global fit to the performance surface. In particular, the gradient estimation information is used at this step and its previous steps, to find a function $\nabla J_n(\theta)$ to approximate the true gradient surface $\nabla J(\theta)$. Then, the zero point of $\nabla J_n(\theta)$ is found and taken as a candidate for the next iteration point, θ_{n+1}.

The GSM approach has the following advantages. The technique can quickly get to the vicinity of the optimal solution because its orientation is global (22, 39). Thus, it produces *satisfying* solutions quickly. Like RSM, it uses all accumulated information. And in addition, it uses gradient surface fitting, rather than direct performance response-surface fitting via single-run gradient estimators. This technique significantly reduces the computational efforts compared with RSM. Similar to RSM, GSM is less sensitive to estimation error and local optimality. And, finally, it is an on-line technique, which mean the technique may be implemented while the system is running.

A typical optimization scheme involves two phases: a search phase and an iteration phase. Most results in analytic computational complexity assume that good initial approximations are available, and the results deal with the iteration phase only. If enough time is spent in the initial search phase, then the time needed in the iteration phase is reduced. The literature contains papers that provide conditions for the convergence of a process (40); a process has to be more than convergent in order to be computationally interesting. It is essential to bound the cost of computation. In this sense, GSM can be thought of as helping the search phase and as an aid to bounding the cost of computation. Standard or simple devices can be adopted for such issues as stopping rules. It is a complementary tool for use in combination with other techniques.

Under smoothness and convexity conditions imposed on $J(\theta)$, the minimum can be found by solving $\nabla J(\theta) = 0$ that is, to optimize $J(\theta)$ is equivalent to finding the zero of $\nabla J(\theta)$, without a closed form expression for it. A linear function is used to estimate $\nabla J(\theta)$ directly fitting $J(\theta)$ by a quadratic surface. Although derivative information can also be used to fit the response surface, it is not done for the following reasons. Denote the gradient surface fitting function $F(\theta) = A\theta + b$, where A is an $N \times N$-dimensional matrix and b is a N-dimensional vector, it is popular to use the least-squares method to estimate A and b. Then, any quadratic response surface will yield gradient solutions, at most, as good as the least squares estimate but no better. Furthermore, fitting a quadratic surface will require one more parameter. Also, the linear function for the estimated gradient surface is used for convenience only; in principle, more complex surfaces can be used. Linear GSM, however, is satisfactory for small-size problems.

Assuming that we have $n(n \geq p)$ estimates of the gradient, the least-squares method provides the best estimate denoted by (A_{n+1}, b_{n+1}). The zero point of the gradient surface $(\theta_{n+1} = -A_{n+1}^{-1} \cdot b_{n+1})$ is taken as a candidate for the next iteration point. Surface fitting is accomplished based on the information about all n points (global behavior of the response surface). As a result, a small change in the estimation error at a particular point will have less effect on the result of surface fitting and its zero point than in ordinary gradient techniques, which can be regarded as a special case of surface fitting, in which only one point is used to define the gradient surface.

Initially, all data points are used to get an approximate global fit of the gradient surface (GS). As we get closer to the optimum, older data points are discarded and data points that are closer together are used to fit the GS and ensure convergence. These considerations suggest the use of a "window size" for surface fitting and also raise the following questions. First, how many points should be chosen to fit the GS? Second, at each iteration, should we use the same number of points to fit GS? And finally, whether a fixed window size or a dynamic window size is used, what is the rule to add or to drop points from the window; for example, should the latest L points where L is the size of the window always be used?

All of these questions suggest that there should be different phases in the search for an optimum, as follows. In the first step, initial points are randomly chosen. With no initial special knowledge, the minimum number of points is used to determine the GS. If the results of this fitting yield a solution that is not acceptable (e.g., the solution is outside the feasible region known to contain the optimal solution); the solution point is discarded. The window size is then increased by one by just randomly adding another new point. When an acceptable candidate is found, the window size is fixed. This iteration stage the "initial phase," or Phase I.

At the next stage, within the fixed window, each new candidate solution is generated using the same procedure as in Phase I. At this stage, it is determined whether the new candidate should be added. If yes, determine which old point should be dropped. Here is a dropping and adding rule. Assume the window size is fixed to be L. Remove the worst point; in minimization problem, $\theta_j = \max [J(\theta_{k-L+1}), \ldots, J(\theta_k)]$. If $j \neq k$; then the new candidate θ_k can be added. This stage of iteration is called Phase II. When θ_k cannot be added (i.e., θ_k is the worst point), then instead of using a randomly chosen new point, use the stochastic approximation techniques to get a new point and then switch back to Phase II. When each new candidate is very close to its predecessor, the optimum may be approaching. At this point, even switching back to Phase II may not produce a good-fitting function.

Then, using pure stochastic approximation techniques may provide a better approach to the optimal solution. This stage of iteration after switching is called the "ending phase" or Phase III. Switching back to Phase II avoids the use of the pure stochastic approximation technique at the beginning stage, which generally causes slow convergence. But to keep switching from Phase III to Phase II would waste simulation time. Hence, a maximum switching number (MSN) should be given. Actually, Phase III is just a degenerate gradient surface method, where the local gradient is used to define the gradient surface $g_k(\theta)$. The detailed algorithm is presented below:

Phase I

Step 0: Given N (minimum window size), M (maximum window size), MSN set $S = 0$, $L = N + 1$.

Step 1: Randomly choose N initial points $\theta_1, \theta_2, \ldots\ldots, \theta_N$.

Step 2: Use any single-run gradient estimators to find the corresponding derivatives $z(\theta_i)$, $i = 1, \ldots L-1$.

Step 3: Use the least-squares method to find the GSM function g_L with θ_i and $z(\theta_i)$, $i = 1, \ldots\ldots, L-1$.

Step 4: Find the zero point of g_L as θ_L.

Step 5: If $L > M$, then switch to Phase III; otherwise,

Step 6: If θ_k is not acceptable (e.g., θ_k does not satisfy some constraints), then discard θ_k and randomly choose a new point, $L = L + 1$, go to 2; otherwise, set the window size to L, and go to Phase II.

Phase II

Start with $k + L$.

Step 7: Use any single-run gradient estimation technique to find the corresponding derivatives $z(\theta_k)$.

Step 8: Remove the worst point $\theta_j = \text{worst}\,(\theta_1, \ldots\ldots, \theta_k)$; if $j = k$ then $S = S + 1$, switch to Phase III; otherwise, go to the next step.

Step 9: Use least-squares method to find the GSM function g_{k+1} with θ_i and $z(\theta_i)$.

Step 10: Find the zero point of g_{k+1} as estimate for θ_{k+1}

Step 11: Set $\theta_{k+1} = (1 - \rho_k)\theta_k + \rho_k\theta_{k+1}$, $0 < \rho_k < 1$ (53)

Step 12: If the stopping rule is satisfied, stop; otherwise, $k = k + 1$, go to 7.

Phase III

Step 13: Use one point to determine estimate

$$\theta_k = \theta_{k-1} - z(\theta_{k+1}) \tag{54}$$

$$\text{set} \quad \theta_k = (1 - \rho_k)\theta_{k-1} + \rho_k\theta_k \tag{55}$$

Step 14: Is $S > \text{MSN}$? No, switch back to Phase II.

Step 15: Is the stopping rule satisfied? If yes, stop; otherwise, $k = k + 1$, go to Step 13.

Notice that the maximum window size M is used to keep from infinitely iterating at Phase I. A different stopping rule may be chosen such as $|J(\theta_{k+1}) - J(\theta_k)| \leq \varepsilon$. Phase II uses the zero point of g_{k+1}, (θ_{k+1}) and the previous point θ_k to predict the new point θ_{k+1}. This is an alternative. If $\rho = 1$, θ_k is just the zero point of g_k, then implement the least squares solution exactly. Whenever $\rho < 1$, decide whether or not to go all the way to the zero point from the current point. This method enables control of how aggressively the least squares solution is implemented.

Similar remarks apply to Phase III. Phase III is simply the stochastic approximation technique. In this technique, use only one previous point to predict a new candidate. Determination of MSN depends on each problem. Usually, if derivative estimates do not require excessive computation, then MSN can be large. Otherwise, using a large MSN will waste simulation resources. The least-squares solution suggests second-order methods, such as the variable metric (VM) method or Davidon-Fletcher's method. The least squares solution of GSM is different in substance and in philosophy because $\theta_{k+1}-\theta_k$ need not be orthogonal to the previous descent direction as in the variable metric method. Furthermore, in GSM the matrix A is determined by using least-squares fit over many more points than the dimension of the θ vector, whereas VM is primarily a deterministic technique. Therefore, GSM is less a stochastic version of the variable metric method than a more efficient version of the response surface method via gradient estimators. Finally, the experimental design problem: In particular, given a window size N, how should points $\{\theta_i\}$, $i = 1, \ldots, N$ be chosen initially? In the technique given above, random sampling design can be used to get these points.

For online optimization, a new design in GSM called "single direction" design may be used. Because for online optimization it may not be advisable or feasible to disturb the system, random design usually is not suitable. Single-direction design gives a starting point and then uses gradient descent steps (i.e., Phase III), to determine the successive $\{\theta_2, \ldots, \theta_{m+1}\}$.

The primary consideration is whether the design is concentrated or widely spread. If the points of the design are concentrated, then most information comes from the estimates of the derivative. Using the performance measures alone gives no information about the optimum. With a design of this type, if the points are centered at the optimum, asymptotically no advantage exists to including the estimates of the performance with the estimates of the derivatives. When the design is not centered, an advantage is gained by including the performance estimates, if they are correlated with the derivative estimates. The higher the correlation, the stronger the advantage will be. As the estimates tend to be highly correlated, and the probability that the design is centered at zero, there is an advantage to including the performance estimates.

When the quadratic model may be assumed to be more than locally reasonable, and the points of the design may be spread out, the advantage clearly goes to the estimates which include the performances. Again, if the performance and derivative estimates are possibly correlated, then it is better to use both.

POSTSOLUTION ANALYSIS

Stochastic models typically depend on various uncertain and uncontrollable input parameters that must be estimated from existing data sets. Focus is given on the statistical question of how input–parameter uncertainty propagates through the model into output–parameter uncertainty. In the case when θ is a controllable or uncontrollable parameter, the decisionmaker is interested in estimating $J(\theta)$ for a small change in $\theta = \theta^*$ to $\theta = \theta^* + \Delta\theta$, where θ^* is the optimal solution or the solution to the goal-seeking problem; that is, the so-called postsolution analysis for the purpose of stability with respect to the solution θ^*, or the "what-if" analysis. This information can be obtained by the following single-run simulation perturbation technique.

Similar to Equation (1), the expected performance measure with perturbed parameter $\theta^* + \Delta\theta$ is:

$$J(\theta^* + \Delta\theta) = \int L(x).f(x; \theta^* + \Delta\theta)dx \tag{56}$$

$$= \int L(x)\frac{f(x; \theta^* + \Delta\theta)}{f(x; \theta)}f(x; \theta)dx \tag{57}$$

$$= E[L(x)].W \tag{58}$$

where the likelihood ratio

$$W = f(x; \theta^* + \Delta\theta)/f(x; \theta) \tag{59}$$

provided $f(x; \theta)$ does not vanish within the set Θ.

Similar to Equation (1), the expected performance measure with perturbed parameter $\theta^* + \Delta\theta$ is obtained while simulating the system at the nominal value θ^*, all in a single run. Notice that the expectation in Equation (58) is with respect to pdf, $f(x; \theta)$ (i.e., the nominal system). This result was achieved by using the Radon-Nikodym measure (49), in Equation (58) to transform all perturbed probability space to the nominal one. This estimator requires only one sample path of the system with parameter θ^*. Using Equation (58), estimates for any number of $\Delta\theta$ are computed simultaneously from a single-run simulation while simulating the nominal system. Because it adds only moderate computational cost, it is efficient.

Although this technique closely resembles Importance Sampling used as a VRT, its intent is different. The rationalization of Equation (58) is that the generated random vector X is roughly representative of X, with pdf $f(x;\theta^*)$. However, each of these random observations could also have hypothetically come from $f(x; \theta^* + \Delta\theta)$. The factor W weighs the observations according to this phenomenon. Regardless of the fact that this approach is not costly, it produces a larger variance than crude simultaneous perturbation, which reruns the simulation for each $\Delta\theta$. Because for regular probability functions,

$$\mathrm{E[W]} = \int \frac{f(x;\theta^* + \Delta\theta)}{f(x;\theta)} f(x;\theta)dx = \int f(x;\theta^* + \Delta\theta)dx = 1 \tag{60}$$

Equation (58) can be written as

$$J(\theta^* + \Delta\theta) = E[L(x)W] = E[L(x).W]/E(W) \tag{61}$$

Other alternative estimators could be:

$$\hat{J}(\theta^* + \Delta\theta) = \sum(L_i\, W_i)/\sum W_i \tag{62}$$

$$\hat{J}(\theta^* + \Delta\theta) = \sum(L_i W_i)/n + \alpha\Big[\sum W - n\Big]\sum L_i \tag{63}$$

and

$$\hat{J}(\theta^* + \Delta\theta) = \sum(L_i\, W_i)/\sum W_i + \alpha\Big[\sum W_i - n\Big]\sum L_i \tag{64}$$

where the sums are over all i, $i = 1, 2, 3,\ldots, n$, and α is the usual *optimal linear control factor*. As always, some pilot runs must be performed to study the effectiveness of these and other filters before implementing them. These estimators have been shown to have less variation than the crude one based on Equation (58) using M/G/1 queues in Ref. 22 and refs. therein. Some of these estimators are biased, but they give reasonable results if the perturbation is small and $L(\theta)$ is well behaved. Clearly, jackknifing and bootstrap may be used to reduce the bias substantially. Other single-run perturbation techniques are proposed in Ref. 22. The ideas in this section are also useful as a *single-run perturbation* to be embedded in optimization techniques, such as simplex type techniques, random search techniques, and simulated annealing, in the earlier stage of implementation. This method saves some computational costs.

THE FUTURE OF OPTIMIZATION BY SIMULATION

With the growing incidence of computer-based modeling and simulation in many diverse fields, such as business, economic and government systems (50), the scope of simulation domain must be extended to include much more than traditional optimization techniques. Optimization techniques for simulation must also account specifically for randomness inherent in estimating the performance measure and satisfying the constraints of stochastic systems.

Given the input parameters θ (which could be a vector) and a performance measure $J(\theta)$, the problem of estimating the sensitivities (i.e., gradient, Hessian, etc.) of $J(\theta)$ with respect to θ can be tackled through FD, SP, PA, the SF Method, the LR Method, and HA, as shown in Fig. 4.

Sensitivity estimation is useful for local information, structural properties, response surface construction, goal-seeking problem, and optimization of DES simulation. This aticle described step-by step the existing methods of sensitivities estimators with the aim of theoretical unification and a few comparisons. All algorithms were presented in English-like format and therefore can be implemented in a variety of operating systems and machines, which provides unlimited portability.

PA yields an unbiased estimate if the interchange of derivative and expectation is permitted. This method imposes constraints on the nature of the sample function and the structure of the system that can be analyzed. For SF and LR, this condition is easier to satisfy. The advantage of SF and LR methods is that estimates of any number of derivatives (gradient) can be computed in a single-run simulation. The major difficulty in applying the SF and LR methods is that the variance of derivatives estimator increases as the length of the simulation increases. Therefore, effective variance reduction techniques must be used to make SF and LR competitive with PA. The PA fails to provide unbiased estimates when the sample function $L(\theta)$ is discontinuous in θ. This problem can be overcome at the expense of obtaining more information during simulation run. Implementation of PA and many of its variants are all problem dependent, whereas SF, LR, FD, SP, and HA are not. However, SP and FD can be seriously limited by, for example, the required stability of the system. For example, traffic intensity must remain less than one for steady-state sensitivity estimation.

Most work has been performed for θ being the parameters of input distribution, and strong theoretical results are available when these methods are implemented on relatively simple systems. More extensions are required to estimate sensitivities for more complex systems. Comparisons between different methods can rarely be performed theoretically in terms of bias, variance, and computational complexity. Many studies (51–53) rely on computer simulations to compare different methods. However, computational complexity in terms of the total computational effort, for reduction in both the bias and variance of the gradient estimator depend on the computational budget allocated for any simulation application. Simulation time is a crucial bottleneck in the sensitivity estimation. Future directions for research in gradient estimation lie in parallelization and distributed versions of the techniques discussed in this study. For example, gradient estimation by these methods for a computer system may require days to simulate only a few second of the system's operation.

We described the most widely used optimization techniques that can be integrated effectively with a simulation model. We also described techniques for postsolution analysis with the aim of theoretical unification of the existing techniques. All techniques were presented in step-by-step format to facilitate implementation in a variety of operating systems and computers, which improves portability.

General comparisons among different techniques in terms of bias, variance, and computational complexity are not possible. However, a few studies rely on real computer simulations to compare different techniques in terms of accuracy and number of iterations. Total computational effort for reduction in both the bias and variance of the estimate depends on the computational budget allocated for a simulation (54, 55).

No single technique works effectively and/or efficiently in all cases. The most promising techniques are the stochastic approximation, simultaneous perturbation, and the gradient surface methods. Stochastic approximation techniques that use perturbation analysis, score function (or likelihood ratio), or simultaneous perturbation gradient estimators optimize a simulation model in a *single simulation run*. These techniques do so by observing the sample values of the objective function; based on these observations, the stochastic approximation techniques update the values of the controllable parameters while the simulation is running and without restarting the simulation. This observing-updating sequence, done repeatedly, leads to an estimate of the optimum at the end of a single-run simulation. Besides having the potential of large savings in computational effort in the simulation environment, this technique can be a powerful tool in *real-time* optimization and control, in which observations are taken as the system is evolving over time.

Response surface methods have a slow convergence rate, which makes them expensive. The gradient surface method combines the advantages of the RSMs and efficiency of the gradient estimation techniques, such as infinitesimal perturbation analysis, score function (or likelihood ratio), simultaneous perturbation analysis, and frequency domain technique. In the GSM, the gradient is estimated, and the performance gradient surface is estimated from observations at various points, similar to the RSM. Zero points of the successively approximating gradient surface are then taken as the estimates of the optimal solution. GSM is characterized by several attractive features: It is a single-run technique and more efficient than RSM; at each iteration step, it uses the information from all data points rather than just the local gradient. It tries to capture the global features of the gradient surface and thereby quickly arrives in the vicinity of the optimal solution, but close to the optimum, it takes many iterations to converge to stationary points. Search techniques are therefore more suitable as a second phase. The main interest is to figure out how to allocate the total available computational budget across the successive iterations.

We expect the four areas for future research in the field of optimization techniques for simulation:

1. Computational studies of techniques presented in this article, for systems with many of controllable parameters and constraints.
2. Effective combinations of several efficient techniques to achieve the best results under constraints on *computational resources*.
3. Development of parallel and distributed schemes
4. Development of an expert system that incorporates all available techniques.

With respect to the third area of future research above, not all techniques lend themselves to parallel and distributed schemes. The last item in the above list would allow a framework for comparing and selecting the right technique(s) for the problem at hand. Realistic visual interfaces could also be devised and linked to the simulation prescriptive and postprescriptive process to provide an accurate visual representation.

ACKNOWLEDGMENTS

I am most appreciative to Dr. David Proctor and the reviewers for their suggestions and comments. This work is supported by the National Science Foundation under grant CCR-9505732.

INFORMATION AGE

INTRODUCTION

The Information Age is a period of time, or era, in which information itself, in its various forms, constitutes a key or dominant ingredient in our delivery of products and services. The Information Age began to emerge in a most serious manner about halfway through the twentieth century, when, for the first time, white collar workers started to outnumber blue collar employees. This newly born and growing Information Age was facilitated, in large measure, by

- pre-existing successes in telegraphy, telephony, radio, and television;
- bringing large-scale computers into our businesses, led by IBM;
- the success of xerography and copying machines, notably by Xerox; and
- the response to the challenge represented by the 1957 launch of Sputnik by the Russians.

All of the above provided initial fuel for the Information Age engine by proving the importance of information-related technologies and demonstrating their economic value in the marketplace. Two additional and extremely significant sets of events included the refinement and market penetration of

- the personal computer (PC) along with its resident applications, and
- connectivity and the Internet.

These events were acknowledged, in the aggregate, as"trends that were shaping the 1980s" in shifting from an industrial society to an information society (1). In doing so, at least four key points were considered to be critical:

- the reality and influence of the information-oriented society,
- computers and communications coming together to support each other,
- new information technologies migrating from old industrial activities to new processes, and
- the need for our education system to step up to difficult challenges associated with the new information orientation.

The above also supported and empowered the"triumph of the individual" (2) in moving from the twentieth into the twenty-first century. As the information age is brain-intensive in distinction to being capital-intensive, the individual with the right idea at the right time has a real opportunity to bring new information-related products and services into the marketplace. At the same time, this distinction has placed pressure on the individual to recognize and deal effectively with new problems as well as opportunities (3).

THE PERSONAL COMPUTER (PC)

The personal computer was a major factor in supporting the Information Age during its early years. In the late 1970s and early 1980s, the PC grew from a sophisticated hobby (Altair, Commodore) into a marginal but useful device (Apple II, TRS-80) and then into a serious home and business machine (IBM PC, Macintosh), with a variety of available software applications (e.g., word processors, spreadsheets, databases) (4). The elementary hardware architecture expanded, and soon we had powerful workstations such as those provided by Apollo Computer and Sun Microsystems. But the PC distinguished itself by continuously improving its performance while retaining its competitive and accessible price (e.g., less than $3,000) so that businesses did not hesitate in providing one to essentially all professional employees. In addition, more and more households found it to be an attractive asset for all members of the family. This unprecedented double-front (office and home) assault had a lot to do with ushering in and sustaining the Information Age. Increasing numbers of people, from all walks of life, at home and at the office, were becoming comfortable with, and dependent on, the PC. And the PC manufacturers, sharpening their products in a flourishing market, responded well to the challenge as new and successful companies were born and thrived (e.g., Compaq, Dell).

The combination of high performance, low price, and extensive software availability changed forever the way in which large numbers of people were dealing with computers and information. Setting a firm foundation for the Information Age, the PC, from palm to lap to desktop, was arguably the most critical ingredient. And the peculiar nature of affordable software, the PC's heart and soul, literally gave"power to the people" in ways never experienced before.

INFORMATION SYSTEMS

From the first"Killer App" (application) known as Visicalc, a spreadsheet produced by Dan Bricklin and Bob Frankston (4), large numbers of software developers have been building new and better application packages for the PC. Early software addressed a single function such as a spreadsheet or a word processor. Soon, multi-function packages were offered such as Microsoft's Office and Lotus' Smartsuite. Application areas continued to spring up that developers felt could be used by general businesses (e.g., accounting packages) as well as the home user (e.g., an encyclopedia). These areas were further expanded to meet

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

15. executive information	30. utility systems

the needs of both government and industry and appeared under the general category of"information systems." However, despite this broad title, they came in numerous subtypes, as illustrated by the list in Table 1. Based on the first 50 years or so of the Information Age (the last half of the twentieth century), there is good reason to believe that even the various system types cited in Table 1 will be expanded substantially during the twenty-first century as the Information Age continues to mature and express itself.

CONNECTEDNESS AND THE INTERNET

The next most powerful force in bringing about the Information Age, given the PCs and workstations, relates to the fact that we learned how to establish computer interconnections in an efficient and cost-effective manner. The stand-alone desktop computer would become only one of many nodes in a network that provided a means for people to communicate and exchange massive amounts of data. As we moved from local area networks (LANs) to wide area network (WANs) to the Internet, all of this connectivity greatly enhanced information exchange and productivity. For example, Lotus Notes was an effective way for everyone within an enterprise to communicate; the Internet was the way to communicate person-to-person(s) and enterprise-to-enterprise, all over the world, and with great speed.

THE ROLE OF SOFTWARE

Underlying the computers and networks, and ultimately the Information Age, is software. As it ranges from operating system to application package to multi-functional integrated information system, software is the "central intelligence" that makes all of it work. Behind the power of the software is the seminal idea, brainpower, and skill of the software creator, the new"warrior" of the Information Age.

Considering the central position of software as we move into the twenty-first century, it remains one of our most serious unsolved problem areas. We are getting better at it, and we are also creating new approaches to it, as in moving from procedural languages to object-oriented techniques (e.g., from "C" to "C++"). To some extent, it is a confusion of plenty, in search of a better way that most will use and benefit from. So whether it be reuse, or the more widespread use of commercial-off-the-shelf (COTS) software, or the renaissance of artificial intelligence (AI), or yet another development paradigm, the software challenge is likely to have many new solutions fitted to it as we move through the Information Age.

EDUCATION

Our education system deals generically with both information and learning and so must at least be cited as an important part of the Information Age. First, our educational institutions need to evolve new and better ways to prepare us to function as well as possible in the Information Age. To accomplish this feat, they must understand what the Information Age is and where it might be going. They need to stay close to industry, as much of it will be in uncharted territories driven by businesses. Second, they need to carry out applied research that will go beyond the foundations of the Information Age and into the problems that industry is and will be facing. Other areas of concern and interest in which our colleges and universities can participate are addressed below.

IMPORTANT ISSUES OF THE INFORMATION AGE

In Need of a Theory

Although we are continually producing information systems, we do not have an adequate "theory" of information that will explain what it is, how it provides value and influence, and how, for example, to convert information into knowledge. In the mid-1950s, a theory was formulated by the name"information theory," but it was applied largely to matters of analyzing and building communications channels and systems (5). One would hope and expect that the academic world will be able to provide the basis for a theory that will help business and government navigate through the Information Age.

Information Security

Information Security may turn out to be the most serious problem of the Information Age. It has a large number of dimensions, ranging from assuring that people are not able to access your bank account to preventing viruses from crashing your system, however large or small, to maintaining your personal and corporate privacy (6). One can be sure that lack of security will be an invitation to prankster as well as criminal intrusion, and all sectors of society must be concerned, from businesses to government to academia to the individual. This problem will also be exacerbated by the continued introduction and expansion of wireless systems.

Information Junk Mail and Overload

Along with all the true and useful information will come increasing amounts of junk (SPAM) as well as information overload. Humans, we know, have limited personal information handling and processing speeds and capabilities. We will therefore need better ways to rapidly discern true information from junk, discard the latter, and deal with the former. Filters to help us through this process are and will continue to be available; but they too may be defeated by the determined junk-mailer.

Information and Intelligence

An integral part of the Information Age is to add the appropriate amounts and types of intelligence to our products and services. Various products, therefore, will“know” some things that are best“remembered” by the product instead of the owner or user. Products will have the improved ability to self-diagnose difficulties in their own operation, pointing the way for the user to initiate a simple switch reset or other type of automated repair routine. Companies will have to understand how much intelligence to add, such that they will constantly be providing additional value to the consumer. These patterns have already shown themselves, for example, in the automobile, but can be expected to be greatly extended during the twenty-first century.

Human Interaction

As suggested above, in the Information Age, both products and services will incorporate unprecedented types and forms of information for use by industry, government, academia, and the individual consumer. In each domain, humans will find themselves part of the loop and at least the following two pressure points will be evident:

- the information transfers and systems will have to take full account of possible ways to optimize the human interactive role, and
- the humans will have to adapt (modify their own behavior) to maintain high levels of utility, effectiveness, and productivity.

Decision support systems in industry are good examples of information systems for which the above factors will be of increasing importance (see the systems listed in Table 1).

Information Technology versus Information Need

Trends during the last twenty years of the twentieth century exhibit an expansive growth of the technology that is able to organize and process bits and bytes ever faster and less expensively. This “technology push,” however, has often outpaced the needs of users, resulting in a gap between what the information technology has provided and what the user truly requires, which has led to overpromising and underdelivering from the perspective of the user. As the information age matures in the twenty-first century, an important issue is whether this gap will, on the whole, increase or decrease. If the former, we will have more solutions in search of a problem, and more problems going unsolved. Enterprises that understand and reduce the gap are likely to outdistance their competitors.

Building Software

As noted earlier, software is likely to remain the underlying force that gives life to the Information Age. We may therefore expect that there will be frontal attacks on the problem of improving the effectiveness and efficiency of software development, with new paradigms and languages coming on the scene and older ones (e.g., C, C++, Java) reengineered for improvements. Promising approaches might well lie in the following directions:

- extensive reuse of software components;
- software that is able to write new software;
- improved notions relative to software systems architecting;
- better metrics that aid in software decomposition, design, and management;
- integrated computer-aided software engineering (CASE) tools; and
- enhanced software team performance.

The reader is likely to find additional related notions in many subject areas of this encyclopedia.

Valuing the Information Enterprise

The economics of the Information Age, in several important dimensions, need to be substantially clarified. One such dimension is the Internet-based enterprise in which many of the prior rules for valuation are being rewritten. Another has to do with the perceived value to the consumer of adding information to a variety of products and services. A third aspect is that of the degree to which historical growth patterns in revenues and profits will be important. The business marketplace is likely to point the direction toward some of these answers. Others, hopefully, will be developed in our universities and financial institutions.

e-Commerce

Electronic commerce (e-commerce) includes any and all ways in which computers and networks are used to rapidly transfer information between a variety of corporate and individual users, which includes electronic data interchange (EDI), electronic funds transfer (EFT), electronic mail (e-mail), on-line catalogs and databases, and the use of the World Wide Web (www) and Internet (7). A part of e-commerce involves business-to-business interactions for purposes of distributing products and information related thereto. Another dimension relates to business-to-consumer transactions (such as amazon.com). Both modes of interaction have been growing and show no signs of abatement. All of the above uses of e-commerce need to be assisted by standards as well as the appropriate levels of security, with its related technologies (e.g., encryption), to maintain trust and viability throughout the Information Age.

Creating and Maintaining the Learning Organization

In the Information Age, it will be particularly important to assure the health and well-being of the Learning Organization (8). This statement would appear to be self-evident as new types and forms of software and information are created and used. The five disciplines that form the basis for the Learning Organization are as follows:

- personal mastery,
- mental models,
- building shared vision,
- team learning, and
- systems thinking.

Enterprises that fail to master the Information Age requirements for learning are not likely to maintain their competitiveness in a fast-changing world. A vibrant learning organization, however, is also likely to be a necessary but insufficient condition for success.

Business Adaptation and Transformation

Related to the above matter of the learning organization is the issue of business and government adaptation as well as transformation (i.e., how well, and how quickly, these take place). Main line businesses (e.g., automobile dealers, hardware stores, appliance manufacturers) will have to answer at least the following key questions:

- How can I utilize the available information technology and systems so as to improve the effectiveness and efficiency of my business?
- How can I extend and advance current information systems to assure that I stay ahead of my competitors?

Businesses that adapt to the changing environment and transform themselves with respect to the integration of information systems of all types are likely to flourish in the Information Age. Government organizations will have to do much the same in order to survive over the long run.

Knowledge Management

Knowledge Management (KM) may be defined as“the way companies generate, communicate, and leverage their intellectual assets” (9). This relatively new term is part of a progression that starts with data, operates upon that to produce information, and then engages in some process that uses such information as an important element in creating knowledge. In this context, knowledge may be viewed as a meta-form of information. Knowledge may also be thought of as that which is created when various“-packets” of information are combined to establish a new level of understanding that did not exist previously. Considerable efforts are underway to try to grasp what it is that constitutes knowledge, the specific stages of knowledge development and how organizations need to approach the matter of assuring the creation and application of knowledge (9). Many of the foundations of and issues related to Knowledge Management are being examined on a continuous basis (e.g., *Knowledge Management* magazine; see www.kmmag.com). Knowledge Management is considered to be an important field that will have to be further explored and instantiated as we continue to move through the Information Age.

Management in the Information Age

Management of our enterprises during the Information Age will have to meet the challenges represented by the above-cited issues, but also may expect organic changes to be taking place in these enterprises. As an example, Peter Drucker, one of our leading management commentators, suggests the following (9):

- a very sharp reduction in the number of management levels and the total number of managers (e.g., one-half the levels, and one-third the managers);
- the strong emergence of specialists to be able to create information, which he defines as “data endowed with relevance and purpose”;
- reliance on task forces (of the above specialists) that will transcend traditional departmental structures;
- providing a sufficient vision as well as motivation to unify an organization of information specialists;
- making sure that top management people are prepared and tested for success in the information-based organization; and

- building the highly competitive enterprise of the Information Age is the "managerial challenge of the future."

METROPOLITAN AREA NETWORKS

INTRODUCTION

A metropolitan area network (MAN) is a network that covers the distances of most cities, about 50 Km. Traditionally, MANs have been data networks. However, as packet voice over the Internet, IP voice, becomes more widely accepted, the distinction between voice and data networks is becoming blurred. Originally, MANs were predominantly used to interconnect the users in a single organization, such as the databases and tellers in the branches of a bank in a single city. However, the Internet has increased the demand for high-speed communications to individual users. The use of MANs has shifted from communications between users in the same metropolitan area to communications between users and the global infrastructure.

A MAN is a shared facility, and Internet traffic is bursty. Internet users require a high data rate for a period of time and then are silent for a longer period. Because of the bursty nature of the communications, the average bandwidth that a user requires is much less than the peak bandwidth that is needed to avoid waiting to download large amounts of data. A shared MAN makes it possible for a user to acquire a large bandwidth during data transmission and to relinquish that bandwidth to other users during silent intervals. When there are many users, the total bandwidth in a shared network can approach the average bandwidth of the users and provide them with their peak bandwidth most of the time when it is needed. In effect, a user can purchase slightly more than his average bandwidth on a shared network and obtain performance close to a dedicated channel at his peak bandwidth.

The utilization statistics during busy hours have long been used to design telephone networks. Before the widespread use of the Internet, and the increased duration of telephone connections, the number of connections in a local telephone switch was about one sixth the number of incoming lines. Statistics showed that the smaller number of connections is sufficient to place almost all of the incoming call requests during the busiest hours. The widespread use of the Internet has decreased the ratio of connections to incoming lines to about one third, but we still do not require a switch connection for every incoming line. Similarly, we can use the utilization statistics of data to design shared MANs with bandwidths that are much less than the peak requirements of the users.

Local area networks (LANs) take advantage of the utilization statistics of data to share the communications facilities. For instance, the Ethernet protocol gives the entire bandwidth to a single user for the duration of his transmission. The users contend for the bandwidth using a protocol called carrier sense multiple access with collision detection (CSMA/CD). In CSMA/CD, a user listens to the channel before transmitting and does not transmit if other users are transmitting (CSMA). When a user transmits, he continues to listen to the channel in case another user has started to transmit at the same time. If more than one user transmits at the same time, there is a collision and all of the users stop transmitting (CD). After detecting a busy channel or a collision a users waits a random amount of time before trying to transmit again. The random wait makes it unlikely that the same users will interfere with one another multiple times. As more users contend for a channel, users experience longer access delays before acquiring the channel. By using the busy hour utilization statistics to limit the number of users sharing a single LAN, the access delays are tolerable.

LANs are designed to cover small distances of a few kilometers, and the protocols take advantage of this characteristic. The CSMA/CD protocol works well when the time it takes to transmit data is much less than the time it takes the packet to propagate between users. However, when the distances and propagation delays increase, so that the propagation delay is greater than the time that it takes to transmit the packet, the signal that the source and receiver detect is different. The source cannot use the signal that it detects to reliably determine when there is interference from other users at the receiver.

A MAN covers greater distances than a LAN, so that the propagation delays are longer. In addition, a MAN is designed for more users than a LAN, so that the shared transmission rate must be higher and the time to transmit a message is less. The protocols that are designed for a LAN cannot be applied directly to a MAN. The first generation of MANs used protocols and network topologies that are specifically designed to span the greater distances and operate at the higher transmission rates that occur in a MAN. In the next section, we describe three of these protocols: the fiber distributed data interface (FDDI), the dual bus distributed queue protocol (DQDB), and the Manhattan Street Network(MSN).

The first generation of MAN protocols is not widely used. The main reasons are economic. In consumer applications, the cost of the device that is at the customer location is particularly important. When television was first introduced, the designers went to great lengths to reduce the cost of TV sets at the expense of the broadcast equipment. In electronics, the first few devices bear the development costs and the cost decreases rapidly as more devices are deployed. Ethernets were common in businesses before consumer MANs evolved. Multilayered MANs that use an Ethernet interface in the consumer location have a possibly insurmountable advantage over any new technology.

All three of the first-generation MANs were designed to operate over fiber-optic networks. In a MAN, the cost of new transmission infrastructure that reaches every location can be prohibitive. Fiber to the home has not been realized. Networks that use existing infrastructure, such as the cable TV network, or reduced infrastructure, such as wireless networks, have an economic advantage over any network that requires new facilities. (In this work, we use

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

CATV to refer to cable TV networks. Although CATV originally signified community access TV, it has become common to use CATV to refer to cable TV.)

In addition to the economic reasons, the DQDB network and the MSN have failed to become accepted because they are compatible with the asynchronous transfer mode (ATM) protocols rather than the Internet protocols that are used in routers. In the mid-1990s, ATM switches could support more high rate communications lines than routers. ATM is based on fixed size cells that can be exchanged between multiple inputs and outputs in a space division switch. A space division switch allows many inputs and outputs to be switched in parallel. The Internet protocols are based on variable size packets that routers passed through a single processor. The processor was a bottleneck that constrained the total input and output rate of routers. Increasing line rates in fiber-optic networks made it likely that ATM switches would replace routers. Many of the current generation of routers partition the variable size packets into fixed-size cells and use a space division switch internally. Once the bottleneck in routers was eliminated, ATM switches failed to replace routers.

In the third section we will describe the most popular MANs. Three technologies are currently used, one based on the telephone network, the second on the CATV network, and the third on wireless networks.

Telephone networks use adaptive equalizers to increase the data rates that can be transmitted on the existing telephone lines. The data rates that can be obtained depend on the quality of the lines between the central office and the subscriber premises. The lines that are being installed have fewer loading coils and alternative branches, which are referred to as "dog legs," than the lines that were installed before data became an important service, and can support higher data rates. Typically, it is possible to obtain data rates between 1.5 Mbps and 6.3 Mbps on local telephone lines. The technology is referred to as digital subscriber loop(DSL). The data rate can be used in a half duplex mode where the entire data rate is first used to transmit from the home to the central office, then used to transmit from the central office to the home, or it can be partitioned so that part of the bandwidth is available in each direction. When more bandwidth is provided in one direction than the other, DSL is referred to as asymmetric DSL (ADSL). ADSL is justified in Internet applications because users download more information from the Internet than they send to the Internet. DSL and ADSL provide dedicated lines to a central office and are not a shared MAN. They are described elsewhere in this encyclopedia.

The CATV infrastructure is evolving from a tree topology, with cables from the head end of the network to each home, to a hub-and-spoke topology, with fibers from the head end to distribution points, the hubs, and smaller trees from the hubs to each home. CATV MANs use one protocol to collect data from the homes connected to a tree that emanates from a hub, a second protocol to send data to the homes, and a third protocol or dedicated lines to transfer data between the hub and the head end of the CATV network. The hub-and-spoke topology makes it possible to use conventional Ethernet interfaces at the customer sites. In the third section, we will describe a variant of the Ethernet protocol that can be used on CATV networks and show how the protocol can be modified to also carry voice communications.

Wireless MANs use separate techniques to collect data from users in a local area and to transfer that data across the metropolitan area. Two LAN technologies are described, the IEEE 802.11 standard, also referred to as WiFi for wireless fidelity, and Bluetooth. The WiFi protocol is a variant of the Ethernet protocol called CSMA/CA, where CA stands for collision avoidance. We also describe a polled mode in this protocol that can be used for voice transmission and multihop protocols that can be used to extend the range of this network. WiFi is becoming widely used because the cost of IEEE 802.11 chips are decreasing and are included in most laptop computers. We also describe the evolving IEEE 802.16 protocol, which cover the distances in a metropolitan area and can lead to an entire wireless MAN. The wireless nature of this solution makes it possible to deploy this network with less investment in infrastructure than in wired networks.

MANs are evolving quickly. The solutions that were described in the previous version of this article have been replaced. In the conclusion we will attempt to predict future changes. These changes are fueled by the need for improved reliability, the emergence of IP voice, the increased use of wireless technologies, the overuse of the cellular bands, the eventual deployment of fiber to the home, and a resurgence of ATM-like, cell-based transmission.

THE FIRST-GENERATION MANS

FDDI

FDDI (1) is a token passing loop network that operates at 100 Mbps. It is the American National Standards Institute (ANSI) X3T9 standard and was initially proposed as the successor to an earlier generation of LANs. FDDI started as a LAN; however, it is capable of transmitting at the rates and spanning the distances required in a MAN.

Token Passing Protocol. FDDI uses a token passing protocol to give each station on the loop a chance to transmit data. The information that is transmitted on the loop is framed by a unique character. A frame may contain a token or a data message. When a station on the loop receives the token, it may remove the token and transmit data. When the station has completed its data transmission, it transmits the token so that the next station on the loop has a chance to transmit. A station that does not have the token forwards the data frames that it receives on the loop, and a station that has the token discards any data frames that it receives. The discarded data were either transmitted by one of the stations that had the token before the token site or was transmitted by the token site. If the data were inserted by another station, it must pass that station to reach the current token site. In either case, the data has circulated around the loop at least once and every station has had a chance to receive it.

In a simple token passing protocol, one station can hold the token for a very long period of time and delay other stations. FDDI uses a target token rotation time (TTRT) to control the amount of time that a station may hold the token and thereby avoids long delays. Two types of stations on an FDDI network exist, priority stations and asynchronous stations. Priority stations can transmit up to a prescribed amount of data each time that the token is received. These stations can be used to transmit real-time voice and video. Asynchronous stations can use all of the transmission capacity that is not currently being used to transmit priority data. These stations can be used to transmit large quantities of bursty data.

Each station uses the same TTRT, which is the time that we would like to have the token take to circulate around the loop. Each station tracks the token rotation time (TRT), which is the time that is left before the token exceeds the TTRT at the current station. When a token arrives earlier than expected, an asynchronous station can hold the token, and transmit data, up to its local calculation of TRT. If the token arrives late, the asynchronous station does not transmit data. In this way, an asynchronous station does not increase the delay of tokens that are late. In actuality, there is a minimum-size data packet, and an asynchronous station that receives the token just before it is due to arrive may forward it slightly later than the TTRT.

Each priority station i can send up to X_i bits, which may be different for each priority station, each time it receives the token. The time it takes to transmit the bits is the maximum token hold time for the station THT_i. The total amount of priority traffic is constrained to $\sum_i \mathrm{THT}_i + \Delta \leq \mathrm{TTRT}$, where Δ is the delay around the loop, including the propagation time and the delay inserted by each station. The constraint guarantees that the token can circulate in less than TTRT when all of the priority stations are transmitting data.

It is shown in Ref. 2 that the maximum time between token arrivals is less than 2 × TTRT and the average time between token arrivals is less than TTRT. When the token does not arrive at a station by 2 × TTRT, it is presumed to be lost, either because of a transmission error or because a token site failed, and a token recovery procedure is initiated. State machines that depict the operation of priority and asynchronous stations are shown in Fig. 1.

Isochronous Traffic. FDDI-II adds the ability to send isochronous, or circuit-switched, traffic on an FDDI loop. An isochronous channel is a regularly occurring slot that is assigned to a specific station.

FDDI-II is implemented by transmitting fixed-size frames. A central station sends out a framing signal every 125 μs. The first part of the frame is used for isochronous channels, and the second part of the frame is used to transmit the bits in the FDDI token passing protocol. An isochronous station that is assigned one byte per frame has a 64-Kbps channel. This channel is adequate for telephone quality voice.

In FDDI-II, the stations that implement the token passing protocol must switch between the two modes of operation when they receive framing signals. When a station that enters the circuit switched mode, it forwards the bits it receives. When the circuit-switched mode ends, the station resumes the token passing protocol where it left off.

Architecture. A single failure of a node or a link disconnects the stations on the loop. Poor reliability prevents loop networks from connecting the number of users associated with MANs. The reliability of an FDDI is improved with a second loop that does not carry data during normal operation, but it is available when failures occur.

FDDI networks have three components as shown in Fig. 2. The type "A" units connect user devices to the primary loop and implement the token passing protocol. The type "B" units manage the reliability. They are connected to both loops and one or more type "A" units. Type "B" units monitor the signal returning from type "A" units and bypass type "A" units that have stopped operating. They also monitor the signal on the two loops and bypass links or other type "B" units that have failed. There is one type "C" unit on an FDDI network that is responsible for signal timing and framing.

The outer loop in Fig. 2 is the primary loop and normally carries the information. The inner loop is the secondary loop and is used to bypass failed links or failed type "B" units. The signal on the secondary loop is transmitted in the opposite direction from the primary loop. Normally type "B" units forward the signal that they receive on the secondary loop. However, when a primary loop failure is detected, by a loss of received signal on that loop, a type "B" unit replaces the lost signal with the signal it receives from the secondary loop and stops transmitting on the secondary

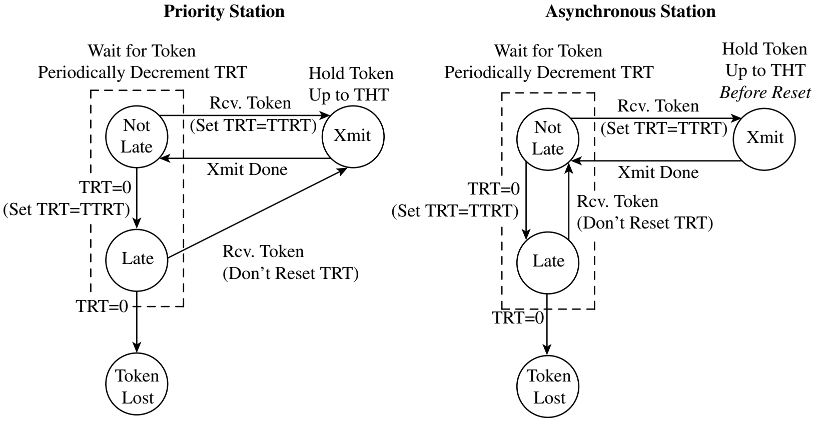

Figure 1. State machines for priority and asynchronous stations.

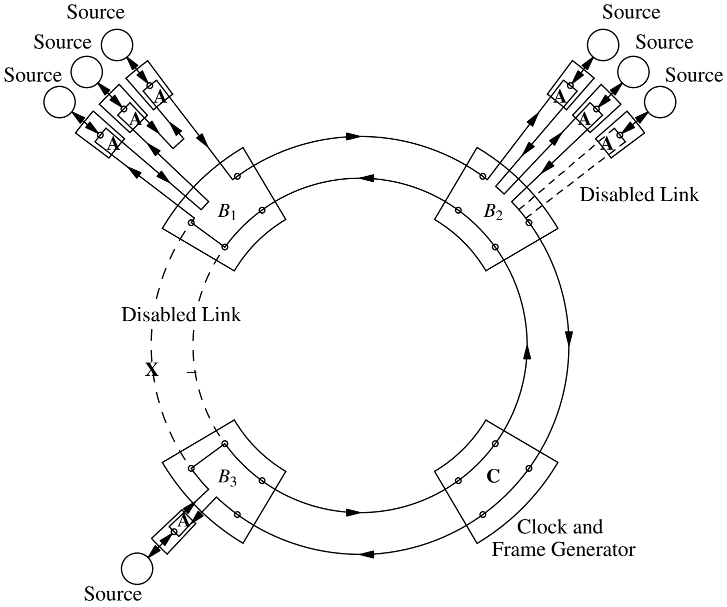

Figure 2. FDDI loop.

loop. When a type "B" unit stops receiving signal on the secondary loop, it replaces that signal with the signal it would have transmitted on the primary loop and stops transmitting on the primary loop. As an example, in Fig. 2, the "X" signifies a link failure. The unit B_1 stops receiving the signal on the primary loop, substitutes the signal that it receives from the secondary unit, and stops transmitting on the secondary loop. The unit B_3 stops receiving the signal on the secondary loop, transmits the signal it would have transmitted on the primary loop on the secondary loop, and stops transmitting on the primary loop. The entire secondary loop replaces the single failed link on the primary loop.

The Distributed Queue Dual Bus (DQDB)

DQDB (3,4) is the IEEE 802.6 standard for MANs. It uses two buses that pass each station, transmits information in fixed size slots, and uses the distributed queue protocol to provide fair access to all stations. Signals on the two buses propagate in opposite directions. A station selects the appropriate bus to communicate with a specific station and uses the other to reserve slots on that bus.

DQDB uses two passive, directional taps on each bus for each station. The first tap reads the signal, and the second tap adds signal to the bus. The taps read and write data on a bus without breaking the bus and are common components in both CATV and fiber-optic networks. The inability to remove signals makes it necessary for the the bus to have a break in the communications path where signals can leave the system.

The taps distinguish directional buses from loop networks, which use signal regenerators. In loop networks, there is a point-to-point transmission link between each station. Each station receives the signal on one link and transmits on the next link. A station can add or remove the signal on the loop. However, a failure in the electronics in a station breaks the communications path. By contrast, the stations on a directional bus networks do not interrupt the signal flow, and a failure in the electronics in a station does not break the communications path.

The directional taps are passive and do not contain active elements that can amplify the signal on the bus. Each tap removes energy from the signal path, and the signal must be restored to its full strength after passing several stations. The DQDB standard provides for erasure nodes (5,6). Erasure nodes are regenerators, similar to the station interfaces on a loop network. They restore the signal to its full strength and remove slots that have already passed their destination, so that the slots may be reused.

The Access Protocol. A baseband signal is transmitted. Energy exists in a bit position when a "1" is transmitted, and no energy is in the bit position when a "0" is transmitted. The station at the beginning of each bus, the head end, periodically transmits a sync signal to divide the transmission time into fixed-size slots.

The first bit in the slot is a "busy" bit, that is initially "0" and is changed to a "1" when the slot is being used. The read tap precedes the write tap at each station. The directional characteristic of the taps makes it possible for a station to read what upstream stations have transmitted on the bus, independent of what the station is transmitting. When a station has data to send, it transmits a "1" in the busy bit, while simultaneously reading what upstream stations have transmitted. If the busy bit was "0," the station transmits its data. If the busy bit was "1," then the slot is occupied and the station stops transmitting. There is no harm in adding energy to the "1" in the busy bit.

The stations on the bus that are closer to the head end have priority access over stations that are further away. In a dual bus network, reservations are used to construct a distributed first-in–first-out (FIFO) queue that services all stations in the order that they arrive. When slots arrive,

Figure 3. Queue formation on Bus A.

a station notifies the upstream stations by transmitting a reservation on the bus traveling in the opposite direction from the direction that it will transmit the slot. Each station maintains a queue of the requests from downstream stations and its slots, for each bus. When an empty slot arrives on a bus, the station examines the queue. If the next entry in the queue is a request from a downstream station, the station allows the empty slot to pass in order to service that request, and it removes that request from the queue. If the next entry in the queue is its own slot, it transmits that slot and removes it from the queue.

The queue at each station is a time-ordered list of its own arrivals and the arrivals at downstream stations. The queue at the head end has the complete list of arrivals, and the head end places its own messages in the slots they would have acquired if the actual messages were all in the queue. The next station on the bus does not have the list of arrivals at the head end in its local queue. However, the slots that these messages would have acquired, if they were in the queue, are busy and are not available to service the queue. By using the remaining empty slots to service its queue, the station places its own arrivals after the arrivals from downstream stations that arrived earlier than its own message. The station at the end of the bus only has its own arrivals in its queue, but all arrivals at upstream stations that arrived before the arrivals in this queue have acquired slots.

To prevent long messages from blocking short messages, the slots from each station are serviced in a round-robin order. Round-robin service can be implemented by maintaining a separate queue of slot requests for each downstream station and servicing each queue in order as empty slots arrive. An equivalent implementation in a reservation system is to have a station issue one slot request at a time, and not issue the next request until the previous request is serviced. DQDB implements a round-robin, FIFO queue with two counters that count the reservation requests that precede its own request, and those that follow it.

To preserve fixed-size slots, DQDB approximates the reservation system with a single reservation per slot. The second bit in each slot is a reservation bit and is initially set to zero. A station sets the bit to one to make a reservation. If two stations try to make a reservation in the same slot, the second station receives a one in that slot and must wait for a susequent slot to make its reservation.

Reservation requests are transmitted to the upstream stations on the opposite bus as the data. Two separate reservation systems exist, one for transmitting data on each bus. In each system, the bus that is used to transmit data is referred to as the data bus, and the other bus is the reservation bus. In Fig. 3, we depict the queue formation on bus A. Figure 3(a) shows the bits transmitted on each bus, (b) shows the operation of the counter in a station that is not transmitting slots, and (c) shows the operation of the counter in a station with a slot to send. In Fig. 3C, the count down counter contains the number of requests that preceded the slot from the local station. When this counter reaches zero, the next empty slot is used to transmit a slot and then the request counter, which is the number of requests that arrived after the slot from the local station, is transferred to the countdown counter and precedes the next slot from this station.

In a DQDB network with multiple priority levels for data, there is one reservation bit and two counters for each priority level. When empty slots are received, the counters for the higher priority levels are emptied first.

The DQDB protocol does not provide guarantees on delay or bit rate. An isochronous mode, similar to FDDI, has been added to support real-time traffic. The slots leaving the head end are grouped into 125 μs frames. In some slots the busy bit is zero and the slots are available for the DQDB protocol. In other slots, the busy bit is one. These slots are reserved for real-time traffic. A station that reserves a single byte in a frame acquires a 64-Kbps channel with at most a 125-μs delay. This same guarantee is provided by the telephone system for digital voice.

Protocol Unfairness. The description of the distributed queue ignores the propagation delay on the buses. The distance-bandwidth product of IEEE 802.6 standard networks creates a potential for gross unfairness (7). The standard was modified to include bandwidth balancing (BWB) (8), which eliminated most of the unfairness.

The IEEE 802.6 standard is designed to operate at 155 Mbps, with 53-byte slots, and is compatible with ATM. At these rates, a cell is only about 0.4 miles long. The standard spans up to 30 miles. Therefore, there may be 75 cells simultaneously on the bus. Assume that a station near the head end of the bus has a long file transfer in progress when a station 50 cells away requests a slot. In the time it takes the request to propagate to the upstream station, that station transmits 50 slots. When the request arrives, the upstream station lets an empty cell pass and then resumes transmission. An additional 50 slots are transmitted before the empty cell arrives at the downstream station. When the empty slot arrives, the downstream station transmits one slot and submits a request for another. The round trip for this request to get to the upstream station and return an empty slot is another 100 slots. As a result, the upstream station obtains 100 times the throughput of the downstream station.

A similar imbalance can occur in favor of the downstream station when that station starts transmitting first. Although the downstream station is the only source, it transmits in every cell, while placing a reservation in every slot. When the upstream station begins transmitting, there are no reservations in its counter, but there are 50 reservations on the bus. Although the upstream source transmits a slot, a reservation is received. Therefore, the upstream station must allow one slot to pass before transmitting its second slot. During the time it takes to service the reservation and the upstream station's next transmitted slot, two reservations arrive. Therefore, the upstream station lets two empty slots pass before transmitting its third slot. The reservation queue at the upstream station continues to build up each time it transmits a slot, and the upstream station takes fewer of the available slots. An imbalance between the upstream and the downstream station is sustained indefinitely because the downstream station places a reservation on the bus for each of the empty slots that the upstream station releases. The imbalance is not as pronounced as when the upstream station starts first, but it is considerable. The exact imbalance depends on the distance between two stations and the time that they start transmitting relative to one another (8).

The BWB mechanism is based on two observations:

1. Each station can calculate the fraction of the slots that are used, whether or not the data pass the station.
2. It is possible to exchange information between stations by using the fraction of the slots that are not used.

Table 1. Convergence of Rates when two Stations use 90% of the Slots Available to them

Station A		Station B	
Measure Bsy+Rqst	Take	Measure Bsy+Rqst	Take
0	0.9×1 = 0.9	–	–
0	0.9×1 = 0.9	0.9	.9×.1 = .09
0.09	.9×.91 = .82	0.82	.9×.18 = .16
0.16	.9×.84 = .76	0.76	.9×.24 = .22
0.22	.9×.78 = .7	0.7	.9×.3 = .27
0.27	.9×.73 = .66	0.66	.9×.34 = .31
0.31	.9×.69 = .62	0.62	.9×.38 = .34
. . .	. . .	. . .	. . .
0.474	.9×.526 = .474	0.474	.9×.526 = .474

A station sees a busy bit for every slot transmitted by an upstream station and a reservation for every slot transmitted by a downstream station. By summing the fraction of the busy bits and reservation bits and adding the fraction of the slots that the station transmits, the station calculates the total fraction of the slots that transmit data on the bus.

Table 1 shows how stations can communicate by using the fraction of unused slots. Each stations tries to acquire 90% of the unused bandwidth on a channel. Station A starts first and uses 90% of the total slots. When station B arrives, only 10% of the slots are available. Station B does not know whether the slots are being used by a single station taking its allowed maximum share or many stations. Station B uses 90% of the available slots or 9% of the slots in the system. Station A now has 91% of the slots available. When station A adjusts its rate to 90% of 91% of the slots, it uses 82% of the slots, making 18% of the slots available to station B. Station B adjusts its rate up to 90% of 18%, which causes the station A to adjust its rate down, and so on until both stations arrive at a rate of 47.4%. Note that this mode of communications cannot be used when stations try to acquire 100% of the slots.

The implementation of BWB in the standard is particularly simple. A station acquires a fraction of the slots available by counting the slots it transmits and by placing an extra reservation in the local reservation queue when the count reaches a prescribed value. In this way, a station lets a fraction of the slots that are available remain empty. For instance, if a station wants to take 90% of the slots that are available, it counts the slots that it transmits and inserts an extra reservation in the reservation counter after every ninth slot that it transmits. As a result, every tenth slot that the station could have taken remains empty.

With BWB, the fraction of the throughput that station i acquires, T_i is a fraction α_i, of the throughput left behind by the other stations:

$$T_i = \alpha_i \left\{ 1 - \sum_{j \# i} T_j \right\}$$

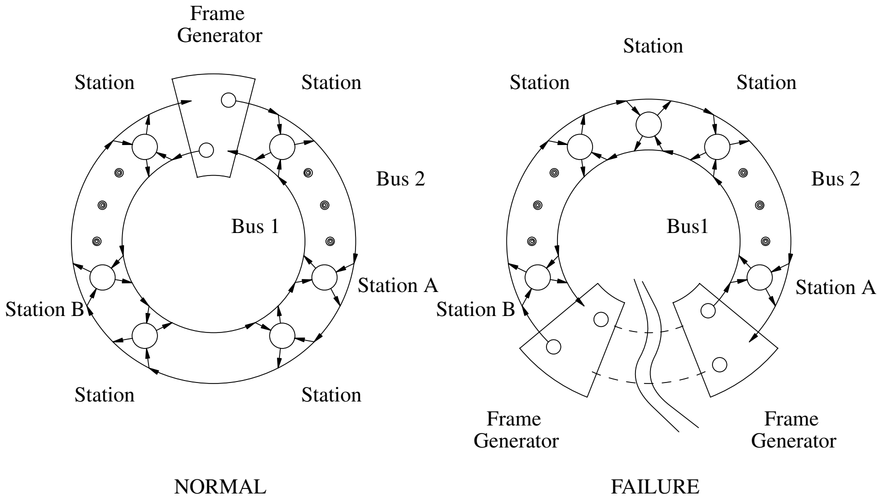

Figure 4. DQDB network before and after a failure.

When N stations contend for the channel, and use the same value of $\alpha = \alpha_\iota$ they each acquire a throughput

$$T = \frac{\alpha}{1 + \alpha(N - 1)}$$

The total throughput of the system increases as α approaches one or the number of users sharing the facility becomes large. The disadvantage with letting α approach one is that it takes the network longer to stabilize. We can see from the example in Table 1 that the network converges exponentially toward the stable state. However, as $\alpha \to 1$, the time for convergence goes to infinity. The original DQDB protocol uses $\alpha = 1$.

Reliability. The dual bus in a DQDB network is configured as a bidirectional loop, as shown in Fig. 4. The signal on the outer bus propagates clockwise around the loop, and the signal on the inner bus propagates counterclockwise. The signal does not circulate around the entire loop, but it starts at a head end on each bus and is dropped off the loop before reaching the head end.

To communicate, a station must know the location of the destination and the head ends and transmit on the proper bus. For instance, station A transmits on the outer bus to communicate with station B, and station B transmits on the inner bus to communicate with station A.

The dual bus is configured as a loop so that the head end can be repositioned to form a contiguous bus after a failure occurs. The head end for each bus is moved so that the signal is inserted immediately after the failure and drops off at the failure. This system continues to operate after any single failure.

The ability to heal failures increases the complexity of stations on the DQDB network. To heal failures, the station that assumes the responsibility of the head end must be able to generate clock and framing signals. In addition, after a failure each station must determine the new direction of every other station. For instance, after the failure in Fig. 4 is repaired, station A must use the inner bus, rather than the outer bus, to transmit to station B.

Manhattan Street Network (MSN)

The MSN (9) is a two-connected network of 2 × 2 switches. A station is attached to each switching node. The connectivity between nodes in the MSN is the same as in an FDDI network and a DQDB network, except that the logical topology of the network resembles the grid of one-way streets and avenues in Manhattan, as shown in Fig. 5. Fixed-size cells are switched between the two inputs and outputs using a strategy called deflection routing. The fixed-size cells can encapsulate ATM cells, so that the MSN is compatible with wide-area ATM networks.

In the MSN, packets are routed independently at each node that they traverse so that the overhead associated with establishing and maintaining circuits is eliminated.

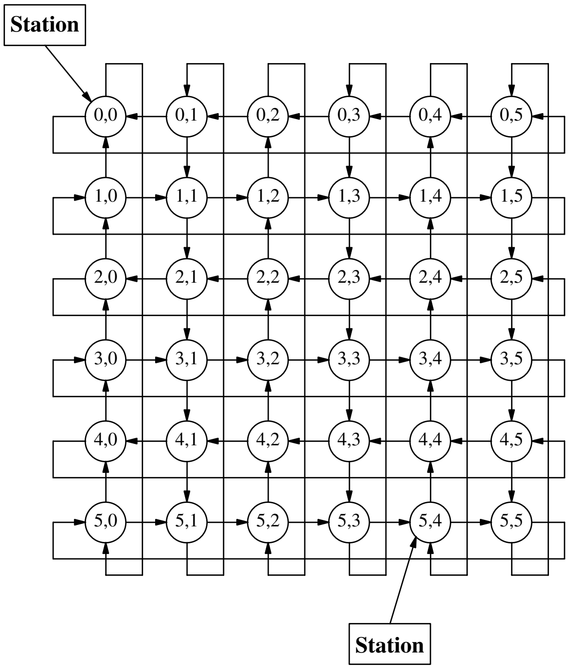

Figure 5. The Manhattan Street Network.

The direction of one-way streets and avenues alternate. By numbering the streets and avenues properly it is possible to get to any destination without having a complete map, and when failures occur, detours around the failure can be determined. The grid is logically constructed on the surface of a torus instead of a flat plane. The wraparound links on the torus decrease the distance between the nodes and eliminate congestion in the corners.

In deflection routing, packets can be forced to take an available path rather than waiting for a specific path. It operates on any network where the nodes have the same number of inputs and outputs and the network transmits fixed-size cells. The cells are aligned at a switching point in a node. In a two-connected network, if both cells select the same output, and the output buffer is full, one cell is selected at random and forced to take the other link. The cell that takes the alternate path is deflected.

Deflection routing gives priority to cells passing through the node. Cells are only accepted from the local source when empty cells are arriving at the switch. Therefore, the number of cells arriving at the switch never exceeds the number of cells that can be transmitted, and cells are never dropped because of insufficient buffering. The link capacities is shared between bursty sources without large buffers and without losing packets because of buffer overflows. The operation of a deflection routing node is shown in Fig. 6. Deflection routing is also used for routing inside some ATM switches (10,11).

The MSN is well suited for deflection routing for three reasons:

1. At any node many destinations are equidistant on both output links. Cells headed for these destinations have no preference for an output link and do not force other cells to be deflected.
2. When a cell is deflected, only four links are added to the path length. The worse that happens is that the cell must travel around the block.
3. Deflection routing can guarantee that cells are never lost, but it cannot guarantee that they will not be deflected indefinitely and never reach their destination. It has been found that this type of livelock does not occur in the MSN when the cell that is deflected is selected randomly (12).

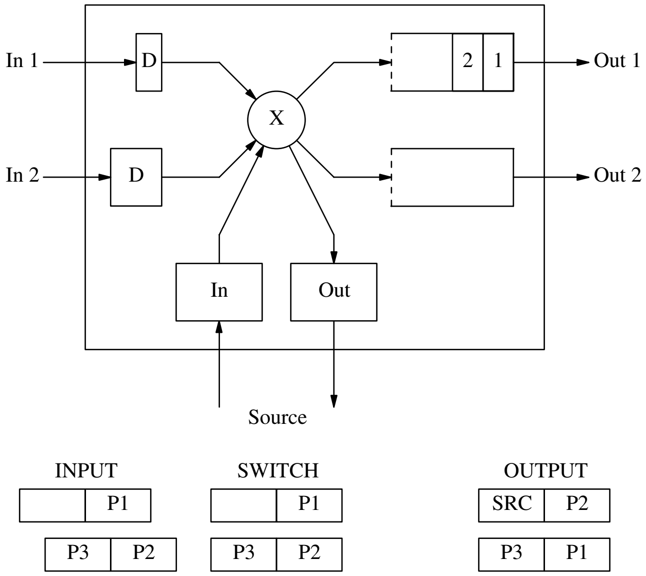

Figure 6. Deflection routing node.

Deflection routing is similar to the earlier hot potato routing (13), which operated with variable-size packets, on a general topology, with no buffers. Fixed-size cells, the MSN topology, and two or three cells of buffering converted the earlier routing strategy, which had very low throughputs, to a strategy that can operate at levels exceeding 90% of the throughput that is achieved with infinite buffering.

Reliability. The MSN topology has several paths between each source and destination. The alternate paths can be used to communicate after nodes or links have failed.

There are two simple mechanisms to survive failures in the MSN, as shown in Fig. 7. Node failures are bypassed by two normally closed relays that connect the rows and columns through. The missing node in the grid in Fig. 7 has failed. Link failures are detected by a loss of signal, as in loop networks. Nodes respond to the loss of signal by not transmitting on the link at right angles to the link that has stopped. When one link fails, three other links are removed from service and the node at the input to the

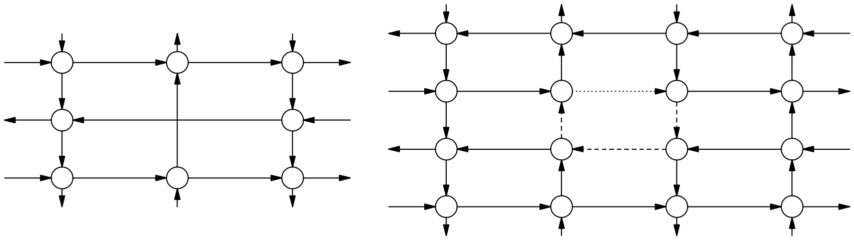

Figure 7. Failure recovery mechanisms in the MSN.

failed link stops transmitting on it. The dotted link in Fig. 7 has failed, and nodes stop transmitting on the dashed links. This link removal procedure works with any number of link failures. The number of inputs equals the number of outputs, so that deflection routing continues to operate without losing cells. In addition, it has been found that the simple routing rules that are designed for complete MSNs continue to work on networks with failures.

Comparison of FDDI, DQDB, and the MSN

DQDB and FDDI are linear topologies. The average number of links that data traverses increases linearly with the number of nodes in the network, and the average throughput that each user can obtain decreases linearly with the number of users. By contrast, in the MSN, the distance between nodes increases as the square root of the number of nodes in the network. As a result, the reduction in the throughput per user, which occurs as networks become large, is much less in the MSN than in the FDDI or DQDB network.

In the DQDB network, the penalty for large networks can be reduced by breaking the network into segments and erasing data that have already been received when it reaches the end of a segment. This strategy works particularly well when communities of users communicate frequently. When those users are placed on the same segment of the bus, the traffic between them does not propagate outside the segment and interfere with users in other segments. When a community in the middle of the bus becomes congested in a DQDB network, communications between nodes at opposite edges of the bus must still pass through that community.

In the MSN, communities of users are supported in a very natural way. If nodes that communicate frequently are located within a few blocks, they only traverse the paths in those few blocks and do not affect the rest of the network. Special erasure nodes are not needed because the protocol removes cells that reach their destination. In addition, when there is heavy traffic within a neighborhood, communications between other neighborhoods can continue without passing through that neighborhood. With deflection routing, cells naturally avoid passing through congested neighborhoods.

Both DQDB and FDDI can survive single failures. However, when multiple failures occur, the network is partitioned into islands of nodes that cannot communicate with one another. Nodes in the MSN are not cut off from one another until at least four failures occur. When four failures have occurred, the likelihood of nodes being disconnected, and the number that are actually disconnected, is small. A quantitative comparison of the reliability of MSN, DQDB, and FDDI networks is presented in Ref. 14.

An advantage of linear topologies is that routing is relatively simple. All data that enter an FDDI system is transmitted on a single path, and there is only one path to select at any intermediate node. In a DQDB network, the source must decide which of the two paths leads to the destination, but once the data are in the network, there are no choices to make. The MSN network has a simple rule to select a path, but a choice must be made at each node.

An important consideration in any large network is how easily it can be modified to add or delete users. In early LANs, there was a correspondence between the topology of the network and the physical distribution of users. A loop network was a daisy chain between adjacent offices and a bus network passed down a hallway. It is more difficult to change the wiring between offices than to have all offices connected to a wiring cabinet and change the interconnections in that cabinet. As a result, most linear networks are physically a star network between users and a wiring cabinet. The users are connected inside to a wiring cabinet to form a logical loop or bus or mesh network. The number of wires that must be changed in the wiring cabinet determines how difficult it is to add or delete users from a network.

In a bidirectional loop or bus network, adding or deleting a user is a relatively simple operation. To add a user, the connection between two users is broken and the new user is inserted between them. In the wiring cabinet, two wires are deleted and four are added. In a complete MSN, two complete rows or columns must be added to retain the grid structure. There are, however, partial MSNs in which rows or columns do not span the entire grid, and a technique is known for adding one node at a time to a partial MSN to eventually construct a complete MSN (15). With this technique, the number of links that must be changed in the wiring cabinet is the same as in the loop or bus network.

DQDB and FDDI have an isochronous mode of operation that provides dedicated circuits to support realtime traffic. The isochronous mode is well integrated into the DQDB protocol. Nodes that only require the data mode do not have to change any protocols or hardware when isochronous traffic is added to the network. The only change that these nodes notice is that more slots are busy. By contrast, when isochronous traffic is added to an FDDI network, every node must be able to perform context switching to move between the data and the circuit modes. The MSN does not have an isochronous mode of operation. Real-time traffic operates like IP voice on the Internet and is dependent on low network utilizations.

THE CURRENT GENERATION MANs

CATV

The CATV network is an existing MAN that is designed to deliver TV programs to a large number of homes. The network is designed for unidirectional delivery of the same signal to a large number of receivers. In most CATV networks, many channels carry signals from the head end to the home in the downstream direction, and a smaller number of channels carry signals in the opposite direction, the upstream direction. The network taps are also directional and receive signals from downstream but not from upstream. Signals transmitted through the directional taps travel upstream. The lines in many homes are not properly terminated and insert significant noise into the network, but this noise travels upstream, it is not received by the other homes, and does not degrade TV reception from the head end. The upstream channel is a noisy channel that cannot be used to carry high-quality analog signals, but it can be used to carry digital data.

The CATV network is increasingly being used to provide high bandwidth data access to the Internet. Several competing standards committees, including the IEEE 802.14 standards committee and the Multimedia Cable Network Systems group (MCNS), are working on standards that are not compatible with one another.

The current practice and the evolving standards have some common characteristics. All channels use 6-Mhz bands that are used for TV transmission. Many homes share the upstream channel to send data to the Internet. The protocols that share this channel include reservation protocols, which allow homes to acquire scheduled slots, and contention-based protocols, which are similar to the CSMA/CD protocol used in Ethernet but may have more complicated contention resolution schemes based on tree searches. The upstream channel is relatively noisy, and cable modems transmit between 1.6 and 10 Mbps in these channels. The downstream channel carries addressed packets from the Internet to the many homes.

The data from the Internet come from a single source, a router, so that there is no contention for this channel. Typically, in Internet applications there is much more data to the home than from the home. The downstream channel has a much higher signal-to-noise ratio than the upstream channel, and cable modems transmit up to 40 Mbps in the downstream channels.

Instead of describing the many contending standards, we will demonstrate the use of the CATV network with the IEEE 802.3 Ethernet standard protocol. This approach has the advantage that the home terminals use standard Ethernet chips, which have become inexpensive because they are widely used, to share the upstream channel. Furthermore, Ethernets typically transmit encapsulated IP packets that can be forwarded directly to the Internet. The CSMA/CD protocol that is used on Ethernets cannot be applied directly to the upstream CATV channel because

1. The stations that are transmitting on the upstream channel cannot listen to the other stations to determine when the channel is busy or when a collision occurs.
2. The distances spanned by a CATV network are much greater than the distances spanned by a local network so that the CSMA/CD protocol become less efficient.

CATV networks have evolved from a tree topology to a hub-and-spoke topology. In the tree topology, cables from the head end of the network are connected to each home. In the hub-and-spoke topology, fibers from the head end carry signals to each hub and smaller cable trees connect the hub to the individual homes. The hub-and-spoke topology has fewer amplifiers and delivers TV signals with a higher signal-to-noise ratio. The hub-and-spoke topology also reduces the distance between users connected to the same hub. The decreased distance between users and the lower transmission rates on the upstream channel make it possible to use CSMA/CD to share the upstream channel between users that are connected to the same hub. When necessary, a transmission plan, called homenets (16), can be used to partition the trees emanating from a hub into several smaller Ethernets.

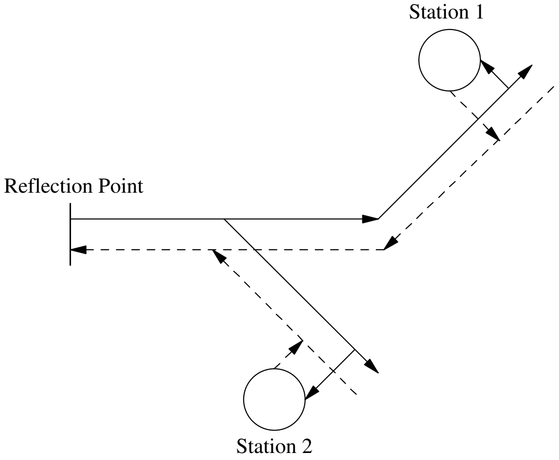

Figure 8. Transmission strategy for CSMA/CD access.

Each hub limits the number of data users who share a single Ethernet. Increasing the number of users on an Ethernet reduces the bandwidth that is available to each user. Proper placement of the hubs can limit the contention and provide a desired service level for data. The same principles can be used to engineer the sharing of the CATV data network as have been used to engineer the sharing of local office switches in the telephone network.

Each user must be able to listen to the signals transmitted by all other users to perform CSMA/CD. At each hub, the signal from the upstream channel is translated to a frequency that is used by a downstream channel and retransmitted on the tree originating at the hub, as shown in Fig. 8. The home terminals listen to the second channel to determine when the channel is busy or when there are collisions.

Movable Slot TDM. As IP voice gains wider acceptance, the data channels on CATV networks will be used to carry voice. The reservation systems that are being considered by the standards committees can provide better delay and bandwidth guarantees than the standard Ethernet protocol. A variation of the CSMA/CD protocol called Movable Slot TDM (MSTDM) (16,17) makes it possible to obtain high-quality voice on the upstream channel without modifying the current Ethernet chips. MSTDM makes it possible to place voice on the upstream channel without modifying the operation of data-only users

MSTDM gives voice packets priority over data packets. The data packets follow the standard IEEE 802.3 protocol. The voice packets listen before transmitting but do not perform collision detection. When a voice and data packet collide, the data packet stops transmitting but the voice packet continues to transmit. There is a preempt interval at the beginning of each voice packet that does not contain bits that are needed to receive the voice packet and is long enough to guarantee that the data packet has stopped

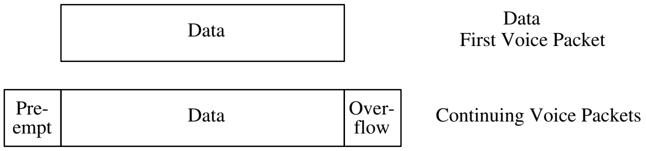

Figure 9. Format of MSTDM packets.

transmitting before the useful data in the voice packet is transmitted. If the channel is busy when a voice packet tries to transmit, it waits until the channel becomes idle and retransmits immediately.

The first packet in a voice connection uses the same protocol as the data packets. Subsequent voice packets in a connection are transmitted a fixed period T_v after the last successful transmission, whether or not the previous packet is delayed. If the previous packet is delayed, it places any voice samples that arrive while it is being delayed into an overflow area in the packet, so that the same number of voice samples are waiting at each scheduled transmission time. The only constraint on the data packet is that its length is less than or equal to the length of a fixed-size voice packet. The packet formats are shown in Fig. 9.

Scheduled voice sources never collide. All scheduled voice packets have the same length, require time X_V to transmit, and are scheduled at least X_V apart. A scheduled voice source preempts a data source that collides with it. A scheduled voice source is delayed by less than X_V by a data source that is currently transmitting, because the data packet length is less than the voice packet length. If a scheduled voice source is delayed, it cannot be further delayed by a data source because it transmits as soon as the channel becomes idle and preempts any data source that starts transmitting at the same time. When a scheduled voice packet is delayed less than X_V, it delays the next voice source by an amount less than or equal to its own delay. Therefore, the delay of successive voice sources is nonincreasing and is less than X_V. And voice sources never collide. The access rule for scheduled voice sources is CSMA, rather than CSMA/CD. CSMA can be implemented with a single NAND gate that turns off collision detection. The NAND gate is external to the commercially available chips that implement the Ethernet protocol.

When a scheduled voice source is delayed, the overflow area is occupied by the samples that arrive during the delay. The overflow area need only be large enough to accommodate the voice samples that arrive in X_V. The delayed packet adopts a new schedule, and the overflow area is empty for successive packets that are not delayed. The upper bound on the delay for a voice sample is $T_V + X_V$. In Fig. 10 we show the operation of the protocol when scheduled packets are delayed by a data source or a new voice source.

When the system bandwidth is completely used by voice sources, MSTDM becomes a simple TDM system and new voice sources and data sources cannot disrupt the operation of the system. Figure 11 depicts the operation of a system that can support 3.5 voice sources. The small number of sources is only used to demonstrate the operation of the protocol. A 10-Mbps system, with 32-Kbps voice sources, can support several hundred active voice sources. In Fig. 11 there is enough bandwidth for half of a new voice source. Source 4 joins the system and delays source 1, 2, and 3. The delayed source 3 delays the newly scheduled source 4, which once again delays sources 1, 2, and 3. The delay is nonincreasing, so the scheduled sources never collide, but the sources are always delayed, so that the overflow area always has samples. Any new voice or data sources find a busy channel or collide with a scheduled source and are preempted.

Wireless Networks

Wireless networks are the most rapidly evolving metropolitan area networks. Wireless networks require less of an investment in infrastructure than wired networks,

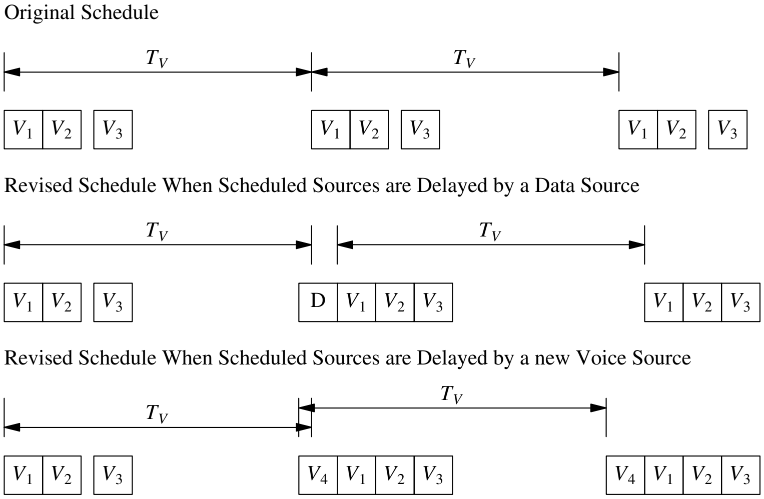

Figure 10. Scheduled voice sources that are delayed by a data source or a new voice source.

Figure 11. Fully utilized MSTDM network.

particularly in metropolitan areas where installing new cables may involve digging up a street. Deploying wireless networks makes it possible to try new services without investing in new cables. In addition IEEE 802.11 wireless interfaces have come down in cost and are included in most new laptop computers. Wireless interfaces in battery- operated computers make it possible for users to work where they they are, rather than searching for power or information outlets. And the wireless interface is a single standard, unlike the many incompatible cable interfaces.

Wireless metropolitan area networks are composed of access networks that interface to the users, and cover relatively small distances, and backbone networks that cover the metropolitan area distances and carry the user traffic to the wide area network. In this article we discuss two access networks, the IEEE 802.11 standard network and Bluetooth. IEEE 802.11 networks operate at higher bit rates and cover longer distances than Bluetooth networks. Initially, Bluetooth interfaces were to cost much less than IEEE 802.11 interfaces. However, the larger number of IEEE 802.11 units that have been deployed has made them less expensive than Bluetooth interfaces. It is likely that IEEE 802.11 networks will dominate and that there will be very few Bluetooth networks. Bluetooth is included in this article because it has had a great impact on the evolving IEEE 802.16 standard. The IEEE 802.16 networks are wireless networks that can cover the distances spanned by metropolitan areas and are possible backbone networks for the wireless access networks.

IEEE 802.11 Networks. IEEE 802.11 networks have two modes of operation, a point coordination function, which is polled, and a distributed coordination function, which uses a protocol called carrier sense multiple access with collision avoidance, CSMA/CA. The polled operation assumes a master station that assigns slots to the active transmitters. The master station also sends unassigned slots in which new sources can transmit when they want to be added to the polling list. When multiple sources transmit during an unassigned slot, there is a collision and the sources must retry. The CSMA/CA protocol is similar to the Ethernet protocol and does not require a master station. Currently, the CSMA/CA protocol is better defined and is more widely used than the polled protocol. However, the polled protocol uses the scarce radio bandwidth more efficiently and can provide the guarantees that are needed for voice communications. When WiFi networks are used to access a base station that connects it with a backbone network, the base station is the logical master station

The CSMA/CD protocol that is used in wired Ethernets cannot be applied directly to wireless networks. It is possible to listen to the channel before transmitting (CSMA) to determine whether another source is transmitting, but it is not possible to listen to the channel while transmitting (CD) to determine whether another source is also transmitting. In addition, hidden nodes interfere with the source at the destination, but they cannot be detected by and cannot detect the source, as depicted in Fig. 12. The area A_{SX} is the region in which the signal from the source can be detected. This area includes the destination. The area A_H is the hidden nodes. A node in A_H cannot detect the signal from the source, but if it starts to transmit, its signal will interfere with the signal from the source at the destination. The area A_{HX} is the region in which nodes detect the signal from a hidden node and includes the destination.

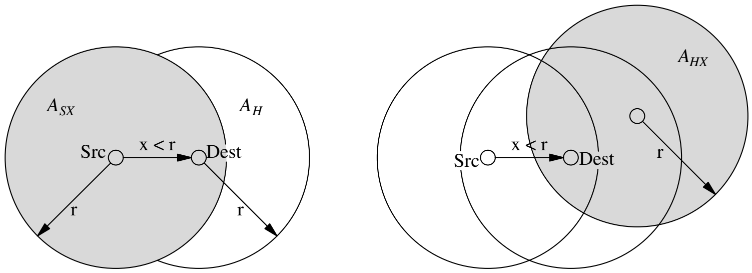

Figure 12. Hidden nodes.

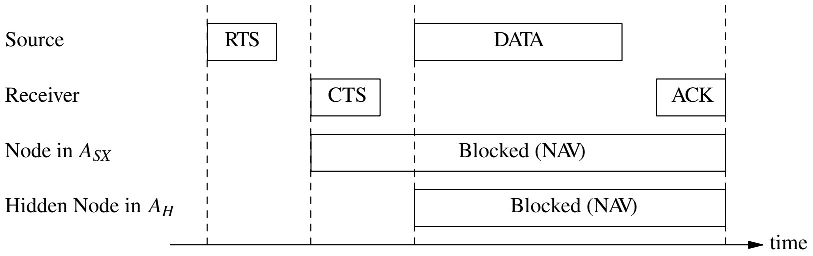

Figure 13. Three-way handshake, CSMA/CA—with ACK.

The CSMA/CA protocol uses a three-way handshake to avoid collisions with hidden nodes, as depicted in Fig. 13. The source senses the channel, and if there is no transmission in progress, it sends a request to send (RTS) to the destination. If the destination receives the RTS, one node that is hidden from the source is not transmitting, the destination sends a clear to send (CTS). When the source receives a CTS, it sends the data packet. If the receiver correctly receives the data packet, it sends an acknowledgment (ACK). The error rate in wireless networks is typically higher than that in wired networks, and the ACK is an integral part of the wireless protocol. In addition, the packet size in wireless networks is typically smaller than in wired networks to increase the probability of correct reception. The nodes in A_{SX} receive the RTS from the source, but it may not receive the CTS from the receiver. The node in A_{SX} sets a network allocation vector (NAV) that stops it from transmitting for a period of time that is long enough for the receiver to transmit an ACK. A node A_H receives CTS but not RTS or the data. The node in A_H sets a shorter NAV that is long enough for the source to send the data and the receiver to send an ACK.

The original IEEE 802.11 networks operated at 1 Mbps. The more recent versions have variable rates and can operate up to 54 Mbps. A source tries to transmit at the highest rate. If the signal is not correctly received, the source reduces its rate, to increase the signal-to-noise ratio, until the signal is correctly received. The achievable rate is related to the distance between the source and the destination. The closer the destination, the higher the signal-to-noise ratio, and the higher the rate. Table 2 is the approximate relationship between the distance and the achievable rate for the current versions of the IEEE 802.11 standard.

Table 2. Approximate Relationship between Distance and Transmission rate in IEEE 802.11 Networks

Rate (Mbps)	802.11a	802.11b	802.11g
1	250	200	250
2	175	175	175
6	175	100	175
9	140	70	140
12	140	40	140
18	80		80
24	70		70
36	40		40
48	20		30
54	10		20

The distance spanned by an IEEE 802.11 network can be increased by using multihop techniques. If the source cannot reach the access point to the MAN directly, it transmits the data to an intermediate node, which forwards the data toward the destination. The intermediate nodes operate as routers and select the next node on the path to the destination. The path to the destination is not fixed and may change as nodes enter and leave the network. The techniques to find paths are covered in the literature on ad hoc, multihop, radio networks. This currently is an active research area and is beyond the scope of the current article.

Bluetooth. Bluetooth is a polled network. It is organized as piconets with one master and up to seven slave nodes. All communications are between the master and a slave node, with half of the slots assigned to the master node. The total bit rate in a piconet is 1 Mbps.

The number of nodes in a network is increased by connecting piconets into a scatternet. A slave node that is in both piconets operates as a gateway between the piconets, as depicted in Fig. 14. Multihop communications is implemented on paths that traverse source, to master, to bridge, to master, . . ., to master, to destination.

IEEE 802.16. The IEEE 802.16 MAN standard is similar to Bluetooth networks. The network is polled, but the distance is longer and the bit rates are higher. The network can span 30 Km, and the slaves can operate at a bit rate that is 50 Mbps, 100 Mbps, or 150 Mbps, depending on the signal-to-noise ratio.

The stations that are polled are dropped from the polling list if they remain inactive for seven consecutive polls. In addition, the master and slave stations can obtain different slot rates to reflect asymmetries in the traffic. IEEE 802.16 networks can be interconnected as scatternets.

CONCLUSION

Metropolitan area networks have evolved rapidly in the last decade because of changes in technology and applications. The cell switching technology of ATM networks has lost to the routing technology of IP networks, and the MANs that were based on cell switching have disappeared. Consumer applications that connect individuals to the Internet have become much more important in MANs than interconnecting users in a corporate network that spans a metropolitan area. As a result, the price of network access has become a much more important consideration and older technologies that are further along the learning

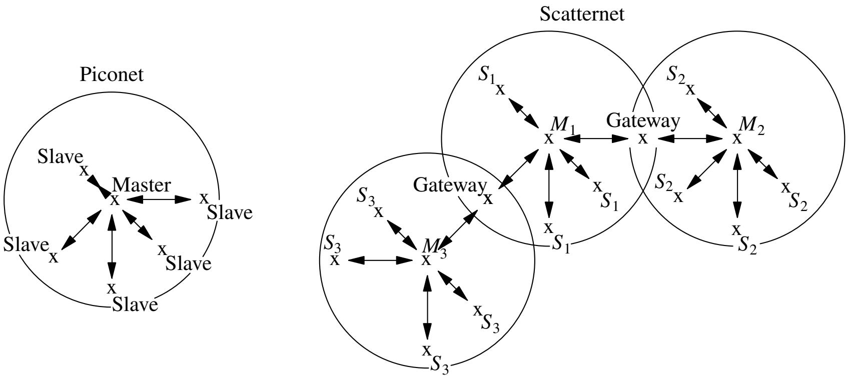

Figure 14. Bluetooth networks.

curve have dominated. Users have come to expect tetherless access to networks, and wireless end-user devices have become the norm for all of our communications.

In the next decade, we expect the rate of change of MANs to increase. Initially, the use of wireless backbone networks will increase, as we explore new and different communications services. Wireless technologies provide the fastest, most economical way to construct new networks. However, as some services succeed, there will not be enough wireless bandwidth in the backbone to support the new demand. The wireless backbone will be replaced by more efficient, higher rate, fiber-optic networks. Wireless will not go away. The end user is hooked on tetherless access. However, the part of the network that is invisible to the user will apply the most cost-effective technologies.

The Internet has been the defining application for the current generation of MANs. IP voice is likely to be the defining application of the next generation of MAN. IP voice is more efficient than circuit-switched voice because the channel is not used during silent intervals. However, the success of IP voice will more likely depend on new services, such as the walkie-talkie functions that are being built into cell phones. If this happens, traffic within the MAN will increase with respect to traffic to the wide-area networks. Networks that are being designed to reflect the traffic imbalance between end users and servers in the Internet will once again be replaced by networks with balanced loads in both directions.

The success of IP voice and the reduced cost of IEEE 802.11 chips is likely to completely change the current cellular voice networks. The success of cellular voice has created a bandwidth crisis in many metropolitan areas. The smaller distances spanned by IEEE 802.11 networks makes it possible to reuse the bandwidth more often, and multihop techniques provide a means to redistribute the traffic in congested areas. In addition, IEEE 802.11 base stations are less visible than the current microwave towers.

As we become more dependent on MANs, reliability will become a more important issue. Currently it is almost impossible to buy multipath reliability in a metropolitan area. Even if we buy two lines from different service providers, both lines may belong to a single provider or traverse the same conduits. Future MANs are likely to have a different protocol architecture than our current layered structure. The new architecture will make more physical attributes visible, rather than hiding them. In addition, more reliable mesh structures, such as the MSN, are likely to replace the current tree, hub-and-spoke, and ring architectures.

Finally, we expect a resurgence of cell transmission in the heart of the network. Routers switch cells internally. Eventually there will be a standard that allows routers to exchange the cells, rather than having multiple conversions between cells and IP packets. The end-user applications are not affected by the internal operation of the network. Cell transmission will also allow the routers to provide quality of service. It is unlikely that the heavyweight ATM standards, or the virtual circuits that are part of ATM, will return, but these standards are not needed to implement cell transmission. The return of cell transmission may make us reconsider the first generation of MANs that also used cell transmission.

MOBILE AND UBIQUITOUS COMPUTING

OVERVIEW

The development of wireless communication technology and portable computing devices in late 1980s and early 1990s has led to a new computing paradigm, *mobile computing,* in which mobile devices capable of wireless communications are used to perform various computing tasks (1). Because of the characteristics of mobile environments, such as user mobility and severe resource constraints of mobile devices, many challenges exist in mobile computing, which include wireless ad hoc communications, mobility, portability, scalability, resource constraints, and adaptability (2–5). Since the 1990s, substantial effort has been made in various areas, which include networking, database, security, and software engineering, to address these challenges. However, many challenging issues still need to be addressed.

The concept of *ubiquitous computing* was first introduced by Weiser in 1991 (6) based on the idea that the most powerful and useful technologies ever invented are those that become indistinguishable from our daily life (6). In his view, ubiquitous computing represents a new computing paradigm in which information processing needed by a person is done by hundreds of computing devices of various scales, from PDAs to desktop PCs and to even supercomputers, connected through wired or wireless networks transparently. Comparing ubiquitous computing with mainframes shared by many users and personal computers owned by individual users, Weiser considered ubiquitous computing the third wave in computing in which many computers serve one user (7). Ubiquitous computing makes computing invisible to people and allows them to focus more on their uses rather than their computers.

Ubiquitous computing has many applications, from intelligent environmental control and smart home appliances, to interactive workspaces, mobile patient-care systems, context-aware tourist guides, and smart classrooms. An exemplified scenario can be found in Ref. 6 to illustrate a day of life in a world of ubiquitous computing. In this scenario, tiny electronic tabs affixed with various objects are used to identify and to locate useful items. In-vehicle devices are used to display the traffic condition and to find parking spaces. Handheld computers as well as large interactive display systems are used to create virtual offices for collaborative works.

Because of user mobility, and because of heterogeneous and dynamically changing computing environments, many research issues need to be addressed in ubiquitous computing, such as design of tiny, inexpensive, and energy-efficient mobile devices; interconnection of wired and wireless networks; lightweight system software for ubiquitous computing devices; techniques and tools for developing smart ubiquitous computing application software; and various security and privacy issues in ubiquitous computing environments. Since early 1990s, much research has been performed to develop the enabling techniques for ubiquitous computing to address these issues, and some technical terms have been created and used to describe similar computing technologies for ubiquitous computing, such as "pervasive computing," "ambient intelligence," and "invisible computing (8–10)." Currently, a common definition for ubiquitous computing is that it is a model of human—computer interaction in which information processing has been integrated thoroughly into everyday objects and activities, or, simply "computing anytime, anywhere (11)."

Mobile computing is related closely to ubiquitous computing, but it has a different emphasis. Mobile computing emphasizes mobility (i.e., the capability to continuously perform computing tasks in mobile environments). Although mobility is one of the important requirements for ubiquitous computing, the major concern of ubiquitous computing is how to make the interactions between human and computers transparent to human users. This concern requires ubiquitous computing systems to be aware of users' needs and the ambient environment and to adapt themselves to provide satisfactory services to users continuously in dynamically changing ubiquitous computing environments. Usually this feature is referred to as *context- / situation awareness*. In addition, computing devices used in ubiquitous computing environments are not limited to mobile devices, and they are connected through wired and/or wireless networks.

Despite these differences between mobile and ubiquitous computing, the technologies for mobile computing are still important for ubiquitous computing because ubiquitous computing environments also have many characteristics similar to those of mobile environments, such as user mobility and usage of wireless networks. Hence, some researchers consider that the research in these two areas should be combined (12), and some researchers even consider that the research of ubiquitous computing subsumes that of mobile computing (10). In this article, we will not distinguish the research in these two closely related areas, and we will use the term "mobile and ubiquitous computing" to refer to the combination of these two areas.

Research on mobile and ubiquitous computing spans across many different aspects, which include networking, databases, artificial intelligence, operating systems, software engineering, security and privacy, and so forth. It is impossible to enumerate and to discuss all the important research issues in this article. Hence, in this article, we will summarize the current state of research in the following four aspects: wireless ad hoc networks, context-/situation-awareness in mobile and ubiquitous computing environments, techniques for developing mobile and ubiquitous computing software, and privacy issues in mobile and ubiquitous computing. The research results in these four aspects not only include important enabling techniques for

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

developing mobile and ubiquitous computing systems, but also provide the most distinct features of mobile and ubiquitous computing systems.

WIRELESS AD HOC NETWORKS

The main advantage of mobile and ubiquitous computing environments is the capability of integrating heterogeneous mobile computing devices in various network domains to provide users with the capability of "anywhere, anytime" computing.

Being different from the Internet in which terminal hosts are connected to routers via a fixed network infrastructure, the heterogeneous mobile computing devices in mobile and ubiquitous computing environments essentially communicate with each other in an autonomous manner to construct a wireless ad hoc network. A *wireless ad hoc network* is a self-configuring network of mobile nodes connected by wireless links. Without a fixed network infrastructure, every node acts as a terminal host and a router simultaneously for the data transmission in the network. The network topology is self-organizing and geographically dispersed in the sense that a link only exists between two mobile nodes if they are within the physical communication range with each other. A wireless ad hoc network may operate in a stand-alone fashion, or may be connected to the larger Internet.

In wireless ad hoc networks, many research challenges have been identified from the mobility and energy constraints of the individual handheld computing devices, which are the major types of nodes in wireless ad hoc networks. In the following sections, these challenges and solutions are reviewed briefly in the categories of different layers of the network protocols hierarchy.

Medium Access Control (MAC) Layer

The major challenge for the MAC layer in the wireless ad hoc networks is how the MAC layer protocols are designed to allocate the communication resources, such as the available bandwidth of wireless channels, and to optimize the network performance efficiently, which can be measured in term of throughput, transmission delay, and fairness. In this subsection, we will discuss briefly the major MAC protocols currently used.

Carrier Sense Medium Access (CSMA). Because of the lack of centralized control in wireless ad hoc networks, the MAC protocols in this area are primarily contention based. CSMA is one of the earliest mechanisms adopted for wireless ad hoc networks. In CSMA, a transmitter first senses the wireless channel in the vicinity and refrains itself from transmission if the channel is already in use. Various methods such as ALOHA (13) and *n*-persistent algorithms (14), can be used to determine how long the deferred node should wait before the next attempt.

Medium Access Collision Avoidance (MACA). MACA is a "virtual sensing" mechanism instead of physical sensing. Such a mechanism is also called packet sensing. Typically, the virtual sensing mechanisms rely on the transmitter and the receiver to perform a handshake prior to the transmission of the data packet. Specifically, the MACA method (15) conducts the handshake via a pair of request-to-send (RTS) and clear-to-send (CTS) messages. When a node wants to send data to another node, it first sends a short RTS packet to the destination. The receiver responds with a CTS packet. On receiving the CTS packet, the sender sends its queued data packet(s). All other nodes that overhear the CTS message will defer themselves from sending out any packets until the predicted transmission period indicated in the CTS packet is passed. Any node that overhears the RTS signal, but not CTS, is allowed to send out packets in a certain time period as either the RTS/CTS handshake is not completed or it is out of range of the receiver.

IEEE 802.11. The IEEE 802.11 MAC protocol (16) is another example of using both physical sensing and RTS/CTS handshake mechanisms. IEEE 802.11 is defined actually as the standard MAC and physical protocols for wireless LANs, not specially designed for multihop wireless ad hoc networks. The MAC layer consists of two core functions: a distributed coordination function (DCF) and a point coordination function (PCF).

DCF controls the medium access through the use of carrier sense multiple access with collision avoidance (CSMA/CA) and a random backoff algorithm. Carrier sense in CSMA/CA is performed using both physical and virtual mechanisms. Basically, a node can access the channel only if no signal is physically detected. RTS/CTS mechanism in IEEE 802.11 can also be used in the situations, where multiple wireless networks utilizing the same channel overlap, as the medium reservation mechanism works across the network boundaries.

Although DCF is designed for asynchronous contention-based medium access, the IEEE 802.11 MAC protocol also defines PCF which is based on DCF and supports allocation-based medium access in the presence of an access point (AP). An AP plays the role of a point coordinator and polls each participating node in a round robin fashion (17) to grant medium access on allocation basis. PCF is not suitable for wireless ad hoc networks because it requires centralized control by the AP, which is not available in such networks.

Routing Protocols in Wireless Ad Hoc Networks

Routing in wireless ad hoc networks encounters severe challenges from node mobility/dynamics, with potentially very large numbers of nodes and limited communication resources, such as the network bandwidth and energy of mobile nodes. The routing protocols for wireless ad hoc networks have to adapt quickly to frequent and unpredictable topology changes and must be efficient in terms of the communication overhead. Furthermore, because bandwidth is scarce in wireless ad hoc networks and the sizes of such networks are usually small compared with the wired Internet, the scalability issue for wireless multihop routing protocols is concerned mostly with excessive routing message overhead caused by the increase of network population and mobility. In this subsection, we will discuss briefly some major routing protocols currently used.

Classifications of Routing Protocols. Generally, routing protocols in wireless ad hoc networks use either distance-vector or link-state routing algorithms (18), both of which find shortest paths to destinations.

In distance-vector routing, a vector that contains the communication cost (e.g., hop distance) and next hops to all the routing destinations is kept and exchanged at each node. Distance-vector protocols suffer from slow route convergence and a tendency to create loops in mobile environments.

The link-state routing algorithm overcomes the problem by maintaining global network topology information at each router through periodical flooding of link information on its neighbors. However, such link-state advertisement scheme generates larger routing control overhead than that of the distance-vector protocols.

In large wireless ad hoc networks, the transmission of routing information will consume most of the bandwidth and unconsequently with block applications, which renders it unfeasible for bandwidth limited wireless ad hoc networks. Thus, reducing routing control overhead becomes a key issue to achieve routing scalability. Such scalability is more challenging in the presence of high-node mobility. When nodes in the network are moving, the hierarchical partitioning must be updated continuously. Mobile IP solutions work well if a fixed infrastructure exists. However, when all nodes are moving, such solutions cannot be applied directly.

Routing protocols in wireless ad hoc networks can be classified into two categories: proactive and reactive. Many proactive protocols stem from conventional link-state routing and will cause large communication overhead in dynamic network topology. *On-demand routing,* however, is an emerging reactive routing in wireless ad hoc networks. It differs from conventional routing protocols in that no routing activities and no permanent routing information are maintained at network nodes if no communication occurs in the network. Hence, it provides a scalable routing solution. Such a feature makes the on-demand routing protocol efficient in controlling the communication overhead in wireless ad hoc networks. Because on-demand routing protocols are the mainstream protocols in wireless ad hoc networks, in the remainder of this section, we will focus our discussion on the on-demand routing protocols only.

On-Demand Routing Protocols. The design of on-demand routing protocols is based on the idea that each node tries to reduce routing overhead by only broadcasting routing requests when the communication of the node is awaiting. Representative examples include ad hoc on demand distance vector routing (AODV) (19), dynamic source routing (DSR) (20), and temporally ordered routing algorithms (TORA) (21). Among these protocols, AODV and DSR have been evaluated extensively in the wireless ad hoc networks literature and are being considered by the Internet Engineering Task Force (IETF) MANET Working Group as the leading candidates for standardization.

Typically, on-demand algorithms have a route discovery phase. Query packets are flooded into the network by the sources in search of a path. This phase completes when a route is found or when all possible outgoing paths from the source are searched. Different approaches for discovering routes exist in on-demand algorithms. In AODV, on receiving a query, the intermediate nodes “learn” the path to the source and enter the route in the forwarding table. Eventually, the intended destination receives the query and can respond “using the path traced by the query.” This function permits the establishment of a full duplex path. DSR uses an alternative scheme for tracing on-demand paths, (i.e., source routing) in which a source indicates in a data packet’s header the sequence of intermediate nodes on the routing path. In DSR, the query packet copies in its header the IDs of the intermediate nodes it has traversed. The destination then retrieves the entire path from the query packet, and it uses the retrieved path (via source routing) to respond to the source, which provides the source with the path at the same time. Data packets carry the source route in the packet headers, and a DSR node caches the routes aggressively to minimize the cost incurred by the route discovery.

Generally, AODV and DSR are used in flat network architectures. However, when the size of the wireless ad hoc network increases beyond a certain threshold, the flat routing schemes become infeasible because of the exponential increase of link and processing overhead. One way to solve this problem and to produce scalable and efficient solutions is hierarchical routing. Hierarchical routing in wireless ad hoc networks is based on the idea of organizing nodes in groups and then assigning nodes different functionalities inside and outside a group. Both routing table size and update packet size are reduced by including only part of the network instead of the whole network; hence, the communication overhead is reduced. The most popular way of building hierarchy is to group nodes geographically close to each other into explicit clusters. Each cluster has a leading node (*clusterhead*) to communicate to other nodes on behalf of the cluster (22). An alternate way is to have implicit hierarchy, in which each node has a local scope, different routing strategies are used inside and outside the scope, and communications pass across overlapping scopes. Because mobile nodes have only a single omni-directional radio for wireless communications, this type of hierarchical organization is referred to as *logical hierarchy* to distinguish it from the physical hierarchy of network structure. Representative examples of hierarchical routing protocols include Clusterhead-Gateway Switch Routing (CGSR) (23) and Zone Routing Protocol (24).

TCP in Wireless Ad Hoc Networks

Transmission control protocol (TCP) is the transport layer protocol that provides reliable end-to-end data delivery in unreliable networks. Because of its wide use in the Internet, it is desirable to keep using TCP remains to provide reliable data transfer services within wireless ad hoc networks. Unfortunately, wireless ad hoc networks differ from wired Internet significantly in terms of bandwidth, propagation delay, and link reliability. The implication of these differences is that packet losses are no longer caused mainly by network congestion. Instead, most packet losses are caused by high bit error rate in wireless channels and route breakages in dynamic network topology. Hence, the TCP performance faces the following challenges in wireless ad hoc networks, in which the network topology is highly dynamic:

- **Channel errors.** In wireless channels, relatively high bit error rate caused by multi path fading and shadowing may corrupt packets in transmission, leading to loss of TCP data segments or acknowledgments (ACKs). If a TCP sender cannot receive the ACK within the retransmission timeout, it reduces its congestion window to one segment immediately, exponentially backs off (25) its retransmission timeout (RTO), and retransmits the lost packets. Thus, intermittent channel errors may cause the congestion window size at the sender small, which results in low TCP throughput.
- **Mobility.** Mobility may cause link breakage and route failure between two neighboring nodes, when one mobile node moves out of the other's transmission range. In turn, link breakage causes packet losses. Because TCP cannot distinguish between packet losses caused by route failures and packet losses caused by congestion, TCP congestion control mechanisms react adversely to such losses caused by route breakages (26). Meanwhile, discovering a new route may take longer time than TCP sender's RTO. If route discovery time is longer than RTO, the TCP sender will invoke congestion control after timeout. The throughput, which has already reduced, will decrease even more because of the packet loss. It will become worse if the sender and the receiver of a TCP connection belong to different network partitions. In such a case, multiple consecutive RTO timeouts lead to inactivity for one or two minutes even if the sender and receiver finally get reconnected.
- **Multi-path routing.** Routes in wireless ad hoc networks are short-lived because of frequent link breakages. To reduce the delay caused by route recomputation, some routing protocols, such as TORA (21), maintain multiple routes between a sender-receiver pair, and they use multi path routing to transmit packets. In such a case, packets that come from different paths may not arrive at the receiver in the same order as they were sent out. Not aware of multi path routing, the TCP receiver will misinterpret such out-of-order packet arrivals as a sign of congestion. The receiver will then generate duplicated ACKs that cause the sender to invoke congestion control algorithms like fast retransmission (on reception of three duplicated ACKs according to TCP protocol).
- **Congestion.** The attempt of TCP to use the network bandwidth fully would easily make wireless ad hoc networks congested. Because of the factors such as route change and unpredictable variable MAC delay, the relationship between congestion window size and the tolerable per-link data rate is no longer maintained in ad hoc networks. The congestion window size computed for the old route may be too large for the newly found route, which results in network congestion as the sender still transmits at the full rate allowed by the old congestion window size.

Three types of performance enhancement schemes have been proposed to improve TCP performance over wireless ad hoc networks. The first scheme (27,28) improves the TCP performance using feedback schemes. Through the use of feedback information to signal non congestion-related causes of packet losses, the feedback approaches help TCP distinguish between true network congestion and other problems, such as channel errors, link contention, and route failures. The second scheme (26,29) makes TCP adapt to route changes without relying on feedback from the network, in light of the concern that feedback mechanisms may cause additional complexity and cost in wireless ad hoc networks. The third scheme (30,31) tailors lower layers, such as routing layer and MAC layer, according to TCP congestion control algorithms.

CONTEXT-AWARE/SITUATION-AWARE COMPUTING

As described in the first section, context-aware/situation-aware computing is a major feature of mobile and ubiquitous computing. In this section, we will discuss the basic concepts and applications of context-aware/situation-aware computing, and how contexts and situations are modeled. Techniques for developing context-aware/situation-aware software will be covered in the next section. Becasue of limited space, other research issues related to context-aware/situation-aware computing, including context sensing, and contextual and situation information management, are not covered in this article. Readers interested in these topics are referred to the conferences and periodicals listed in the last section.

Basic Concepts

Although several issues related to context-aware computing have been discussed in Refs. 32–35, the term "context-aware computing," which was first introduced in 1994 (36), is defined as the "ability of a mobile user's applications to discover and react to changes in the environment they are situated in," and the term *context* is defined as "the location of use, the collection of nearby people and objects, as well as the changes to those objects overtime".

Since then, much research has been done in the mobile and ubiquitous computing community on context-aware computing. Various definitions of context have also been made (36–44). For example, Dey and Abowd (40) defined context as "any information that can be used to characterize the situation of an entity. An entity is a person, place, or object that is considered relevant to the interaction between a user and an application, including the user and applications themselves." Chen and kotz (41) defined context as "the set of environmental states and settings that either determines an application's behavior or in which an application event occurs and is interesting to the user."

Based on various definitions of context, a context has the following properties: (*1*) A context changes over time and

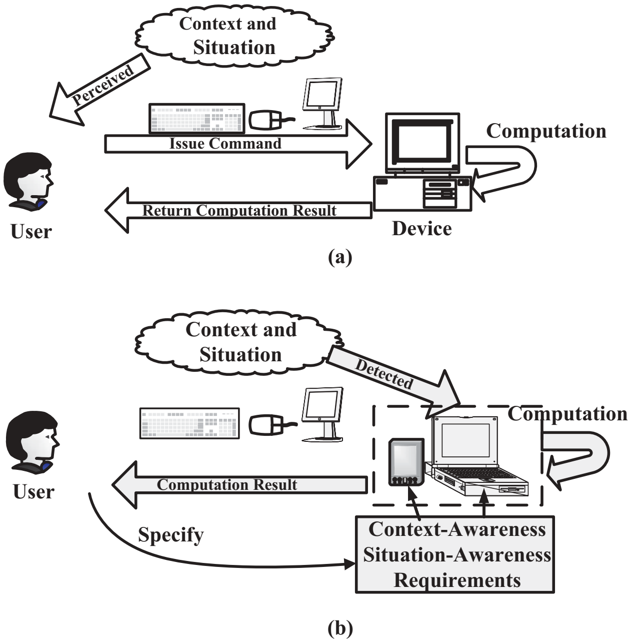

Figure 1. Different types of human-computer interactions: (a) user-initiated human-computer interaction and (b) context-aware/situation-aware human-computer interactions.

is meaningful only when it is associated with a time instant, (*2*) A context must be detectable with appropriate hardware or software support so that it could be used in computing, and (*3*) A context must be relevant to the interactions between a user and an application. Based on these properties, Yau, et al. (42,43) defined context as "any instantaneous, detectable, and relevant property of the environment, the system, or users."

Besides the differences in the definitions of context, various ways exist to categorize contexts (37,40,41). Schilit, et al. (37) considered context in computing, user, and physical environments. Dey and Abowd (40) considered location, identity, time, and activity as four primary types of contexts, and they considered other types of contextual information as secondary pieces because they can be indexed by the four primary types of contexts. Chen and Kote (41) suggested to categorize contexts as computing, user, physical, and time. Nevertheless, these characterizations of context are informal and only aim at helping developers identify context to be used in their applications.

Another concept related closely to context is situation. Although context is considered sometimes the same as situation (45,46), normally context and situation are considered different (41–43,47). In Refs. 42 and 43, a *situation* is defined as a set of context attributes of users, systems, and environments over a period of time that affect future system behavior. Although other definitions exist for situation (48,49), it is agreed commonly that "situation" is a higher-level concept built upon "context," and a situation provides a higher-level understanding of the status of users or other objects involved in computing than a context. Similar to context-aware computing, situation-aware computing can be defined as the awareness of situations and adapting the system's behavior based on situation changes (42,43).

The importance of context-aware/situation-aware computing in mobile and ubiquitous computing environments lies on the new way of human-computer interaction in context-aware/situation-aware computing systems. Dey and Abowd (50) defined context-aware computing system as follows: "A system is *context-aware* if it uses context to provide relevant information and/or services to the user, relevancy depends on the user's task." As shown in Fig. 1, unlike traditional computing systems that operate on explicit inputs (data and commands) from users, context-aware computing systems consider contexts as implicit inputs and operate on both contexts and the explicit inputs from users (51). Hence, the interactions between human users and computers in context-aware computing are no longer initiated only by human users. Changes in contexts can also trigger and guide interactions between users and computers. This technique is extremely useful in mobile and ubiquitous computing environments, in which computing is expected to be invisible or distraction-free to users.

Applications of Context-Aware/Situation-Aware Computing

Context-aware/situation-aware computing is very useful in various mobile and ubiquitous computing applications, which are usually categorized based on how contextual and situation information is used in applications. Schilit, et al. (37) first classified context-aware applications in the following four categories:

- Proximate selection, which refers to applications that automatically find and display objects, such as documents, printers, and monitors, based on a user's location to allow easier access to these objects.

- Automatic contextual reconfiguration, which refers to applications that automatically add, remove, or change their components to satisfy users' needs in dynamically changing environments.
- Contextual information and commands, which refer to applications that augment or parameterize users' commands with context to allow users to access appropriate data or functions based on current contexts.
- Context-triggered actions, which refer to applications that automatically take actions under certain conditions based on predefined rules provided by users.

This categorization of context-aware applications has been refined, augmented, or simplified by others (40,52,53). Among these, Dey (40) provided the simplest and most general categories that describe possible features provided by context-aware applications:

- *Presentation* of information and services to users (based on contexts). An example for this category is an application that provides location-based services, such as searching nearby restaurants and printing documents on the nearest printer.
- Automatic *execution* of services (based on contexts). An example for this category is an environment control application that automatically adjusts brightness of lights at home based on residents' activities.
- *Tagging* of context to information for later retrieval. An example for this category is an address book application that provides not only the phone numbers, but also the current status (busy or free) of an addressee so that a caller can determine whether he wants to postpone the call (52).

Context and Situation Modeling

To facilitate the development and the operations of context-aware/situation-aware computing systems, proper models for contexts and situations are needed for specifying context-aware/situation-awareness requirements.

Context models have been classified into the following types: key-value pairs, object-oriented models, logic-based models, markup language-based models, and graph-based models (41,46). A key-value pair is the simplest form of context models, in which a key is the identifier of a particular context, and the corresponding value is the actual contextual information. In object-oriented models, contexts are properties of objects that represent physical or conceptual entities in mobile and ubiquitous computing environments. Logic-based models use logic programming languages, such as Prolog, to represent and reason contextual information. Markup language-based models describe contexts using various elements defined in markup language-format documents, such as XML. Graph-based models represent contexts and various activities to be performed based on contexts as nodes in graphs, and they represent relations among contexts and activities as edges in graphs.

Inspired by the development of the semantic web, recent research on context modeling has resulted in ontology-based models, such as CONON (54) and SOUPA (55), which are usually based on standard ontology languages like OWL (56). Compared with earlier work on context modeling (41,46), ontology-based context models can express semantic-rich information related to contexts and have better support for reasoning with contexts. These advantages of ontology-based models make them more suitable for developing ubiquitous computing applications, which need to adapt to environment changes intelligently.

Early work on situation modeling was mainly conducted in the artificial intelligence community. Situation Calculus and its extensions (57–60) were developed for describing and for reasoning how actions and other events affect the world, and assume that all actions and events that change the world are known or predictable. In Situation Calculus, a situation is considered as a complete state of the world, which leads to the well-known Frame Problem and Ramification Problem (58). Barwise (61) defined a situation as a part of "the way the world M happens to be," which supports the truth of a sentence Φ in M. In addition, Barwise formally defined the semantics of a situation (62) based on a "scene," which is a "visually perceived situation" that consists of not only the objects and individual properties associated with the objects, but also the relationships among objects. Barwise's definition of situation is more practical compared with the definition of situation in Situation Calculus because it allows the precise description of situations, and it can be supported easily by the prevailing object-oriented modeling techniques. Currently, many researchers have adopted Barwise's definition of situation and developed their own formalisms of situations for various purposes, such as supporting information fusion (63,64), situation-aware software development (65–67), and effective human-computer interaction (68). For example, a core situation awareness (SAW) ontology was introduced in (63,64) based on a similar view of situations as Barwise's, which defines a situation as a collection of situation objects, including objects and relations as well as other situations. Another example is a declarative SAW model presented by Yau et al, (65,66), which provides developers the capability to specify the situations of interest, the contexts required for analyzing the situations, and the relations among various situations and actions graphically. Software tools have been developed based on this declarative SAW model to translate graphical specifications automatically to specifications based on formal languages, such as F-Logic and AS^3 logic, and to synthesize software agents automatically for distributed context acquisition and situation analysis (65–67).

TECHNIQUES FOR DEVELOPING MOBILE AND UBIQUITOUS COMPUTING SOFTWARE

How to develop software for mobile and ubiquitous computing is a problem, which has attracted substantial attention since the very beginning of mobile and ubiquitous computing research. The major challenges in developing mobile and ubiquitous computing software include location transparency, disconnected operations, interoperability, context-awareness/situation-awareness (1,69). Research in this area has mainly focused on middleware and software toolkits that provide appropriate development and runtime support to address these challenges. Hence, in this section we will focus on middleware and software toolkits facilitating the development of mobile and ubiquitous computing software. Readers interested in other related research topics, such as testing mobile and ubiquitous computing software, are referred to the conferences and periodicals listed in the last Section.

Existing middleware for mobile and ubiquitous computing can be divided into two major categories based on how they support the coordination among mobile devices: (1) object based, and (2) tuple-space based. Notable work from the first category includes ALICE (70), Mobiware (71), GAIA (72), RCSM (42,43), and MobiPADS (73), which are based on object-oriented middleware architecture like CORBA (Common Object Request Broker Architecture) (74). Notable work in the second category includes LIME (75) and TSpace (76). Their tuple-space based coordination model supports location transparency and disconnected operations, and mobility is viewed as transparent changes in data stored in the tuple space (75,76).

Besides middleware for mobile and ubiquitous computing, various embedded operating systems, such as Windows CE (77), embedded Linux (78) and Plan 9 (79), along with platform-specific software development kits have been developed to facilitate the development of mobile and ubiquitous computing software.

Among the major challenges in developing mobile and ubiquitous computing software, the incorporation of context-awareness/situation-awareness has attracted most attention because it has not been previously addressed in traditional distributed computing research. Many challenging issues for developing context-aware/situation-aware software in mobile and ubiquitous computing environments have been identified, which include the discovery and the management of heterogeneous context sources, persistent storage of contextual and situation information, analysis of collected context data for determining the situation, interfacing context-aware/situation-aware software with heterogeneous hardware platforms (40,50,80,81).

Figure 2. RCSM's architecture.

Several frameworks, toolkits and infrastructures have been developed for providing support to context-aware application development. Notable results include CALAIS (82), Context Toolkit (50), CoolTown (83), MobiPADS (73), GAIA (72,84), TSpaces (76,85) and RCSM (42,81). CALAIS (82) focuses on applications accessible from mobile devices, and supports acquisition of context about users and devices, but it is difficult to evolve existing applications when the requirements for context acquisition and the capabilities and availabilities of sensors change. Context Toolkit (50) provides architectural support for context-aware applications, but it does not provide analysis of complex situations. CoolTown (83) supports applications that display contexts and services to end-users. MobiPADS (73) is a reflective middleware designed to support dynamic adaptation of context-aware services, and hence enables runtime reconfiguration of context-aware applications. GAIA (72,84) provides context service, space repository, security service and other QoS for managing and interacting with active spaces. TSpaces (76,85) uses tuple spaces to store contexts and allows tuple space sharing for application software to read and write, but it ignores the status of the device where the application software executes, network conditions, and the surrounding environment as part of the overall context. RCSM (Reconfigurable Context-Sensitive Middleware) (42,81) provides development and runtime support for situation-aware (SA) application software. Because of limited space, we will only give a brief overview in the following subsections on two middleware, RCSM and MobiPADS, which provide context-awareness/situation-awareness. Readers interested in this are referred to the conferences and periodicals listed in the last Section.

RCSM

RCSM is a lightweight SA middleware, which provides development and runtime support for SAW, dynamic service discovery and group communication for ubiquitous computing applications (42,43,80,81). A conceptual architecture of RCSM, which is shown in Fig. 2, consists of the following major components:

1. SA Processor provides the runtime services for situation analysis and manages the SAW requirements of SA objects. The SAW requirements of SA objects are defined using situation-aware interface definition language (SA-IDL). An SA-IDL compiler was developed to generate the situation-aware object skeleton codes and corresponding configuration files, to be used by the SA Processor to perform situation analysis. The SA object skeleton codes provide the standard interfaces for SA objects to interact with the SA Processor.
2. RCSM object request broker (R-ORB) provides the runtime services for context discovery and acquisition, and SA communication management. The context manager in R-ORB implements an efficient context discovery protocol (86) to support adaptive context discovery and acquisition in ubiquitous computing environments based on the requirements on

contexts extracted from the configuration files of SA applications by the SA processor. SA object discovery protocols enable efficient and spontaneous communication between distributed SA objects.

Using SA-IDL, contexts can be described precisely as context objects, and situations can be composed by not only the current values of multiple contexts, but also the historical values of multiple contexts over a period of time. The SA processor is designed to cache and analyze the context history to determine the situation. In addition, the SAW requirements, such as the definitions of situations, can be modified in runtime through the SA Processor. Once the requirements are changed, the R-ORB and SA Processor will reconfigure themselves to collect the necessary contexts and perform situation analysis based on the new requirements.

MobiPADS

Mobile platform for actively deployable service (MobiPADS) (73) is a reflective middleware, which serves as an execution platform for context-aware mobile computing. MobiPADS enables active service deployment and reconfiguration in response to context changes, and hence it can optimize the performance of mobile applications when the context changes.

MobiPADS consists of two types of agents: MobiPADS server agents, which reside in the network infrastructure and are responsible for most of the optimization computations, and MobiPADS client agents, which reside in the mobile devices and provide various services for mobile applications. MobiPADS adopts the idea of mobile codes, and stores the codes of service objects in MobiPADS agents. Service objects can be deployed on either the client or server agent, and can migrate between the client and server agents when needed (e.g., when the device, where the client agent resides, moves), to enable flexible reconfiguration of mobile applications. Each MobiPADS agent also has a set of system components for managing system (MobiPADS client and server, and service objects) configurations, migrating service objects between MobiPADS server and client, recording known services, contextual event notification, and establishing virtual communication channels between service objects. Each MobiPADS service is a pair of mobilets: a slave mobilet at the server agent for providing actual processing capabilities, and a master mobilet at the client agent for instructing the slave mobilets and for presenting results to the client. The mobilets can be chained together to support necessary service composition for mobile applications, similar to workflows in workflow systems. An XML-based language was developed in MobiPADS to describe how service objects interact with each other and how they are configured.

MobiPADS uses an event subscription-notification model to provide context-awareness. The idea is similar to the ECA (event-condition-action) model in active databases (87). All contexts are modeled as event sources to generate contextual events when certain conditions are satisfied. All entities (system components, mobilets and mobile applications) can subscribe to contextual events of interests, and they are notified when certain events occur to achieve context-awareness. MobiPADS also supports event composition, which allows combining multiple events from different context sources to express complex semantics. However, MobiPADS only focuses on the current events, and it does not consider historical events, which are important for achieving SAW.

PRIVACY ISSUES IN MOBILE AND UBIQUITOUS COMPUTING

Currently, most research in mobile and ubiquitous computing focuses on how to connect users and service providers in heterogeneous and dynamically changing computing environments, and how to develop applications cost-effectively. However, lack of privacy protection in mobile and ubiquitous computing would hinder its practical usage, and hence should be considered seriously from the beginning of system design. Although many privacy techniques are available to protect digital communications, the context-aware/situation-aware property of mobile and ubiquitous computing creates many new challenges and makes many existing techniques unsuitable (88–91). In such an environment, we need to consider the following two important aspects: (*1*) the protection of context information and (*2*) the authentication based on context information. In this section, we will focus on these two aspects. Other privacy issues, such as identity protection, secure communication, and key management, can be addressed using existing techniques (88–91) developed for general distributed computing systems, and hence they will not be discussed in this chapter.

Context Information Privacy

In mobile and ubiquitous computing, the contexts of users are very important because service providers may control or adapt their services according to their users' contexts, such as providing local weather information on users' locations. Hence, context information of users should be available to service providers to help them improve service qualities and provide personalized services. However, context information should be protected because revealing such information, which may be considered sensitive in certain applications, creates significant privacy risk, such as allowing malicious service providers to trace users. These two conflicting requirements on context information make the protection of context information difficult. So far, most research in this area focuses on the protection of location information (92).

A possible solution for these two conflicting requirements is to develop anonymity techniques, which will break the associations between users' identities and their contexts. Thus, service providers can use users' context information, but they cannot link two different contexts to the same user. The anonymous use of location information can be accomplished easily if a centralized trusted location server (93–95) exists, which serves as the proxy between users and service providers. The location server receives the location information from users and disseminates it to service providers without revealing the information sources. However, whereas the centralized trusted location server can perfectly make the location information anonymous, it is the performance bottleneck and may become the single point of failure. Although distributing the service provided by the centralized trusted location server to several servers may reduce such negative impact, it is difficult for administrators to protect and for users to trust multiple servers. A possible solution presented in Ref. 96 is to separate the protection of identities and the protection of locations. The distributed servers will only be responsible for the protection of users' identities. Users' locations can be protected by grouping several users together and revealing only the group locations.

Other researchers have developed techniques to reduce the risk of revealing users' location information rather than making the location information anonymous (96). Obfuscation was proposed to provide only inaccurate information to service providers, like referring the exact location as the location around a landmark (97), or replacing one user' location with the location of a group (98). Because different services have different requirements on the precision of locations (e.g., city names are sufficient for weather services, but more accurate location is required to find the nearest hospital), the idea of obfuscation is developed even more to allow users and service providers to negotiate for the precision of location information (99,100), which ensures that only the information required for providing satisfactory services is revealed to service providers.

Although many approaches have been developed to protect users' locations, these approaches cannot be extended easily to protect other context information. Hence, more investigations on how to protect other context information are needed.

Context-Based Authentication

Authentication is to ensure that users and service providers have the identities as they have claimed. In mobile and ubiquitous-computing environments, besides the requirement of the users' identities, additional requirements exist on the users' environment because some service providers only provide services for users with a particular context, such as in a certain building. Hence, the authentication in such environments should include not only users' identities, but also users' contexts, such as the characteristics of communication channel (101) or users' locations (102–105).

To authenticate users' contexts, the service providers need to collect users' context information. This task can be done using various types of sensors, such as infrared beams (102), laser beams (106), and ultrasound (107). Based on the properties of sensors, various types of sensors can collaborate when the requirement on users' context information is too complex to be collected and preprocessed by a single mechanism. For example, the RF sensor and the ultrasound sensor (105) can be combined to determine whether a user is in the room and whether three users are in line.

During the context information collection process, the authentication for the identities of service providers is required to distinguish one service provider from others to avoid revealing users' context information to malicious service providers. To solve this problem, various physical and software-based solutions have been developed to ensure the associations between users and service providers (102,106,108–111).

Because context-based authentication also authenticates users' context information, the collected context information should be integrated into the authentication protocols. In spatial reference (105), the distance between a user and a service provider is represented as time latency. Once the user receives an RF signal from the service provider, the user inserts a certain delay before sending the service provider a response. This delay represents the distance between the user and the service provider. However, this approach will degrade the performance, especially when the encoded information is large. Another solution for integrating the context and the authentication is to derive the key from the collected context information directly (112,113).

Similar to existing research on the protection of context information, the research on context-based authentication focuses mainly on location-based authentication. Authentication based on other context information need to be investigated even more.

SUMMARY

In this chapter, we have presented a brief overview of mobile and ubiquitous computing, and we reviewed four important research areas in mobile and ubiquitous computing: wireless ad hoc networks, context-aware/situation-aware computing, techniques for developing mobile and ubiquitous computing software, and privacy issues in mobile and ubiquitous computing. Because of limited space, the materials are presented at a relatively high level. Readers interested in this topic are referred to the references. More references can be found in the following conferences and periodicals: Annual International Conference on Mobile Computing and Networks (MobiCom), International Conference on Distributed Computing Systems (ICDCS), International Conference on Ubiquitous Computing (Ubicomp), International Conference on Pervasive Computing and Communications (PerCom), International Conference on Mobile Data Management (MDM), Annual International Computer Software and Application Conference (COMPSAC), Network and Distributed System Security Symposium (NDSS), *IEEE Transactions on Software Engineering, IEEE Transactions on Mobile Computing, IEEE Transactions on Parallel and Distributed Systems, Journal of Parallel and Distributed Computing, IEEE Personal Communication, IEEE Pervasive Computing, Journal of Systems and Software, Journal of Software Practice and Engineering,* and *International Journal of Network Security.*

MULTICAST PROTOCOLS AND ALGORITHMS

INTRODUCTION

One way to characterize communication is by the number of parties involved. The traditional communication modes are *unicast*, i.e., one-to-one, and *broadcast*, i.e., one-to-all. Between these two extremes we find *multicast*, the transmission of a message or datastream to an arbitrary set of receivers, i.e., one-to-many. Multicast can be seen as a unifying communication mode, as it is a generalization of both unicast and broadcast. Multicast is examined separately, however, because the specification of receivers as a set introduces features and complications that are not present in traditional unicast and broadcast. A more general term is *multipoint communication*, which implies many-to-many bidirectional data exchange.

The multicast model of communication is ideal for applications where data and control are partitioned over multiple entities. Examples include updating replicated databases, contacting any one of a group of distributed servers of which the composition is unknown (more appropriately termed *anycast*) and interprocess communication between multiple cooperating processes. The prototypical multicast applications, however, are real-time interactive multimedia conferencing and near real-time media distribution to multiple receivers.

Multicast efficiency is a fundamental requirement for the success of many group applications. Selective multicast replaces indiscriminate broadcasting to everyone, reducing the waste of resources caused by transmitting information to all receivers. To be more economical than unicast, multicast must conserve resources via *sharing*: Instead of transmitting information from a sender to each receiver separately, routes to receivers that share links must carry the information only once over each shared link. We can picture a multicast route as a *tree* rooted at the sender with a receiver at each leaf and, possibly, some receivers on internal nodes. This tree must be designed to maximize link sharing and thus minimize resource consumption.

Besides the obvious issue of how to construct multicast routing trees, multicast also raises other issues related to the extension of unicast mechanisms to a multicast context. For example, the sender in a reliable transport protocol can recover from communication errors based on error reports from the receiver. By simply extending this mechanism to multicast, we run the risk of *feedback implosion*, when many receivers send such reports toward the sender, thus swamping the network and the source with control information. In addition to the scalability issues raised by this approach, another issue is how the sender should react when conflicting reports arrive from different receivers.

MULTICAST MODELS

The difference between multicasting and separately unicasting to several destinations is best captured by the Internet host-group model of Cheriton and Deering (1): A host-group is a set of network entities sharing a common identifying multicast address. All group members receive any data packets addressed to this multicast address. The senders have no knowledge of group membership and may or may not belong to the group, corresponding to *closed* or *open* groups, respectively. Multicast messages on the Internet are sent on a best-effort basis, like unicast messages; i.e., they may be reordered, lost, or duplicated.

This definition allows group behavior over time to be unrestricted in multiple dimensions; it may have local (LAN) or global (WAN) membership, be transient or persistent, and have static or dynamic membership. From the sender's point of view, the multicast service interface is identical to unicast; only the address differs. Therefore, it is the network's responsibility to manage the multicast communication, transparently to the users. This extra work compared with unicast is expected to result in a more efficient usage of resources, which is the primary motive for network providers to support multicast in the first place.

The host-group model imposes specific requirements for the implementation of the multicast service. First, there must be a means for routing packets from a sender to all group members, which implies that the network must locate all members of the group and make appropriate routing arrangements without any assistance from the sender. Second, as group membership is dynamic, the network must continuously track membership during a session's lifetime, which may range from short to very long periods of time. Tracking is required both to start forwarding data to new group members and to stop the wasteful transmission of data to members that have left the group. This dynamic nature of multicast groups has a considerable impact on multicast routing.

It should be noted that the Internet host-group model is by no means unique for multicasting. Some applications require delivery of messages addressed to a group to be *atomic*; that is, each message sent to a multicast group must be received by either all receivers in the group or none at all. Atomicity further implies that all received messages must be processed in the same order by all receivers, i.e., that multicasts are also totally ordered. As atomic multicast is complex to implement, it is usually built on top of a simpler multicast facility, such as the one offered by the Internet.

MULTICAST ROUTING ALGORITHMS

Unicast routing attempts to minimize either transmission cost or delay, depending on the metric used for optimization. Although these goals seem different, from an

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

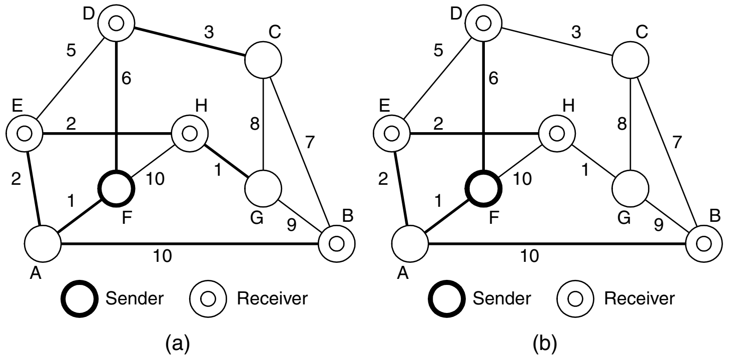

Figure 1. (a) The broadcast tree formed by the shortest paths from the sender to all nodes. (b) The multicast tree obtained by pruning all links that do not lead to receivers from the broadcast tree.

algorithmic point of view, they are both equivalent to finding shortest paths over a network with cost-labeled links; link costs may stand for either transmission cost or delay. A shortest path algorithm finds optimal routes between one node (the sender) and *all* other nodes in the network. Two common examples of such algorithms are those due to Dijkstra and Bellman–Ford. An optimal route minimizes the sum of the costs of all links included in the route. The union of all these routes forms a *shortest path tree* rooted at the sender. As this is a broadcast tree, as shown in Fig. 1(a) a straightforward (but not optimal) solution to the multicast routing problem is to prune off that tree all links that do not lead to any members of the group, as shown in Fig. 1(b).

The advantage of these algorithms is that they are easy to implement and deploy, as they are direct extensions of existing ones. Each path is optimal by definition, regardless of changes in group membership, and this optimality comes essentially for free, because shortest paths need to be computed anyway for unicast routing. The disadvantage of these algorithms is that they concentrate on pairwise optimizations between the sender and each receiver and only conserve resources as a side effect, when paths happen to overlap. For large networks with widely dispersed group members, either the scale of the network or the continuous network changes will necessarily restrict the use of these algorithms to subnetworks, requiring a hierarchical routing technique to support global multicasting.

To achieve the economies promised by multicasting, optimization must be viewed from the perspective of the entire distribution tree. This requires building trees that exploit link sharing as much as possible, duplicating packets only when paths diverge, so as to minimize the total distribution cost even at the expense of serving some receivers over longer paths. In algorithmic terms, what is needed is a minimal cost tree that reaches all receivers, possibly using additional nodes on the way. This is equivalent to the *Steiner tree* problem, analyzed by Hakimi (2). In this problem, a cost-labeled graph and a set of nodes, the Steiner points, are given and a minimal cost tree is sought connecting all Steiner points, including both the sender and all receivers, as shown in Fig. 2(a).

If all nodes were Steiner points, the above problem would coincide with the *spanning tree problem*, which can be solved efficiently. Unfortunately, the Steiner tree problem belongs to the class of NP-complete problems, as shown by Garey et al. (3). Fortunately, approximation algorithms exist for it with proven constant worst-case bounds and very good average behavior. As an example, trees built with the heuristic by Kou et al. (4) have at most twice the cost of Steiner trees, whereas simulations of realistic network topologies described by Kabada and Jaffe (5) have shown their cost to be within 5% of the optimum.

The advantage of Steiner tree algorithms is their overall optimality with respect to a single cost metric, such as transmission cost. Their disadvantages are also important, however: These algorithms must be run in addition to the unicast routing algorithm, and they suffer from scaling problems for large networks. Furthermore, optimality is generally lost after changes in group membership and

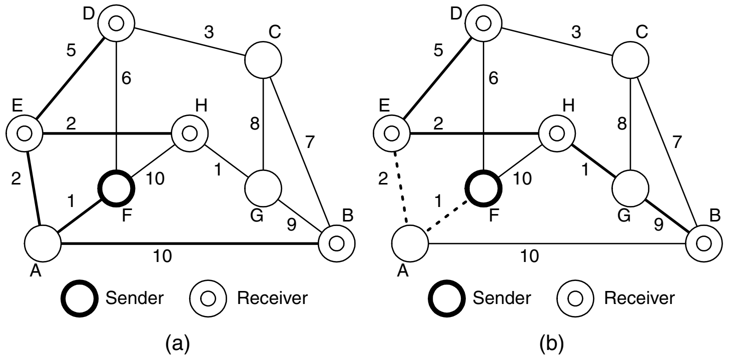

Figure 2. (a) The Steiner tree obtained by minimizing the overall cost from the sender to all receivers. (b) The core-based tree formed by the shortest paths from the core (node H) to all receivers. The sender uses the shortest path to the core for data transmission.

network reconfigurations, unless the tree is repeatedly recomputed from scratch. Approaches for extending these algorithms to deal with changes in group membership without tree recomputation include extending the existing tree in the cheapest way possible to support new group members and pruning redundant links when group members depart. The quality of the tree will deteriorate over time after several such modifications, eventually leading to the need for tree recomputation. Thus, Steiner tree algorithms are best suited to static or slowly changing environments because changes eventually lead to expensive tree recomputation to regain optimality.

Shortest path trees and Steiner trees are optimal with respect to a sender; therefore a separate tree must be built for each sender in both cases. A different approach is to employ a *center-based tree*, which, instead of being rooted at the sender, is rooted at the topological center-of the receivers. A single center-based tree serves as a common infrastructure for all senders; therefore, maintenance of the tree is greatly simplified and nodes belonging to the tree need only maintain state for one shared tree rather than for many source-rooted trees. Even though such a tree may not be optimal for any one sender, it may be an adequate approximation for all of them together. Unfortunately, the topological center of the receivers, apart from being hard to find (this problem is also NP-complete), is not even permanent in a dynamic multicast environment.

A more practical proposal is to abandon the topological center as the root of the tree, keeping the basic idea of a single shared multicast tree for all senders to a group. In this approach, routing is performed by defining one or more arbitrarily selected *core* (or *rendez-vous*) points to serve as the basis for tree construction for a group. All senders transmit their data to the core using an optimal (in the unicast sense) route, and the core uses a shortest path tree to distribute these data to all group members, as shown in Fig. 2(b). As in any shortest path tree, merging of paths is exploited whenever possible, but it is not an explicit goal of the routing calculations. Due to the concentration of paths around the core, though, common paths are expected to arise. Although this approach uses an underlying unicast routing algorithm, it is independent of it.

The disadvantage of this approach is that a single shared multicast tree, especially if it is rooted at an arbitrary node, is not optimal in any strict sense. The advantages of shared multicast trees are numerous, however. First, the shared tree means that this approach scales well in terms of maintenance costs as the number of senders increases. Although there is still a tree emanating from each sender, these trees merge near the core and the distribution mesh is common from there on. Second, the trees can be made efficient by choosing appropriately the core points. Third, routing is performed independently for each sender and receiver, with entering and departing receivers influencing only their own path to the core points of the shared tree. This last property means that network and group membership dynamics can be dealt with without global recomputation. Finally, the independence from specific unicast routing schemes, coupled with the scalability of the shared trees, makes this approach ideal for use on large networks. The core points may even be selected to facilitate hierarchical routing; i.e., a top-level tree can distribute data to the core point of each subnetwork, and each core point can then distribute data to the group members in its subnetwork.

Despite the differences between the approaches discussed above, simulations have shown that even simple multicast routing using shortest path trees is not significantly worse in terms of total tree cost from the optimal solutions. For realistic network topologies, Doar and Leslie (6) have found that the cost of a shortest path tree is less than 50% larger than that of a near-optimal heuristic tree, whereas path delays for heuristic trees are 30% to 70% larger than shortest path delays. As shortest path trees are easily built and modified using the underlying unicast routing algorithm and they never deteriorate in terms of delay, but simply vary in their inefficiency in terms of total cost, an application prepared to accept this overhead can avoid special multicast tree construction and maintenance methods by simply employing the shortest paths.

A similar cost versus simplicity tradeoff is involved when using shared trees, for all senders to a group. With shared trees, optimality is hard to achieve and even harder to maintain; a simple approach is to choose the best core point among group members only. With this limitation, when path delay is optimized, simulations show that delays are close to 20% larger than with shortest paths, and tree cost is about 10% lower than that of shortest path trees. Furthermore, even though a single tree minimizes state and maintenance overhead, this approach suffers from traffic concentration, exactly due to the single tree used, because it routes data from all senders through the same links around the core. Simulations show that delay-optimal member-centered shared trees can cause maximum link loads to be up to 30% larger than in a shortest path tree.

FEEDBACK CONTROL

When the basic service offered by the network is a best-effort one, as in the Internet, generalizing it for multicast is straightforward: Just send the data along the multicast routing tree without providing any guarantees with respect to reliability, throughput, or delay. Many applications, however, cannot be satisfied by such a service; therefore, mechanisms such as flow, congestion, and error control have to be provided on top of this best-effort service. These mechanisms depend on feedback to the sender, which is based on either network- or receiver-generated reports.

Error control ensures that packets transmitted by the sender are received correctly. Packets may be received corrupted (detected by error-detection codes), or they may be lost (detected by missing sequence numbers). Flow control assures that the sender does not swamp the receiver with data that cannot be consumed in time. Congestion control limits the transmission rate of the sender to avoid overloading the intermediate network nodes on the way to the receiver. Although error and flow control require feedback from the receiver, congestion control would be best served by feedback from the intermediate nodes themselves. In best-effort networks like the Internet, however, it is only the receivers that provide feedback about packet losses to the sender, thus leading to confusion between error-induced and congestion-induced losses.

In the unicast case, flow, error, and congestion control rely on feedback from a unique receiver. For example, loss reports may cause the retransmission of lost packets. With multicast, however, this approach faces the feedback-implosion problem: If all receivers respond with status information, they will swamp the sender with, possibly conflicting, reports. Ideally, senders would like to deal with the multicast group as a whole, not on an individual receiver basis, following the host-group model. The sender cannot simply treat all receivers identically, though, because this requires either ignoring the feedback of some receivers or wasting resources by satisfying the worst-case receivers. For example, the sender could retransmit only packets lost by all receivers, thus ignoring some losses, or retransmit any packets lost by any receiver, thus duplicating some packets.

As there is no evident solution to this problem, several approaches exist emphasizing different goals. The simplest approach is to ignore the problem at the network and simply provide a best-effort service. Delegating the resolution of these problems to higher layers may be an adequate solution in many cases, because these layers may have additional information about application requirements and be able to implement more appropriate mechanisms than what is possible inside the network. Even in this case, though, higher layers will have to implement one of the alternative approaches discussed below.

A second solution sacrifices the host-group model's simplicity by keeping per-receiver state at the sender during multicasts. After transmitting a multicast packet, the sender waits until a stable state is reached before sending the next one. For example, in error control, retransmissions may be made until all receivers receive the data. To economize on resources, retransmissions may be multicast when many receivers lose a packet, or unicast when few do. To reduce the risk of feedback implosion, receivers should use negative rather than positive acknowledgments, i.e., send responses only when problems occur, rather than to confirm that packets were received correctly. Furthermore, these negative acknowledgments may be multicast to all receivers after waiting for a random period of time, so as to suppress identical negative acknowledgments from multiple receivers, as suggested by Towsley et al. (7).

Even with these optimizations, the scalability of such schemes is doubtful for large and widely dispersed groups, even when errors, overflows, and congestion are very rare, because the sender remains solely in charge of all receivers. In addition, with these schemes the service provided to a group member is the lowest common denominator, which may be the slowest or most overloaded receiver, or the slowest or most congested link. While more sophisticated variations of this approach exist, their complexity and inefficiency makes them appropriate only for specific applications.

A third solution is to distribute the feedback control mechanism over the entire multicast tree, so as to avoid propagating the receiver's feedback all the way to the sender. In a hierarchical scheme, the intermediate nodes may either respond directly to feedback from downstream receivers or merge their feedback into a summary message and recursively propagate it upstream. If the added complexity of making local decisions on each node (not only group members) is acceptable, this approach narrows down the impact of problems to specific parts of the tree, relieving the sender from dealing with individual receivers. Note that even though this scheme avoids feedback implosion, the problem of dealing with possibly conflicting requests remains.

An alternative non-hierarchical method for distributed feedback control, targeted especially to error control, is to let all receivers and senders cooperate in handling losses, as proposed by Floyd et al. (8). When receivers discover a loss, they multicast a retransmission request, and anyone that has that message can multicast it again. Both requests and replies can have local scope, if the network supports it, so as to avoid burdening the entire group. To avoid feedback implosion, these requests and replies are sent after a fixed delay based on the distance from the source of the message or the request, respectively, plus a randomized delay. The result is that most duplicate requests and replies are suppressed by the reception of the first one. By varying the random delays, the desired balance between recovery delay and duplicates can be achieved, and in contrast to hierarchical schemes, only group members participate in recovery.

A fourth solution is for the sender to act based on an estimation of the average conditions across the group. A scalable feedback mechanism for this estimation has been proposed by Bolot et al. (9): It first estimates the number of receivers in a group and then what the average quality of reception is, using probabilistic techniques. This method can be used to detect congestion problems and adapt the transmission rate (to relieve congestion) or the error redundancy factor (to increase the chances of error recovery). In a refinement of this approach, proposed by Cheung and Ammar (10), the sender splits the receivers into groups according to their capabilities and only sends to each group the data that it can handle. This scheme prevents very fast or very slow receivers from dragging the whole group toward one extreme case.

Finally, another approach (mostly orthogonal to the above) tries to minimize the need for feedback by taking preventive rather than corrective action. For error control, this is achieved by using forward error correction (FEC) rather than error detection codes and retransmissions. For flow and congestion control, this is achieved by reserving resources in advance so that both receivers and intermediate nodes can support the sender's data rate. Although FEC imposes considerable processing and transmission overhead, it requires no additional network mechanisms. Resource reservations, however, require additional network mechanisms to set up and maintain the resources for each session.

MULTIMEDIA MULTICASTING

A common use of multicasting is for multimedia communication, i.e., the exchange of multiple interdependent media types, such as text, audio, and video. As continuous media, i.e., audio and video, require considerable transmission bandwidth, the economies promised by multicasting are especially attractive in this context. The issues arising when multimedia are combined with multicasting are treated more extensively by Pasquale et al. (11).

Host and Network Heterogeneity

Several representational formats exist for each media type, and each participant in a multicast group may support a different set of formats. In unicast, translation is equally effective at either the sender, or the receiver. In multicast, translation at the sender would require the stream to be duplicated and translated for each different type of receiver, preventing link sharing over common paths, placing excessive load on the sender, and requiring the sender to be aware of each receiver's capabilities, thus violating the host-group model. Translation at the receiver is the most economical and scalable approach in this case, because it fully exploits sharing and moves responsibilities away from the sender.

As continuous media impose heavy demands on both networks and hosts, it is likely that not all receivers will be able to receive all of a sender's traffic. This argues in favor of prioritization of the traffic generated through *hierarchical* coding. Hierarchical or *layered* coding techniques decompose a signal into independent or hierarchically dependent components, subsets of which can be used to provide partial reconstruction of the original. Receivers can thus choose only those parts of the media that they can use or are most important to them. For example, a high-resolution component of a video could be dropped from a congested subnetwork, allowing low-resolution components to be received and displayed in that subnetwork, without impacting uncongested subnetworks.

To avoid complicating the host-group model, each component of a hierarchically coded stream may be transmitted to a different multicast group, making the choice of a particular component equivalent to subscribing to the corresponding group. Based on this approach, Vicisano et al. (12) have proposed a purely receiver-driven congestion control scheme, where each receiver estimates the capacity of the network based on packet losses and only subscribes to as many groups as can be realistically delivered by its subnetwork. The sender periodically doubles its transmission rate for each component so as to enable the receivers to decide whether improved network conditions allow the reception of additional media components.

Resource Reservations

For interactive multimedia applications to be practical, the network must be able to provide some type of bandwidth and delay guarantees. If any such guarantees are to be provided, resources must be reserved at the various network nodes traversed. The exact nature of the reservations depends on the required service guarantees and the approach taken toward satisfying them. In any case, the first component of any resource reservation scheme is a specification model for describing flow characteristics; this depends heavily on the model of service guarantees supported by the network. The second component is a protocol for communicating these specifications to the receivers and reserving resources along the transmission path so as to support the requested services.

The simplest unicast approaches to resource reservations are source-based. A setup message containing the flow specification is sent to the destination, with the intermediate nodes committing adequate resources for the connection, if available. Resources are normally overallocated early on in the path, so that even if nodes encountered further along the path are short on resources, connection setup may still succeed. After the setup message reaches its destination, and assuming the connection can be admitted along the path, a response message is returned on the reverse path, allowing intermediate nodes to relax any excessive commitments made on the first pass.

Similarly, for multicast, there must be a way for senders to notify receivers of their properties, so that appropriate reservations may be made. In a homogeneous environment, reservations should be made once on each outgoing link for all downstream receivers, so as to minimize resource usage. Reserved resources may even be shared among multiple senders to the same group. However, receiver and network heterogeneity often prohibits use of this simplistic scheme, because the amount of resources that are available at each part of the multicast tree may be quite different. A modified scheme is to allocate resources as before during the first message's trip and then have all receivers send back their relaxation (or rejection) messages. Each node that acts as a junction only propagates toward the source the most restrictive relaxation among all those received. However, as paths from such junctions toward receivers may have committed more resources than are now needed, additional passes will be required for convergence or resources will be wasted.

An alternative is to abandon reservations during the sender's setup message, instead reserving resources based on the modified specifications returned by the receivers. Again, resource reservations are merged on junction points, but as these requests are expected to be heterogeneous, each junction will reserve adequate resources for the most demanding receiver and reuse them to support the less demanding ones. This approach supports both heterogeneous requests and resource conservation, thus maximizing the possibility for a new session to be admitted. As this mechanism converges in one pass, the reservation state in the switches can be periodically refreshed, turning the fixed state of a static connection into adaptive state suitable for a dynamic environment. Therefore, this mechanism can accommodate both group membership changes and routing modifications without involving the sender.

Quality-of-Service Routing

When multicast is used for multimedia communications, link sharing can lead to considerable economies in transmission bandwidth, but routing must also take into account two additional factors: delay constraints, particularly for interactive applications, and media heterogeneity. Separate handling of media streams allows using the most effective coding technique for each stream. The question arises then of whether the same or separate distribution trees should be used for each stream. Considering the load that continuous media put on network links, separate trees seem preferable. Thus, each media stream could ask for the appropriate quality-of-service (QoS) parameters and get routed accordingly, with receivers choosing to participate in any subset of these trees. On the other hand, the management overhead of multiple trees per source may be prohibitive, whereas routing each media stream separately may complicate inter-media synchronization.

Turning to delay constraints, assuming that we use delay as the link cost during routing, we already saw that the shortest path tree and the Steiner tree are different: The former minimizes individual path delays, whereas the latter minimizes overall distribution delay and maximizes link sharing. As the global tree metric and the individual receiver-oriented metrics are potentially in conflict, we cannot hope to optimize both. We can, however, try to optimize the global metric subject to the constraint that the individual metrics are tolerable. As interactive applications can be characterized by upper bounds on end-to-end delay, it is reasonable to design the tree to optimize total cost while keeping individual paths within some bound. Normally, all receivers are satisfied by the same delay bound, as this is determined by human perception properties.

This problem is essentially a version of the Steiner tree problem with additional constraints on the paths. Even though it is also NP-complete, fast heuristic algorithms that are nearly optimal have been developed, for example, by Kompella et al. (13). Almost identical formulations are obtained when the constraints are delay *jitter*, i.e., the variation of delay, or a probabilistic reliability constraint. For example, in the case of independent link losses, a loss probability can be assigned to each link. By using logarithms, the reliability metric can be calculated in linear form between a source and each destination by adding the logarithms along the path. Thus, the problem reverts to tree cost minimization with a constraint on an additive path-based metric. Finally, the constraint may be a link capacity that must not be exceeded. Again, heuristic algorithms exist to solve this variant of the problem.

MULTICAST PROTOCOLS ON THE INTERNET

The IP Multicasting Model

The Internet, due to its open architecture, has been extensively used as a testbed for multicast algorithms and protocols. IP multicasting is based on special (class D) multicast IP addresses. By simply using a class D address as the destination of a *datagram*, i.e., an IP packet, it is multicast to all group members rather than unicast. To achieve multicasting in a wide-area network, such as the Internet, a mechanism is needed to keep track of the dynamic membership of each group and another mechanism is needed to route multicast datagrams from a sender to these group members without unnecessary duplication of traffic. IP multicasting implements these mechanisms in two parts: Local mechanisms track group membership and deliver multicasts to group members within a local network, and global mechanisms route datagrams between local networks.

In each local network, at least one router acts as a multicast router. A multicast router keeps track of local group membership and is responsible for forwarding multicast originating from its local network toward other networks, as well as for delivering multicasts originating elsewhere to the local network. The delivery of multicast datagrams to local receivers, as well as the reception of local multicasts by the router for subsequent propagation to other networks, depend on the underlying network technology. Therefore, the information needed within the local network regarding group membership in order to achieve multicast delivery may vary.

In contrast, cooperation among multicast routers for the delivery of multicast datagrams between networks is based on a network-independent interface between each network and the outside world. The information needed to decide whether multicasts should be delivered to target networks is whether at least one group member for a destination group is present there, regardless of the information the multicast router needs for local purposes. A multicast router uses the list of groups present on its attached local networks along with information exchanged with its neighboring routers to support wide-area multicasting. Based on this interface, alternative algorithms can be used for global routing without affecting local mechanisms. Conversely, as long as this interface is provided by the local mechanisms, they can be modified without affecting global routing.

Global Mechanisms

A variety of global, wide-area, multicast routing mechanisms exist. The earliest one, proposed by Deering and Cheriton (14), is the distance vector multicast routing protocol (DVMRP). The original version of DVMRP is a variant of the truncated reverse path broadcasting algorithm. Routers construct distribution trees for each source sending to a group, so that datagrams from the source (root) are duplicated only when tree branches diverge toward destination networks (leaves). To construct the tree, each router identifies the first link on the shortest path from itself to the source, i.e., on the shortest *reverse* path, using the Bellman–Ford distance vector unicast routing algorithm. Datagrams arriving from this link are forwarded toward downstream multicast routers, i.e., those routers that depend on the current one for multicasts from that source. A broadcast distribution tree is thus formed, with datagrams reaching all routers. As each router knows which groups are present in its local networks, redundant datagrams are not forwarded there and the tree is truncated at the lowest level. The latest version of DVMRP implements the improved reverse path multicasting algorithm, where links leading to networks with no members for a group are pruned off the tree and are grafted back when members appear for these groups. Although initially all data are broadcast, eventually the tree becomes a real multicasting one.

Another protocol proposed by Moy (15), multicast open shortest path first (MOSPF), extends Dijkstra's link state unicast routing algorithm. Routers flood their membership lists among them, so that each one has complete topological information concerning group membership. Shortest path multicast distribution trees from a source to all destinations are computed on demand as datagrams arrive. These trees are real multicast ones, but the flooding algorithm used to construct them introduces considerable overhead.

A radically different approach is the core-based tree (CBT) protocol proposed by Ballardie et al. (16), which employs a single tree for each group, shared among all sources. This tree is rooted on an arbitrarily chosen router, the *core*, and extends to all networks containing group members. It is constructed from leaf network routers toward the core as group members appear; thus, it is composed of shortest reverse paths. Sending to the group is accomplished by sending toward the core; when the datagram reaches any router on the tree, it is relayed toward tree leaves. Routing is thus a two-stage process that can be suboptimal, as datagrams may be sent away from the receivers during the first stage.

As both shortest path trees and center-based trees have advantages and disadvantages, the protocol independent multicast (PIM) protocol proposed by Deering et al. (17) provides both. PIM supports two modes, the dense mode and the sparse mode. The dense mode is similar to DVMRP but independent of the underlying unicast routing algorithm. The sparse mode starts similarly to CBT, constructing a shared tree for all receivers using a core, called a *rendez-vous* point in PIM, but it allows paths to individual receivers to be switched to shortest delay ones upon receiver request.

Networks supporting IP multicasting may be separated by multicast unaware routers. To interconnect such networks, tunnels are used, i.e., virtual links between two endpoints, composed of a, possibly varying, sequence of physical links. Multicasts are relayed between routers by encapsulating multicast datagrams within unicast datagrams at the sending end of the tunnel and decapsulating them at the other end. Multicast routers may choose to forward through the tunnels only datagrams that have time-to-live (TTL) values above a threshold, so as to limit multicast propagation across networks.

For unicast routing to scale, the Internet is divided into autonomous systems (AS), i.e., areas that internally run a single routing protocol, probably different for each AS. The border routers of each AS run a common routing protocol to achieve global unicast routing. Similarly, although multicast routing within an AS can use any of the above protocols, a common protocol, such as the border gateway multicast protocol (BGMP) proposed by Kumar et al. (18), must be used among the border routers of each AS to achieve global routing. BGMP constructs shared trees between those ASs containing group members, using as the core the AS where the multicast group was originally created, thus bridging the multicast routing protocols used within each AS.

Local Mechanisms

Unlike global mechanisms, only a single set of local mechanisms exists. These local multicasting and group management mechanisms are based on shared-medium broadcast-based networks, such as Ethernet. Delivery is straightforward on such networks, because each host can listen to all messages and select only those with the appropriate addresses. As an optimization, class D IP addresses may be mapped, if possible, to native multicast addresses so as to filter datagrams in hardware rather than in software.

On these networks, multicasts with local scope do not require any intervention by the multicast router, whereas externally originated multicasts are directly delivered to the local network by the router. The router monitors all multicast transmissions on the local network so that it may forward to the outside world those for which receivers exist elsewhere. The router does not need to track individual group members; the only information needed to decide whether an externally originated multicast must be delivered to the local network is whether at least one group member exists in the network. Therefore, the multicast router only requires a local group membership list.

The Internet group management protocol (IGMP) provides a mechanism for group management well suited to broadcast networks, because only group presence or absence is tracked for each group. In the original version of IGMP, the multicast router periodically sends a query message to a multicast address to which all local receivers listento. Each host, on reception of the query, schedules a reply to be sent, after a random delay, for each group in which it participates. Replies are sent to the address for the group being reported, so that the first reply will be heard by all group members and suppress their transmissions. The multicast router monitors all multicast addresses, updating its membership list after receiving each reply. If no reply is received for a previously present group for several queries, the group is assumed absent. When a host joins a group, it sends several unsolicited reports to reduce join latency if it is the first local member of the group. No explicit action is required when a host leaves a group, as group presence eventually times out.

During the time interval between the last host leaving a group and the router stopping multicast delivery for that group, called the *leave latency*, local transmissions to the group are wasted. To reduce this phenomenon, in the latest version of IGMP a host must send a leave message when abandoning a group if it was the last host to send a report for that group. As this last report may have suppressed other reports, the router must explicitly probe for other group members by sending a group-specific query to trigger membership reports for this group. The router can only assume the group absent if no reports arrive after several such queries. Group-specific queries may use much shorter response intervals than general queries, so as to minimize leave latency.

For networks consisting of point-to-point links, such as dialup links between home users and their Internet Service Providers, only a single member per multicast group can exist at the end-user side. An extension to IGMP for such networks, proposed by Xylomenos and Polyzos (19), uses only explicit join and leave messages from the end-user side to the multicast router, thus reducing both join and leave latency, as well as avoiding periodic queries and reports.

Related Protocols

In addition to protocols ensuring multicast delivery, many other protocols, directly or indirectly related to multicast, exist on the Internet. The multicast address-set claim (MASC) protocol, proposed by Kumar et al. (18), allows the entire range of class D IP multicast addresses to be distributed between ASs, so as to avoid addressing conflicts when multicast groups originating in different networks choose the same address.

The session announcement protocol (SAP) is used to announce the existence of multicast sessions along with their addresses, so that interested receivers may join the group. The session description protocol (SDP) describes the media formats comprising a session so that interested receivers will know what to expect after joining the group.

If the receivers require QoS guarantees, they may use the resource reservation protocol (RSVP) by Zhang et al. (20), to signal their requirements to the sender. When RSVP requests from multiple receivers meet on the way to the sender, they are merged into a single reservation that satisfies the most demanding request. As RSVP reservations are periodically refreshed, dynamic reservation modifications and network reconfigurations are supported.

Unresolved Issues

Although multicasting is widely considered to be a valuable service, it is still not universally supported over the Internet. Many explanations for this phenomenon are proposed by Diot et al. (21), including security and scalability issues. Although the traditional security issues raised by unicast, such as data confidentiality and integrity, are also valid for multicast, in the multicast context, they are more difficult to address. For example, secure group communication can be provided by using independent end-to-end secure unicast channels between all pairs of participants, albeit by negating the link sharing advantages of multicast. In the host-group model adopted by the Internet, group membership is unknown to the sender; therefore, it is impossible to set up security associations between the sender and the receivers without tracking additional information.

Another issue that became apparent when multicast started becoming popular is that the amount of forwarding state required at each multicast router for global multicasting does not scale well, because separate entries are needed for every multicast group, even if a single tree is used for delivery. If shortest path trees are used instead, the number of forwarding entries must be multiplied by the number of senders to the group. In unicast routing, this problem is solved by aggregating the forwarding state based on the fact that networks with similar unicast IP addresses are usually geographically close; therefore, routers only need a single aggregate entry for many different IP addresses, pointing in the appropriate direction. Unfortunately, multicast groups may have members everywhere on the Internet; therefore, this type of aggregation is not generally possible. Various other aggregation methods have been proposed, as described by Zhang and Mouftah (22).

NETWORK FLOW AND CONGESTION CONTROL

INTRODUCTION

Communication networks are a conglomeration of processing units of so-called *nodes* that are connected via communication *links*. The processing units can be computers, mobile phones, routers, sensors, and so on, that have varying capabilities and limitations in the available memory (buffer) space, processing speed, and transmission rates. Similarly, the communication links can have varying reliability characteristics and capacities, and they can be classified as wireless or wireline (e.g., coaxial and fiber-optic cables). Although a wireless connection allows for mobility, its supported rate is smaller than what can be achieved by, say, a fiber-optic cable. Examples of communication networks include cellular networks, ad hoc wireless networks, the Internet, the Public Service Telephone Network, and sensor networks.

Typically, numerous applications are served by communication networks simultaneously. These applications vary in their characteristics and demands. For example, real-time traffic (also called *inelastic* traffic), such as a voice call or a video transmission, has very stringent delay characteristics and fixed-rate requirements. Such traffic does not benefit from a rate that is greater than its required amount. In comparison, *elastic* traffic such as a file download is tolerant to delays but prefers the highest possible average rate. In the remainder of this article, we will use the terms *congestion control* and *flow control* interchangeably.[1] Also, we will call each flow associated with an application *a session*. Different sessions will have differing quality-of-service (QoS) constraints associated with them based on their demands. The following subsections discuss the circumstances that motivate the need for flow control.

Buffer Overflows and Delay

Because the resources of a network are shared by all the sessions that coexist, the performance—in throughput, delay, energy dissipation, and so on—experienced by each session is dependent on the behavior of the other sessions with which it has to compete. When the network resources are insufficient to support all the sessions satisfactorily, the interdependence among the performance of the sessions may hurt the performance of *all* the sessions that share the same resources. This situation is demonstrated in the following example (see Ref. 1 for a deeper analysis).

Example 1. Consider the scenario depicted in Fig. 1 with two sessions, one from S_1 to D_1 and the other from S_2 to D_2. The capacities of the links are given in the figure in bits per second (bps). The relay node R maintains a single finite buffer of size B to serve both of the sessions that traverse it. We assume that R can send packets over each of its outgoing links independently (i.e., it can send Session-1 packets to D_1 and Session-2 packets to D_2 simultaneously). However, the total number of packets that R can hold is limited by B. Consider the scenario when the rate of Session-2 is fixed at a rate slightly less than 1 bps, and the rate of Session-1 is variable, denoted by λ bps. When λ is less than 1, the buffer at R is lightly loaded and the total throughput is approximately $1+\lambda$ bps, which can be as high as almost 2. But, as λ exceeds 1, the buffer is overloaded and starts dropping packets. Those packets that are dropped need to be retransmitted to R. In such a scenario, S_1 and S_2 will be almost always busy sending new as well as dropped packets. But because the link capacity between S_1 and R is four times the capacity between S_2 and R, Session-1 has four times the chance of capturing a vacancy at the buffer than Session-2. Thus, the throughput of Session-1 will be four times the throughput of Session-2. Because the throughput of the first session can be at most 1 bps (because the capacity of the link from R to D_1 is 1), the throughput of the second session can be at most 0.25 bps, which yields a total throughput 1.25 bps. Thus, the total throughput drops to approximately 1.25 bps from approximately 2 bps because Session-1 overflows the buffer, and Session-2 cannot fully use the link from R to D_2 because of the packet drops. ◇

This example shows that the overloaded system may perform more poorly than a moderately loaded system. Flow/Congestion Control is a mechanism that, either proactively or adaptively, regulates the traffic load on the network to prevent performance degradations caused by overloading of the system.

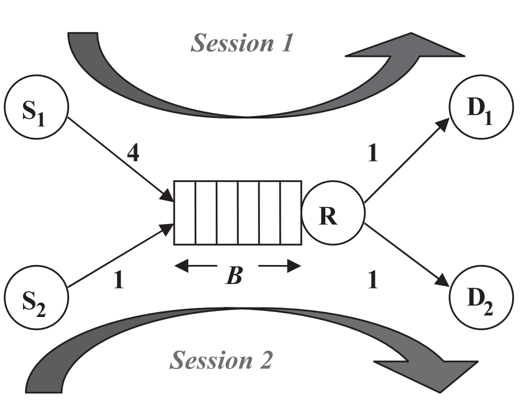

Figure 1. The scenario investigated in Example 1 that demonstrates the throughput performance degradation caused by overloading.

[1] To distinguish, the term congestion control may used to identify mechanisms that specifically aim to prevent congestion in the network, whereas the term flow control may be used to achieve other goals such as throughput, delay, fairness, or other quality-of-service constraints. We will avoid such subtle differences in this article and use these terms interchangeably.

Fairness

Because the network resources are limited, it is necessary to divide the available bandwidth fairly among the competing sessions. In the absence of a fairness mechanism, one session may dominate other and exhaust the resources of the network, leaving no service for others. There are various notions of fairness defined in the literature (see Ref. 2 and references therein for an extensive discussion). The following example introduces a canonical scenario to facilitate the discussion of different types of fairness.

Example 2. Three sessions exist as shown in Fig. 2, in which Session-1 traverses both links a and b, and Sessions-2 and 3 traverses link a and link b, respectively. If the capacity of each link is 1 bps, then what is a fair distribution of the service among the flows? We let x_1, x_2, and x_3 denote the rates of the three sessions, and we discuss two types of fairness: *max-min* fairness and *proportional* fairness.

- An allocation is said to be *max-min* fair if the rate of a session cannot be increased without decreasing the rate of another session with a smaller rate (than the one being increased). Thus, this fairness concept aims at the maximization of the minimum rate provided by the network. For the scenario in Fig. 2, a max-min fair allocation would be $x_1 = x_2 = x_3 = 0.5$ bps. Notice that according to this allocation, the total rate is 1.5 bps, although it is possible to achieve a total rate of 2 bps by setting $x_1 = 0$ and letting $x_2 = x_3 = 1$ bps.
- An allocation is said to be *proportionally* fair if for any other feasible allocation, the sum of the proportional changes in each user's rate is less than or equal to zero. Mathematically, $\mathrm{x}^\star = (x_1^\star, x_2^\star, x_3^\star)$ is a proportionally fair allocation if for any other feasible allocation x, we have $\sum_{i=1}^{3}(\frac{x_i - x_i^\star}{x_i^\star}) \leq 0$. A proportionally fair allocation for the scenario in Fig. 2 is $x_1^\star = 1/3$, and $x_2^\star = x_3^\star = 2/3$. Notice that the total rate provided by this allocation is 5/3, which is still smaller than the maximum but larger than the total rate of the max-min fair allocation. ◇

The fairness concept that is most suitable for a given scenario may be different. It is generally a difficult process to choose the most convenient fairness criterion for a given scenario. Once the fairness measure is determined, one of the primary goals of flow control is to achieve fairness among the sessions.

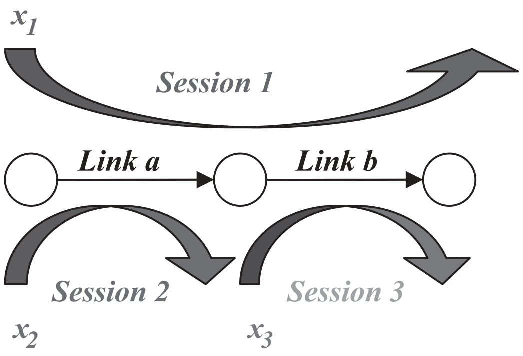

Figure 2. Different fairness goals will lead to different allocations (see Example 2).

Moreover, in a real network, no central authority decides how the resources should be allocated. Therefore, the flow control mechanism needs to operate in a decentralized manner to achieve the fairness goals.

MEANS OF CONGESTION CONTROL

Various techniques and strategies can be used to control congestion in communication networks. In the subsequent subsections, several such techniques are discussed. Some of these techniques are exemplified later in the document.

Buffer Management and Scheduling

It is sometimes useful to separate the buffers associated with different sessions. For example, in Example 1, if two separate buffers are maintained at node R, one for each session traversing it, then no performance degradation would be experienced by the second session because of the high load generated by the first session. Also, buffer management enables differentiated services by prioritizing service according to the importance or urgency of the sessions.

The presence of multiple buffers at a given node necessitates a scheduling mechanism. When packets of different sessions are waiting to be transmitted over a given link, the scheduling mechanism determines the order in which they should be transmitted. Thus, the scheduling mechanism critically affects the performance of the sessions. Numerous cross-layer mechanisms combine scheduling and congestion-control mechanism to achieve optimal performance (e.g., Refs. 3–8). We will return to this topic later in the section entitled "Mathematics of Congestion Control."

The buffer management mechanism may be first-in–first-out, in which packets are served in the order in which they enter the buffer, or some other priority mechanism. For example, in Ref. 9, more generalized processor-sharing mechanisms are investigated.

Packet Dropping/Marking

Another means to congestion control is through dropping and/or marking of packets that overload the network. Such operations may be used to send feedback to the source of the associated session and implicitly trigger it to reduce its traffic generation rate and reduce congestion. For example, in Example 1, if Session-1's packets are marked or dropped even before the buffer at R is full, then Session-2 could maintain its high-throughput level when the network is overloaded. We will observe in a later section how such a mechanism is used in practice.

Call Blocking

Sometimes it might be useful to block those calls that would congest the network if allowed. This strategy may also be thought of as a packet dropping at the session level. Call blocking may be needed if the session has some strict minimum rate requirement such as in real-time applications. In such a case, the call is admitted into the network if the minimum service can be guaranteed. Otherwise it is blocked. We will discuss this strategy more in the next section under the name of admission control.

TAXONOMY FOR CONGESTION/FLOW CONTROL

Various ways are available to classify congestion control mechanisms into broad categories. In the following subsection, we discuss some of these taxonomies.

Reservation-Based and Adaptive

The congestion-control mechanisms can be categorized into two classes: *reservation-based and adaptive*. Reservation-based mechanisms aim to prevent congestion from happening by predicting the effect of incoming sessions on the overall performance, and admitting or rejecting them based on the outcome. Such mechanisms, which are also called *admission-control mechanisms*, can be implemented in various ways (see Ref. 2):

1) *Resource Reservation*. Here, the strategy is to check whether the network has sufficient resources to support the QoS constraints of the incoming session. It aims at reserving resources for the incoming session so that it can be served satisfactorily. If all the links that will be used by the session have the sufficient capacity, then the session is admitted to the network. Otherwise, it is rejected. This strategy requires a fairly good understanding of the dynamics of the networks so that the potential effect of a new session can be accurately predicted. Also, it is less robust to changes in the network topology or capabilities.
2) *Probing*. In the strategy, a set of probing packets are transmitted to estimate the performance that will be experienced by the new session if it is admitted. If the estimated performance is acceptable, then it is admitted. Otherwise, it is rejected.

Admission control provides high performance to the admitted sessions. Typically, admission control mechanisms are used in circuit switched networks. Distributed admission control mechanisms are investigated in the literature (10).

Adaptive mechanisms, on the other hand, observe the congestion level in the network continuously and keep the session rates at an acceptable level. Also called *feedback-based controllers*, such mechanisms are robust to changes in the network conditions and require minimal information about the network topology or traffic characteristics. These qualities render such mechanisms attractive for large and changing networks such as the Internet and wireless networks. However, they may be less attractive for serving real-time traffic because of their dynamic nature.

Window-Based and Rate-Based

Congestion/flow control mechanisms generally determine the rate of flow that a session is allowed to pump into the network. Window and rate-based flow control are two different ways to implement this traffic generation. In this section, we discuss the general mechanism of both of these strategies along with their advantages and disadvantages. More references on this subject can be found in Refs. 1,2,11.

1) *Window-Based Flow Control*. The basic idea behind window-based flow control is to limit the number of packets that a session is allowed to have in the network at a given time. Many different versions of this strategy are available, such as router-centric or end-host-centric versions. The router-centric version performs a node-by-node implementation in which a window is maintained for each hop of a session's route. The end-host-centric version is implemented at the session sources and performs an end-to-end window implementation. Because it is the dominant version implemented in the networks, we describe the window-based flow control for the end-host-centric case.

We describe the operation of the mechanism for one of the sessions, say i. Each Session-i packet that is injected into the network has a packet ID, and traverses a set of intermediate links before it is received by its destination. At the successful reception of each packet, the destination sends a small acknowledgment (ACK) packet with the ID of the received packet back to the source. The duration between the time of injection of a packet into the network by the source and the time of reception of its ACK by the source is called the *round-trip time (RTT)*. RTT captures the queueing delay, processing time, and propagation delay that is experienced by the packets. Of course, this quantity is normally random and is dependent on the congestion level of the network. For the purposes of our discussion however, we will assume that the RTT of Session-i is fixed at T seconds.

We assume that the window size associated with Session-i is fixed to W. Thus, the maximum number of unacknowledged Session-i packets is limited to W. The window-based flow control operates as follows: The source of Session-i keeps track of the number of its packets that are in flight in a counter. It is allowed to inject new packets into the network as long as the counter is less than W. When the counter hits W it stops and awaits ACK(s) from the destination indicating that it has received one or more of the packets. If such ACKs arrive, then the counter is decreased by the number of acknowledged packets and new packets can be transmitted (see Fig. 3). If no ACKs are received within a certain duration, then the corresponding packets are assumed to be lost because of congestion. Then, the window is emptied and the packet transmission restarts with the unacknowledged packets.

Next, we discuss the rate achieved by Session-i for a given W and T. We assume that C gives the capacity that the network can provide to Session-i in packets per second. We can consider C as the maximum rate at which packets can be injected into the network by the source. Although C and T are actually dependent on the presence and rate of other

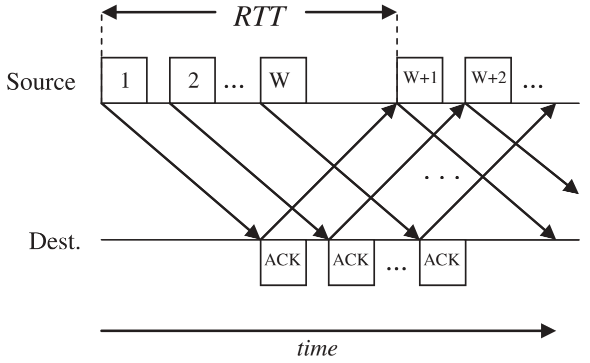

Figure 3. Operation of the end-to-end sliding window with a window size of W.

sessions that share the resources, for the moment, we assume that these values are fixed. When C is sufficiently large, the rate is limited by W and T as follows. Because W packets are in flight at any given time and each of these packets are acknowledged in T seconds, the rate of flow R is given by $R = W/T$. However, when C is smaller than this value, $R = C$. Combining these two arguments, we have that $R = \min(C, W/T)$.

Notice that this expression captures the effect of high RTT on the rate of the session for fixed W. In particular, when RTT is large, the session must have a small data injection rate to keep the congestion level low. For high-speed networks, where C is large, an efficient implementation of the window-based flow control requires W to be also large. This size reduces the reaction time to a potential increase in congestion.

So far, we assumed that the values of C and RTT are fixed. In reality, the choice of W directly affects the value of RTT. Specifically, as the W increases, the queueing delay and hence the RTT may increase dramatically. Therefore, a tradeoff occurs between throughput and delay. One metric to balance them is to consider the throughput/delay ratio, in which the goal would be to keep this ratio high. The following example investigates this metric for a simple network.

Example 3. Consider the single session in Fig. 4 that traverses a single relay node with a service rate C packets/sec. Assume that the queueing delay at the relay in terms of the arrival rate R is $\frac{1}{C-R}$ seconds.[2] Also assume that the processing and return time of the ACKs is fixed at d seconds. Then, the RTT is given by

$$d + \frac{1}{C - R}$$

We are interested in maximizing R/RTT. In Fig. 4, we plot the R/RTT as a function of R/C. We observe that this metric is maximized at a moderate load. This finding is intuitively meaningful because when R is low, the network is under-utilized, whereas when R is close to capacity, the delay is too high.

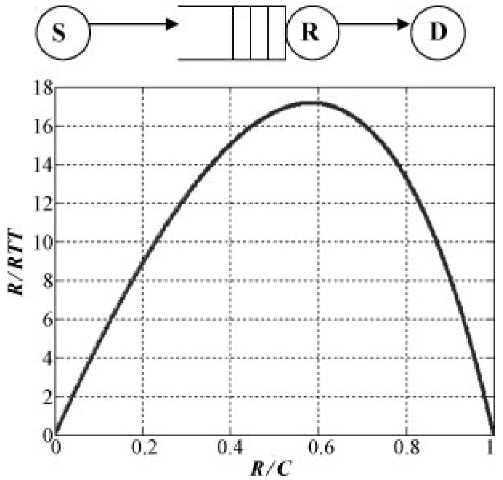

Figure 4. Throughput/delay ratio for the single session system depicted above when $d = 100$ milliseconds and $C = 10$ packet per second. The ratio is maximized at an intermediate level of load as indicated in the graph.

It is also true that when multiple sessions share the resources of a node, the capacity available for one session is influenced by the rate of the other session. Therefore, the window size of a session affects the C available to other flows.

Because both C and RTT are dynamic parameters that depend on the window size of coexisting sessions, it is often necessary to consider *adaptive* window flow mechanisms for congestion control. In fact, most current implementations use such adaptive schemes to achieve congestion control. We will investigate some mechanisms used in the Internet in the next section.

Window-based flow mechanisms react to congestion relatively quickly (within one window duration). In particular, if the congestion level increases, then the packet ACKs are received slowly and the packet injection rate is decreased. However, window-based flow control does not guarantee a minimum rate. Thus, it may be unsuitable for serving fixed-rate traffic, such as voice or video transmissions.

2) *Rate-Based Flow Control*. Another flow-rate regulation mechanism is rate-based flow control. This mechanism differs from the window-based mechanism in that it directly controls the rate of data injection into the network. Such a strategy is attractive for high-speed networks in which a window-based flow control would require extremely large window sizes and hence incur large delay. Also, rate-based control can guarantee minimum transmission rates, and hence it is well suited for serving real-time traffic.

The rate of packet injection of different flows must be determined based on their QoS constraints and the

[2] This is a well-known mean delay formulation of an M/M/1 queue (see Ref. 12).

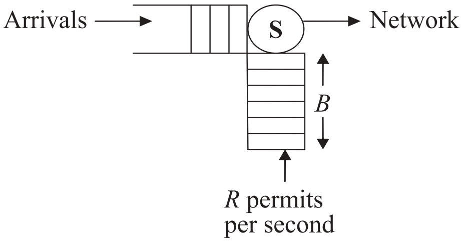

Figure 5. Leaky bucket implementation for rate-based flow control.

limitations of the network resources. For example, for voice traffic, it must be guaranteed that the minimum rate requirements are met, and the rate is no more than what is discernible by the listener.

Once the average rate is determined, say at a value of R packets per second, then rate-based flow control can be implemented in various ways. One way is to allow B packets to be injected into the network every B/R seconds, where B is some fixed parameter. The choice of B determines the amount of burstiness that the mechanism can accommodate.

Another common implementation is the *leaky bucket scheme*, in which a bucket of size B that holds *permits* is maintained at the source. A packet is injected into the network only when a permit is present in the bucket. One permit enters the bucket every $1/R$ seconds as long as the bucket is not full. This way, an average rate of R packets per second can be achieved for the flow.

Proper choice of bucket parameters is critical for the performance of the scheme. For example, if B is too small, then bursty traffic is delayed, whereas if B is too large, then the traffic may cause too much congestion in the network. As in the window-based flow control, rate-based flow control can also be adaptive. In particular, the allowed rate R and/or the bucket size B may be adjusted based on the congestion feedback to react to congestion.

CONGESTION CONTROL IN PRACTICE

In this section, we discuss several practical implementation mechanisms for congestion control in networks. We will focus on the Internet congestion control mechanisms, namely the Transmission Control Protocol (TCP) and its variants, because it is the dominant congestion-control mechanism implemented in today's communication networks.

TCP Flow Control

TCP is an adaptive window-based flow-control mechanism that is implemented in the Internet. It is primarily used to establish reliable, in-sequence delivery of a stream of packets from the source to the destination. A first version was originally developed by Jacobson in the late 1980s (13). In what follows, we describe the main components of Jacobson's algorithm as implemented in TCP, and then we describe several variants of this original version.

The basic idea behind all variants of TCP is to increase/decrease the window size of a session adaptively based on the congestion feedback as measured by delayed and/or lost ACKs. Jacobson's algorithm is composed of two phases of window-size adaptation:

1) *Slow-Start Phase*. The purpose of this phase is to increase the window size quickly to a relatively high level before congestion starts to kick in. In particular, it starts the window with a minimal size (usually 1) and it increments the window size W with every new ACK. For example, on the reception of the first ACK, W becomes 2, after another RTT two ACKs are received and W is increased to 4, and so on. Thus, the size grows to roughly twice its previous value in every RTT rounds. This phase continues until W reaches a threshold value Th. The threshold value Th is set at the beginning of the connection to half the maximum allowable window size. If packets are lost before Th is reached, then Th is set to half the window size at that time, and slow-start is restarted with the new Th value.
2) *Congestion-Avoidance Phase*. During this phase, the congestion level is regulated in the network. It implements an *additive increase/multiplicative decrease* operation to achieve this regulation. In particular, W is incremented by 1 for every W ACKs received. Notice that this increase is much slower than in the slow-start phase, and it is called additive increase. Whenever a packet loss is detected the size of the window is decreased, and different versions of TCP (Tahoe, Reno, NewReno, and SACK) implement different strategies. We will assume a particular multiplicative decrease strategy where Th is set to half the current window size, and the slow-start phase is restarted with the new Th value.

Because of the additive increase and multiplicative decrease nature of the implementation, a typical throughput pattern of TCP is in the form of a sawtooth, where the rate gradually increases up to the point where a packet loss is experiences when an abrupt decrease occurs. Figure 6 depicts the evolution of the window size under a typical TCP implementation. The slow-start phase is in operation between T_0 and T_1 where the window size quickly grows up to a level of W_0. Then the congestion avoidance phase kicks in and increases the window size gradually up to W_1 until time T_2 at what epoch the ACKs of the outstanding packets are no longer received by the source. After a time-out

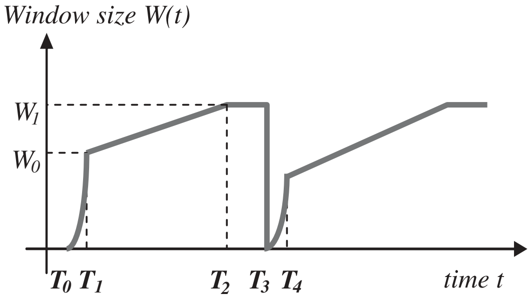

Figure 6. Typical evolution of the window size under TCP.

interval the window size is reduced to 1 at time T_3, and the slow-start phase is restarted with the window size threshold Th set to $W_1/2$. At T_4, this threshold is reached and the congestion avoidance phase is initiated, and so on.

All the variations of TCP described so far use packet losses as an indicator of congestion. Another measure of congestion can be the queueing delay at the links. TCP-Vegas (14) reacts to such indicators. The idea is similar: The source increases its window size when the queueing delay is low, and it decreases its window size when the queueing delay is high. This form of reaction is different in that it adapts the source rate before packet drops start to occur. More detail can be found in Refs. 2 and 14. One attractive feature of TCP-Vegas is that it has been shown to converge to a proportionally fair allocation (cf. Example 2). For a comparison of the performance of different versions of TCP, the reader is referred to Refs. 2,15–18.

Although TCP has been a success in the Internet, some of its basic assumptions render it unsuitable for next generation communication networks. In particular, TCP assumes that packet losses and delays as indicators of congestion. Whereas it is typically true for reliable wireline networks, it is not true for wireless and mobile networks. In a wireless network, packet drops and delays may also occur because of temporary channel fluctuations, even when the congestion level is very low. Thus, TCP performs poorly under wireless fading environments. References 19 and 20 discuss several improvements on TCP to deal with such deficiencies.

Congestion Avoidance Mechanisms

Most TCP implementations in operation require packet drops in their congestion control. This method may not be attractive because of the additional delay incurred because of the retransmission of lost packets. Several congestion avoidance mechanisms are proposed to avoid congestion rather than reacting to it. We discuss some of these in the following section.

1) *Random Early Detection (RED)*. RED is a mechanism introduced in Ref. 21 to inform the sources of potential future congestion in the network by marking or dropping packets based on queue-length levels. Specifically, based on its current average queue-length estimate, each intermediate node randomly decides to mark/drop some of its packets with a probability that is linearly related to the average queue length (see Fig. 7). Thus, when used together with TCP, such marking/dropping implicitly indicates that the intermediate node is becoming heavily congested. TCP reacts to such indicators by dropping its rate and reducing the congestion. RED helps the system reduce its average queue-length levels and hence decrease the queueing delay experienced by the flows.
2) *Explicit Congestion Notification (ECN)*. Another method to indicate congestion is through what is called an ECN mechanism (22–24). Here, a single bit is reserved in every packet as an indicator of congestion. As a packet traverses intermediate nodes, the nodes can set the ECN bit to one if their congestion level is high. For example, RED can use this bit to mark the packets when the congestion level is high. The ECN bit can also be used by other mechanisms such as the mechanisms to be discussed in the next section.

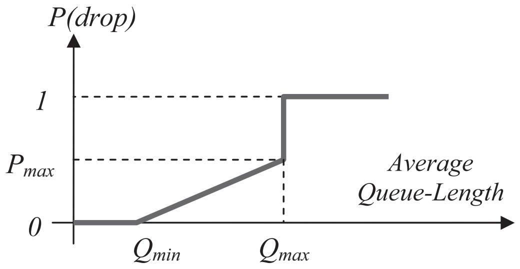

Figure 7. Dropping probability function of RED. The mechanism aims to discourage congestion by dropping packets when the average queue length exceeds $Q_{\min}$ with the probability of drop increasing linearly with the queue-length level.

MATHEMATICS OF CONGESTION CONTROL

Although congestion control mechanisms have been proposed and implemented in practice for decades, their mathematical formulation has been relatively recent. In this section, we will discuss a mathematical model of congestion control for general topology networks that is based on an optimization framework. This line of work is initiated by the seminal work of Kelly et al. (25,26), and then it is extended in subsequent works (e.g., see Refs. 1,27–29; also see Refs. 2 and 30 for excellent overviews).

Utility Maximization Framework

In this framework, the preferences of sessions and the aimed fairness characteristics are captured through a *utility function* formulation. For each session, say i, there exists a concave and strictly increasing function $U_i(x_i)$ that is a function of its mean rate. The concave form of the function reflects the law of diminishing returns, and says that the same increase in the rate is more valuable at a small rate than at a large rate. We assume that each session, say i, has a fixed route $R(i)$ associated with it, and each link, l, in the network has a fixed capacity denoted by c_l. Then, $y_l \triangleq \sum_{i:l \in R(i)} x_i$ gives the total rate of flow over link l. The goal of congestion control can be considered to set the session rates, (x_i), to optimize the following:

$$\begin{array}{lll} \max\limits_{(x_i)\geq 0} & \sum\limits_i U_i(x_i) & \\ \text{subject to} & y_l \leq c_l & \text{for each link } l \end{array} \qquad (1)$$

This model primarily captures the wireline network model with general topologies. It is very general in that it can capture various forms of fairness criteria (such as max-min or proportional fairness) depending on the choice the utility functions (see Ref. 31). For example, when $U_i(x_i) = \log(x_i)$

the solution of Equation (1) is the proportionally fair allocation.

Under the stated assumptions, Equation (1) is a convex optimization problem and various methods can be used to solve it (see Refs. 32 and 33). Amongst these methods is the Lagrangian method that leads to a *decentralized solution*, and hence is most attractive for the network setting. Although the details of the analysis can be found in the literature (e.g., Refs. 7,8,26 and 27), here we discuss the high-level description of the solution.

The operation can best be described through the perspective of two agents: the network and the source. These two agents interact with each other through a *pricing* mechanism. In particular, each link, l, in the network determine a price, p_l, for using its resources based on its current load y_l. The price is high if y_l is close to its capacity c_l, and it is low if y_l is much smaller than c_l. Thus, the price of each link measures its usage at the time. Given a set of link prices (p_l), the price associated with session-i is $p^i \triangleq \sum_{l \in R(i)} p_l$ which gives the total price of the links that session i traverses. p^i can be interpreted as the price that session i has to pay per unit flow of data it sends in the network. Then, the source of session i adjusts its data rate x_i so that the utility it gains from the network minus the cost is maximized. Mathematically, x_i maximizes $(U_i(x_i) - x_i p^i)$ for each session i. This operation is intuitively meaningful because those flows with high utility values will afford to pump more data into the network, whereas those with low utility values will have to reduce their rates, and consequently the total utility will be high. The adjusted set of session rates are then used at each link to update the prices such that the price of the under-utilized links are reduced whereas the overloaded links are increased. When this procedure of price adjustment by the network and rate adjustment at the sources are repeated indefinitely, the rate allocation vector $(x_i)_i$ converges to the solution of Equation (1). A pictorial overview of this iterative strategy is depicted in Fig. 8.

Various open problems require more attention. The assumed concave form of utility functions is well-suited for applications such as file transfer, they do not accurately capture real-time traffic. Several works have addressed the operation under nonconcave utility functions (e.g., Ref. 34). Yet, there is need for capturing QoS constraints of real-time traffic. Also, the question of convergence rate of the iterative algorithm is of interest for both theoretical and practical reasons.

$p_l \leftarrow p_l + \varepsilon\,(y_l - c_l)$

Figure 8. Iterative procedure of congestion control that solves Equation (1). In the iteration, ε is a small positive constant that determines the step size of the evolution.

Cross-Layer Design

The utility-based formulation discussed in the previous section can also be used to develop cross-layer controllers that include scheduling and routing decisions in addition to congestion control. Here, the routes of the sessions are not fixed and are to be determined by the controller. Such mechanisms are investigated recently in the literature (e.g., Refs. 3–7,20,35). In what follows, we describe the high-level idea behind these schemes.

Again the operation of the cross-layer mechanism can be separated into two agents: the network and the source. Here, in contrast to the previous algorithm (see Fig. 8), the network is also responsible for the scheduling and routing decisions of packets. Thus, each node must determine which packets to transmit over which of its outgoing links. The routing capability allows the network to use underutilized links in the network, whereas the scheduling capability allows the network to give more priority to sessions that experience higher congestion. The source, as before, is responsible for the congestion control decisions.

The solution uses *buffer management* (cf. the second section) strategy to maintain separate queues at each node for those packets that are destined for the same end node. The lengths of these queues are used by the network and the source to make the scheduling-routing and congestion-control decisions. In particular, the network uses the queue-lengths to give priority to those queues with a high backlog compared with the queues in the neighboring nodes. Also called the *back-pressure* strategy (36), this strategy aims to spread packets of each session throughout the network to establish the most efficient routes. The source uses the queue-length information as the price that must be equalized to the utility to be gained from service. Thus, the cross-layer mechanism is coupled through the occupancy level of the queues maintained at the nodes. This high-level interaction is depicted in Fig. 9.

It is shown that such a scheme will provide the optimal performance (in terms of utility maximization) that any scheduling-routing-congestion control mechanism can provide. It is surprising that a loose coupling through appropriately maintained queue-lengths can provide such optimal behavior. All of these strategies extend to wireless networks (see Ref. 8).

FINAL REMARKS

In this brief overview, we observed that congestion/flow control aims at keeping the load of the network at a moderate level so that certain objectives can be reached. The objectives may be to provide certain QoS guarantees that

the competing traffic requires and/or to satisfy certain fairness criteria. No congestion control mechanism can achieve all these in the most general sense. We have discussed the most critical issues related to congestion control, as well as some methods and strategies that can be used to achieve the assumed objectives. Although there are some successful practical implementations of congestion control, these require significant improvements to be applicable to next generation high-speedwireless networks. We discussed several recent designs that are based on an optimization framework, and we have pointed out to some of the open problems.

NETWORK RELIABILITY AND FAULT-TOLERANCE

When we make a telephone call, the call is connected through a communication network to the receiving party. Similarly, when we send an e-mail using the Internet, the message is sent through a communication network to the recipient. Such communication networks are made up of nodes and links that connect the nodes by hardware as well as the software components that allow for the functionality to communicate through such networks. Network reliability refers to the reliability of the overall network to provide communication in the event of failure of a component or components in the network. The term *fault-tolerant* is usually used to refer to how reliable a particular component (element) of a network is (e.g., a switch or a router.) The term *fault-tolerant network*, on the other hand, refers to how resilient the network is against the failure of a component.

Communication network reliability depends on the sustainability of both hardware and software. A variety of network failures, lasting from a few seconds to days depending on the failure, is possible. Traditionally, such failures derived primarily from hardware malfunctions that result in downtime (or "outage period") of a network element (a node or a link). Thus, the emphasis was on the element-level network availability and, in turn, the determination of overall network availability. However, other types of major outages have received much attention in recent years. Such incidents include accidental fiber cable cut, natural disasters, and malicious attack (both hardware and software). These major failures need more than what is traditionally addressed through network availability. For one, these types of failures cannot be addressed by congestion control schemes alone because of their drastic impact on the network. Such failures can, for example, drop a significant number of existing network connections; thus, the network is required to have the ability to detect a fault and isolate it, and then either the network must reconnect the affected connections or the user may try to reconnect it (if the network does not have reconnect capability). At the same time, the network may not have enough capacity and capability to handle such a major simultaneous "reconnect" phase. Likewise, because of a software and/or protocol error, the network may appear very congested to the user (1–3). Thus, network reliability nowadays encompasses more than what was traditionally addressed through network availability.

In this article, we will use the term *network reliability* in a broad sense and cover several subtopics. We will start with network availability and performability and then discuss survivable network design, followed by fault detection, isolation, and restoration as well as preplanning. We will conclude with a short discussion on recent issues and literature.

NETWORK AVAILABILITY AND PERFORMABILITY

Network availability refers to some measure of the reliability of a network. Thus, network availability analysis considers the problem of evaluating such a measure. [Note that in current literature, this is often termed as the network reliability analysis (4)]. Moore and Shannon did early work in this area (5). We discuss network availability through an example. Figure 1 shows that two telephones are connected by distribution segments (A) to local switches (S), while the switches are connected by the facility (B). The following allocation of outage/downtime percentage is assumed for the different elements: S 0.01%; A, 0.01%; B, 0.03%. Then, the availability of this connection is $(1-0.0001)^4(1-0.0003) = 99.93\%$; this translates to the maximum downtime of 368 min per year.

In general, network availability computation addresses the availability of a network in operational states, and discrete probability models are often used in analysis. Let $\mathscr{E}$ denote the set of elements of a network (for examples all the nodes and links). Each element may be in up or down state, where up refers to fully operational and down refers to total loss of the element. Let p_e denote that probability that element $e \in \mathscr{E}$ is up—this is also referred to as the availability of element e. Now consider the subset E_i of $\mathscr{E}$ consisting of the up elements of state i. Then, the probability that the network is in up state E_i is given by

$$Pr(E_i) = \prod_{e \in E_i} p_e \prod_{e \in \mathscr{E} \setminus E_i} (1 - p_e) \tag{1}$$

Note that there are $2^{|\mathscr{E}|}$ possible states (where $|\mathscr{E}|$ denotes the cardinality of the set $\mathscr{E}$); thus, usually network availability computation needs to deal with the problem of this exponential growth in states. A variety of algorithms for efficient computation have been developed over the years for different availability measures; the interested reader is directed to 4 and the references therein for additional information.

A related issue to availability is the performability. Most availability measures deal only with the connectivity aspect of the network; for example, what is the availability of a path from a source node to a destination node. However, when a failure occurs, the network may not be able to perform at the same level as when there was no failure. For example, the average network blocking in voice telephone networks (circuit-switched networks) is typically the measure for grade-of-service (GoS). A common value of GoS is 1% blocking under the normal operational mode, but under a specific outage, this may increase to more than 10% blocking; similarly, in a packet-switched network, the average packet delay may increase by an order of magnitude during a major failure compared to under the normal circumstances. Thus, the network failure performability addresses the performance of the network under various failure states. Consider a network with m elements that can

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

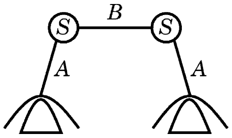

Figure 1. Network view for availability example.

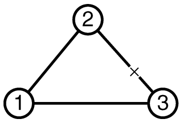

Figure 2. Three-node network.

each be either in operational or in a completely failed state; then, the total number of states is 2^m. The performability measure P is given by

$$\mathscr{P} = \sum_{k=1}^{2^m} Pr(k)X(k) \tag{2}$$

where $Pr(k)$ is the probability of state k, and $X(k)$ is the measure (e.g., network blocking in circuit-switched networks or average delay in packet-switched networks) in state k. Again, we face the issue of the exponential number of states. This can, however, be bounded by considering most probable t states as was first shown by Li and Silvester (6). Often, with the proper choice of t, the performability measure can be quite accurately computed. For example, if in a network, multiple simultaneous link failure scenarios are extremely unlikely, then the most probable states are the failure of each link independently. Accordingly, one may limit the computation to these states.

SURVIVABLE NETWORK CAPACITY DESIGN

While network availability and performability address important measures for evaluating the reliability of a network, designing the networks for survivability is extremely important for overall network reliability. In this section, we address this topic for the capacity design problem using separate examples for circuit-switched networks and packet-switched networks.

Circuit-Switched Traffic Networks Example

Consider the three-node circuit-switched network (Fig. 2) for which we are given that the availability of each link is 99.9%. We assume that the network has symmetric offered traffic (or load) and capacity. Offered load in circuit-switched networks is given in erlangs; this load is the product of the average call arrival rate and the average call holding time. For example, if the average call arrival rate is 200 calls/h and the average call holding time is 3 min, then the offered load is 10 erlangs (=3 × 200/60).

For the symmetric three-node network, offered load between any pair of nodes is assumed to be 10 erlangs, and the link capacity on each link is given to be 21 trunks (or circuits). We assume that the traffic between each pair of nodes is routed on the direct link that connects the end nodes of the pair, and we would like to know the call-blocking probability. For an offered load of a erlangs, and c trunks, and under the assumption that call arrival follows a Poisson process, Erlang-B loss formula can be used for computing the blocking probability, which is given by

$$E(c, a) = \frac{a^c/c!}{\sum_{k=0}^{c} a^k/k!} \tag{3}$$

Thus, in our example, we have $E(21, 10) = 0.000889 \approx 0.001$. That is, the network is providing a service quality (grade-of-service) of 0.1% blocking. (In actuality, the blocking for each pair of nodes is slightly different because any traffic blocked on the direct link can try the alternate route.)

Now, suppose that the link 2–3 fails; in this case, the network is still connected because node 1 is connected to node 3 via node 2. Assuming that the network still has the same amount of offered load, the load between node 2 and node 3 is now required to be routed through node 1; thus, the load offered to each link is 20 erlangs, whereas the capacity on each link is still 21 trunks. Thus, the blocking seen by traffic on each link is $E(21, 20) = 0.13144$, and the blocking seen by pair 2–3 traffic going through node 1 is even higher. Under the link independence assumption, the blocking on a path consisting of two links is given by $1 - (1 - b)^2$, where b is the link blocking probability. Thus, in our example, the blocking for traffic between 2–3 going through node 1 is $1 - [1 - E(21, 20)]^2 = 0.24558$.

Thus, we can see that, under no failure, the network provides a grade-of-service of 0.1%, whereas under a single link failure, the worst traffic pair blocking is 24.558%, although the network connectivity is still maintained. Recall that the link availability was assumed to be 99.9%; this means that the link can possibly be down for as long as 8 hours in a year. If we assume one event per link per year, then this link could conceivably be down for up to 8 hours straight! In some networks, this may be unacceptable given that the worst traffic pair blocking jumps to 24.558% from 0.01%. If we assume that the network should still provide a 0.1% blocking grade even under a single failure for every traffic pair, then to accommodate for the worst path blocking, we need link blocking on each of the remaining links to be b such that the path blocking for traffic between node 2 and node 3 using links 2–1 and 1–3 needs to satisfy $1 - (1 - b)^2 = 0.001$; this translates to $b = 0.0005$ for each link. Because we now have an offered load of 20 erlangs on each link, we need to find the smallest c such that $E(c, 20) = 0.0005$. Solving for integral c, we find that c needs to be at least 36 (i.e., we need to have 36 units of capacity on links 1–2 and 1–3 each). By the same argument, if we consider the failure of a different link independently, then the other two links each need 36 trunks. Thus, to cover for failure of each link independently, each link needs 36 trunks to provide the same level of blocking as was originally wanted for the network in the nonfailure mode. In other words, the network needs 80% more capacity to cover for a link failure compared to the no-failure case although network availability requirement was met.

Packet-Switched Networks Example

Consider this time a three-node packet-switched network. We will use Fig. 2 again. In packet networks, the offered traffic is usually given by the average packet arrival rate (packets per second, pps in short). If the average packet arrival rate to a network link is λ and follows a Poisson process, the average packet size is exponentially distributed with mean $1/\hat{\mu}$ kilobits, and the link speed is C kilobits per second (kbit/s), then the average packet delay (caused by the queueing phenomenon) can be obtained from the M/M/1 queueing system and is given by

$$T(\lambda, C, \hat{\mu}) = \frac{1}{\hat{\mu}C - \lambda} \tag{4}$$

For the three-node example, we assume unit mean packet size (i.e., $\hat{\mu} = 1$), in addition to assuming that the average arrival traffic between each pair of nodes is 10 packets per second and that the capacity of each link is 30 kbit/s. If all traffic between each node-pair is routed on the direct link, this provides an average delay of $T(10, 30, 1) = 0.05$ s, or 50 ms. Now suppose that the link 2–3 fails, then the traffic between node 2 and node 3 is routed through node 1; this induces an offered traffic of 20 pps on each remaining link. Thus, the average delay on each link (1–2 and 1–3) is 100 ms which is observed by traffic between nodes 1 and 2 and between nodes 1 and 3. On the other hand, the traffic between nodes 2 and 3 will go over two links and will thus experience a delay of $2 \times 100 = 200$ ms; this delay is four times more than under the no-failure situation.

If the network goal is to provide the average delay for any pair to be less than or equal to 50 ms under a single link failure, then to meet this condition we need link capacity C such that $2\,T(20, C, 1) = 2/(C - 20) = 0.05$ which implies that C needs to be 60 kbit/s on each of the remaining links. Similarly, if we consider the independent failure of a different link, then the other two links will require 60 kbit/s to provide the same level of service. Thus, in this network, we see that we need to double the capacity to provide the same level of service obtained under a single-link failure.

Discussion

We can see from these examples that if the network is *not* provided with additional capacity, then the traffic blocking can be very high in circuit-switched networks, which can result in excessive retry by users, or the packet backlog (queue) can build up in packet-switched networks. Thus, a transient effect can take place. From these two examples for two different networks, we can also see that, in some circumstances, the network capacity needs to be 80% to 100% more to provide the same level of service under a single link failure. This of course depends on the network objective (in our examples, we have used the objective that worst-pair traffic blocking or delay is minimized). In some networks, this near doubling of capacity can be cost-prohibitive; thus, the network performance requirement under failure may be relaxed. For example, under a single-element failure, it may be acceptable to have 5% blocking under a single link failure for the circuit-switched network case, or the average delay is acceptable to be 100 ms for the packet-switched network case. It is easy to see that this will reduce the additional capacity requirements in both cases.

Even though additional capacity can meet GoS requirement under a failure, the actual network topology layout and routing are also critical for survivable design (7). Thus, we also need to understand the network connectivity requirement for the purpose of survivability. For instance, a network needs to be minimally two-edge connected to address a single-link failure; this means that there must be two links connected to each node so that if one of them fails, a node can still be connected to the rest of the network through the other link; this avoids isolation of a node or a part of a network from the rest of the network. If a network is prone to multiple link failures at a time, this would require the network to have a higher degree of connectivity, which, in turn, would usually mean more network resource requirement to address for such failure situations. Survivable design for different node and edge connectivity level is extensively discussed in Ref. 8; the interested reader is directed to this reference for additional information.

Going back to the three-node examples, recall that the routing choice was limited to taking the *only* two-link path in the event of a failure. In a larger network, usually multiple routes between each origin and destination nodes are available; in the event of a failure, traffic can be sent on any of the unaffected paths. However, the actual flow on each path would depend on the actual routing rule in place as well as the availability of network capacity. Thus, it is not hard to see that the actual capacity requirement to address a failure in the network depends also on the actual routing schemes available in the event of a failure.

In any case, the overall network survivability and reliability depends on a number of issues. Network capacity design for survivability, as we see from these examples, plays an important part. In the next section, we discuss fault detection and isolation as well as network restoration—another key piece in network reliability.

FAULT DETECTION, ISOLATION, AND RESTORATION

Usually, different elements in a network are equipped with alarm generation capability to indicate the occurrence of any abnormal condition, which may cause the reduction or complete loss of the element. This abnormal condition is sometimes labeled as a fault. When an actual failure occurs, depending on the triggers set by various elements in the network, multiple alarms may be generated by a number of network elements—this is the fault-detection phase. Then, the network management system that monitors the network needs to determine the root cause of the fault. Fault isolation is the process of identifying the root cause of the fault. Thus, an issue that first needs to be addressed is correlation of alarms (9) to determine and isolate the actual point of failure in the network. Such fault-detection systems are needed to determine the cause of a fault quickly so that appropriate action can be taken. It is easy to see the relation of fault isolation to network reliability. The longer it takes to detect the cause of a fault, the longer it takes to fix it, and thus, conceivably the network is affected for a longer period of time, which decreases the performability of the network. Rule-based and model-based systems are used for fault isolation. Both centralized and distributed fault localization can be used; see Ref. 10 for a survey of different techniques.

Along with the fault-isolation phase, the restoration/repair phase begins. First, the network may be provided with additional capacity. If the additional capacity is provided so that even after failure the quality of service is met, then from the user's viewpoint, the failure is not perceived! Thus, a way of "restoring" the network is through additional capacity in the network (although, in actuality, the fault is not physically repaired yet). As we have already seen, to address for a single failure, the network may need twice the capacity, which may be sometimes cost prohibitive. Thus, the network may be provided with less than full spare capacity to address for a failure. In such cases, if the network has adaptive routing capability, then some of the traffic can be rerouted around the failure; thus, the users may not perceive the full impact of a failure.

Sometimes, the spare capacity can be provided in a different layer in the network because of cost and technological considerations. In the simplest architectural view of the communication network infrastructure, services such as voice or Internet are provided over *logical* switched or router-based networks; the capacity required for these logical networks is then provided over the physical transmission network, which may be connected by the digital cross-connect systems or SONET (Synchronous Optical Network) rings. For example, if a network is equipped with fast automated digital cross-connect system and/or SONET self-healing ring capability at the transmission network, the network where the services are provided may not perceive any failure because of fast automated restoration (11,12). At the same time, the transmission network level restoration schemes do not address failures such as a line card failure, or a switch or router failure; thus, restoration at the logical network level also needs to be triggered; this may include rerouting and automatic reconnection of affected connections. It is clear from this discussion that to restore from a failure, the network should be equipped with capacity as well as the proper network management system and software components to detect, isolate, and recover from a failure.

Other types of failures such as a software attack or a protocol operation failure cannot be addressed through the restoration process discussed earlier. An example is the SYN attack (2) in transmission control protocol (TCP), which severely affected an Internet service provider (TCP is the transport layer protocol on which services such as email, file transfer, and web browsing are provided in the Internet). In this case, the mechanism is needed to identify where such attacks are coming from so as to stop such attacks.

ADVANCED PREPARATION FOR NETWORK RELIABILITY

To provide network reliability, it is also important to do preplanning and/or advanced preparation. Of course, one way is to have additional spare capacity in the network. However, there can be a failure in the network that can actually take away the spare capacity if the network is not designed properly because of dependency between the logical network and the physical network (7). Thus, it is necessary to audit the network and find the vulnerable points in the network and then to equip the network with additional capabilities to avoid such vulnerabilities. For example,

1. The network may be provided with transmission-level diversity so that for any transmission link failure there is at least another path not on the path of the failure.
2. A redundant architecture at network nodes can be built to address for a node component or nodal failure; this may include dual- or multihoming to provide for multiple access and egress points to and from the core network.

To address for failures due to a software or protocol operations error or a software attack, different types of preparations are necessary. Several software errors that have occurred on various data networks such as the ARPANET, Internet, and SS7 Network (the data network that carries the signaling information for the public telephone network) (1,2) have caused such severe congestion in the network that it cannot be adequately addressed by normal congestion control schemes. Although enormous efforts go into developing robust software, it is not always possible to catch all possible software bugs (and sometimes bugs in the protocol operation). Should any software errors occur, the network should be provided with the capability to go to a known state in a speedy manner [e.g., speedy manual network reinitialization (1)]. If an error occurs as a result of a new feature, then it should have the ability to disable this feature and go to a known state for which the track record is good (3). To address for a software attack that can take advantage of a protocol's "loop hole," however, requires the development of intrusion-detection schemes.

RECENT ISSUES

Much research remains to be done to address network reliability in today's complex networking environment. We briefly touch on two areas in this regard: multilayered networking architecture and software errors/attacks.

Networking environment is evolving to various services being provided over multiple interconnected networks with different technologies and infrastructure. For example, the voice service is provided over circuit-switched networks, which are carried over the transmission network. Similarly, for Internet, applications such as web, email, and file transfers are carried over internet protocol (IP) layer connected by routers, which can be connected to the same transmission network or carried over an asynchronous transfer mode (ATM) or frame relay layer and then over the same transmission network. Thus, we are moving to an environment that we have coined the *multinetwork* environment. In such environment, in each of these networking layers, different types of failures/attacks and responses are possible. Some work in recent years has addressed this subject to some extent (7,13-17). It remains to be seen the impact of the failure propagation from one network to another, how the restoration process at each of these layers interacts with one another, whether they can make the best use of the network resources, and what type of network management coordination is needed for this purpose. Thus, network reliability in such interconnected multitechnology architecture needs further research.

Software/protocol operations errors and software attacks encompass the other area where mechanisms are needed to provide network reliability. This subject is relatively new—research on intrusion detection mechanisms is currently being explored to determine if an attack has occurred. Also, we need to see more work that helps us understand how severely the network will be affected in terms of network performance if a software attack or protocol failure occurs and how to recover from this anomaly. Also, the network architecture should be revisited to identify if there are ways to reconfigure the network after an attack so that parts of the network remain operational.

NETWORK SECURITY FUNDAMENTALS

OVERVIEW

Communication is at the heart of computer systems. Information stored at one location is moved to another location, combined with data from other sources, and processed to meet the needs of the users. Rarely can user commands or the information they access avoid traversing networks, which leaves the data and systems vulnerable to a variety of attacks. A malicious intruder might intercept, falsify, damage, or altogether prevent the networked communications. This chapter focuses on security goals, vulnerabilities, and defenses for networked systems. When we use the word *security*, it is in the context of networked computer systems; other use will be made clear by context.

In discussing security issues, we will often make use of examples, using the characters *Alice*, *Bob*, and *Eve*. Normally, Alice and Bob are attempting some sort of communication, a *message*, and Eve is maliciously interfering with or intercepting it. These examples are representative, but they should not be taken too literally. Alice and Bob are likely to be computer programs exchanging information, perhaps performing a *handshake* to initiate a session. Eve may be some sort of eavesdropping program logging communication between Alice and Bob, or she might be an *agent* actively introducing falsified messages. Therefore, in our context, Eve can be either a passive attacker or an active attacker.

A common theme in both networking and security is the idea of a *protocol*—a prescribed sequence of events designed to facilitate communication among the participants. In particular, *cryptographic protocols* are used to exchange information that should remain confidential.

Security Goals

A variety of goals can be identified with regard to network security, but three basic ones stand out: *confidentiality*, *integrity*, and *availability* (sometimes reduced to the acronym CIA). Information must be readily accessible when needed. Alice has sent Bob a message, and he wants to get it. It must be available to him. Information must be intact, and accurate, secure from both accidental and malicious change. The message Bob gets from Alice should be that message exactly as Alice sent it. Its integrity must be preserved as it crosses the network. Access must be restricted to confidential data. Eve should not be able to read the message Alice has sent to Bob. Things intended to be private must remain private.

Principles

A few key principles are recognized when discussing security First, security is an ongoing process rather than a tool or simple action (Bruce Schneier's dictum is "Security is a process, not a product"). Second, security may be dependent on technology, but both people and business processes are crucial elements and often vulnerable. If Bob keeps his password on a sticky note on his monitor, Eve may have an easy time reading Bob's messages from Alice! *Social engineering* is a term for attacking security simply by deceiving the people involved and lying to them to gain passwords or other *keys* to access systems or data. Eve calls Bob, claims to be from the IT department, and says she needs his password to correct a (nonexistent) problem with his e-mail. Third, security has an inescapable economic element—any security effort requires some cost and in exchange reduces some risks. Careful *risk analysis* is necessary to ensure that the security process is cost effective. Finally, *defense in depth* is necessary, with layers of security protecting resources. Any one layer might be compromised, but if yet more layers exist the information remains secure.

Policies

Any organization interested in security needs a *security policy*, a clear statement of the organization's specific goals, defining security for their information systems. Policies serve a variety of purposes. They define what is and is not acceptable use of an organization's information resources. They identify what *assets* are to be protected from what *threats*, and they establish priorities for dealing with the various risks. They provide plans, practices, and processes to follow to improve security and to deal with breaches of security. Among other roles, an organization's security policy can be an effective tool for educating personnel about both the importance of security and the practices for achieving it.

Elements

Security is a broad field, and it requires broad knowledge, particularly of software and networking. Our approach to organizing the topic is to first discuss the foundations of security in cryptography. Then we will discuss various security *services* offered on networks. The following section will discuss the various attacks against our security goals and services. After discussing *vulnerabilities* and attacks, we address defense mechanisms that can be used to thwart the attacks. Finally, we briefly discuss some issues specifically related to wireless network security.

FOUNDATIONS

When two or more computers want to talk in a "secure" way, they may expect their communication to meet one or any combination of the following security requirements, which are an extended set of the traditional security goals, CIA:

- *Confidentiality* (or privacy)—Ensuring that no one can access the information except the intended receiver.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

- *Integrity*—Ensuring that data are not maliciously tampered with during transmission and operation and can be altered only by those authorized.
- *Availability*—Ensuring that computer services are operable and resources are accessible throughout their lifetimes.
- *Authentication*—Ensuring that the identity of an entity in the communication is genuine.
- *Authorization* (access control)—Determining and enforcing who is allowed access to what resources, hosts, software, and network connections.
- *Non-repudiation*—Ensuring that it can be definitely established that an entity has sent a particular message, and that they cannot deny having done so.

To meet these requirements, use of *cryptography* is necessary, although not sufficient. Generally speaking, cryptography is the art of scrambling information into some unintelligible form and (usually) providing a secret method of recovering the original message. When a message is in its original, unscrambled form, it is called *plaintext* (or *cleartext*). The scrambled message is known as *ciphertext*. The process of converting plaintext to ciphertext is known as *encryption*, whereas recovering the original plaintext message from the encrypted ciphertext is called *decryption*.

Three main types of cryptographic schemes exist: *secret key* (also called *shared key* or *symmetric*) cryptography, hash functions, and *public key* (or *asymmetric*) cryptography. To implement such schemes, modern cryptographic technology makes extensive use of mathematics, especially *number theory*. As is obvious from the names, a *key* plays a special role in cryptography. A *key* is a parameter to a cryptography algorithm that controls details of its behavior. It is common practice to assume that someone attacking a cryptographic scheme knows all the algorithm and process details except for the key. Among other consequences, this dictates that *security through obscurity* is not an acceptable approach, and that open security processes and algorithms may be more secure as they can be thoroughly tested by the entire community.

Basic Number Theory

In this section, we will describe some concepts and theorems that have been commonly used in cryptographic algorithms.

Most public key cryptographic algorithms are based on *modular arithmetic*. Modular arithmetic is arithmetic where the results of operations are restricted to non-negative integers less than some fixed number n, a range of $[0\ldots(n-1)]$. An integer converted to this range is *modulo n* or *mod n*. Conceptually, modular operations perform ordinary arithmetic operations (such as addition, multiplication, or exponentiation) and then convert the result to the appropriate range by returning the remainder after division by n. So, for example, $23 \; mod \; 10 = 3$; and $(5 + 8) \; mod \; 10 = 3$.

First we define some basic concepts:

A *prime* number is a positive integer that is evenly divisible by exactly two positive integers (itself and 1).

The largest number that divides two numbers n and m is called the *greatest common divisor (gcd)* and denoted $gcd(n, m)$.

Two integers are *relatively prime* if and only if their *gcd* is 1.

The *multiplicative inverse* of x, denoted x^{-1} or $1/x$, is the number that, when multiplied by x, yields 1. For example, 7 is the multiplicative inverse of 3 *mod* 10, because $7 \times 3 \; mod \; 10 = 1$. A multiplicative inverse does not always exist. A positive integer x has a multiplicative inverse *mod n* if $gcd(x, n) = 1$.

Some modular arithmetic properties are important in cryptographic algorithms, such as:

Modular addition: $(a + b) \; mod \; n = [(a \; mod \; n) + (b \; mod \; n)] \; mod \; n$.

Modular subtraction: $(a - b) \; mod \; n = [(a \; mod \; n) - (b \; mod \; n)] \; mod \; n$.

Modular multiplication: $(a \times b) \; mod \; n = [(a \; mod \; n) \times (b \; mod \; n)] \; mod \; n$.

These three properties are particularly useful, because we can substitute the expressions on the right for those on the left, applying the *mod* operator early and often and keep the values in our calculations smaller than n.

Modular addition and multiplication form a commutative ring with the laws of (where a, b, and c are all positive integers):

Associativity: $[(a + b) + c] \; mod \; n = [a + (b + c)] \; mod \; n$.

Commutativity: $(a + b) \; mod \; n = (b + a) \; mod \; n$.

Distributivity: $[(a + b) \times c] \; mod \; n = [(a \times c) + (b \times c)] \; mod \; n$.

Fermat's theorem (or *Fermat's little theorem*)—If p is a prime number, then for any integer a, $a^{p-1} mod \; p = 1$.

Euler's totient function—the totient $\phi(n)$ of a positive integer n is the number of positive integers less than n and relatively prime to n. Therefore, if n is prime, $\phi(n) = n-1$. If $n = p \times q$, and p and q are primes, $\phi(n) = (p - 1)(q - 1)$.

Euler's Theorem—for every a and n that are relatively prime, $a^{\phi(n)} mod \; n = 1$. Then we can prove that, for modular exponentiation, we have $x^y \; mod \; n = x^{y \; mod \; \phi(n)} mod \; n$, where x and y are positive integers too.

The *Euclidean algorithm* (also called *Euclid's algorithm*)—one of the earliest algorithms developed, it can be used to find the *gcd* or to find the modular inverses of a number n, given n and a modulus m. The algorithm does not require factoring the two integers (a slow process) but works by repeatedly dividing the two numbers and their remainder in turns.

Secret Key Cryptography

Secret key cryptography uses a single, shared key for both encryption and decryption. It leads to the necessity of sharing the keys securely, called the *key exchange* or *key distribution* problem.

Based on how data are processed in encryption, secret key cryptography schemes are usually categorized as either *stream cipher* or *block cipher*.

Stream ciphers operate on plaintext digits one at a time and constantly changes the key used in transformation of successive digits. The sequence of keys used is called a *keystream* and is often generated from a simpler key. A stream cipher generates successive digits of the keystream based on an internal state. Based on the two essential ways that the state can be updated, stream ciphers are categorized into two types: *synchronous stream ciphers*, where the state is updated and therefore the keystream is generated independently of the plaintext and ciphertext, and *self-synchronizing ciphers*, where the state is updated based on the previous ciphertext.

Stream ciphers are often used when the length of the plaintext is unknown in advance. Examples of stream ciphers include RC4, LEVIATHAN, A5/1, A5/2, Chameleon and FISH. RC4 was designed by Rivest for RSA Security. It uses a keystream of variable size and operates on bytes. RC4 is used for file encryption. LEVIATHAN is a *seekable* stream cipher, which means that the user may efficiently skip forward to any part of the keystream. LEVIATHAN generates a keystream efficiently using its unique tree structure.

Block ciphers operate on a large block of plaintext digits each time, and the transformation uses a fixed key. Block ciphers can operate in different modes, of which the following four modes are common:

Electronic Code Book (ECB)—the simplest but the "worst" method. In ECB, each block is independently encrypted with the secret key and then all ciphered blocks are assembled together. A problem of ECB is that identical blocks will generate identical ciphertext. As such it is susceptible to brute-force attacks, and malicious alteration is also possible.

Cipher Block Chaining (CBC)—avoids the problem in ECB by exclusively-ORing (XORing) the previous block of ciphertext with the next plaintext before applying encryption with the secret key. As no previous block for the very first data block exists it uses an initial random number known as an Initialization Vector (IV). The use of an IV guarantees that repeated identical blocks of plaintext result in different ciphertext each time they are encrypted.

Output Feedback (OFB)—allows encryption of blocks of varying sizes. It generates a sequence of one-time pads by encrypting the previous feedback and then feeding it into a shift register. Only *k* bits (size of the blocks) are kept, and the remaining is discarded. The initial pad is generated from an IV. The one-time pad is XORed with plaintext to generate the ciphertext. OFB does not propagate errors but is vulnerable to message alteration if an attacker knows the plaintext and the ciphertext.

Cipher Feedback (CFB)—similar to OFB but takes the previous ciphertext (not the previous feedback) to generate the one-time pads.

A few secret key cryptographic algorithms in use today, which employ block ciphers, are *Data Encryption Standard (DES)*, *International Data Encryption Algorithm (IDEA)*, and *Advanced Encryption Standard (AES)*.

DES was published in 1977 by the National Bureau of Standards (NBS) [now the National Institute of Standards and Technology (NIST)]. It was designed by IBM based on their Lucifer cipher. DES uses a 56-bit key and operates on 64-bit blocks. DES employs complicated rules and rounds of transformations, which is asserted to be specifically designed to yield efficient implementation in hardware but relatively slow implementation in software. However, advances in CPUs have made it feasible to implement in software. DES is now considered to be insecure for many applications, mainly because of its small key size. Some other weaknesses have been proved in theory but remain infeasible to mount in practice.

Two variations of DES are Triple-DES (3DES) and DES-X (DESX). 3DES uses up to three 56-bit keys (to prevent brute-force attacks) and makes three encryption passes over each block (to prevent man-in-the-middle attacks). DESX was designed to increase the difficulty of brute-force attacks by XORing an extra 64-bit key to the plaintext before applying DES, and then XORing another 64-bit key after the encryption.

IDEA was developed by Xuejia Lai and James L. Massey of ETH Zurich and published in 1991. It was originally called IPES (Improved Proposed Encryption Standard). IDEA was designed to improve efficiency in software implementation. IDEA uses a 128-bit key and operates on 64-bit blocks as does DES. However, IDEA relates the encryption and decryptions keys in a more complicated manner. IDEA is patented by Ascom.

AES, also know as *Rijndael*, is a successor of DES and has replaced DES for many applications where 3DES was too slow. The algorithm was designed by Belgian cryptographers Joan Daemen and Vincent Rijmen. AES allows variable block and key sizes, and the latest specification allows a choice of any combination of block sizes and key sizes of 128 bits, 192 bits, or 256 bits.

Other secret-key cryptographic algorithms include *blowfish*—a 64-bit block cipher invented by Bruce Schneier, which is optimized for 32-bit processors with large data caches; *twofish*—a 128-bit block cipher using 128, 192, or 256 bit keys; and *CAST-128*—a DES-like substitution-permutation algorithm using a 128-bit key operating on a 64-bit block.

Public Key Cryptography

As secret key schemes require that the shared key(s) be exchanged before any secure communication can take place, an alternative that does not require prior preparation is appealing. *Public key encryption* makes use of two keys, a *public key*, used for encryption, and a *private key*, used by the recipient of a message to decrypt it. As the public key can only be used for encryption, it is safe for anyone to know and use, because all they can do is create a message that only the holder of the private key can decrypt. The two keys are related mathematically through a *trapdoor one-way* function—one that is easy to compute in the forward direction but hard to invert without the knowledge of the trapdoor (private key). The common (and widely used) example of such a trapdoor one-way function is *prime factorization*: It is easy to compute the product of two large prime numbers, but difficult to factor such a product, unless you already know one of the factors.

Public key schemes are used for a variety of purposes. The public key can be used to encrypt a message sent to the holder of the corresponding private key. The holder of a private key can use it to sign (encrypt a copy of) a message, which allows recipients to verify the signature using the public key. Public key schemes may also be used to securely exchange the shared keys needed for a secret key scheme. Secret key schemes are often markedly more efficient than public key schemes, so using public key encryption to exchange a (relatively small) key, which is then used to encrypt the bulk of the communications, is an effective use of computation resources.

The *Diffie–Hellman key exchange* is the earliest example in the literature. Rivest, Shamir, and Adelman developed what has become known as the *RSA* algorithm, perhaps the best known of public key schemes. More recent examples include *ElGamal* and the NIST Digital Signature Algorithm (DSA).

Hash Functions

Hash functions, also called *message digests* or *one-way transmissions*, are algorithms for creating small fixed-size digital "fingerprints" for any kind of data. The output of a hash function is called the *hash value*. Let H denote a hash function, m denote the input message, and h denote the hash value. Then $h = H(m)$. Hash functions used for security must be *one-way*; that is, given a hash value h, it is computationally infeasible to find an input x such that $H(x) = h$.

Besides the one-way property, properties required of hash functions include *randomness* and *collision free*. Randomness means that the resulting output should appear random and is not affected by the pattern of the message. Collision free means it should be computationally infeasible to determine two different messages with the same hash values (two different inputs with the same hash value is referred to as a *collision*). Collision-free hash functions protect message integrity because it will not be feasible to substitute a forged message for another message still produces the same hash value. Other properties of hash functions include *flexibility* (the function can be applied to messages of any block size), *convenience* (the function produces short output value), and *performance* (it is fast to compute a hash value).

Because of these properties, hash functions can be used to provide security services such as authentication of users, authentication of messages by generating a *message authentication code* (*MAC*), data integrity, and encryption. Because hash functions are not reversible, both encryption and decryption need to run the algorithm in the forward direction—usually a hash value is Exclusive-ORed with a message to produce the ciphertext, whereas the same hash value is Exclusive-ORed with the ciphertext to recover the original message.

The hash algorithms that are in common use today include:

Message digest (MD) produces a 128-bit hash from a message of arbitrary size. There are a series of MD algorithms, such as MD2, MD4, and MD5. MD2 was designed for systems with limited memory (1). It takes a message of an arbitrary number of octets and produces a 128-bit digest. MD4 was designed to be 32-bit word oriented for fast processing on 32-bit CPUs. MD4 can handle messages with an arbitrary number of bits, whereas MD2 requires the message to be an integral number of octets. MD4 was developed by Rivest. Also developed by Rivest to diminish potential weaknesses reported in MD4, MD5 makes more manipulation on the original data to achieve better security but with compromises on performance. MD5 has been implemented in a large number of products.

Secure hash algorithm (SHA) was proposed by NIST in the *secure hash standard* (*SHS*). The first member of the SHA family was published in 1993. SHA-1 was published two years later. It takes a message of at most 2^{64} bits long and produces a 160-bit hash value (2). Compared with MD5, SHA-1 is a little slower to execute but presumably more secure. SHS proposed four other versions of the algorithm: SHA-224, SHA-256, SHA-384, and SHA-512, which produce hash values of length 224-, 256-, 384-, or 512-bit, respectively.

RIPEMD is a series of hash functions that came from RACE Integrity Primitives Evaluation Message Digest. RIPEMD is based on the design principles used in MD4. RIPEMD-160 was developed by Hans Dobbetin, Antoon Bosselaers, and Bart Preneel, and first published in 1996. It is a 160-bit hash function and has similar performance to SHA-1. Other members of the RIPEMD family include RIPEMD-128, RIPEMD-256, and RIPEMD-320, which are 128-, 256-, and 320-bit versions of the algorithm, respectively. RIPEMD-256 only reduces the chance of accidental collisions and does not offer a higher level of security than RIPEMD-128. The reason lies in the fact that RIPEMD-256 is similar to RIPEMD-128 but initializes two parallel lines with different initial values and then exchanges a chaining variable between the two parallel lines after each round. Therefore, RIPEMD-256 does not introduce more complexity than RIPEMD-128 for attackers to launch *collision attacks* (to find two different inputs that will produce the same hash value). This feature also applies to RIPEMD-320 with respect to RIPEMD-160.

Some other hash functions include *HAVAL (HAsh of VAriable Length)*, a hash algorithm with many levels of security, and *Whirlpool*, a relatively new function.

Researchers have found collision attacks can be launched against MD5, SHA-0, RIPEMD, and other hash functions. Despite these attacks, there are many products that use these hash functions, and it will take years to substitute other functions (once such functions have been agreed on).

SECURITY SERVICES

Once cryptographic fundamentals are in place, one can deploy them as part of various services to provide security. Managing the keys for cryptography, authenticating users, and authorizing access to resources are all examples of such services. A clear distinction should be maintained between *authentication*, establishing a positive identification, and *authorization*, permitting a known individual to access some resource.

Key Management

Keys are an essential element of secure communications, and services must support their use. Services needed include generating keys (or key pairs in the case of public key systems); distributing keys—Alice must first obtain Bob's public key before she can encrypt a message using it; and storing keys—if we want to verify Alice's digital signature on a document, we need access to the public key corresponding to the private key she used to sign it. Such services provide a point of attack against cryptographic systems. If the stored keys can be compromised, then falsified documents can be sent and authentication efforts can be foiled. Often, discussions of system security assume that key management is secure—it is conducted by a *trusted third party*. Another (and necessary) service is the ability for users to revoke a key pair if their private key is ever compromised. The keys were (and remain) valid for messages transmitted prior to their revocation but can no longer be used for new messages.

Identity Authentication

A crucial service is authenticating the identity of an entity. When Alice and Bob communicate, they want to authenticate each other, because Eve might be masquerading as either of them. When users connect with a banking service, they want to be certain they are providing their PIN or password to their bank and not to someone who will use it to empty their account. *Phishing* attacks work by masquerading as a service provider and then collecting usernames, passwords, and other crucial information from victims. Authentication is usually by means of a *password* or *identity token* of some sort. Authentication testing relies on the information, physical item, or biological characteristic being unique to (and in possession of) the individual being identified. Iris scanning, fingerprinting, and DNA analysis make use of biological tokens. Keys, badges, or smart cards are physical items often used for authentication. Information tokens include passwords and such familiar security questions as, “What is your mother's maiden name?”

Password Authentication

A common approach to authentication in computer systems is the use of usernames and passwords. The system maintains a store associating usernames with passwords, and so long as a user provides a valid username and the corresponding password, they are authenticated (so far as the system is concerned). This approach assumes that the password has not been compromised. The simplest approaches transmit or store passwords in clear text. *telnet* and *ftp* were popular programs vulnerable because of cleartext passwords. Their use has largely been replaced by *ssh* or *sftp* (secure ftp). Common improvements on password based authentication include storage and transmission of passwords in a hashed form and the addition of *salt*, a random value hashed with the password. A good example is the LDAP (Lightweight Directory Access Protocol) Authentication Password Schema (3).

Digital Signatures

Similar to authentication of a user is the need to determine the author of a document. This determination is accomplished via digital signatures. Using an asymmetric encryption technique, Alice can sign a document using a hash of the document that she encrypts with her private key. Bob can verify the signature using Alice's public key. Assuming her private key has not been compromised, Alice cannot deny sending a message with her digital signature (*nonrepudiation*). As keys can be compromised, this a need then exists to revoke a public–private key pair. Documents signed with a key after revocation are no longer assumed valid.

SECURITY ATTACKS

A wide variety of attacks are aimed at breaking system security and privacy. To understand the need for certain defense mechanisms, it is vital to understand how a system might be insecure without it. In this section, we provide a brief discussion of different attacks.

Sniffing

Sniffing is a category of passive attack. An attacker can use a special program, denoted as *sniffer*, to passively monitor a computer network for key information without interfering much with normal activities in the network. The key information may be authentication information such as a password or any other information transmitted in packets such as IP address and TCP ports. In some case, even traffic characteristics of packets such as frequency, size, and interarrival time may be critical for security.

Sniffing's principle is simple. In a broadcast-based environment such as Ethernet, a network card can be used to monitor traffic on the media. If the frame's destination MAC address is the card's MAC address, the frame is accepted by the card and forwarded to upper layers of the protocol stack. Otherwise the network card discards the incoming frame. To deploy sniffing, a sniffer puts a network card into *promiscuous mode*, so that all frames on the network segment are accepted and captured. The sniffer generally listens on a special network programming socket, denoted as *raw socket*, and captures all packets. Typically sniffers run a protocol analysis of the captured packets and extract the interesting information. In a switched network, additional techniques are necessary to divert the traffic to a machine for capture and analysis.

A popular sniffing and protocol analysis tool is the open source Wireshark (www.wireshark.org, formerly known as Ethereal). Although Wireshark is available for both UNIX and Windows. Besides its sniffing capabilities, Wireshark is an excellent protocol analyzer of captured packets. Many other sniffing tools are tailored for special purposes, such as tcpdump (command line version of Wireshark), dsniff, ettercap, and Cain & Abel. Many of these tools are multipurpose programs, providing features in addition to sniffing.

Session Hijacking

Session hijacking is a category of active attack. In a session hijacking, an attacker puts herself in the middle of the communication path between a client and a server, takes over the communicating session, and pretends to be one of the participants. Session hijacking is usually an extension of sniffing.

An attacker may use a variety of other attacks to redirect the traffic through her own box. These attacks may include ARP poisoning, MAC flooding, port stealing, DHCP spoofing, DNS spoofing, and various routing games such as ICMP redirect. Once an attacker puts herself between the client and the server, she can change the content of a session. For example, if the client is downloading software, the attacker can attach a Trojan horse code to the download. An attacker may also hijack SSL and SSH sessions by providing fake certificates. Session hijacking may be used against both TCP and UDP sessions. To hijack TCP sessions, the attacker must make an extra effort to deal with sequence numbers and other TCP details.

Popular hijacking tools include ettercap, dsniff, and hunt. Ettercap runs on most popular systems such as Linux and Windows. Ettercap on Linux is stable. It is a multipurpose program used primarily for sniffing, capturing, and logging traffic on switched LANs by using attacks such as ARP poisoning. For example, ettercap can redirect an HTTP session through its host and change the HTTP page.

Spoofing

Spoofing is a category of active attack. In such an attack, an attacker intentionally "provides false information about a principal's identity in order to obtain unauthorized access to systems and their services" (4). In an IP spoofing attack, the attacker changes the source IP address within the IP header of a packet so that the packet source IP address can be random and the packets appear to have come from a different source other than the real sender. This is a simple way for an attack over a network to obscure its origin. E-mail headers are also easy to spoof so that the e-mail appears to be sent from another person. A web page may also be spoofed so that users think they are accessing a known site, but actually they are receiving web pages controlled by an attacker. This can be achieved in the following way: Recall the DNS service maps website names to their IP addresses. An attacker may use DNS spoofing to redirect user requests to a malicious website by replying to DNS requests with the IP of the malicious site rather than the IP of the actual site.

Password Cracking

In modern computer systems, passwords are not stored in clear text in case attackers break into the system and obtain the password store. Passwords are normally hashed and then stored with user names as indexes. Even when passwords are stored in a hashed form, if an attacker obtains the list of hashed passwords, they can use either a dictionary attack or a brute force attack to retrieve the original passwords.

In a dictionary attack, an attacker first obtains a list of common passwords. Those common passwords might be common names, words, place names, or acronyms. Then the attacker hashes all those common passwords and compares them with the victim's password hash. If there is a match, the attacker obtains the original password. The attacker may precompute hashes of these common passwords to speed the password cracking. If a dictionary attack does not work, the attacker may also resort to a brute force attack. In a brute force attack, the attacker tries all combinations of password elements such as letters, numbers, and special symbols until there is a hit.

A cracking dictionary might contain a great number of common words, names, and variations, and the size of such a popular dictionary could be over 19 MB. Therefore, it is important to choose a good password (i.e., one incorporating random elements) because it is just a matter of time for an attacker to crack the hashed password. A good password will greatly increase the cracking time and extend the life span of the password. Choosing an appropriate hash function is also important. Popular hash functions include DES (by early UNIX systems) and MD5. MD5 is safer than DES because MD5 creates a hash of 128 bits and generates a much larger password pool.

Popular password cracking tools include John the Ripper, Crack, L0phtCrack, and Cain & Abel. John the Ripper is a powerful password cracking tool that works under both UNIX and Windows.

Denial of Service

A *denial-of-service* (*DoS*) attack is a category of active attack. In a DoS attack, an attacker tries to exhaust a limited resource available to users. Basically, if some resource is limited, the attacker may use a variety of approaches to use it up so that no one else can access it. Thus, access to the resource is denied to authorized users.

An attacker may attack a resource locally. Those resources may include the local system process table, CPU time, disk space, and index node (*inode*) of a UNIX system. An attacker may also attack a resource remotely. These resources may include the entire remote system, a specific service, or network bandwidth. For example, in a ping of death attack, an oversized ping packet could cause a remote Windows 95 system memory leakage and crash the system. In a SYN flood attack, flooding SYN packets arriving at a host may overfill the TCP half-open connection buffer so that no more legal connections will be allowed.

Distributed Denial of Service (DDoS)

The *distributed denial-of-service* (*DDoS*) attack uses multiple attacking entities to prevent the legitimate use of a service. On the Internet, each entity such as a host, network, and service has limited resources. If these resources are consumed by too many users, no more users can access them. Because of the administration and privacy requirements, security mechanism deployment on the Internet is often not coordinated across multiple domains; yet Internet security is highly interdependent, which is why an attacker may deploy a DDoS attack on the Internet.

A DDoS attack has two phases. First, attackers compromise several hosts. These hosts become *masters*, which are also called *handlers*. Masters then compromise hundreds or even thousands of additional hosts, called *zombies*, and install DDoS flooding tools on the zombies. Zombies are also called *daemons*, *slaves*, or *agents*. This compromising process is normally automated and searches for a large number of vulnerable hosts, such as those without recent security patches. When attackers are ready to attack, a signal is transmitted from masters to all zombies, which all generate attacking traffic to throttle the target. Using masters allows attackers to hide their origin. To further hide their traces, attackers may access masters through a sequence of stepping stones, i.e., intermediary compromised machines, which may be scattered around countries across different continents. IP spoofing is often used by zombies to further obscure the attackers.

Popular DDoS tools include trinoo, Tribe Flood Network (TFN), Tribe Flood Network 2000 (TFN2K), stacheldraht, shaft, and mstream. TFN is made up of client (master) and zombie programs and is capable of deploying ICMP flood, SYN flood, UDP flood, and Smurf style attacks. It can also work as a backdoor and provide an "on-demand" root shell bound to a TCP port.

Cryptanalysis

Cryptanalysis is an attack that may retrieve secret information such as the encryption key from ciphertext (encrypted message). Four types of cryptanalysis exist. The *ciphertext only* cryptanalysis refers to the case where only ciphertext is available for an attacker. The *known plaintext* cryptanalysis refers to the case where a <plaintext, ciphertext> pair is available. The *chosen plaintext* cryptanalysis refers to the case where the attacker introduces specific plaintext and obtains the corresponding ciphertext. The *chosen ciphertext* cryptanalysis refers to the case where the attacker chooses a ciphertext and decrypts it with an unknown key in such a scenario as an unattended decryption machine. The above four cases are roughly ordered by the amount of information available to the attacker.

Many concrete cryptanalysis attacks exist. *Frequency analysis* is the study of the frequency of letters or groups of letters in a ciphertext. The method is very useful against mono-alphabetic ciphers such as the Caesar cipher, which does not change the plaintext character frequency in the ciphertext. In English, "e" tends to be common, whereas "q" is rare. Likewise, "st," "ng," "th," and "er" are common pairs of letters. So if "m" has the highest frequency in the ciphertext of a mono-alphabetic cipher message, it is highly possible that ciphertext "m" corresponds to plaintext "e." *Linear cryptanalysis* and *differential cryptanalysis* are two widely applicable attacks on modern block ciphers.

DEFENSE MECHANISMS

We have discussed a variety of attacks. Various security systems and protocols have been designed to combat those attacks. In the following discussion, we introduce a few of them, which may achieve security goals such as confidentiality, integrity, authentication, and nonrepudiation to different extents.

Kerberos

Kerberos is an authentication system developed at MIT, which uses secret key cryptography. The system is available for both UNIX and Windows platforms. The Kerberos protocol is named after the three-headed dog, Kerberos, from Greek mythology. The protocol also consists of three parts: the Key Distribution Center (KDC), the client (also known as the *principal*), and the server with the service the principle wishes to access. The KDC maintains a centralized authentication mechanism and provides two functions: Authentication Service (AS) and Ticket-Granting Service (TGS).

Kerberos is based on the Needham–Schroeder Protocol with minor modifications. In Kerberos, if a user wants to use a service available on a target server, the authentication follows the following procedure:

1. AS Exchange: The client and KDC share a secret key, which can be derived from the client password hash. The client sends a request of Ticket to Get Tickets (TGT) with her name to KDC. KDC searches for the client name in the centralized database, and AS replies to the client request. The AS reply has two sections: a TGT (encrypted with a key known only to TGS) and a session key (encrypted with the shared key between the client and KDC) to handle future communications between the client and KDC.
2. TGS Exchange: If the client wants to use the service, she sends the TGT to TGS, which decrypts this TGT. If approved, a service ticket is generated by TGS and sent to the client. The service ticket has two portions: client portion and server portion, both containing the same secret for the client and the server. The client decrypts the client portion of the service ticket by using the TGS session key obtained from the earlier AS reply. The client blindly sends the server portion of the TGS reply to the target server.
3. Client/Server Exchange: The server decrypts the server portion of the service ticket from the client by using its own long-term key with the KDC. Then an authentication protocol such as the challenge-response protocol based on the secret key cryptography can be used to authenticate the client. A service session is then built between the server and client.

IPsec

IPsec (Internet Protocol Security) is a set of protocols that support secure communication at the network layer. It was developed by the International Engineering Task Force (IETF) (5), to provide "interoperable, high quality, cryptographically-based security" for IPv4 and IPv6. IPsec can provide security services such as access control, connectionless integrity, data origin authentication, anti-replay service, and data confidentiality.

IPsec can be run in two encryption modes: *transport mode* and *tunnel mode*. Transport mode encapsulates only each packet's payload and provides secure connections between two endpoints in a network, or an endpoint and a gateway, if the gateway serves as the destination host. Tunnel mode encapsulates the entire IP packet (including not only the payload but also the header) and thus provides a secure path between two gateways. Tunnel mode is used to deploy a Virtual Private Network (VPN) as a secure virtual tunnel that can be established across the untrusted Internet.

IPsec provides two security services: *Authentication Header (AH)* (6) and *Encapsulating Security Payload (ESP)* (7). AH provides authentication, integrity, and optional anti-replay services, whereas ESP may provide all of the above as well as confidentiality (encryption). AH and ESP can be used alone or in combination with each other to provide desired security services.

In AH protocol, an authentication header is inserted between the IP header and the higher layer protocol header such as TCP and UDP (transport mode), or between a new IP header and the original IP header (tunnel mode). The authentication header contains a cryptographic hash-based message authentication code over nearly all the fields of the IP packet.

The ESP header is inserted after the IP header and before the higher layer protocol header (transport mode) or before the encapsulated entire IP packet (tunnel mode).

Both ESP and AH rely on *security associations* (SAs), which are collections of connection-specific parameters that specify some shared secrets such as key, algorithm, and policies to use. These secrets are established to seed the authentication function and to key the encryption algorithm. SAs are stored in the Security Associations Database (SADB).

IPsec Key Management

Encryption and authentication keys are used in IPsec for encoding and decoding. The two parties using IPsec in their communication share and exchange the keys that their security protocols use. Key management is an essential and important issue for IP security. The primary security protocol that supports this purpose is called "Internet Key Exchange" (IKE).

IKE allows IPsec-enabled devices to exchange their security associations to populate their security association databases. IKE is considered a "hybrid" protocol because it combines three key management protocols: ISAKMP (Internet Security Association and Key Management Protocol), Oakley, and SKEME.

ISAKMP is a generic protocol that supports many different key exchanges. It also defines the procedures for authentication, creation and management of SAs, key generation, and provisions for DoS and replay attacks.

Oakley describes a specific mechanism for key exchanges through definition of various key exchange modes. The keys generated using Oakley might be used to encrypt data with a long privacy lifetime, e.g., 20 years or more. Oakley is used to establish a shared key with an assigned identifier and associated authenticated identities for the two parties.

SKEME uses a different key exchange mechanism than Oakley. It provides several modes to perform fast and frequent rekeying. SKEME provides scalability and flexibility to key exchanges.

Several other key management protocols have been proposed, such as SKIP and Photuris. SKIP (Simple Key-management for Internet Protocols) is a key management protocol for sessionless datagram-oriented protocols such as IPv4 and IPv6. Photuris is a session-key management scheme that is used with AH and ESP. Photuris is primarily used for creating VPNs, establishing sessions for mobile nodes over bandwidth-limited channels, and short-lived sessions between a great number of clients and servers.

IP Traceback

DoS has become a pressing problem for today's Internet. DDoS has even more impact than DoS because a DDoS attacker uses many compromised slave systems to increase the impact when attacking. Highly automated attack tools have been developed and used to falsify the source ID supplied in the IP packets (called IP spoofing) obscuring the origin of the attack. The problem of finding the source of an IP packet is called *IP traceback*, and most IP traceback approaches have targeted DoS attack detection.

A brute force solution to traceback is to have every router mark every packet or keep a record of each packet as it is transmitted. However, this solution is not feasible because of the storage space and performance overhead required.

Most existing IP traceback approaches try to store some information about packets either in routers along the way or in the packet itself, and to reduce space and communication overhead. Some approaches are probabilistic, and some are deterministic. These approaches fall into four categories: *packet marking, logging, link testing,* and *ICMP-based traceback*.

Packet marking approaches work by inserting traceback data into the packet to be traced, to mark the packet when it passes through routers on its way to the destination. Stefan Savage et al. (8) proposed a Probabilistic Packet Marking (PPM). In PPM, routers mark the packet with low probability (e.g., 1/20,000), with either the router's IP address or the edges of the path that the packet has traversed before reaching the router. When enough packets are received, all edges and all fragments will be collected to reconstruct the attack path. The low probability of marking reduces associated overhead. Several modified PPM approaches have also been proposed.

Logging is an intuitive solution to establish the true origin of attack traffic. It logs packets handled by key routers throughout the Internet and then uses data mining approaches to extract information about the attack path. This approach allows accurate analysis of attack traffic, but the amount of processing and storage space for the logs is very demanding.

Link testing methods work through hop-by-hop tracing. The testing is started from the victim, and upstream links are tested to determine which one carries the attack traffic. The testing is recursively repeated until it reaches the origin of the attack. Link testing can only be carried out while an attack is active.

The ICMP-based traceback was proposed by Steven Bellovin. It works by probabilistically sending an ICMP traceback packet to the destination with a low probability (say, 0.005%). These ICMP packets contain partial path information, including information that indicates the origin of the packet, the time when it was sent, and its authentication. The low probability suppresses the processing overhead and the bandwidth requirement.

While traceback approaches have been deployed, other efforts are made to restrict illegitimate packets, such as *ingress filtering*. Ingress filtering restricts spoofed packets at ingress points by blocking traffic except from authorized source networks that can use the router.

SSL/TLS

Secure Sockets Layer (SSL) and its successor, *Transport Layer Security* (TLS), are cryptographic protocols that provide secure communications on the Internet.

SSL was developed in Netscape Navigator in 1995 and is now used by both Netscape and Internet Explorer. Many web services use SSL to protect communications between clients and servers, especially when clients need to provide confidential information such as credit card numbers. An example of the protocols for this service is *https*. Numerous other SSL-enhanced protocols (e.g., SSLtelnet, SSLftp, or stunnel) also take advantage of SSL. Two versions of SSL, versions 2 and 3 (v1 was only used internally at Netscape and was never released), are commonly used, and v3 is rapidly replacing v2.

TLS was developed by the IETF, based on and extending SSLv3.0. It is not compatible with SSL. TSL 1.1 is the current approved version of TLS. TLS 1.1 is very similar to TLS 1.0, but version 1.1 uses a modified format of encrypted RSA premaster secret, which is done to prevent an attack found in TLS 1.0.

SSL/TLS runs on top of TCP and beneath application protocols such as HTTP, FTP, and SMTP. The protocols use two keys, a public key and a secret key. SSL/TLS provides security services such as authentication, confidentiality, and integrity. It has two layers: *record protocol* and *handshake protocol*. The record protocol ensures that communication privacy is protected by using symmetric encryption and ensures the communication is reliable. The handshake protocol allows the server to authenticate itself to the client with public key cryptography and then allows the negotiation of symmetric cryptographic keys before the transmission. The reason for using a combination of public key encryption and symmetric key encryption is that public key encryption provides better authentication, whereas symmetric key encryption provides better performance. The handshake protocol involves four phases:

1. *Hello*—the client sends a *clientHello* message specifying a list of cipher suites, compression methods, and the highest version it supports. Then the server chooses from among the connection parameters that the client has offered and sends the choices back in a *serverHello* message.
2. *Server key exchange and authentication*—the server sends a certificate and a server_key_exchange message. The currently used certificates are based on X.509, but specifications for the use of OpenPGP based certificates are also available.
3. *Client key exchange and authentication*—the client sends a certificate if the server asked and a client_key exchange message. A certificate_verify message is also sent.
4. *Finish*—client and server send wrap-up messages.

In SSL/TSL, authentication is provided only on the server's side. To provide mutual authentication, PKI (public key infrastructure) needs to be deployed at the client.

Firewalls

A firewall is a system that sits between a private network (or a computer) and the rest of the network and attempts to keep malicious traffic away from the private network. All traffic entering or leaving the private network must pass through and be examined by the firewall, which will block traffic that does not meet the specified security criteria. Firewalls can provide controlled access to network information and protect against risks such as DoS, unauthorized access, or modification of internal data. Firewalls cannot protect against internal traffic or traffic that routes around the firewall.

A firewall can be implemented in hardware or software, or a combination of both. It must be configured correctly to function properly. Generally speaking, three types of firewall techniques exist:

Filter—deployed at the ISO network layer. Two types of filtering exist: *packet filtering* and *session filtering*. In packet filtering, decisions to blocking or transmit is made on a per-packet basis. No state information is examined or maintained during the filtering. Therefore, the firewall does not know whether a packet belongs to an existing connection or is trying to establish a new one. This type of firewall is also called *stateless*. An example of packet filtering is Linux iptables. The firewalls that use session filtering are *stateful firewalls*. That is, they extract and maintain "state" information of connections. In session filtering, decisions are made based on the context of the connection. If a packet is a new connection, the firewall will check against security policy; if the packet is part of an existing ongoing connection, the firewall will look it up in a state table and an update table, which maintain the state information. Filtering is fairly effective and transparent to users, but it is susceptible to IP spoofing and difficult to configure.

Circuit-level firewalls (or gateways)—applies security policies when a TCP or UDP connection is established. Once the connection has been established, the packets of the connection will be allowed through without additional checking. An example of a circuit-level gateway is SOCKS.

Application firewalls (or gateways)—applies security mechanisms to specific applications, such as telnet, ftp, or http servers. An application firewall examines packets more thoroughly and therefore is considered more secure than a circuit-level firewall. But application firewalls cost more in terms of money and resources. Another disadvantage of application gateways is that they may not be applicable to all types of connections.

Both application firewalls and circuit-level firewalls use proxy servers, which sit between the two hosts or networks and intercept all messages passing through. External hosts will establish connections with the proxy server, and the proxy server performs communications with the internal hosts. Proxy servers can hide the topology of a private network so that the external hosts only see the IP address of the proxy server and can only communicate with the internal hosts through the proxy. However, transparent application gateways have been introduced, which means the internal hosts do not have to be aware of the existence of a proxy server or to run special software to communicate with the server.

Secure Email

To understand the necessity of securing e-mail, we need to review how an e-mail message is sent and received. When a sender sends an e-mail, the sender's e-mail client software such as Thunderbird uses *Simple Mail Transport Protocol* (*SMTP*) to contact the sender's SMTP server. The sender's SMTP server relays the e-mail to the recipient's SMTP server, which delivers the e-mail to the inbox of the right e-mail account. The e-mail may be stored on any intermediate SMTP servers for later forwarding. Then a recipient uses *Post Office Protocol* (*POP*) or *Internet Message Access Protocol* (*IMAP*) to download a message stored at the recipient's SMTP server. In the case of webmail, the sender and recipient communicate to their respective SMTP servers through a *webmail server*. A sender first uses the HTTP protocol to put messages on the webmail server, which contacts its SMTP server for delivery. The recipient may have a webmail server, which uses POP/IMAP to download the user message to the webmail server. Then a recipient may use HTTP to get access to e-mail messages.

Normal e-mail messages are transmitted on the wire and stored at intermediate servers in cleartext. SMTP, POP, IMAP, and webmail may ask a user to input user name and password, which may lead to identity theft. To protect the user name and password, SSL should be used between a user and the corresponding SMTP server. Most modern SMTP servers and e-mail client software provide this capability. In the case of webmail, HTTPS should be used.

SSL only protects the e-mail path between a user and the corresponding SMTP server. Beyond that, the e-mail is still stored and transmitted in cleartext. To provide the end-to-end content protection, we may use S/MIME and PGP. Both protocols use public key cryptography. Each user has a key pair <public key, private key>. If Alice wants to send a message to Bob, Alice uses Bob's public key to encrypt the message and Bob uses his private key to decrypt the message. E-mail content confidentiality is maintained in this way. Alice may also use her own private key to create a hash of the message in order to use as a digital signature to her e-mail. Then Bob can use Alice's public key to decrypt the signature (encrypted email hash), compute his own version of the e-mail hash, and compare these two hashes. If they match each other, the message integrity is verified. This process is called *signature verification*. Such signatures also support authentication of Alice and nonrepudiation.

S/MIME is built into many e-mail clients like Microsoft Outlook, but a certificate needs to be bought from a third-party company such as Thawte.com or Verisign.com. PGP is open source and available for free. Enigmail is an extension to the mail client of Mozilla/Netscape and Mozilla Thunderbird, which allows users to access the authentication and encryption features provided by GnuPG for secure e-mail.

Virtual Private Networks (VPNs)

A VPN is a secure tunnel from a remote site, through the Internet, to the user's home network. When a VPN client logs onto a VPN server within a domain, the client computer will work as though it is in the same domain as the server. A VPN server can act as a gateway into a whole network or to a single computer. It listens for VPN clients attempting to connect to it. Using VPN, we can transparently integrate several physically separate working systems on the Internet as a single (virtual rather than physical) local network.

A VPN client may communicate with a VPN server with either of two protocols: the Point-to-Point Tunneling Protocol (PPTP) or Layer Two Tunneling Protocol with Internet Protocol security (L2TP/IPSec). PPTP has good encryption coupled with the function of user authentication. IPSec is safer because of its sophisticated encryption schemes but does not include authentication routines. L2TP is IPSec with authentication built in.

There are VPN servers for both Linux and Windows. Linux uses *iptables* and other software packages. Setting up a VPN server on a Windows XP Professional is straightforward. Many VPN client software packages exist.

Intrusion Detection

According to Amoroso in *Wykrywanie intruzów*, "intrusion detection is the process of identifying and responding to malicious activity targeted at computing and networking resources." An intrusion detection system (IDS) can be classified based on different criteria. Based on where an IDS is positioned, there are host based IDS (HIDS) residing on a single host and protecting that host, network based IDS (NIDS) monitoring an entire network segment, and perimeter IDS residing on a gateway or edge router and monitoring traffic between networks, usually an intranet and the Internet.

An IDS can also be classified based on intrusion detection approaches. An IDS may use anomaly detection, so host or network behaviors deviating from normal daily routine may be identified as suspicious. An IDS may also use attack signatures for detection. Packets and software for attacks often have unique patterns, such as special code that may cause a specific buffer overflow. Such patterns serve as the signature of an attack. Different attacks have different signatures. An IDS using signatures maintains a database of those signatures. An IDS may analyze audit trails, log files, processes, and network traffic for anomaly detection or signature detection.

There are a lot of commercial and open-source IDS tools such as Internet Security Systems' RealSecure IDS, Cisco's Secure IDS, and snort. Snort is a popular network intrusion open-source package. It allows a user to specify a set of rules that include the patterns to be detected in packets, along with corresponding IDS actions such as an alert for matched packets. A large database of rules for known attacks is included. Snort also allows the user to create custom plug-ins to extend detection beyond that available through the default pattern matching. Snort is used by many other packages and products. A packet passes through phases in Snort's detection engine: packet acquisition, packet decoder, preprocessor, detection engine, and intrusion report. Snort is often coupled with a database for storing alert data and an interface such as the Basic Analysis and Security Engine (BASE) for user-friendly alert display and data management.

Digital Forensics

Digital forensics involves obtaining and analyzing digital information for use as evidence in civil, criminal, and administration cases. There are a few phases during a digital forensics process (9): (*1*) Notification: an incident is detected, and the response team is informed; (*2*) preservation: make an exact copy of the digital crime scene; (*3*) survey: examine the crime scene for obvious pieces of digital evidence; (*4*) search: a more thorough search for additional evidence to support or refute hypotheses; (*5*) reconstruction: test the existing evidence and hypotheses to form a final theory; and (*6*) presentation: the final theory is presented to the parties requesting the investigation.

Digital forensics includes computer forensics and network forensics. Computer forensics is concerned with recovering, searching, and preserving digital evidence from floppy disk, hard disk, memory, CDs, and other media. The task of network forensics includes analysis of network traffic for violation evidence and traceback to the attacker. This task is where network forensics differs from intrusion detection, which focuses on detection of intrusions. For example, in the case of an e-mail Trojan horse, intrusion detection is concerned with detection and thwarting such a threat, whereas network forensics is also concerned with finding the source of the malicious e-mail.

Digital forensics is an active frontier for cyber security. Researchers and companies have been developing sophisticated software for safely preserving and recovering evidence from digital data. Tools include AccessData's Forensic Toolkit (FTK), Digital Intelligence's Encase Forensic Edition, and X-Ways Forensic Addition. These tools provide an integrated environment for recovering a variety of evidence such as deleted files from a storage media.

WIRELESS NETWORK SECURITY

Wireless technology provides a user the capability of communication with great flexibility and freedom. Wireless networks have been rapidly extending their capabilities and are becoming the communication infrastructure of choice. Wireless communication channels are also interoperable with the traditional Internet. With the increasing use of wireless technology, the security of wireless networks has become a serious concern.

The risk to users of wireless networks has been increasing exponentially as the service becomes more and more popular. Any security threats that exist in conventional wired networks also exist for wireless networks. Wireless networks use open shared media, and in many cases, communication is broadcast, making wireless networks more vulnerable to attacks such as eavesdropping, DoS (including signal jamming on communication channels and bogus requests and messages injection at the network level), identity theft, masquerading, and unauthorized access to wireless devices or networks. Besides these threats, malicious entities can also intrude on the privacy of legitimate users and track their physical movements.

Wireless networks are usually categorized into three types based on their coverage range: Wireless Wide Area Networks (WWANs), Wireless Local Area Networks (WLANs), and Wireless Personal Area Networks (WPANs). WWANs include wide area technologies such as 2G cellular, Global System for Mobile Communication (GSM), Cellular Digital Packet Data (CDPD), and Mobitex.

The IEEE 802.11 standard, the original WLAN standard, was first developed in 1997 to support medium-range, higher data rate applications and to address mobile and portable stations. The standard uses WEP and WPA to protect it security.

Wired Equivalency Privacy (WEP) was the original encryption standard for wireless communications. WEP comes in different key sizes. The commonly used key lengths are 128 and 256 bits. WEP intended to make wireless networks as secure as wired networks, but security flaws have been discovered and exploited. A demonstration held by a group from the FBI showed that publicly available tools can be used to break a WEP protected network, and it took only three minutes. WEP protection is better than nothing, but deployment of WPA encryption can be more secure.

WPA stands for *Wi-Fi Protected Access*. It is an early version of the 802.11i security standard and was developed by the WiFi Alliance to replace WEP. WPA has two improvements over WEP: improved data encryption through the temporal key integrity protocol (TKIP), and it provides user authentication, which is generally missing in WEP, through extensible authentication protocol (EAP).

Bluetooth is an industrial specification for WPAN. Bluetooth dynamically connects remote devices such as PDAs, cell phones, and laptops. Bluetooth provides security services such as authentication, confidentiality, and authorization. As with the 802.11 standard, Bluetooth does not address other security services such as nonrepudiation or audit. Bluetooth offers several security modes, and device manufacturers determine which mode to include in a Bluetooth-enabled device.

Besides wireless cellular networks that rely on an infrastructure of non-mobile access points (such as base stations), wireless networks without infrastructure, a mobile ad hoc network (MANET), have also been widely studied. MANETs are defined as peer-to-peer networks between mobile devices that do not have an access point in between. Mobile ad hoc networks are characterized by the absence of a fixed infrastructure, rapid topology change, and high node mobility. Absence of infrastructure makes ad hoc networks more difficult to secure, because it is hard to deploy control points. Additionally, limits on energy consumption, computation resources, and bandwidth force ad hoc network security mechanisms to be lightweight in both computation and communication. Asymmetric cryptography is usually considered too expensive for MANETs. Symmetric cryptographic algorithms and one-way functions are commonly used to protect data integrity and confidentiality.

A wireless sensor networks (WSN) is a large-scale mesh network that consists of a great number of small sensor nodes communicating via radio. WSNs can be applied in areas such as military, home, and health. Compared with ad hoc networks, WSNs tend to have even more rapidly changing topology, even severe constraints on power, computation, and space. Communications in sensor networks are usually broadcast, whereas most communication in an ad hoc network is point-to-point. End-to-end encryption is impractical in sensor networks. Usually hop-by-hop encryption mechanisms are used, in which sensor nodes store encryption keys with their immediate neighbors.

ACKNOWLEDGMENT

The book chapter is a brief survey of network security fundamentals. During the writing, we have referred to many online sources, articles, and books. We thank those authors for their brilliant work.

OPTICAL COMMUNICATION

Optical communication is a form of telecommunication that uses light as the transmission medium.

For most of human history, long-distance communication posed many challenges. Optical communication in its primitive form played a crucial role. In ancient China, the beacon towers on hilltops of the Great Wall that spans more than 4000 miles often played a key role in military communication in ancient war times. Once the enemy pressed toward the border, the signal from the beacon tower would be sent by beacon (fires or lanterns) during the night or by smoke signals in the daytime. When the city of Troy fell, the ancient Greeks learned the news from a system of fire beacons on adjacent islands that carried a prearranged signal nearly 400 miles. In the eighteenth century, a French visionary named Claude Chappe built a series of towers, each adorned with giant arms that could be clearly seen with a telescope from adjacent towers. These arms would be positioned differently to represent the various letters of the alphabet, and in this fashion, messages could be passed from tower to tower and across the whole of France. Over 100 years ago, Alexander Graham Bell invented the "photophone," an ingenious system that was beyond his time for sending sound on a light beam. This important invention is recognized as the progenitor of the modern fiber optical communication that carries an increasing amount of the world's telecommunication traffic.

Today, optics-enabled visual communication is still widely used in our daily lives. For example, aircrafts use the landing lights at airports to land safely, especially at night and under adversary weather conditions. Aircrafts landing on an aircraft carrier use a similar system to land correctly on the carrier deck. Ships often use a signal lamp to signal in Morse code or use international maritime signal flags to exchange messages. Distress flares are used by sailors in emergencies, whereas lighthouses and navigation lights are used to communicate navigation hazards.

In general, an optical communication system consists of a transmitter or a light source that encodes a message into an optical signal, a channel, or a waveguide that carries the signal to its destination, and a receiver that reproduces the message from the received optical signal. The modern guided optical communication is based on the light's total internal reflection principle, explained by the Snell's Law, which has been known for centuries and was used to illuminate streams of water in elaborate public fountains in Victorian times. The development of modern optical communication is indebted to technological breakthroughs and improvements realized in several areas: light source—LED and laser, materials and the manufacturing of low-loss lightwave guides—optical fibers, and other components and devices essential for effective optical transmission and communication as well as sophisticated electronics and signal processing techniques.

Optical fiber offers much higher bandwidths [nearly 50 terabits per second (Tb/s)] than copper cables and is less susceptible to various kinds of electromagnetic interferences and other undesirable effects. It possesses a lot of nice properties: low signal attenuation (as low as 0.2 dB/km), low signal distortion, low power requirement, low material usage, small space requirement, and relatively low cost. Optical fiber transmission has played a key role in increasing the bandwidth of telecommunications networks, especially in the last 20 years as the Internet has penetrated our daily lives. In the first-generation optical networks, optical fiber was used purely as a transmission medium, serving as a replacement for copper wires, and all the switching and processing of the bits were handled by electronics. These optical networks are widely deployed today in all kinds of telecommunications networks. Examples of first-generation optical networks are SONET (synchronous optical network) and SDH (synchronous digital hierarchy) networks, which form the core of the telecommunications infrastructure in North America and in Europe and Asia, respectively, as well as a variety of enterprise networks. Incorporating some switching and routing functions that were performed by electronics into the optical part of the network, the second-generation and future generation optical networks are capable of providing more functions than simple point-to-point transmission, for example, lightpath service, dynamic service provisioning, and so on. Optical communication networks will essentially serve as optical transport networks (OTNs) that enable everything over optics integration, e.g., IP over WDM (wavelength division multiplexing) integration, leading to the building of the next-generation optical Internet.

The applications of optical communication are abundant, including short-distance interconnection inside computers, digital optical audio cables, optical transport networks, backhaul networks that carry traffic and network control information between wireless base stations and other network elements, medical applications (such as gastroscope, endoscopy, and laparoscopic surgery), industrial fiberscope or borescope for inspecting anything hard to reach (such as jet engine interiors), and fiber-to-the-curb (FTTC) or fiber-to-the-home (FTTH) as a solution to the first-mile problem.

There are two main types of optical communications based on the medium or optical waveguide that optical signals traverse: (1) fiber optical communication and (2) free-space optical communication.

THE BASIC COMPONENTS

The research on optical communications was started substantially in 1960 by the invention of the laser and followed by studies simultaneously in three facets: light source, transmission line, and light detector. The optical communication system is composed of optical fiber to transmit light, laser to emit light, photodiode to detect light, and

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

various optic components to control the flow of light signals. In particular, the optical fiber has provided significant motive power to the growth of optical communications, because of its low loss and enormous capacity of signal transmission in the single mode fiber, excellent mechanical properties such as small diameter, and adequate tensile and bending strength.

Optical Fiber

The optical fiber works on the principle of total internal reflection. Total internal reflection is an optical phenomenon that occurs when light crosses materials with different refractive indices. When the light in the material with a larger refractive index strikes the medium boundary with a large enough angle of incidence with respect to the norm, the light will stop crossing the boundary altogether and instead totally reflect back internally. The development of optical fiber as the waveguide for effective signal transmission did not occur until the 1950s. At that time, researchers focused on the development of fiber bundles for image transmission, primarily for medical applications such as flexible gastroscopes. The first fiber optic semiflexible gastroscope was invented by Basil Hirschowitz, C. Wilbur Peters, and Lawrence E. Curtiss, researchers at the University of Michigan in 1956. Initially, optical fibers had relied on air as the low-index cladding material. During the development of the gastroscope, simply bundling a large number of such optical fibers together resulted in the loss of total internal reflection as well as the image transmitted. This loss prompted Curtiss to invent the first glass-clad fibers that use a layer of low-index glass as the cladding material that wraps the high-index glass core (Fig. 1).

However, fiber attenuation that light dims significantly after passing through just a few meters of glass was a big problem. In 1965, Charles K. Kao and George A. Hockham, then of British company Standard Telephones and Cables, first recognized that attenuation of contemporary fibers was caused by impurities in glass rather than by fundamental physical effects such as scattering, and they suggested how signal loss could be greatly reduced so that optical signals could run for kilometers instead of just a few meters. In a paper published in 1966, they reported, in concrete terms, on the potential of massive optical communications, through estimation of transmission capacity of optical fiber and transmission distance derived from the magnitude of expected loss and acceptable light power. They demonstrated that optical fiber could be a practical medium for communication if the attenuation could be reduced below 20 dB per kilometer. Subsequently, researchers Robert D. Maurer, Donald Keck, Peter Schultz, and Frank Zimar of American glass maker, Corning, Inc., developed a low-loss optical fiber with 17-dB/km optic attenuation in 1970 by doping silica glass with titanium, to make a long stride to the commercialization of low-loss, large-capacity optical fiber communication. In 1977, General Telephone and Electronics (GTE) sent the first live telephone traffic through fiber optics in Long Beach, California. The first transatlantic telephone cable using optical fiber went into operation in 1988.

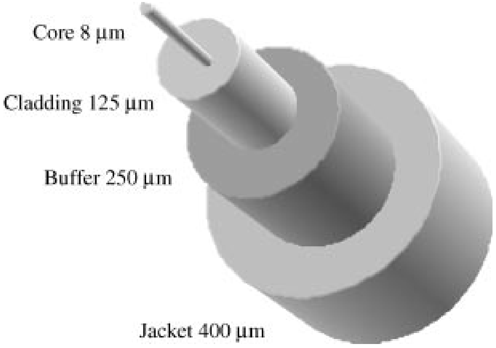

Figure 1. A typical single-mode optical fiber with diameters of the component layers.

Optical fiber is a composite material constructed of two layers of glass or plastic (Fig. 1). Typically optical fiber consists of a silica-based core and cladding surrounded by one or two layers of polymeric material that provides mechanical protection of the glass surface. The inner layer, the core, has a higher refractive index than the outer layer, the cladding. Light injected into the core and striking the core-to-cladding interface at greater than the critical angle will be reflected back into the core. Two basic types of fiber exist: multimode fiber and single-mode fiber. Figure 1 shows a typical single-mode fiber with component layers. A mode is a path that a light signal takes through a fiber. Modes result from the fact that light will only propagate in the fiber core at discrete angles within the cone of acceptance.

Multimode Fiber

A multimode fiber is one in which the guided light ray takes different paths through the fiber. Multimode fiber, the first to be manufactured and commercialized, is best designed for short transmission distances. This type of fiber has a core diameter from 50 μm to 85 μm, much larger compared with single-mode fiber, and therefore it is easier to couple light into the core of multimode fiber than of single-mode optical fiber. The most common multimode fiber deployed in the late 1970s and early 1980s had a core diameter of 50 μm. The large core allows many modes or rays of light to propagate. Therefore, light entering the fiber at the same time may arrive at the other end at slightly different times, which results in the light being spread out, a phenomenon called *modal dispersion*(1). The effect of modal dispersion is that the signal (i.e., the digital pulse) becomes smeared as it travels down the fiber. Today, multimode fiber is used almost exclusively for private premises systems in which distances are usually less than 1 km.

Single-Mode Fiber

A way to eliminate modal dispersion is to reduce the core's diameter until the fiber will propagate only one mode efficiently; i.e., the energy of the light signal travels in the form of one mode. A single-mode fiber is one in which the guided light ray takes one path through the fiber. The diameter of single-mode fiber is only 8–10 μm. Single-mode fiber allows for a higher capacity to transmit information because it can retain the fidelity of each light pulse over longer distances and exhibits no dispersion caused by multiple modes. Single-mode fiber also enjoys lower fiber attenuation than multimode fiber. Like multimode fiber, early single-mode fiber was generally characterized as step-index fiber, which means the refractive index of the fiber core is a step above that of the cladding rather than graduated as it is in graded-index fiber. Modern single-mode fibers have evolved into more complex designs such as matched clad, depressed clad, and other exotic structures. Because of the smaller core diameter, coupling light into the core of single-mode fiber is more difficult. The requirements for other single-mode connectors and splices are also much more demanding. Single-mode fiber suffers from *chromatic dispersion* (1) in that different wavelengths of light travel at different speeds in the fiber, or the spectral components of the pulse travel at different speeds, which makes the optical signal smeared as it travels down the fiber.

Three basic classes of single-mode fiber are used in modern telecommunications systems. The oldest and most widely deployed type is *non-dispersion-shifted fiber* (NDSF). These fibers were initially intended for use near 1310 nm because of zero-dispersion property in the 1310-nm region. Later, 1550-nm communication systems made NDSF fiber undesirable because of its very high chromatic dispersion at the 1550 nm wavelength. To address this shortcoming, fiber manufacturers developed *dispersion-shifted fiber* (DSF) that exhibits zero dispersion in the 1550-nm region. However, when multiple, closely spaced wavelengths in the 1550-nm region were transmitted in the dense wavelength division multiplexing (DWDM) systems, DSF exhibits serious nonlinearities as data rates, power, and number of channels increase. A new class of fibers, *non-zero-dispersion-shifted fibers* (NZ-DSF), was developed to address the problem of nonlinearities. The fiber is available in both positive and negative dispersion varieties and is rapidly becoming the fiber of choice in new fiber deployment, especially for DWDM systems.

Although most fibers are made of silica glass, low-cost plastic fibers can be made of polymers that are cheap materials and allow a simple production by extrusion. Plastic optical fibers have found widespread applications in consumer markets (e.g., home networks), the automotive and aircraft industry, and so on.

One of optical fiber's key performance properties is fiber attenuation that characterizes the decay of light signal's strength as it travels down the fiber. Figure 2 shows the spectral attenuation performance of typical silica-based multimode fiber and single-mode fiber. Notice the two low-loss wavelength windows: 1310-nm and 1550-nm regions. The 1550-nm window is preferred for long-haul transmission because of its low attenuation, width, and the availability of optical amplifiers.

Light Source

Light is part of the electromagnetic spectrum. In optical communication and networking, the practice is to use wavelength rather than frequencies to define an optical channel. The wavelength is usually measured in nanometers (nm) or micrometers (μm). The relationship between frequency and wavelength of a signal is given by Frequency (in Hertz) = Speed of light in a vacuum (in meters/second) / Wavelength (in meters). Therefore, the higher the frequency of the signals, the shorter the wavelengths. For example, a frequency of 192.1 THz operates with a wavelength of 1560.606 nm, whereas a frequency of 194.7 THz operates with a wavelength of 1539.766 nm. Three low-loss windows in the 0.8-, 1.3- and 1.55-μm infrared wavelength bands are used for optical communication because optical fibers transmit infrared wavelengths with less attenuation and dispersion.

Many different types of light sources can be used for optical communication. The most important one is the laser. A laser (light amplification by stimulated emission of radiation), first demonstrated in 1960, is an optical source that emits photons in a coherent beam (1). The early lasers were multilongitudinal mode (MLM) Fabry-Perot lasers. These MLM lasers emit light over a fairly wide spectrum of several nanometers to tens of nanometers. The actual spectrum consists of multiple discrete spectral lines, which can be thought of as different longitudinal modes, hence, the term MLM. For high-speed optical communication systems, the spectral width of the source must be as narrow as possible to minimize the effects of chromatic dispersion. Likewise, a narrow spectral width is also needed to minimize cross-talk among channels in WDM systems. A single-longitudinal mode (SLM) laser emits a narrow single-wavelength signal in a single spectral line that reduces the spectrum of the transmitted optical signal

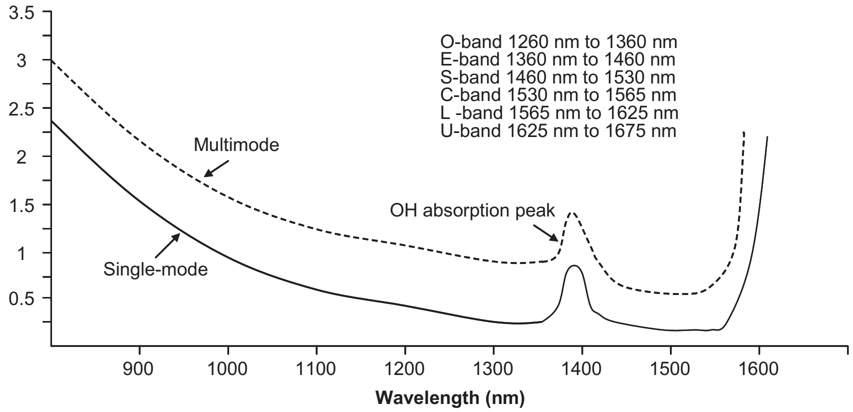

Figure 2. Fiber spectral attenuation performance.

to close to its modulation bandwidth. The penalty from chromatic dispersion is significantly reduced. Lasers have been used as transmitters and to pump or power optical signal amplifiers. Semiconductor lasers are the most popular light sources for optical communication systems.

A distributed-feedback (DFB) laser is a laser where the whole cavity or resonator consists of a periodic structure, which acts as a distributed reflector in the wavelength range of laser action, and contains a gain medium that compensates for the resonator losses. The DFB laser structure, which excels in wavelength precision, ensures stable single-wavelength oscillations of laser emissions. DFB lasers are required in almost all high-speed transmission systems today.

A tunable laser is a device that can tune over a range of wavelengths. The following tuning mechanisms are typically used: (*1*) Injecting current into a semiconductor laser causes a change in the refractive index of the material, which in turn changes the lasing wavelength; (*2*) temperature tuning; and (*3*) mechanical tuning that is used in lasers that use a separate external cavity mechanism. Some successful types of widely tunable lasers are the superstructure grating distributed Bragg reflector laser (SSGDBR), the grating-assisted codirectional coupler with sampled grating reflector laser (GCSR), and the sampled grating DBR laser (SGDBR) (2). All of these devices are capable of continuous tuning ranges greater than 40 nm. Another way to obtain a tunable laser source is to use an array of wavelength-differentiated lasers and turn one of them on at any time; e.g., an array of DFB lasers can be fabricated, each of them at a different wavelength. Tunable lasers are highly desirable components for WDM networks because fewer lasers are needed to support a multichannel WDM system and network operators need to stockpile fewer spare ones in the event that transmitters fail in the field and need to be replaced. Tunable lasers are also one key enabler of reconfigurable optical networks as well as for optical packet-switched networks, where data need to be transmitted on different wavelengths on a packet-by-packet basis.

Light-emitting diodes (LEDs) (1,3) provide a cheaper alternative to laser in many applications where the communication data rates are low and distances are short. An LED is a forward-biased *pn*-junction in which the recombination of the injected minority carriers (electrons in the *p*-type region and holes in the *n*-type region) by the spontaneous emission process produces light. The light output of an LED has a fairly broad *continuous* spectrum of several nanometers to tens of nanometers. LEDs are not capable of producing high-output powers, and typical output powers, are on the order of −20 dBm. They cannot be directly modulated at data rates higher than a few hundred megabits per second. A laser provides higher output power than an LED and therefore allows transmission over greater distances.

Detector

A receiver converts an optical signal into a usable electrical signal. Photodetectors perform the opposite function of light emitters (1,3). The most common detector is the semiconductor photodiode, which produces current in response to incident light. Detectors operate based on the principle of the *pn*-junction. An incident photon striking the diode gives an electron in the valence band sufficient energy to move to the conduction band, which creates a free electron and a hole. If the creation of these carriers occurs in a depleted region, the carriers will quickly separate and create a current. As they reach the edge of the depleted area, the electrical forces diminish and current ceases. Because the *pn*-diodes are insufficient detectors for fiber optic systems, to improve the efficiency of the photodetector, both *p-i-n*(PIN) photodiodes and avalanche photodiode (APDs) are designed to compensate for the drawbacks of the *pn*-diode. Once the detector converts optical signals back into electrical currents proportional to the incident optical power, the currents are then amplified to a usable level and fed to the decision circuit of the digital communication system that estimates the data bits from the electrical currents received. This process depends on the modulation schemes used at the transmitters.

Modulation

The process of imposing data on the optical signal is called modulation. The most widely used modulation scheme for optical communication is called on-off keying (OOK), where the light signal is turned on or off, depending on whether the data bit is 1 or 0. Other forms of modulation include return-to-zero (RZ) modulation, phase shift keying (PSK) modulation, frequency shift keying modulation, and so on. OOK modulation can be realized in two ways: (*1*) by direct modulation of a semiconductor laser or an LED, where the drive current to the light source is turned on or off based on whether the data bit is 1 or 0; and (*2*) by using an external modulator. Direct modulation is simple; its application is, however, limited to certain types of lasers. Direction modulation will result in a phenomenon wherein the carrier frequency of the transmitted pulse varies with time, which causes a broadening of the transmitted spectrum. In external modulation, an OOK external modulator is placed in front of a light source and turns the light signal on or off based on the data to be transmitted, whereas the light source itself is continuously operated. External modulators become essential in transmitters for communication systems using other forms of modulation, e.g., RZ modulation. Two types of external modulators are widely used today: lithium niobate modulators and semiconductor electroabsorption (EA) modulators. A summary of reported modulator results is provided in Ref. (4), which takes into account design considerations and applications. In Ref. (5), a tandem electroabsorption modulator with an integrated semiconductor optical amplifier is developed that is capable of both non-return-to-zero and return-to-zero data transmission at 40 Gb/s.

Optical Fiber Amplifier

One milestone in the evolution of optical fiber communication systems was the development of erbium-doped fiber amplifiers (EDFAs) in the late 1980s and early 1990s, which are capable of amplifying signals at many wavelengths in the 1550-nm window simultaneously in the optical domain and therefore reduces the cost of long-distance fiber systems by eliminating the need for optical-electro-optical regenerators. This technology enables the transmission capacity of optical communication systems to be significantly increased by using multiple wavelength channels simultaneously through wavelength division multiplexing (WDM). Under WDM, the optical transmission spectrum is carved up into several nonoverlapping wavelength bands, with each wavelength supporting a single communication channel. WDM provides the ability to turn on capacity quickly by lighting up new wavelengths in fibers already deployed. WDM systems with EDFAs are widely deployed today and are achieving capacities over 1Tb/s on a single fiber. Other types of optical amplifiers exist, each suitable for a spectral range; e.g., thulium-doped fiber amplifiers can be used for amplification in the *S* band around 1460–1530 nm, praseodymium-doped fiber amplifiers are for the 1.3-μm window, neodymium and ytterbium fiber amplifiers are for 1-μm laser sources, and Raman amplifiers can potentially generate gain in very different large wavelength regions.

Other Components

Various other optic components have been developed to control the flow of light signals. Optical filters are devices for selecting wavelengths from optical signals. Optical filters are essential components to construct multiplexers and demultiplexers used in WDM terminals wherein multiplexers combine wavelength channels into a single optical signal before transmission and demultiplexers extract individual wavelength channels from the optical signal after reception. Multiplexers and demultiplexers can be cascaded to realize static wavelength crossconnects (WXCs). The device routes signals from an input port to an output port based on the wavelength. Dynamic WXCs can be constructed by combining optical switches with multiplexers and demultiplexers such that wavelengths of signals from an input port can be dynamically selected and routed to an output port. Many different technologies are available to realize optical switches (1): (*1*) mechanical switches, e.g., using a mirror arrangement whereby the switching state is controlled by moving a mirror in and out of the optical path; (*2*) two-/three-dimensional (2-D/3-D) micro-electro-mechanical system (MEMS) switches (6,7); (*3*) bubble-based waveguide switches; (*4*) liquid crystal switches; (*5*) electro-optic switches; and (*6*) thermo-optic switches. Among the various technologies, the 3-D-MEMS beam steering mirror technology offers the best potential for building large-scale optical switches.

Optical switches are used inside WXCs to reconfigure them to provision lightpath, a circuit-switched end-to-end optical channel. Multiplexers and demultiplexers are components for constructing wavelength add/drop multiplexers (WADMs), devices used in WDM systems for mixing and routing different channels of light into or out of a single mode fiber. “Add” and “drop” refer to the capability of the device to add one or more new wavelength channels to an existing multiwavelength WDM signal, or to remove one or more channels, routing those signals to another network path. A wavelength converter is a device that converts data from one incoming wavelength to another outgoing wavelength. Wavelength converters can be used to improve the utilization of the available wavelengths on the network links.

OPTICAL FIBER COMMUNICATION

Evolution of Optical Fiber Transmission System

The construction of a communication network, which has and will continue to bring forth an extensive social innovation from the past decades to this new millennium, owes very much to the recent progress in the communication technologies. Above all, the development of optical fiber communication technology, which allows transmitting a large quantity of information over longer distance at reduced cost, has intensively promoted the progress. The evolution of an optical communication system has gone through several generations (1,8) (Fig. 3).

Early systems of the late 1970s through the early 1980s used LEDs or MLM laser transmitters in the 0.8- and 1.3-μm wavelength bands and multimode fibers, which enables the signal to be transmitted for a reasonable distance before the signal needs to be regenerated every few kilometers (e.g., 10 km) through an optical-electro-optical regeneration process. During regeneration, the receiver converts the incoming optical signal to an electrical signal. The signal is amplified, reshaped by sending it through a logic gate, and retimed. Retiming is a bit-rate-specific function. This signal is then modulated and retransmitted using a light source. This regeneration with reshaping and retiming completely resets the effects of nonlinearities, fiber dispersion, and amplifier noise; moreover, it does not introduce additional noise. Regenerators were expensive devices and continue to be expensive today. The distance between regenerators is limited because of attenuation and modal dispersion. These early systems operated at bit rates ranging from 32 to 140 Mb/s. Such systems are still used for low-cost computer interconnection at a few hundred megabits per second over a few kilometers, e.g., fiber channels for connecting computer servers to shared storage devices and for interconnecting storage controllers and drives.

The next generation of systems deployed starting around 1984 used MLM lasers in the 1.3-μm wavelength band and single-mode fiber that eliminates modal dispersion, therefore dramatically increasing the bit rates and distances possible between regenerators. Typically, the regenerator spacing in these systems is about 40 km or higher, limited primarily by fiber attenuation, and a few hundred megabits per second of bit rates are achieved. With improved optical fiber—single-mode fiber and laser as the transmitters—in the late 1980s, a new generation of systems in the 1.55-μm lower loss wavelength window was deployed. This generation increased the span between regenerators further. However, the data bit rates were limited by chromatic dispersion, which did not exist in the 1.3-μm band. This effect was offset by the development and deployment of dispersion-shifted fibers as well as by using SLM lasers that transmit pulses with significantly

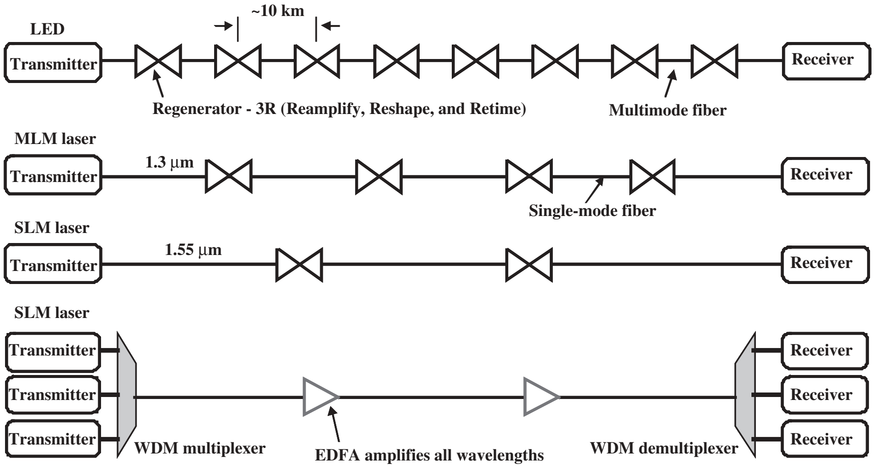

Figure 3. Evolution of optical fiber transmission systems.

reduced spectrum width. As a result, data bit rates were increased to more than 1 Gb/s.

The invention of EDFA optical amplifiers made it feasible to deploy a new generation of WDM systems, taking advantage of EDFA amplification of signals at many wavelengths simultaneously in the optical domain. The capacity increase of optical communication systems experienced a quantum leap. Instead of increasing the bit rate alone, using WDM, more than one wavelength can be used for transmission concurrently while the bit rate on individual wavelength channel can remain unchanged or be further increased. WDM techniques can thus be used to bridge the mismatch between electronic speeds and that of fiber equipment. Fewer regenerators are needed because, at a regenerator location, a single optical amplifier can replace an entire array of expensive regenerators, one per fiber. Another advantage of optical amplification is protocol transparency. WDM systems allow incremental capacity upgrade on demand. Starting in the mid-1990s, WDM systems with EDFAs were deployed. Today, almost all long-haul carriers have widely deployed amplified WDM systems. Transmission bit rates on a single channel have risen to 10–40 Gb/s. High-capacity amplified terabits/second WDM systems have hundreds of channels at 10 Gb/s with distances between electrical regenerators extending to a few thousand kilometers. Nowadays, achievable transmission capacity continues to grow while the cost per bit transmitted per kilometer continues to get lower to a point where it has become practical for carriers to price circuits independently of the distance.

Optical Fiber Networks

Early deployment of optical data communication networks included metropolitan area networks, such as the 100-Mb/s fiber distributed data interface (FDDI), and networks to interconnect mainframe computers, such as the enterprise serial connection (ESCON). At the same time, synchronous optical network (SONET), a standard for connecting fiber optic transmission systems, was proposed by Bellcore in the middle 1980s. SONET defines a hierarchy of interface rates that allow data streams at different rates to be multiplexed. SONET establishes optical carrier (OC) levels from 51.8 Mbps (OC-1) to 9.95 Gbps (OC-192). Prior rate standards used by different countries specified rates that were not compatible for multiplexing. With the implementation of SONET, communication carriers throughout the world can interconnect their existing digital carrier and fiber optic systems.

Today, a public network can be divided into a long-haul network and a metropolitan or metro network. The metro network spans a large campus or a region, typically reaching tens to a few hundred kilometers. The long-haul network interconnects different regional networks and can be as large as a few thousand kilometers. The metro network consists of a metro access network and a metro interoffice network. The access network extends from a central office out to individual businesses or homes as far as a few kilometers away, mostly collecting traffic from customer locations into the carrier network. The metro interoffice network interconnects central offices within a region. Optical fiber pairs and WDM technology have been used as the links in both the long-haul and the metro networks. Ring topologies have been widely deployed because of their simplicity and low cost and their ability to offer an alternative path to reroute traffic in case of failure. Metro access networks are almost exclusively ring based. In long-haul networks, mesh topologies are getting more attention recently because they offer more alternative paths and can be more resource efficient if properly managed. In many cases, a mesh network is actually implemented in the form of interconnected ring networks.

Point-to-Point WDM Systems

Driven by the increasing demands on communication bandwidth, WDM technology has been widely deployed for point-to-point communications in the Internet infrastructure. When the bandwidth demand exceeds the capacity in existing fibers, WDM can be more cost-effective than laying more fibers, especially over a long distance because more wavelength channels can be lit up as necessary. The trade-off is between the cost of installation/burial of additional fibers and the cost of additional line terminating equipment.

Broadcast-and-Select Local Area Optical WDM Networks

A broadcast-and-select local area WDM optical network consists of nodes connected by two-way fibers via a passive star coupler. Nodes are equipped with fixed tuned or tunable transceivers. A node's transmission over an available wavelength is received by the star coupler, which combines the received transmission with signals from other sources. The combined signal power is equally split and forwarded to all of the nodes on their receive fibers. A node's receiver then tunes to a wavelength agreed upon between the transmitter and the receiver using a distributed protocol. Two types of network architecture are possible (9): (*1*) single-hop architecture where a transmitter and a receiver communicate directly via the coupler; and (*2*) multi-hop architecture where information is forwarded via nodes in the network.

Metro Optical Ring Networks

Much of today's optical ring networks are built around SONET rings. A pair of fibers is used in unidirectional path-switched ring (UPSR) where one fiber is used as the working fiber and the other as the protection fiber. Traffic from node *A* to node *B* is sent simultaneously on the working fiber in the clockwise direction and on the protection fiber in the counterclockwise direction. As a result, if a link fails on one fiber, node *B* will be able to receive from the other fiber. The bidirectional line-switched ring (BLSR) connects adjacent nodes through one or two pairs of optical fibers, which corresponds to BLSR/2 and BLSR/4, respectively. BLSRs are much more sophisticated than UPSRs by incorporating additional protection mechanisms. Unlike a UPSR, working traffic in a BLSR can be carried on different fibers in both directions and is routed along the shortest path in the ring. Half of the capacity of each fiber is reserved for carrying the protection traffic in BLSR/2. In the event of a link failure, the traffic on the failed link is rerouted along the other part of the ring using the protection capacity available in the two fibers. A BLSR with four fibers (i.e., BLSR/4) uses a pair of fibers for protection and employs a span switching protection mechanism first. If a transmitter or receiver on a working fiber fails, the traffic is routed on the protection fibers between the two nodes on the same span. BLSRs provide spatial reuse capabilities by allowing protection capacity to be shared between spatially separated connections. BLSRs are significantly more complex to implement than UPSRs because of the extensive signaling required between the nodes. The WDM technology has provided the ability to support multiple SONET rings on a single fiber pair by using wavelength add/drop multiplixers (WADMs) to separate the multiple SONET rings. This tremendously increases the capacity as well as the flexibility of the optical ring networks. However, additional electronic multiplexing equipment is needed, which dominates the cost component and needs to be minimized via traffic grooming (10).

Wavelength-Routed Optical Networks

The massive increase in network bandwidth from WDM has heightened the need for faster switching at the core of the network (i.e., long-haul networks) to move from point-to-point WDM transmission systems to an all-optical backbone network that eliminates the need for per-hop packet forwarding. Wavelength-routed networks have been a major focus area since early 1990s. Wavelength-routed networks are considered to be an ideal candidate for wide area backbone networks.

A wavelength-routed network physically consists of several optical cross-connects (OXCs) or wavelength routers, taking an arbitrary topology. Each wavelength router takes in a signal at each wavelength at an input port and routes it to a particular output port, independent of the other wavelengths. The wavelength routers may also be equipped with wavelength converters that allow the optical signal on an incoming wavelength of an input fiber to be switched to some other wavelength on an output fiber link. The basic mechanism of communication in a wavelength-routed network is a *lightpath*. A lightpath is an all-optical communication channel that may span more than one fiber link between two nodes in the network. The intermediate nodes in the physical fiber path route the lightpath in the optical domain using the wavelength routers. If no wavelength converters are used, a lightpath must use the same wavelength on each hop of its physical fiber link, which is known as the *wavelength continuity constraint*. However, if converters are available, a different wavelength on each fiber link may be used to create a lightpath. A fundamental requirement of a wavelength-routed optical network is that two or more lightpaths traversing the same fiber link must use different wavelengths so that they do not interfere with each other. The end-nodes of the lightpath access the lightpath with transmitters and receivers that are tuned to the wavelength used by the lightpath.

Because of limitations on the number of wavelengths that can be used, and hardware constraints at the network nodes, it is not possible to set up a lightpath between every pair of source and destination nodes. The particular set of lightpaths that are established on a physical network constitutes the virtual topology or logical topology. Careful design of virtual topologies over a WDM network is to combine the best features of optics and electronics. The trade-off is between bandwidth flexibility and electronic processing overhead. The traffic on the lightpath does not have to undergo optoelectronic conversion at intermediate nodes. Traffic delay can be reduced through the use of virtual topologies and appropriate routing. However, because lightpaths are circuit-switched, forming lightpaths locks up bandwidth in the corresponding links on the assigned wavelength. A good virtual topology trades some ample bandwidth inherent in the fiber to obtain a solution that is the best of both worlds. Different virtual topologies can be set up on the same physical topology, which allows operators to choose or reconfigure a virtual topology that achieves the best network performance given network conditions such as average traffic between network nodes.

Passive Optical Networks

The access network or first-mile network, once called the last mile, connects the service provider central offices to business and residential subscribers. Currently, a variety of technologies and services are in use: dial-up service, DSL technology, cable modem, point-to-point microwave radio, and metro wireless access networks, which suffer from several drawbacks, e.g., limited reachable distances, limited data rates (shared in the case of cable TV network), and so on. Subscribers demand first-mile access solutions that are broadband and offer low-cost media-rich services. Fiber-to-the-home solution is still costly in most cases. To alleviate the problems and minimize fiber deployment cost, passive optical networks (PONs) (11,12) deploy a remote switch close to the subscribers' neighborhood and use a point-to-multipoint optical network with no active elements in the signals' path from source to destination. PONs allow for a long reach (over 20 km) between central offices and customer premises and much higher bandwidth per customer. All transmissions in a PON are performed between an optical line terminal (OLT) and optical network units (ONUs). The OLT resides in the central office, connecting the optical access network to the metro network. The ONUs are located at the customer location. From OLT to ONUs, a PON is a point-to-multipoint broadcast network (Fig. 4), and in the reverse direction, it is a multipoint-to-point network (Fig. 5) where bandwidths are shared by, for instance, TDM.

Ethernet is an inexpensive technology that is ubiquitous and interoperable with a variety of legacy equipment, and it is a logical choice for an IP data-optimized access network. The IEEE P802.3ah Ethernet in the First Mile Task Force completed its work with the approval of IEEE Std 802.3ah-2004 on Ethernet PON (EPON). An Ethernet PON (EPON) is a PON that carries all data encapsulated in Ethernet frames. PONs use a single wavelength in each of the two directions, and the wavelengths are multiplexed on the same fiber through coarse WDM. For example, the Ethernet PON (EPON) uses the 1490-nm wavelength for OLT to ONUs (downstream) traffic and the 1310-nm wavelength for ONUs to OLT (upstream) traffic. An enhancement of the PON supports an additional downstream wavelength, which may be used to carry video and cable TV services separately. PONs are in the initial stages of deployment in many parts of the world to support converged IP video, voice, and data services. In the near future, WDM-PONs in which multiple wavelengths may be supported in either or both upstream and downstream directions may become commercialized as technologies and markets mature (12).

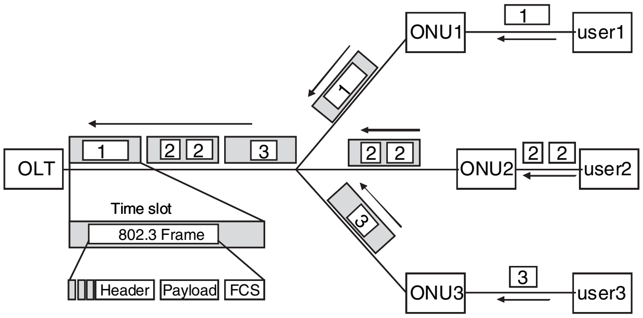

Figure 5. Upstream traffic of Ethernet over passive optical networks.

FREE-SPACE OPTICAL COMMUNICATION

Invented in the 1970s, free-space optics (FSO) (13), fiber-optic communication without the fiber, is an optical communication technology that uses low-power light propagating in free space to transmit two-way data between two points at gigabit-per-second rates (Fig. 6). Small-scale FSO systems have already been installed around the world. The reinvigoration of FSO is from the demand of advanced bandwidth-intensive services and applications as well as the inability of traditional copper wires and coaxial cables to keep up with the gigabits-per-second capacity needed in the first mile. Traditional fiber-oriented access networks incur high installation costs. Commercially available FSO equipment provides data rates much greater than those of digital subscriber lines or coaxial cables—from 10 Mb/s to 1.25 Gb/s. In addition, FSO systems can cost one third to one tenth the price of conventional underground fiber optic installations. Moreover, an FSO link can be up and running in a matter of days, whereas it could take 6 to 12 months to lay optic cables.

The operational principle of FSO is essentially the same as that of fiber optical communication. Similarly, FSO can also support multiple channels using WDM. The narrow transmitted infrared light beam suffers from beam disper-

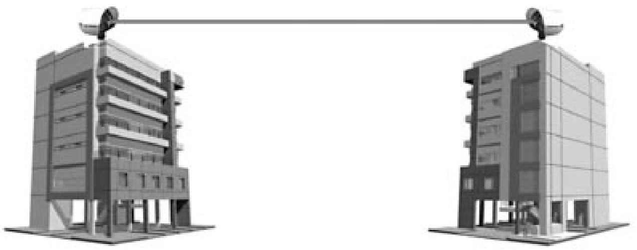

Figure 6. Free-space optical communication link connecting two office buildings.

sion where the light beam diverges over distance to form a cone with a fairly large breadth, rapidly reducing the amount of energy collectable by the receiver and energy received decreases inversely with the square of the distance. The lasers' limited power restricts their range to up to a few kilometers. Another critical issue is to align the light transmitter and receiver. As the light beam is narrow, alignment is affected easily by building sway and the thermal expansion and contraction of materials. Therefore, automatic active tracking systems are necessary that use movable mechanical platforms with feedback controls for regular adjustment to keep the transmitter and receiver on target in both directions, which adds complexity and cost to the FSO systems.

When used in vacuum, for example, for inter-space craft communication, FSO may provide similar performance to that of fiber optic systems. However, for terrestrial applications, the distance and data rate of FSO connections are highly dependent on atmospheric conditions. FSO links are prone to frequent failures caused by atmospheric absorption. Fog is vapor composed of water droplets, which are only a few hundred microns in diameter but can modify light characteristics or completely hinder the passage of light through a combination of absorption, scattering, and reflection. Fog causes significant loss of received optical power with 10–100 dB/km, which considerably limits the maximum range of an FSO link. This optical attenuation factor scales exponentially with distance. Rain and snow have little effect on FSO technology. Scintillation and pollution (smog) also cause varying degrees of attenuation. These factors result in an attenuated receiver signal and lead to higher bit error rates (BERs). Physical obstructions such as flying birds or construction cranes can temporarily block a single-beam FSO system, but this tends to cause only short interruptions, and transmissions are easily and automatically resumed.

To overcome these issues, solutions such as multibeam or multipath architectures are devised, which use more than one transmitter and more than one receiver. Each optical transceiver node can be set up to communicate with several nearby nodes in a network arrangement. Some state-of-the-art devices also have larger fade margin (e.g., extra power, reserved for rain, smog, and fog). Specifically, to increase the link range/reliability and network availability, FSO systems can be designed with limited link lengths as part of an interconnected optical mesh topology that connects FSO nodes. Each FSO node is equipped with multiple transceivers. These transceivers allow the nodes to communicate with nearby neighbors. Traffic generated by the clients of these nodes is ultimately relayed by the multihop optical mesh to the wired access infrastructure, e.g., a fiber ring add/drop multiplexer or an end-office switch. In addition to requiring a few optical transceivers, each repeater station in a mesh system must contain an electronic switch to combine (multiplex) the traffic from the local clients with that beamed from other nearby FSO nodes and to route traffic between the wired access infrastructure and each client served in the network. One approach to the reliable operation of a low-cost, free-space optical mesh is adequate density of switching nodes. If the density is sufficiently high, the length of each optical link will be sufficiently small such that fog attenuation can be negligible and mechanical tolerances can be loose. The FSO link expenses associated with tight link margins (e.g., pointing accuracy, optical beam-width, focusing, high-power lasers, and sensitive photo-receivers) can be eliminated or significantly reduced. The mesh topology can also be connected to several different locations of the wired access infrastructure, thereby providing greater overall capacity of the network. Intelligent routing and network management, e.g., multipath routing, can be implemented to choose a path for each FSO node's traffic through the mesh that passes through one of the system's outlets to the wired access infrastructure. Should a link fail, traffic would be redirected along an alternative path, making use of redundant routes and thereby facilitating rapid recovery from equipment failures. By reserving some unallocated capacity on each optical link, the network designer can ensure that sufficient capacity exists to reroute and recover from single- or multiple-link failures that might occur. The network reliability and availability can be further boosted by combining 60-GHz microwave radio with FSO because severe rain (which might cause a radio link failure) and dense fog (which might cause an FSO link failure) do not exist simultaneously, and microwave radio has some advantages, e.g., a longer distance and less attenuation by fog. Linking these two technologies, high access capacity can be economically and reliably delivered over a wide service area.

The advantages of FSO are many, including quick link setup, license-free operation, high transmission security, high bit rates, protocol transparency, and no interference. FSO is useful where physically connecting transmit and receive locations is difficult or economically prohibitive. The applications of FSO networks are abundant. FSO can be used for constructing community wireless networks where the network should largely self-configure and have robust connectivity, scalable network capacity, and low capital cost. Optical wireless networks are emerging as a viable, cost-effective technology for rapidly deployable broadband sensor communication infrastructures. The use of directional, narrow beam, optical wireless links provides great promise for secure, extremely high data rate communication between fixed or mobile nodes, which is very suitable for sensor networks in civil and military contexts. FSO can also be used for communications between spacecrafts, including elements of a satellite constellation.

ADVANCED TOPICS

Many areas of optical communication and networking are under intensive research and development. For example, integrated optics is to develop miniaturized optical devices of high functionality on a common substrate. The state-of-the-art of integrated optics is still far behind its electronic counterpart. Today, only a few basic functions are commercially feasible. However, a growing interest exists in the development of more and more complex integrated optical devices. New types of fibers are still being developed. The emerging field of photonic crystals led to the development of photonic crystal fiber, which guides light by means of diffraction from a periodic structure, rather than total internal reflection. The first photonic crystal fibers became commercially available in 1996. Photonic crystal fibers can be designed to carry a higher power than conventional fiber, and their wavelength-dependent properties can be manipulated to improve their performance in certain applications. The Internet Engineering Task Force (IETF) is investigating the use of Generalized Multi-Protocol Label Switching (GMPLS) and related signaling protocols (14) to set up and tear down lighpaths as well as for traffic engineering. GMPLS is an extension of Multi-Protocol Label Switching (MPLS) that supports multiple types of switching, including switching based on wavelength (a.k.a. Multi-Protocol Lambda Switching). With GMPLS, the OXC backbone network and the IP/MPLS subnetworks will share common functionality in the control plane, which makes it possible to seamlessly integrate all-optical networks within the overall Internet infrastructure. Various protection and restoration schemes and protocols for increasing the survivability and availability of WDM optical networks have been developed (1). Traffic grooming (10,15), dynamic service provisioning, and support for multicast services in optical networks are also active areas of research in both academia and industry. Finally, new network architectures such as optical burst switching (OBS) and optical packet switching (OPS) are currently under active research, experimentation, and evaluation.

PARALLEL AND VECTOR PROGRAMMING LANGUAGES

A parallel programming language is a formal notation for expressing algorithms. The meaning of this notation can be defined by appealing to a parallel computational model.

Parallel programming languages have more complicated data and control models than sequential programming languages. The data model in sequential languages is that of the random access machine (RAM) model in which there is a single address space of memory locations that can be read and written by the processor. The analog in parallel languages is the *shared-memory* model in which all memory locations reside in a single address space and are accessible to all the processors (the word *processors* in this article always refers to the logical processors in the underlying parallel execution model of the language and not to hardware processors). A more decoupled data model is provided by the *distributed-memory* model in which each processor has its own address space of memory locations inaccessible to other processors. The choice of the data model determines how processors communicate with each other—in a shared-memory model, they communicate by reading and writing shared locations, but in a distributed-memory model, they communicate by sending and receiving messages.

The control model in a parallel programming language determines how processors are coordinated. The simplest parallel control model is *lock-step* (vector) *synchronization.* At every step of program execution, each processor is either turned off or is required to perform the same operation as all other processors. The active processors at each step work on different data items, so this control model is also called the *single-instruction–multiple-data* (SIMD) model. SIMD-style parallel execution can be exploited in performing vector operations like adding or multiplying the elements of a set of vectors. *Bulk synchronization* is a more decoupled control model in which processors synchronize occasionally by using a *barrier* instruction. No processor is allowed to execute a statement past a barrier until all processors have arrived at that barrier. Between the execution of successive barrier statements, processors are autonomous and may execute different operations. Bulk synchronization can be used to exploit the *data parallelism* that arises when a function *f* is applied to each of the elements of a data structure such as a vector. All evaluations of *f* can be performed in parallel, so processors synchronize only at the beginning and end of this computation. Since *f* may have conditionals inside it, the processors may end up performing different computations, which is permitted in the bulk synchronous model. The most decoupled form of synchronization is *fine-grain synchronization* in which two or more processors can synchronize on their own whenever they need to, without involving other processors. This form of parallel execution is sometimes called *multiple-instruction–multiple-data* (MIMD) parallelism. The MIMD model is appropriate for exploiting *task* parallelism, which arises when autonomous computations (tasks) can execute concurrently, synchronizing only for exclusive access to resources or for coordinating access to data that is being produced and consumed concurrently by different tasks.

Figure 1 classifies the languages discussed in this article according to their control and data models. A survey of parallel programming languages can be found in Ref. 1.

LOCK-STEP SYNCHRONOUS PARALLEL LANGUAGES

Lock-step (SIMD) parallel languages are used mainly to program vector and array processors for performing scientific computations in which matrices are the primary data structures. Not surprisingly, most of these languages are extensions of FORTRAN. Programs in these languages contain a combination of scalar and vector operations. On array processors such as the Connection Machine CM-2 (Thinking Machines) (2) the scalar operations are usually performed by a front-end high-performance workstation, while the vector operations are performed on the array processor. Vector processors such as the CRAY processor (3) can execute both scalar and vector instructions. Therefore, the key problem in designing a SIMD language is to design constructs that expose as many vector operations as possible to the compiler.

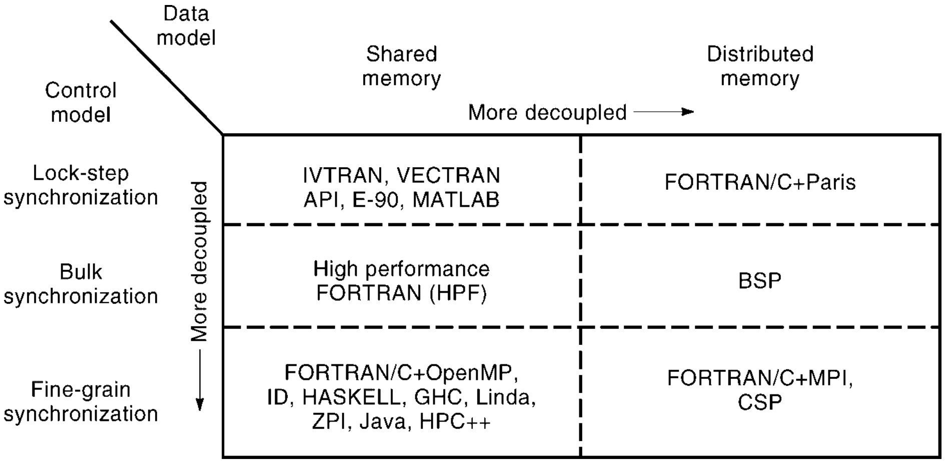
Shared-Memory SIMD Languages

The simplest vector operations involve the application of an arithmetic or boolean function to each element of an array (or arrays), thus computing the sum of two arrays by elements. These operations can be expressed quite simply by overloading arithmetic and boolean operators. For example, the FORTRAN-90 (4) statement `C = A + B` specifies that the sum by elements of arrays `A` and `B` is to be stored into array `C`.

In many applications, however, vector operations must be performed on some but not all of the elements of an array. For example, in solving partial differential equations, it may be necessary to apply one operator to points in the interior of the domain and a different one to points at the boundaries. Operator overloading is not sufficient to permit the expression of conditional vector operations, so a variety of constructs for describing sparse index sets have been invented.

Many SIMD languages provide the programmer with constructs for specifying the array section on which the vector operation is to be performed. One approach is to use *control vectors,* first introduced in the Burroughs Illiac IV FORTRAN language (5)—a value of *true* in a control vector indicates that the vector operation should be performed for the corresponding data element. An asterisk indicates a control vector of arbitrary length in which all elements are true. The following code shows the use of control vectors in this language. The first array statement adds the elements of the `A` and `C` arrays pointwise and assigns the results to `A`.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.



Control model \ Data model	Shared memory	Distributed memory
Lock-step synchronization	IVTRAN, VECTRAN API, E-90, MATLAB	FORTRAN/C+Paris
Bulk synchronization	High performance FORTRAN (HPF)	BSP
Fine-grain synchronization	FORTRAN/C+OpenMP, ID, HASKELL, GHC, Linda, ZPI, Java, HPC++	FORTRAN/C+MPI, CSP

Figure 1. A classification of parallel programming languages.

Because only the odd elements of B are true, the second array assignment adds only the odd elements of A and C and assigns the results to odd elements of A.

```
do 10 i = 1, 100,2
  B(i) = .true.
  B(i + 1) = .false.
10 continue
  A(*) = A(*) + C(*)
  A(B(*)) = A(B(*)) + C(B(*))
```

An important special case of conditional vector operations is *constant-stride* vector operations in which the elementary operations are applied to every *k*th element of the vector(s) for some integer *k*. On many vector computers, it is difficult to generate efficient code for these operations if control vectors are used. The operands and results of vector operations are usually stored in memory, so it is usually not worth performing an arithmetic operation in vector mode unless the loads and stores can also be done in vector mode. However, some computers [such as the CRAY-1 and CRAY-2 (3)] permit only constant-stride loads and stores from memory. Unless the compiler can determine that the *true* entries in a control vector occur with a fixed stride, it is forced to generate scalar loads and stores.

The IBM VECTRAN language (6) addressed this problem by introducing *array triplets,* which can describe many constant-stride array sections. An array triplet consists of three expressions separated by colons and specifies the start, end, and stride of the range of execution of a statement. If the stride is 1, the last expression and its preceding colon can be omitted. There is an obvious similarity between triplets and the specification of DO loop index sets in FORTRAN. The following code shows a use of triplets. After the last statement is executed, A(2) contains 1, A(4) contains 2, etc. Multidimensional arrays can be handled by using a triplet for each dimension of the array. Array triplet notation is also used in other array languages like MATLAB (7) and FORTRAN-90 (4).

```
  do 10 i = 1, 10
10 A (i) = i
  A(2:10:2) = A(1:5)
```

Although triplet notation is powerful, it is not a replacement for control vectors since it cannot describe arbitrary index sets. Therefore, VECTRAN supplemented the triplet notation with where statements, an example of which is given below.

```
where (A(1:100) .LT. 0)
   A(1:100) = − A(1:100)
otherwise
   A(1:100) = 0.0
endwhere
```

The where statement first evaluates a logical array expression. Statements in the body of where are executed for each index for which the logical array expression is true, while statements in the otherwise clause are executed for indices for which the logical expression is false. The clauses can contain only assignment statements where statements are in FORTRAN-90 as well.

The approaches described so far for expressing conditional vector operations are data-oriented in the sense they require the programmer to specify the array section on which the vector operation must be performed. A complementary approach is to embellish the control constructs in the language. One such construct, which was introduced in the IVTRAN language (8), is the forall statement in which the sparse index set is specified in terms of the control variables of the loop. The following code shows an example of its use. The loop has a two-dimensional index space in which all iterations can be performed in parallel, and in each iteration (i, j), the assignment is performed if A(i, j) is less than zero. Note that the forall construct permits assignment to constant-stride array sections such as diagonals, which cannot be described using triplet notation.

```
forall (i = 1:100:2, j = 1:100, A(i, j) .LT.
  0)
  A(i, j) = B(i, j)
```

Although reduction operations such as adding all the elements of a vector can also be done in vector mode, shared-memory SIMD languages have traditionally not had constructs to support these operations. However, most of them provide library routines that can be invoked by the programmer to perform reduction operations in vector mode.

Other shared-memory vector languages are LRLTRAN (9) from Lawrence Livermore Laboratories, BSP FORTRAN (10) from Burroughs, and Cedar FORTRAN (11) from the University of Illinois, Urbana. Cedar FORTRAN permitted the expression of both SIMD and MIMD parallelism. None of these languages, other than FORTRAN-90 and MATLAB, is in use.

Distributed-Memory SIMD Languages

The CM-2 machine (2) from Thinking Machines was a distributed-memory array processor and its assembly language, called Paris (parallel instruction set) (12), had FORTRAN, C, and Lisp interfaces that permit programmers to write high-level language programs with Paris commands embedded in them. The resulting languages were called FORTRAN/Paris, C/Paris, and Lisp/Paris, and they are examples of distributed-memory SIMD languages.

The programming model of Paris has an unbounded number of virtual processors (VPs) that can be configured into Cartesian grids of various sizes. Each VP has *local memory* for storing data, a *context flag* that controls instruction execution, and a unique *address* that can be used by other VPs to send it messages. Each VP can perform the usual arithmetic and logical operations, taking operands from its local memory and storing the result back there (one of the operands can be an immediate constant that is broadcast from the front-end processor). The execution of these operations can be made conditional on the context flag. Interprocessor communication is performed by executing the `send` instruction. Since processors operate in lock step, a separate instruction for receiving messages is not required; rather, the execution of the `send` instruction results in data transfer from the source VP to the destination VP. Therefore, the `send` instruction has to specify the address of the receiving processor and the memory addresses of the source and destination locations of the message. A given VP may receive messages from several other VPs during a `send` operation. If so, the data in these messages can be combined using a reduction operator specified in the `send` instruction. A noteworthy feature of Paris is that it was the first SIMD language to include a rich set of instructions for performing global reductions and parallel prefix operations on data stored in the VPs.

BULK SYNCHRONOUS PARALLEL LANGUAGES

Lock-step synchronization provides a simple programming model but it can be inefficient for programs with many data-dependent conditionals. Since processors operate in lock step, every processor must participate in the execution of *both* clauses of a conditional statement even though it performs computations in only *one* of the clauses. Bulk synchronization is a more relaxed synchronization model in which processors execute instructions autonomously but must rendezvous at intervals by executing a barrier instruction. No processor can execute an instruction past a barrier until *all* processors have arrived at that barrier. The interval between two successive barriers is called a *superstep*.

The requirement that all processors rendezvous at all barriers means that the most natural approach to programming in this model is to require all processors to execute the same program even though they can take different paths through that program to arrive at the same sequence of barrier instructions. This approach is sometimes called single-program–multiple-data (SPMD) parallelism, but this term has been abused sufficiently that we will not use it any further in this article.

Bulk synchronization is appropriate for exploiting data parallelism in programs. The simplest kind of data parallelism arises when a function is applied to each element of a data structure (like *mapcar* in LISP). A more subtle form of data parallelism arises when an associative operation such as addition or multiplication is used to combine all the elements of a data structure together. There is a well-known parallel algorithm ("tree reduction") for performing this operation in time proportional to the logarithm of the number of elements in the data structure (13). Data parallelism is also present in the computation of parallel prefix operations.

Shared-Memory Bulk Synchronous Languages

We use High-Performance FORTRAN (HPF) (14) as our example. HPF is somewhat unique among parallel languages in that it was designed by a group of no less than 50 researchers. It has two parallel loop constructs called the `FORALL` loop and the `INDEPENDENT` directive for expressing bulk synchronous parallelism. The body of the `FORALL` must consist of a sequence of assignments without conditionals or invocations of general procedures, although side-effect functions, declared to be `PURE` functions, can be invoked in a `FORALL`. These functions can contain conditionals. There is an implicit barrier at the end of every statement in a `FORALL`. The semantics of the `FORALL` is that all iterations of the first statement can be executed concurrently, and when these are completed, all iterations of the second statement can be executed concurrently, and so on. The right hand side of each statement is fully evaluated before the assignment is performed.

The `INDEPENDENT` directive before a DO loop tells the compiler that the iterations of the loop can be done in parallel since they do not effect each other. There is an implicit barrier at the end of the loop but loop iterations do not have to be synchronized in any way. This directive is often used to expose opportunities for parallel execution to the compiler, as shown in the following code. The `NEW` clause asserts that `J` is local to the outer loop. Iterations of the outer loop can be executed concurrently if the values of `IBLACK(I)` are distinct from the values of `IRED(J)` and if the `IBLACK` array does not have repeated values. This information cannot be deduced by a compiler, so the `INDEPENDENT` directive is useful for conveying this information.

```
!HPF$ INDEPENDENT, NEW(J)
  DO I = 1, N
    DO J = IBEGIN(I), IEND(J)
      X(IBLACK(I)) = X(IBLACK(I)) + X(IRED(J))
  END DO
  END DO
```

In HPF, the assignment of computational work to processors is not directly under the control of the programmer. Instead, it relies on a combination of data-distribution directives and compiler technology to produce code with good locality, as described in Refs. 15 and 16. The two basic distributions are *block* and *cyclic* distributions. Block distributing an array gives each processor a set of contiguous elements of that array; if there are p processors and n array elements, each processor gets a contiguous block of n/p elements. In a cyclic distribution, successive array elements are mapped to successive processors in a round-robin manner; therefore, element i is mapped to processor i mod p. HPF also supports a block–cyclic distribution in which blocks of elements are dealt to processors in a round-robin manner. The compiler can exploit data distributions in assigning work by assigning an iteration to a processor if that processor has most of the data required by that iteration. Alternative strategies like the owner-computes rule (16) are also popular.

An HPF program for computing π is shown below. It approximates the definite integral $\int_0^1 4/(1 + x^2)\ dx$ by using the rectangle rule, computing the value of $(1/n)$ $\Sigma_{i=1}^{n} 4/\{1 + [(i - 0.5)/n]2\}$. In this program, n is chosen to be 1000. SUM is a built-in function for computing the sum of the elements of a distributed array.

```
  PURE REAL FUNCTION F(X)
  REAL, INTENT(IN) :: X
  F = 4.DO/(1.DO + X*X)
  END FUNCTION F
  PROGRAM COMPUTE_PI
  REAL TEMP(1000)
!HPF$ DISTRIBUTE TEMP(BLOCK)
  WIDTH = 1.DO/1000
  FORALL (I = 1:1000)
  TEMP(I) = WIDTH * F((I - 0.5DO)*WIDTH)
  END FORALL
  T = SUM(TEMP)
  END
```

A second version of HPF called HPF-2 with support for irregular computations and task parallelism has been defined. IBM, PGI, DEC (now Compaq), and other companies have HPF compilers targeted to distributed-memory computers like the IBM SP-2 computer. However, the quality of the compiler-generated code is relatively poor in comparison to handwritten parallel code, and source-level performance prediction has proved to be difficult since performance depends greatly on decisions about interprocessor communication made by the compiler (17). For these reasons, interest in HPF is on the wane.

Distributed-Memory Bulk Synchronous Languages

The first theoretical study of bulk synchronous models was done by Valiant, who proposed the bulk synchronous parallel (BSP) model (18) as a bridging model between parallel hardware and software. A parallel machine in the BSP model has some number of processors with local memories, interconnected by a routing network. The computation consists of a sequence of supersteps; in each superstep, a processor receives data sent by other processors in the previous superstep, performs local computations, and sends data out to other processors that receive these data in the following superstep. A processor may send and receive any number of messages in each superstep. Consecutive supersteps are separated by barrier synchronization of all processors. Communication is therefore separated from synchronization.

Although BSP is a model and not a language, a number of libraries that implement this model on a variety of parallel platforms have been written (19,20). In this article, we describe the BSP Green library (19), which provides the following functions:

1. `void bspSendPkt(int pid, const bspPkt *pktPtr)`: Send a packet to the process whose address is `pid`; the data to be sent are at address `pktPtr`.
2. `bspPkt *bspGetPkt()`: Receive a packet sent in the previous superstep; returns NULL if all such packets have already been received.
3. `void bspSynch()`: Barrier synchronization of all processors.
4. `int bspGetPid()`: Return the process ID.
5. `int bspGetNumProcs()`: Return the number of processes.
6. `bspGetNumPkts()`: Return the number of packets sent in the previous superstep to this process that have not yet been received.
7. `bspGetNumStep()`: Return the number of the current superstep.

The first three functions are called *fundamental* functions since they implement the core functionality of the BSP model, and the last four are called *supplemental* functions. This set of functions is somewhat limited, and a more user-friendly library would provide other supplemental functions such as one to perform reductions, while remaining true to the BSP spirit. For example, the BSPLib project (http://www.BSP-Worldwide.org/) includes support for one-sided communication and high-performance unbuffered communication.

The following program (from Ref. 19) uses the BSP Green library functions to perform a trivial computation with three processors connected logically in a ring. Each processor sends the value of a local variable A to its neighbor in the ring and then performs a local computation with the value it receives. This takes two two supersteps. Note that some of the code (such as the calls to memcpy) is at a fairly low level of abstraction. The philosophy behind the decision to expose such details to the programmer is that all expensive operations should be evident when reading the program text.

```
void program(void)
{ int pid, numProcs, A,B,C;
  bspPkt pkt, *pktPtr;
  pktPtr = &pkt;
  pid = bspGetPid();    //get process ID
  numProcs = bspGetNumProcs();  /get number of
    processes
  if (pid==0){ A=3; B=12;} //initialize A and B
  if (pid == 1) { A = 1; B = 18;}
  if (pid == 2) { A = 5; B = 7;}
  memcpy((void*)pktPtr, (void*)&A, 4); //Store
    A into packet buffer
  bspSendPkt((pid+1)%numProcs, pktPtr); //send
    data to neighbor in ring
  bspSynch();    //superstep synchronization
  pktPtr = bspGetPkt();  //receive packet
  memcpy((void*)&C, (void*)pktPtr, 4);  //store
    data in C
    C = C + B;
  fprintf(stdout, ``Process %d, C = %d\n'', pid,
    C);
  bspSynch();  // superstep synchronization
}
```

One of the goals in the design of BSP is to permit accurate performance prediction of parallel programs. Performance prediction of BSP programs is made using a model with three parameters: (1) the number of processors p, (2) the gap g, which reflects the network bandwidth available to each processor, and (3) the latency L, which is the time required to send a packet through the network and perform a barrier synchronization. If a BSP program consists of S supersteps, the execution time for superstep i is $w_i + gh_i + L$, where w_i is the longest computation time required by any processor in that superstep and h_i is the largest number of packets sent or received by any processors in that superstep. This performance model assumes that communication and computation are not overlapped. The execution time for the program is $W + gH + LS$, where $W = \Sigma w_i$ and $H = \Sigma h_i$.

A major contribution of BSP has been to highlight what can be accomplished with its minimalist approach to communication and synchronization. However, the exchange of a single message between just two processors requires the cooperation of all processors in the machine! The BSP counterargument is that worrying about optimizing individual messages makes parallel programming too difficult and that the focus should be on getting the large-scale structure of the parallel program right.

FINE-GRAIN SYNCHRONOUS PARALLEL LANGUAGES

The most relaxed form of synchronization is *fine-grain* synchronization in which two or more processors can synchronize whenever they need to without the involvement of other processors. This style of programming is usually called multiple-instruction–multiple-data (MIMD) programming. Fine-grain synchronization is appropriate for exploiting *task parallelism* in which autonomous computations (tasks) need to synchronize either to obtain exclusive access to shared resources or because they are organized as a pipeline in which data structures are produced and consumed concurrently.

Shared-Memory MIMD Programming

We discuss FORTRAN/OpenMP (21), which is a new industry standard API (Applications Programmer Interface) for shared-memory parallel programming and contrast it with the more "expression-oriented" approach of Multilisp (22).

OpenMP. OpenMP is a set of compiler directives and run-time library routines that can be used to extend FORTRAN and C to express shared-memory parallelism. It is an evolution of earlier efforts like pthreads and the now-moribund ANSI X3H5 effort. An OpenMP FORTRAN program for computing π is shown below. A single thread of control is created at the start, and this thread executes all statements till the PARALLEL directive is reached. The PARALLEL directive and its corresponding END PARALLEL directive delimit a *parallel* section. At the top of the parallel section, a certain number of slave threads are created that cooperate with the master to perform the work in the parallel section and then die at the bottom of the parallel section. In our example, the only computation in the parallel section is the do loop. Furthermore, the DO directive asserts that the iterations of the loop can be performed in parallel. Optional clauses in this directive permit the programmer to specify how iterations should be assigned to threads. For example, the SCHEDULE(DYNAMIC,5) clause specifies that iterations are assigned to threads in blocks of five iterations; when a thread completes its iterations, it returns to ask for more work, and so on. There is an implicit barrier synchronization at the bottom of the parallel DO loop, as well as at the end of the parallel region. The barrier synchronization may be avoided by specifying the clause NOWAIT at these points. Once the parallel region is done, all threads except the master die. The master completes the execution of the rest of the program.

By default, all variables in a parallel region are shared by all the threads. Declaring a variable to be PRIVATE gives each thread its own copy of that variable. By default, loop control variables like i in our example are PRIVATE. Note that all the threads in our program write to the sum variable. Declaring sum to be a REDUCTION variable permits the compiler to generate code for updating this variable atomically. The compiler may also generate more elaborate code such as performing the reduction in a tree of processors.

```
  program compute_pi
  integer n,i
  double precision w,x,sum,pi,f,a
  f(a) = 4.d0/(1.d0 + a*a)
  print *, 'Enter the number of intervals'
  read *,n
  w = 1.0d0/n
  sum = 0.0d0
!$OMP PARALLEL
!$OMP DO SCHEDULE(DYNAMIC,5), PRIVATE(x),
  REDUCTION(+: SUM)
  do i = 1, n
    x = w * (i - 0.5d0)
    sum = sum + f(x)
    enddo
!$OMP END PARALLEL
  pi = w*sum
  print *,
  computed pi = ‘, pi
  stop
  end
```

Fine-grain synchronization in OpenMP is accomplished by the use of critical sections. The `CRITICAL` and `END CRITICAL` directives restrict access to the enclosed region to one thread at a time. For example, instead of declaring `SUM` to be a reduction variable as before, we can use a critical section to update it atomically as shown below.

```
!$OMP PARALLEL
!$OMP DO SCHEDULE(DYNAMIC,5), PRIVATE(x,temp)
  do i = 1, n
  x = w * (i - 0.5d0)
  temp = f(x)
!$OMP CRITICAL
  sum = sum + temp
!$OMP END CRITICAL
  enddo
!$OMP END PARALLEL
```

OpenMP also has a *parallel section* directive. Each section contains computations that can be performed in parallel with the computations in the other sections of this construct. OpenMP is being supported by SGI, KAI (Silicon Graphics Inc., Kuck and Associates Inc.), International Business Machines, and other companies.

Multilisp. It is instructive to contrast OpenMP with Multilisp (22), which is also a shared-memory MIMD parallel language, but one in which synchronization between producers and consumers of data can often be folded quite elegantly into the data accesses themselves. Multilisp is a parallel extension of Scheme, which was intended for writing parallel programs for the MIT Concert multiprocessor. There are two parallel constructs, one for evaluating the arguments to a function in parallel (`pcall`), and another for computing a value in parallel with executing code that will eventually use that value (`future`).

The expression (`pcall F A`) is equivalent to the Scheme procedure call (`F A`) except that the expressions `F` and `A` are evaluated in parallel. The function that expression `F` evaluates to is invoked after that evaluation of the argument `A` is complete. The `pcall` construct can be nested; for example, the expressions `F` and `A` may themselves contain `pcall` constructs.

The `future` construct can be used to fork off a computation that is performed in parallel with execution of code that may ultimately need the value of that computation. For example, the expression (`pcall cons A B`) evaluates `A` and `B` in parallel, and builds the `cons` cell when the evaluations are complete. The construction of the data structure need not wait for the termination of the computations of `A` and `B` since these computations can immediately return “place holders” for the ultimate values, replacing these place holders with the actual values when those become available. This can be accomplished by the invocation (`pcall cons (future A) (future B)`). While the computation of `A` and `B` is taking place, the `cons` cell can be used to build other data structures or be passed to other procedure invocations. An operation such as addition that tries to use the value of `A` or `B` before that value is available is blocked until the corresponding place holder is replaced with the value; when that value becomes available, that computation is allowed to continue. This is a form of fine-grain data-flow synchronization at the level of data structure elements.

The following program shows a Multilisp version of Quicksort (taken from Ref. 22). The `partition` procedure uses the first element `elt` of list `l` to divide the rest of `l` into two lists, one containing only elements less than `elt` and the other containing elements greater than or equal to `elt`. These lists are themselves sorted in parallel recursively, and the resulting lists, together with `elt`, are appended together to form the output. To reduce the overhead of explicitly appending lists, `qs` takes an additional argument `rest` that is the list of elements that should appear after the elements of `l` in the sorted list.

```
(defun qsort (l) (qs l nil))
(defun qs (l rest)
  (if (null l) rest
  (let ((parts (partition (car l) (cdr l)))) ;
  sort the two partitions in parallel
    recursively
  (qs (left-part parts)
    (future (cons (car l) (qs (right-part
    parts) rest)))))))
(defun partition (elt lst)
  (if (null lst)
  (bundle-parts nil nil)
  (let ((cdrparts (future partition elt (cdr
    lst))))
    (if (> elt (car lst))
      (bundle-parts (cons (car lst)
        (future (left-part cdrparts)))
      (future (right-part cdrparts)))
    (bundle-parts (future (left-part
      cdrparts))
       (cons (car lst)
        (future (right-part cdrparts))))))))
(defun bundle-parts (x y) (cons x y))
(defun left-part (p) (car p))
(defun right-part (p) (cdr p))
```

It can be seen that this Multilisp program is a functional program to which `future`’s have been added. The problem of deciding where it is safe and profitable to insert `future`’s in a general Multilisp program is a nontrivial one since Multilisp is an imperative language in which expression evaluation can have side effects. The suggested programming style is to write mostly functional code and look for opportunities to evaluate data structure elements as well as function arguments in parallel.

As in Scheme, the linked list is the key data structure in Multilisp. The role of lists in parallel programming is somewhat controversial because unlike arrays, lists are sequential access data structures and this sequentiality can limit acceleration in some programs. For example, consider applying a function *f* in parallel to each data item in a list. The list must traversed sequentially to spawn the parallel tasks, so parallel speed-up will be limited especially if the time for each function evaluation is small. If an array is used instead, the time required for the entire computation may be as small as the maximum of the times required for the individual function evaluations. Although linked lists are not used very often in parallel programming, note the future construct and its associated dataflow synchronization can be used in the context of other data structures.

The Linda language (23) also folds synchronization into data accesses, although in the case of Linda, synchronization is done during associative access of a shared tuple space.

Object-Oriented MIMD Languages

We describe HPC++ (24) and Java (25). There are both shared-memory languages.

HPC++. HPC++ (24) is a C++ library and language extension framework. For exploiting loop level parallelism, HPC++ has compiler directives called pragmas which are similar to the OpenMP directives. For example, parallel loops are exposed to the compiler by the `HPC_INDEPENDENT` directive, used in the following code to compute the ComputePi function.

```
double ComputePi(int n) {
  double w = 1.0/n;
  double sum = 0.0;
  #pragma HPC_INDEPENDENT, PRIVATE x
  for (int i = 1; i < n; i++) {
    double x = w * (i − 0.5);
    #pragma HPC_REDUCE
    sum += f(x);}
  return sum;}
double f(double a) {
  return 4.0/(1.0 + a*a);
}
```

One of the innovative aspects of HPC++ is its extension of the standard template library (STL) to support data parallelism. The STL in C++ provides (1) *containers* that define aggregate data structures like vector, lists, and queues, (2) *iterators* for enumerating over the contents of containers, and (3) *algorithms* that allow operations by element to be applied to containers. HPC++ has a parallel standard template library (PSTL) that provides parallel versions of these.

The most important container class in PSTL is the `Array` container (STL does not have multidimensional arrays that are crucial for scientific programming). By default, array containers are block-distributed but the programmer can specify a custom distribution by providing a *distribution object* containing a function that maps array indices to processors. The `par_for_each` iterator in PSTL is the parallel analog of the `for_each` iterator in STL. HPC++ also has a number of parallel algorithms such as `par_apply` for applying a function to each element of a container, and `par_reduction`, which is a parallel apply followed by a reduction with an associative binary operation. The following code shows HPC++ code for summing all the positive elements of a vector. The vector `v` is block distributed. The parameters to the `par reduction` algorithm are the associative combining operation, the function to be applied to each element of the container, and the starting and ending parallel iterators for the reduction.

```
BlockDistribution d(100, 100/numcontexts());
distributed_vector⟨double⟩ v(100, &d);
class GreaterThanZero{
  public:
    double operator() (double x){
      if (x > 0) return x;
      else return 0;
    }
};
...
double total = par_reduction(plus⟨double⟩(),
  GreaterThanZero(),
v.parbegin(),
    v.parend());
...
```

HPC++ is under active development. Planned enhancements to the existing implementation include a library for distributed active objects and an interface to CORBA via the IDL mapping. Another approach to extending C++ for parallel computing is the Charm++ effort (26).

Java

Java is a new object-oriented programming language that has a library of classes that support programming with threads. The thread library is intended primarily for writing multithreaded uniprocessor programs such as GUI managers. A parallel Java program consists of a number of threads executing in a single global object namespace. These threads are instances of user-defined classes that are usually subtypes of the `Thread` class in the Java library that override the run method of the `Thread` class to define what threads must do once they are created. Threads are first-class objects that can be named, passed as parameters to methods, returned from methods, etc. In addition, methods inherited from the `Thread` class permit a thread to be suspended, resumed, put to sleep for specified intervals of time, etc. Java also supports the notion of *thread groups.* Threads in a group can be suspended and resumed collectively.

Synchronization in Java is implemented using *monitors.* A monitor is associated with every object that contains a method declared to be *synchronized.* Whenever control enters a synchronized method in an object, the thread that invoked that method acquires the monitor for that object until the method returns. Other threads cannot call a synchronized method in that object until the monitor is released.

Java was not intended to be a language for parallel scientific computation. For example, it does not support multidimensional arrays nor are there any constructs for performing collective communication operations like reductions. However, there are efforts under way to use Java as a coordination language for multiplatform computational science applications (27).

Distributed-Memory MIMD Languages

One of the earliest distributed-memory MIMD languages is communicating sequential processes (CSP) (28) which spurred a lot of work on the theory and practice of message-passing language constructs. More recent languages in this area have taken a message-passing library like PVM (Parallel Virtual Machine) (29) or MPI (Message Passing Interface) (30) and grafted it onto a sequential language to obtain a distributed-memory parallel programming language. We will use FORTRAN/MPI to discuss this class of languages. In this programming model, a certain number of processes are assumed to exist, each having a unique name (usually a non-negative integer) and its own address space. Processes communicate by sending and receiving messages. A process can send data to another process by executing a SEND command, specifying the data to be transferred and the name of the recipient. The receiving process gets the data by executing a RECEIVE command, specifying the name of the sending process and the variable into which the data should be stored.

There are a number of variations on this basic SEND–RECEIVE theme. *Blocking* SEND–RECEIVE constructs requires the two processes to rendezvous before the data transfer takes place, which allows data to be transferred from one process to another without buffering in the operating system. However, if one process gets to the rendezvous considerably in advance of the other one, it cannot do useful work till the other process catches up with it. This problem led to the development of *nonblocking* SEND and RECEIVE constructs. A nonblocking SEND permits the sending process to continue execution as soon as the data has been shipped out to the receiving process even if the receiving process has not executed a RECEIVE command; the nonblocking RECEIVE construct is like a probe that permits the receiving process to check for availability of data without getting stuck if the data has not yet been received.

In addition to these SEND/RECEIVE commands, MPI has a number of collective *communication calls* that are useful for doing reductions, broadcasts, etc., collectively among *process groups*. These collective operations can be implemented using send and receive commands, but it is often possible to exploit the topology of the interconnection network to implement them more efficiently. MPI permits processes to belong to any number of process groups (called *communicators* in MPI terminology). All processes are members of the universal group `MPI_COMM_WORLD`.

The following code computes the value of π. The invocations of `MPI_COMM_SIZE` and `MPI_COMM_RANK` permit a process to determine the number of processes in the system and its own ID. The broadcast of the value of `n` is performed by invoking `MPI_BCAST`. The parameters to this call are the (1) the starting address of the data to be broadcast, (2) the number of values to be broadcast, (3) the type of the data, (4) the ID of process initiating the broadcast, (5) the process group to which the broadcast is performed, and (6) an error flag. Global reductions may be performed with a similar invocation.

```
program compute_pi
include ‘mpif.h’
double precision mypi,pi,w,sum,s,f,a
integer n, myid, numprocs,i,rc
f(a) = 4.d0/(1.d0 + a*a)
call MPI_INIT(ierr)
call MPI_COMM_RANK(MPI_COMM_WORLD,myrid, ierr)
call MPI_COMM_SIZE(MPI_COMM_WORLD, numprocs,
  ierr)
if (myid .eq. 0) then
  print *, ‘Enter number of intervals’
  read *, n
endif
call
  MPI_BCAST(n,1,MPI_INTEGER,0,MPI_COMM_
    WORLD,ierr)
w = 1.0d0/n
sum = 0.0d0
do i = myid+1,n,numprocs
  x = w*(i - 0.5d0)
  sum = sum + f(x)
enddo
mypi = w*sum
call MPI_REDUCE(mypi,pi,1,MPI_DOUBLE_
  PRECISION,
  MPI_SUM,0,MPI_COMM_WORLD,ierr)
if (myid .eq. 0) then
  print *, ‘computed pi =’ , pi
endif
call MPI_FINALIZE(rc)
stop
end
```

IMPLICITLY PARALLEL PROGRAMMING LANGUAGES

Many of the parallel programming languages described previously are in active use, but none of them is particularly *abstract* since they are all close to particular implementation models of parallel computing. It is likely that as better compiler and run-time systems technology becomes available, languages for programming parallel machines will become more abstract. This evolution would then parallel the evolution of sequential programming language that started out being very close to the hardware on which programs ran, but have since evolved to higher levels of abstraction. For example, early sequential languages like FORTRAN had GOTO statements which were manifestations of jump instructions in the underlying hardware, but GOTO statements have since been replaced by more abstract structured programming constructs. Similarly, variables in FORTRAN were names for fixed-memory locations and existed for the duration of the program just like memory addresses in the machine model, but the data models of modern programming languages are built on abstract notions like type, scope, and lifetime.

Although existing compiler and run-time systems technology is inadequate to permit efficient parallel programming in high-level abstract programming languages, many such languages have been proposed. In this section, we describe ZPL (Z-level Programming Language), an imperative array language that relies on parallelizing compiler technology to find opportunities for parallel execution, the functional languages Id and Haskell, and the logic programming languages Concurrent Prolog and PARLOG. An even more ambitious approach is taken by Unity (31), which attempts to derive parallel programs from high-level specifications written in a variation of temporal logic.

ZPL

In a FORTRAN or C program, statements that read and update disjoint memory locations can be executed concurrently. Therefore, it is possible in principle to use a sequential programming language like FORTRAN to program a parallel machine if one has a parallelizing compiler that can extract opportunities for parallel execution from sequential programs. An early compiler of this sort was PARAFRASE (32), which took FORTRAN programs and attempted to find parallel DO loops through program analysis. However, automatic parallelization has proved to be difficult in general, although there has been noteworthy success in some problem domains like numerical linear algebra.

ZPL (33) is an imperative array language without explicitly parallel constructs that relies on compiler technology to identify opportunities for parallel execution. A novel feature of this language is its *region* construct, an alternative to the *triplet* notation for describing the constant-stride index sets that was presented earlier. A disadvantage of the triplet notation is that it must be repeated for every subarray reference with this index sets (as in[1 : n] = B[1 : n] + C[1 : n] .) ZPL permits a more compact expression of such statements by providing the region construct that permits the definition and naming of index sets. The declaration region R = [1..n] can be viewed as defining a template of virtual processors of the appropriate size. Regions can be used with both data declarations and blocks of statements, as shown in the following code. An integer Intval is allocated on each virtual processor of the region; similarly, the statements in the block are executed by each virtual processor. Index1 is a keyword that permits each virtual processor to determine its index.

```
program Compute_pi;     – Program to approx. pi
  config var n : integer = 100;     – Changeable
    on Cmd Line
  region R = 1..n;     – Problem space
procedure f(a : double) : double; – Fcn for
  rectangle rule
    return 4 / (1 +  2);
procedure Compute_pi();     – Entry point
var Intval : [R] double;     – A vector of rect.
  pt.s
    pi :    double;    – Scalar result
[R] begin
  Intval := (Index1 − 0.5) / n; – Figure
    interval pts
  pi    := +< f(Intval) / n; – Approximate,
    sum, div
writeln(‘‘Computed pi = ’’ , pi);– Output to
  standard out
end;
```

Regions in ZPL may also be defined by applying operations like shifts to previously defined regions. Although ZPL compilers have been written for a variety of parallel platforms, it remains to be seen if the performance of the compiled code is sufficient to persuade programmers to move away from writing explicitly parallel programs in a language like FORTRAN with MPI.

Functional Languages

One approach to addressing the difficulty of determining noninterference of statements in languages like FORTRAN or C is to use functional language. These languages are based on the notion of mathematical functions that take values as inputs and produces values as outputs. When executing a functional language program, all functions whose inputs are available can be evaluated in parallel without fear of interference. This *data-driven* parallel execution model is the foundation of a number of functional languages like VAL (34), ID (35), and SISAL (36). An alternative execution model called *lazy evaluation* evaluates a function only if its inputs are available and it has been determined that the result of the function is required to produce the output of the program. Lazy evaluation permits the programmer to define and use infinite data objects such as infinite arrays or infinite lists (as long as only a finite portion of these infinite objects is required to produce the output), a feature that has been recommended for promoting modularity. Miranda (37) and Haskell (38) are languages that are based on the lazy evaluation model. Neither language is intended for parallel programming, but there is interest in defining a parallel verison of Haskell.

Operations like I/O do not fit naturally into the functional model since they are effects and not functions. Haskell uses *monads* to integrate I/O into a purely functional setting. A monad provides the illusion of an object with updatable state on which all actions are sequenced in a well-defined manner, which is sufficient for performing I/O. Monads permit the introduction of a limited form of side effects into functional language in a controlled manner, but these side effects are limited since monads cannot be used to define objects that can be updated concurrently.

Two problems have limited the impact of functional languages on the parallel programming community. The first is *aggregate update problem,* which refers to the difficulty of manipulating data structures like large arrays efficiently. Data structures are treated as values in functional languages, so they cannot be updated in place. The effect of storing a value v into element i of array A must be obtained by defining a new array B that is identical to A

except in the *i*th position where it has the value *v*. A naive implementation that makes a copy of *A* will be very inefficient. A variety of compiler optimizations (39) and language constructs like [*I structures* in Id (40)] have been proposed to address this problem but it is not clear to what extent these address the problem. A second problem is locality. In principle, an interpreter for a functional language can keep a work list of expressions whose inputs are available and evaluate these expressions in any order. Unless this is done carefully, it will have an adverse effect on locality, making it difficult to exploit caches and memory hierarchies. One solution is to remove caches from the implementation model and rely on *multithreaded processors* like dataflow processors that are latency tolerant. A complementary solution is to use compiler techniques to extract long sequential threads of computation from functional programs, and exploit locality in the execution of these threads. However, there appears to be little commercial interest in building multithreaded processors at this time; furthermore, the problem of sequentializing functional programs does not appear to be any easier than the problem of parallelizing imperative language programs.

Logic Programming Languages

Although functional languages eliminate the notion of sequential control from the programming model, they still retain the notion of *directionality* in the sense that the inputs of a function are distinct from its output. Logic programming languages provide an even higher level of abstraction by eliminating directionality through the use of relations (predicates) instead of functions. A logic program consists of a set of clauses that describe relations either explicitly by enumerating the tuples in the relation or implicitly in terms of other relations. Clauses that describe a relation explicitly are called *facts,* while those that describe relations implicitly are called *rules.* The first three facts in the program shown below specify that the `father` relation contains the tuples ⟨`Adam,Abel`⟩, ⟨`Adam,Cain`⟩, and ⟨`Abel,Bill`⟩. The parent relation is described by a rule: for all `X` and `Y`, the tuple ⟨`X,Y`⟩ is contained in the `parent` relation if it is contained in the `mother` relation (informally, `X` is the parent of `Y` if `X` is the mother of `Y`). The `grandfather` clause is defined implicitly as well: for all `X`, `Y` and `Z`, the tuple ⟨`X,Y`⟩ belongs to the `grandparent` relation if ⟨`X,Z`⟩ and ⟨`Z,Y`⟩ belong to the `parent` relation.

```
father(Adam, Abel).
father(Adam, Cain).
father(Abel, Bill).
mother(Eve, Abel).
mother(Eve, Cain).
parent(X,Y) :− mother(X,Y).
parent(X,Y) :− father(X,Y).
grandparent(X,Y)  :−  parent(X,Z),parent(Z,Y).
:− grandparent(Adam,W).
```

In terms of formal logic, the symbol :− stands for logical implication, and the symbol, on the right-hand side of clauses stands for conjunction. Variables like `X` and `Y` are universally quantified over the clause in which they appear. Each clause is therefore a *Horn clause,* and the program is a conjunction of Horn clauses.

Given the relations, it is possible to make a variety of queries such as asking if a given tuple occurs in a relation. *Bottom-up query evaluation* starts from the facts and uses the rules repeatedly to compute the tuples in the relations of the program, terminating when enough information has been obtained to answer the query. This kind of data-driven evaluation obviously exposes a lot of parallelism but it can lead to an unbounded amount of useless computation in general. *Top-down* query evaluation generates subproblems from the original query and solves them recursively to answer the query. The query `grandfather(Adam,W)` can be answered if we can find a `Z` and `W` such that `parent(Adam,Z)`*and* `parent(Z,W)`. The first subproblem can be solved in two ways: either by solving `mother (Adam,Z)`*or* by solving `father(Adam,Z)`. These explorations can be described compactly by an AND-OR tree, shown in Fig. 2.

Parallelism in top-down query evaluation comes in two flavors called *and-parallelism* and *or-parallelism.* In and-

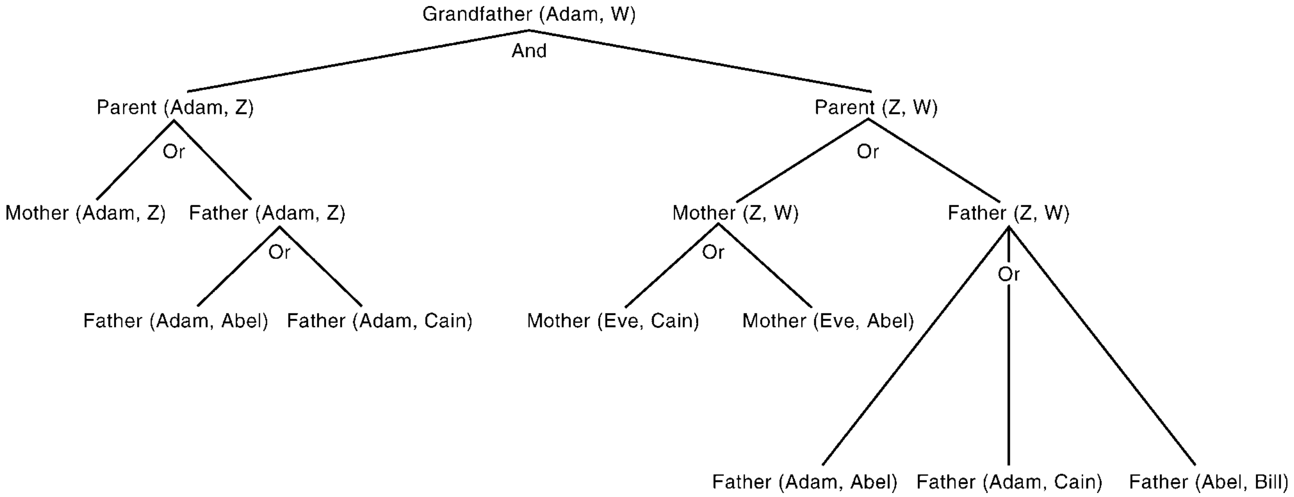


Figure 2. And-or tree.

parallelism, conjunctive subgoals such as `parent(Adam,Z)` and `parent(Z,W)` in our example are solved concurrently. The first subgoal produces possible solutions for `Z`, the second subgoal produces possible solutions for `Z` and `W` and the natural join of these solution sets produces the answers to the original query. Similarly in or-parallelism, disjunctive subgoals are solved in parallel and the results are unioned together.

The idealized model of parallel logic programming described here is difficult to implement efficiently, so researchers have proposed adding constructs to give programmers some control of parallel execution. To avoid having to compute the natural join of solutions from conjunctive subgoals solved in parallel, *mode declarations* can be used to specify that some subgoals will produce solutions that will be consumed by other subgoals. For example, Concurrent Prolog (41) has *read-only* annotations (?) using which we can write the `grandfather` clause as follows:

```
grandparent(X,Y) :— parent(X,Z),parent(Z?,Y).
```

This requires the first subgoal to produce `Z` and the second subgoal to read it. Similarly, PARLOG (42) has *mode declarations* on variables in the left-hand side of clauses. A limited form of or-parallelism called *committed choice or-parallelism* that uses Dijkstra's guards has been proposed in Guarded Horn Clauses (43) and PARLOG.

Logic programming ideas continue to be used in areas such as artificial intelligence, but there is little mainstream interest at this point. The early enthusiasm for separating the logic of algorithms from their control did not last very long, and logic programming found themselves introducing extralogical constructs like guards and modalities to improve program efficiency. In addition, a real programming language has to have arithmetic functions like addition and multiplication, but interpreted functions have always existed somewhat uneasily in the relational model. Some of these concerns are being addressed by Concurrent Constraint Programming languages like OZ (44).

CONCLUSION

Parallel programming today is done in languages that are very close to particular parallel implementation models. Thus, efficiency comes at the cost of portability. It is likely that parallel programming languages will become more abstract when the necessary compiler and runtime systems technology becomes available.

PARALLEL ARCHITECTURES

INTRODUCTION

The need for solving increasingly complex problems has led to the design of fast computers capable of performing several things at once. Although it is difficult to give a single, precise definition that would describe all parallel architectures, one can think of these machines in terms of their parallel computational capabilities to speed up the execution of real applications. With large, compute-intensive applications, more operations can potentially be performed in parallel. To realize the speed up desired in executing an application, three components must work together: solution algorithms involving many independent operations, explicit or implicit parallel programming languages that identify parallel operations used to implement the algorithms, and the architecture of an underlying computer that can execute multiple operations simultaneously (1). In an attempt to define and distinguish between various types of parallelism that may be implemented in parallel architectures, Flynn (2) has characterized architectures based on the presence of single or multiple instruction streams and data streams. Single instruction stream (SI) combined with single data stream (SD) leads to *SISD* computers (single instruction stream, single data stream), which are the traditional sequential machines (also known as von Neumann). Single instruction stream combined with multiple data (MD) are *SIMD* or vector computers. In these machines, multiple processing elements (PEs) simultaneously execute the same instruction on different data. For example, an SIMD computer with 64 PEs can add the elements of two vectors A and B with 64 elements each in one single instruction $A + B$. This instruction is the equivalent of 64 addition operations on a sequential machine. However, everything else being equal, it is performed in roughly 1/64 of the time it would take in the sequential version. Multiple instruction streams combined with multiple data, *MIMD*, are *multiprocessor* architectures. Multiprocessors consist of several autonomous processors capable of executing independent sequential programs concurrently or cooperatively execute a single parallel program. The first results in increased system throughput but individual programs do not run faster, whereas the second approach leads to executing individual applications fast, which is the primary purpose of using these powerful computing machines. MIMD computers are capable of thread-level parallelism that is more generally applicable than data-level parallelism of SIMD computers. Multiprocessors are further distinguished by the way in which memory is accessed by processors. If all processors can access all system memory locations, then the multiprocessor is characterized as shared memory. If each processor has access to only its own memory, then it is characterized as distributed memory. In shared memory MIMD computers, parallel processors communicate with each other by writing and reading shared memory locations, whereas in distributed MIMD machines, processors must communicate through sending and receiving messages to and from each other. Other variations of memory access that result in multiprocessor hybrids not classified by Flynn's taxonomy will be described in a later section. The last combination of multiple data stream and single data stream is not very practical, although there are a few research machines that it may fit. Implied in all parallel types of architectures described here as SIMD or MIMD is the existence of some form of network to provide connectivity between their components (processor to processor or processor to memory) to facilitate communication and cooperation among parallel units (3). Parallel computer systems are at times categorized even more by the number of physical parallel units (processors) they provide. A massively parallel system (MPP) is often the term used to refer to parallel systems with hundreds and thousands of processors. The interconnection networks in these large-scale parallel systems must be highly concurrent and capable of delivering many simultaneous messages very fast.

A DEEPER LOOK INTO PARALLELISM IN COMPUTER ARCHITECTURES

In general, two main approaches to building faster computers are a faster clock rate, driven by the advances in the technology, and concurrency in operations, driven by architectural design. Sequential computer designers have been exploiting successfully both of these techniques to build very fast SISD computers. The next step in achieving a higher speed is parallel architectures. To gain insight into the variety of parallelism and to distinguish the concurrency within SISD and parallel computers, the focus here will be on architectural parallelism introduced at various levels of computer design instead of clock rates. The two main approaches to introduce operational concurrency are *overlap* and *replication*. In the original von Neumann architecture, the major components consisted of a control unit (CU) and an arithmetic logic unit (ALU) together forming the central processing unit (CPU) and the main memory (M). Today, these still form the major components, but much has been done to improve performance of this early computer (Fig. 1). When a computer is started, it repeatedly executes a hardware loop known as *fetch/execute* cycle. Initially the program instructions are stored in the main memory. To execute the program, the CPU must fetch instructions from the memory. The program counter register (PC) in the CPU always holds the address of the next instruction in the memory to be fetched and executed. To make sure the following terminologies are not new to the reader, without going into details, let us assume a machine instruction of the form $c = a \text{ op } b$, where "op" refers to one of the machine operations implemented in hardware, such as addition,

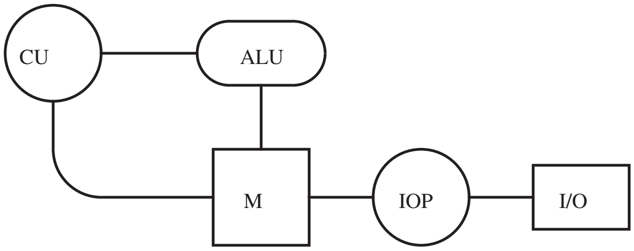

Figure 1. von Neumann architecture with I/O processor for I/O and CPU overlap. (Reprinted from Ref. 1 with Permission from Pearson Education.)

subtraction, and multiplication. a, b, and c are addresses of operands of this instruction in memory, and from the instruction, their addresses can be calculated in the CPU. A typical fetch/execute cycle for a von Neumann computer consisted of the following sequential steps:

1. IF: Fetch instruction from M at address pointed to by PC; bring it into the CPU.
2. ID: Decode instruction and increment PC to point to the next instruction.
3. Effective operand address calculation.
4. Operand fetch: Fetch operands from M at above address(es) and bring them into the CPU.
5. Execute: Perform the operation indicated by the instruction.
6. Store result: Store at the result operand address in M.

Improvements on this base machine started with adding features for faster input/output (I/O) processing where the concepts of overlap and parallelism were first introduced as are currently used and applied. The next major architectural advance toward concurrency in SISD architectures, also applied to many parallel computers, is a powerful technique known as *pipelining*. Going back to the sequential steps of the fetch/execute cycle in the von Neumann, it is clear that once an instruction is fetched from memory, no new instruction may be fetched until the current one has completed its execution. Using additional hardware, the steps of fetch/execute cycle can be overlapped as shown in Fig. 2. In this *instruction pipeline*, instructions follow each other through the pipeline stages that correspond to the fetch/execute cycle described above. Instructions are being executed sequentially and enter the pipeline in order, but once the pipeline is full (*start-up time*), five different instructions are being processed at different pipeline stages simultaneously and one instruction completes at every pipeline step rate. Theoretically, this design can be five times faster than the non-pipelined processor. However, complexities are associated with pipelining that make this peak performance unachievable although still by far faster than the non-pipeline design. The major issues here have to do with branches (*control hazard*) and dependencies between instructions (*data hazard*) in the pipeline. From the fetch/execute cycle, it can be seen that the next instruction being fetched is always coming from the next address relative to the current instruction being executed. However, when the instruction is for example a conditional branch, depending on the true/false outcome of the test, the next instruction may be coming from a different address called the target of the branch. In such an instruction, the content of PC is changed to that of the target. In a pipelined processor, the outcome of the branch is not known at the time the next instruction is to be fetched; therefore, the pipeline must be emptied. Performance degradation can also occur when an instruction in the pipeline needs the result of another instruction in the pipeline as its operand, which are known as data hazards. Solutions to deal with these types of dependencies (data and control hazards) may introduce bubbles or null operations into the pipeline. Various methods to deal with branch instructions and data hazards and to optimize the pipeline performance have been developed (4). Multiple arithmetic units in SISD computers introduced a different means for parallelism (replication). In this case, the CPU design is modified so that it consists of several arithmetic units capable of executing one operation each, but they can perform simultaneously. In this type of computer, potentially as many instructions as there are arithmetic units can be executing concurrently. To increase the potential for parallel execution, special hardware to prefetch several instructions from memory (*look-ahead buffer*), test for resource and data conflicts, and issue instructions out of program order (*score boarding*) is necessary. The two types of parallelism described here, instruction pipeline and multiple arithmetic (functional) units, for SISD computers are known as low-level parallelism and because of technological advances are included in most desktop computers of today. *Instruction-level parallelism (ILP), very long instruction word (VLIW)* architectures, and *superscalar* machines

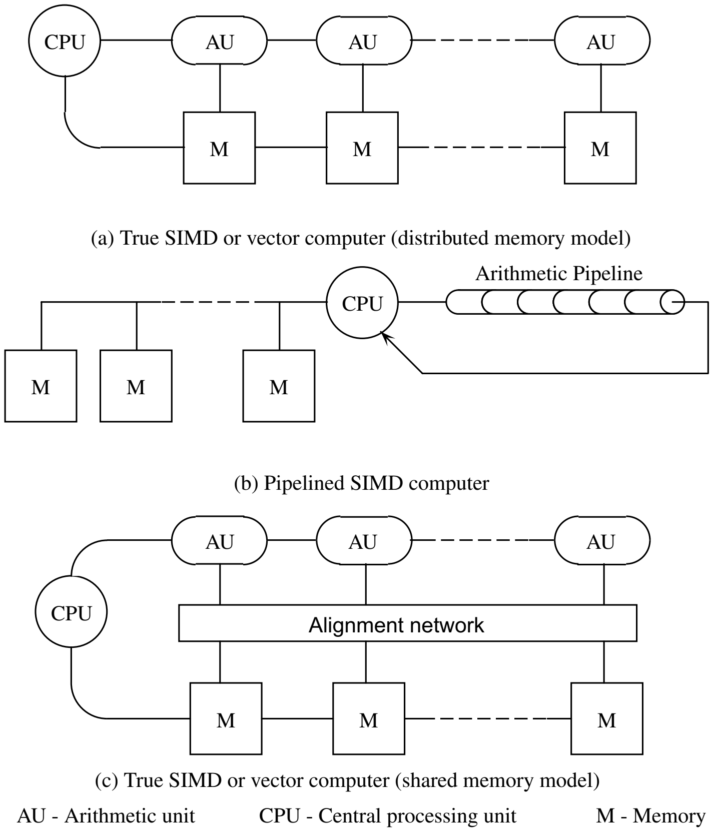
are also advances based on these basic parallel techniques. These machines are still classified as SISD even though they incorporate much concurrency in their design.

PARALLEL ARCHITECTURES

Technological advances combined with sophisticated architectural design resulted in uniprocessor performance growth throughout the 1986–2002 period. During this time, a large number of diverse, innovative, and expensive parallel computer architectures (*supercomputers*) have been designed with varying success mostly for the scientific community with compute-intensive applications. Networking available microprocessors to build affordable multiprocessors (*commodity multiprocessors*) made the field of parallel processing available to the larger community. The uniprocessor performance growth is reaching its limit because of high clock speed, resulting in problems with power consumption and heat dissipation, and a limited amount of ILP that can be exploited from sequential programs. The increasing capacity of a single chip has enabled placement of multiple processors on a single die resulting in *multicore* architectures. These machines can run at a lower clock speed to reduce heat dissipation and power consumption, they allow exploitation of a higher degree of concurrency from parallel programs instead of sequential programs, and they provide greater system density. Multicore architectures, which contain multiple logical processors in a single package available in almost all computers today, have renewed the interest in parallel computers as they are being mass produced. Different forms of multiprocessors with SIMD parallelism on a single cell chip have also been designed. Effective use of these computers through parallel algorithms, programming languages, compilers, and operating systems will greatly improve the overall system and application performance. Parallel computer architectures are mainly defined based on providing an explicit and coherent framework for high-level parallel solutions to application problems. This definition distinguishes the type of parallelism these machines must provide from those of SISD described earlier.

SIMD Computers

SIMD architectures provide hardware to execute the same instruction on many data items. SIMD computers incorporate this parallelism either through several *arithmetic pipelines (pipelined SIMD),* which is the most common (5), or through replicating PEs (*true SIMD*), (Fig. 3). These computers have a control unit that is capable of fetching and decoding instructions. SIMD computers have a single program counter in the control unit and perform the concurrent operations in locked steps using a global clock. The control unit sends the vector instructions either to the complete replicated arithmetic units in the true SIMD or issues them into arithmetic pipelines to be processed in an assembly fashion in the pipelined SIMD. SIMD Computers implement special vector and communication instructions for data routing in addition to the typical SISD machine



(a) True SIMD or vector computer (distributed memory model)

(b) Pipelined SIMD computer

(c) True SIMD or vector computer (shared memory model)

Figure 3. SIMD architectures. (Reprinted from Ref. 1 with Permission from Pearson Education.)

instructions. The true SIMD computers can further be organized as a distributed memory where each PE has access to its own memory [Fig. 3(a)]. In this model, an interconnection network provides communication between the PEs. Alternatively, SIMD computers may be organized as shared memory SIMD where an interconnection network allows for data routing between PEs and memory modules, [Fig. 3(b)]. Pipelining keeps the amount of parallel activity high while reducing the hardware requirement, [Fig. 3(c)]. Pipelined SIMD computers consist of pipelined arithmetic units that are different from instruction pipelining described for the SISD computers. Pipelining of arithmetic operations divides each operation, for example floating point addition, into several smaller ones and executes the subfunctions in parallel on different data as shown in Fig. 4.

SIMD Issues. Partitioning and data layout in memory for parallel access and interconnection networks for routing data are two key performance issues in SIMD machines. In a true distributed SIMD computer with 64 PEs, the addition of two 64-element vectors such as $C = A + B$ can be thought of as storing the corresponding vector elements (a_i, b_i, c_i) in the ith memory for the ith PE. Upon issuing the add instruction, the 64 PEs in the distributed model will simultaneously fetch their corresponding a and b operands from their memories, perform the addition, and store the result in the corresponding c locations. The key to obtaining good performance in this machine is to store the data to be accessed for parallel operation in different memory modules for parallel access. The interconnection network between the PEs must provide enough concurrency for PEs to exchange data. If the array elements are stored in the same memory module, then the array elements will have to be accessed from the memory sequentially and sent to the correct PE degrading performance to that of a sequential machine. The prime memory system is a technique for avoiding multiple references to the same memory module with regular access patterns (6). Although data layout in memory is the responsibility of the programmer, programming language, or compiler, the machine must provide an interconnection network to allow for routing the data to the correct PE needing it. In the shared memory model, the machine architecture must provide high concurrency interconnection networks between the memory modules and the PEs to allow data from different memories to be routed to the PEs in parallel. In pipelined SIMD, elements of A and B vectors are streamed into a floating point add pipeline as shown in Fig. 4. Although the vector components are not accessed simultaneously, successive references must still be made to different memory modules to attain full memory bandwidth and to match the pipeline speed. Most pipelined SIMD architectures provide fast vector registers where the vector operands are fetched into from memory and results are stored in before the final store in memory, *vector register pipelined SIMD*. Pipeline chaining, where the result of one arithmetic pipeline is fed as input into another arithmetic pipeline, is used to improve performance by reducing the number of memory accesses. An example for a chaining operation is $D = A(B + C)$, where the result from $B + C$ pipeline is fed into the multiple pipeline with elements of vector A synchronized with the first result from the adder. Some pipelined SIMD machines do not provide vector registers. In these machines, vector operands are pipelined from memory in a stream fashion to the arithmetic pipeline and results are stored similarly into memory, *memory-to-memory pipelined SIMD*. A larger memory bandwidth is needed to supply the pipelines with data at the pipeline speed. In this type of machine, the best performance is achieved for very long vector operations. As with instruction pipeline, a startup cost is associated with filling the pipelines. But once the pipeline is full, one result is produced at every minor pipeline cycle.

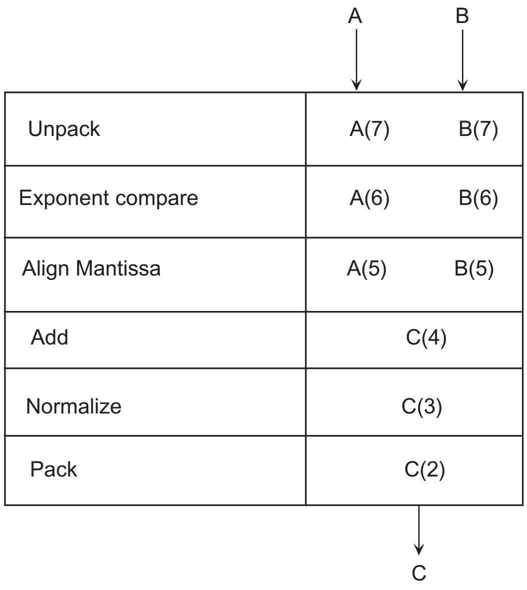


Figure 4. Floating point add pipeline. (Reprinted from Ref. 1 with Permission from Pearson Education.)

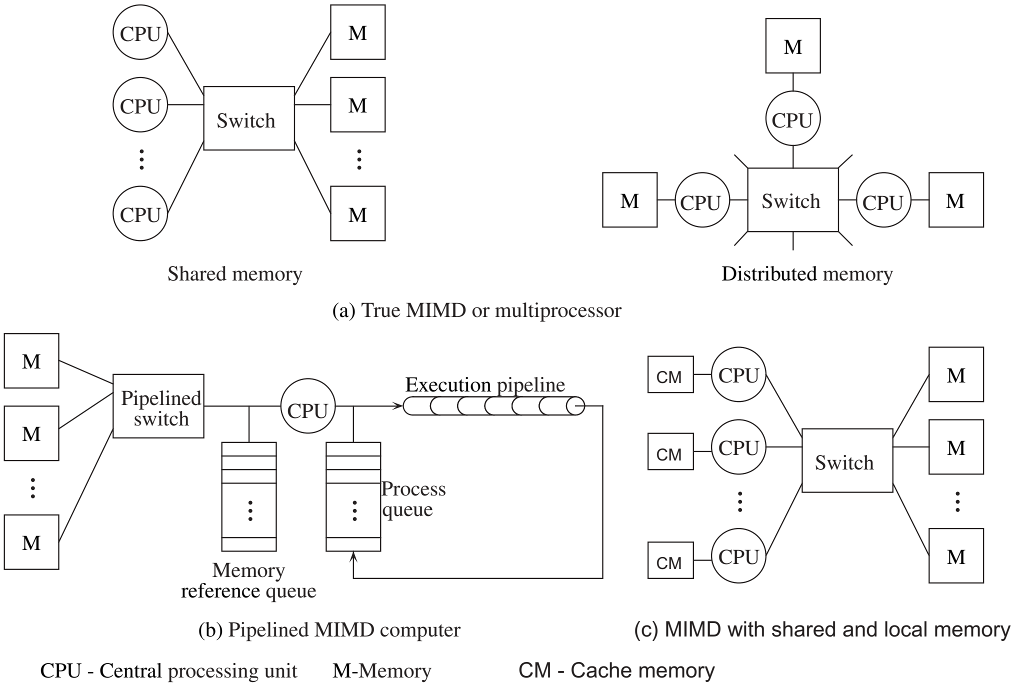
The parallelism provided by SIMD architectures is at the instruction level and is well suited to applications needing regular-patterned parallel operations. Today, SIMD processors most commonly are organized within an MIMD configuration to provide higher degrees of parallelism.

MIMD Architectures

A multiprocessor is a computer system that consists of multiple processors capable of executing independent instruction streams and one integrated system for moving data among the processors, memory, and I/O devices. MIMD computers can support higher levels of parallelism such as subprograms and tasks in comparison with SIMD-type parallelism. The parallelism in these machines can be exploited by numerous types of parallel operations that may be identified in the application programs. Many configurations of multiprocessors have been realized. What distinguishes the various configurations is the way in which results produced by one processor are made available to the others. Unlike SIMD, little difference exists between the programmer's view of one processor of an MIMD and the single processor of an SISD computer. The two basic types of MIMD computers, shared memory and distributed MIMD, are shown in Fig. 5.



(a) True MIMD or multiprocessor

(b) Pipelined MIMD computer

(c) MIMD with shared and local memory

Figure 5. MIMD architectures. (Reprinted from Ref. 1 with Permission from Pearson Education.)

Shared-Memory MIMD. The general interconnection network (switch) between the processors and system memory of Fig. 5(a) indicates that any processor can access any memory location. The communication and cooperation among processors that execute a parallel program takes place through reading and writing of shared memory locations. Synchronization operations must be provided to control access to shared data and to control the rate of progress of cooperating processes. Similar to SIMD machines, good performance depends on the interconnection network providing enough concurrency and bandwidth for fast and parallel memory accesses by processors. Shared memory MIMD computers may be designed as pipelined processors as in the SISD case instead of multiple complete processors [Fig. 5(b)]. However, unlike the SISD pipeline where the instructions issued into the pipeline come from a single process, instructions issued into the MIMD pipeline come from different instruction streams (processes). Therefore, the number of bubbles inserted into the MIMD pipeline caused by instruction dependencies is reduced significantly in comparison with SISD pipelining. The pipelined MIMD architectures are also known as *multithreaded* computers (7–10).

MIMD computers with various configurations, mainly due to the type of memory access they are organized to provide, have been designed. For example, each processor of the shared memory model in Fig. 5(a), may have some local (private) memory [Fig. 5(c)]. The private memories may be cache memories if they are controlled by hardware.

The issue in this type of architecture is how the local memories are used. The simplest is when they are used for read-only data and program stacks in shared memory MIMD. When the local cache memories in a shared memory MIMD are used for shared variables that may be both read and written, then a *cache coherence* protocol is needed to ensure the information in the main memory and the cache memories will remain consistent during program execution. Several approaches to providing coherent caches in these types of MIMD architectures have been implemented (11,12). A shared memory MIMD computer is referred to as *uniform memory access (UMA)* if it is configured such that any memory location can uniformly be accessed in the same amount of time. If the machine is organized so that access to some locations in the shared memory takes longer than others, then it is called a *non-uniform memory access (NUMA)*. A *cluster* is formed by connecting several shared memory multiprocessors through a communication network that they can use to send and receive instructions. In this case, the shared memory of each component of the cluster is considered private with respect to the other components. The recent multicore computers take the place of a cluster node where each multicore provides a shared memory MIMD configuration.

Distributed-Memory MIMD. Each node of this architecture consists of an autonomous processor and its local memory. The communication and cooperation among processors executing a parallel program takes place by processors explicitly send and receipt messages through the interconnection network. In these architectures, the synchronization is tied to the send and receipt of messages. Distributed memory architectures are distinguished from each other by the topology of the interconnection network through which their processors are connected. The network topologies will directly impact the way messages are routed from one processor to another, the number of messages that can concurrently be exchanged, the latency of message

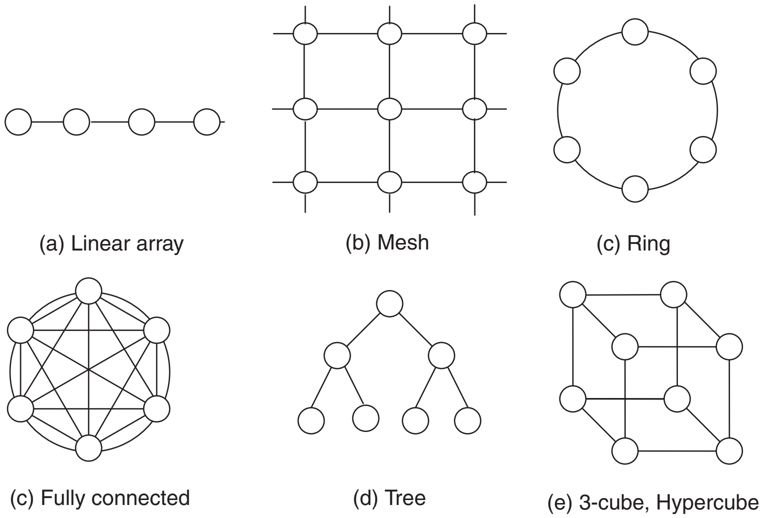


Figure 6. Common distributed memory MIMD toplogies. (Reprinted from Ref. 1 with Permission from Pearson Education.)

delivery, and the performance of executing parallel programs on the distributed memory architecture. Some of common topologies are shown in Fig. 6. The *ring* topology has commonly been used to interconnect a number of computers. In a unidirectional ring connecting N processors, each node is connected to one source and one destination processor. A message may have to travel through N-1 nodes (*hops*) to arrive at its destination. This longest path between any two nodes is called the *diameter* of the network. A bidirectional ring will improve the network diameter so that the longest path a message travels is $N/2$. The ring topologies have simple logic and can be used effectively with few processors, but several architectures have been implemented using more complex extensions of the ring such as multilevel hierarchy of unidirectional rings (13). Mesh topologies have been used extensively in designing distributed memory MIMD machines. Many topologies may be listed under this topology from a simple *linear array* to high-dimensional meshes. Two-dimensional mesh topologies are the most common. They are distinguished by the way the boundary nodes are connected to their neighboring processors. For example, *Wrap-around* connections reduce the network diameter. In a k- dimensional network with N^k nodes on each dimension, the diameter is $k(N^k-1)$. Hypercube topologies arrange $N = 2^n$ processors in an n-dimensional cube. Each node of this machine is directly connected to $n = \log_2 N$ other processors through a bidirectional link. Tree topologies with parent–child-type connections support divide-and-conquer problem-solving approaches. For two processors to communicate in this architecture, a path ascending from the two to a common parent is used. In these machines, the links closer to the root have a high traffic rate than the leaf nodes resulting in a bottleneck. Fat trees, where the number of links connecting parent–child processors increases as we get closer to the root, have been used to alleviate the problem. Full connectivity, although desirable, is not practical to implement for multiprocessors with large number of processors, N, as N^2 connections will be needed.

It may be noteworthy to consider that by replacing the single processor at each node with a shared memory MIMD, a cluster architecture can be configured. In general, hardware and software techniques may be devised to implement a distributed memory MIMD computer as a shared memory multiprocessor that results in a *distributed shared memory machine (DSM)*, which is also referred to as a shared address space multiprocessor.

Issues in MIMD. The performance of a parallel architecture is impacted significantly by inter-related factors such as the algorithm design, programming languages, operating systems, processor design, interconnection networks, memory hierarchy, cache and memory management, and latency tolerance mechanism. The performance capabilities of computers are often reported with measures such as Hertz ratings or peak-floating-point-operation-per-second (FLOPS) ratings. Careful interpretation of these processor-centered measures is needed as they do not reveal enough information regarding the architecture's overall performance. The data transfer capacity of the machine is a more accurate way to express performance and is measured by bandwidth and latency. The basis for this performance measure is that data have to arrive at the processor before they can be operated on. The layers of memory hierarchy and interconnection networks that may separate data from the processor will influence the amount of delay associated with getting data to the processor. For example, in shared memory MIMD, a processor may be slowed down when it has to wait for large shared memory access latency, for either data transmission or cache coherence information. In a distributed memory MIMD, the movement of messages containing intermediate results is the principal reason for not obtaining a peak operation rate in the processor. Discussions regarding the scalability of parallel architectures mostly favor distributed MIMD computers. However, regardless of the memory organization, a scalable computer system is defined as one in which data transport depends on the bandwidth and not on the latency, so that as the system size is increased, bandwidth increases but not the latency. Latency in computer architectures is mainly dealt with in two ways: (*1*) latency reduction as in cache memories or cut-through routing in interconnection networks, and (*2*) latency tolerance mechanisms as in overlapping operations in pipelining and multiprogramming. Thus, a computer architecture that can reduce its performance dependence on latency through one or a combination of these techniques will be the most scalable. In general, the optimal balance occurs when bandwidths above and below a given level differ by the amount of data reuse at that level, which is a difficult goal to achieve. When traffic is bursty, latency to satisfy a request for the next higher level can prevent the bandwidth from being fully utilized. Cluster computer organizations have become popular and are used commonly today. The cluster architectures are also highly vulnerable to most of these issues. They need to address issues of latency, synchronization, fine-grain parallelism, memory management, deep memory hierarchy, data movement, application types, form and degree of parallelism within applications in order to achieve high performance.

Other Parallel Architectures

Dataflow Architectures. Parallelism in computation is normally stated by specifying which operations can be executed in parallel, allocating storage to data, and scheduling those operations on parallel units. *Dataflow* is a concept that allows a computation to be represented without specifying any control flow or other dependence constraints on the order of operations except those of flow dependence among data. The concepts of dataflow have been central in the field of parallel processing and were originated by Dennis in 1973 (14). Computations can be represented accurately with *dataflow graphs*, which consist of directed edges, nodes (or actors), and tokens. The nodes or actors represent an operation corresponding to a program instruction and are connected by directed edges. The tokens are data values that move over directed edges; they are operated on at the node and are transformed into result tokens. Program instructions are executed (or *fired*) when their needed data tokens arrive at the instruction node. In this way the traditional control flow in other programming paradigms is replaced by dataflow. Dataflow architectures that are capable of executing dataflow graph concepts have processing elements that receive input data tokens (operands), perform the specified operation upon receipt of the operands, form new result tokens, and send them to the destination actor (instruction) in the dataflow graph. This capability is a major departure from the conventional von Neumann model that uses a program counter in the processor to address and fetch instructions. In this model, instructions are stationary, but data flows to the instruction that needs them as operands. The architecture of dataflow machines is impacted by the type of dataflow representations it must implement. In a static model, only one instance of a data token value is allowed per input edge of a node at a time. A typical static dataflow architecture is shown in Fig. 7. In a dynamic model, multiple instances of data tokens may exist on an input edge at a given time. Tokens belonging to different instances must be distinguished using matching tags. Dynamic dataflow is more flexible, can achieve higher parallelism, and results in a more complex architecture. Storage is a major issue that dataflow computers need to address. The ideal dataflow representation requires replication of data for every use or modification as no allocation of a memory location to data (variables) exists. Efficient scheduling of all ready operations for parallel execution is also another challenging issue that needs to be carefully addressed in dataflow architectures.

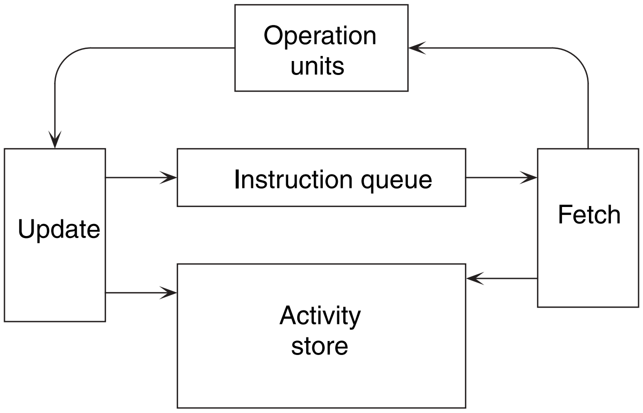

Figure 7. A typical dataflow architecture. (Reprinted from Ref. 1 with permission from Pearson Education.)

Systolic Arrays. Systolic arrays are special-purpose architectures consisting of simple computing cells with regular design patterns that are constructed in a modular layout well suited for VLSI implementations (15,16). Data are pumped through computing arrays in a pipeline fashion. In most cases, the computing cells in an array are identical and the design of the array is geometrically regular. For example, two-dimensional systolic arrays can be designed to perform fast matrix multiplication operations where each cell of the array can perform a multiply–add operation on its input operands as the appropriate elements of the two matrices flow through the cells of the array. Systolic arrays represent data dependences in the cell interconnections and can result in very efficient implementation of special-purpose algorithms (17).

PARALLEL DATABASE MANAGEMENT SYSTEMS

A *database* is a collection of data. A *database management system,* also called a DBMS, allows users to create a new database by specifying the logic structure of the data. For instance, the world of interest is represented as a collection of tables in relational DBMSs. This simple model is useful for many applications, and it is the model on which the major commercial DBMSs are based today. After a database has been created, the users are allowed to insert new data and query and modify existing data. The DBMS provides the users with the ability to access the data simultaneously, without allowing actions of one user to interfere with those of other users. The DBMS ensures that no simultaneous accesses can corrupt the data accidentally. In this article, we discuss how parallel processing technology is used to effectively address the performance bottleneck in DBMSs. After a brief discussion of the various parallel computer architectures suitable for DBMSs, we present the techniques for organizing data in such machines and the strategies for processing these data using multiple processors. Finally, we discuss some future directions and research problems.

Modern DBMSs are designed to support the client–server computing paradigm. In this paradigm, applications running on client computers or workstations are allowed to store and access data from a remote database server. This configuration makes best use of both hardware and software resources. Both the client and the database server can be dedicated to the tasks for which they are best suited. This architecture also provides an opportunity for both horizontal (i.e., more servers) and vertical (i.e., larger servers) scaling of resources to perform the task.

Today's database servers are generally general-purpose computers running database management software, typically a relational DBMS. These servers employ essentially the same hardware technology used for the client workstations. This approach offers the most cost-effective computing environment for a wide range of applications by leveraging the advances in commodity hardware. A potential pitfall of this approach is that the many equally powerful workstations may saturate the server. The situation is aggravated for applications that involve very large databases and complex queries. To address this problem, designers have relied on parallel processing technologies to build the more powerful database servers (1–4). This solution enables servers to be configured in a variety of ways to support various needs.

PARALLEL DATABASE SERVER ARCHITECTURES

The disk input/output (I/O) limitation problem has long been the obstacle for database applications. The disk I/O bottleneck sets a hard limitation on the performance of a database server. To address this problem, all parallel database approaches distribute the data across a large number of disks to take advantage of their aggregate disk bandwidth. The different types of parallel database servers are characterized by the way their processors are allowed to share the storage devices. Existing systems employ one of the three basic parallel architectures (5): shared everything (SE), shared disk (SD), and shared nothing (SN). None emerges as the undisputed winner. Each has its advantages as well as its disadvantages.

Shared Everything Architecture

The processors share all disks and memory modules [see Fig. 1(a)]. Examples of this architecture include IBM mainframes, HP T500, SGI Challenge, and the symmetric-multiprocessor (SMP) systems available from PC manufacturers. A major advantage of this approach is that interprocessor communication is fast because the processors can cooperate via the shared memory. This system architecture, however, does not scale well for very large databases. For an SE system with more than 32 processors, the shared memory would have to be a physically distributed memory to accommodate the aggregate demand on the shared memory from the large number of processors. An interconnection network (e.g., multistage network) is needed, in this case, to allow the processors to access the different memory modules simultaneously. As the number of the processors increases, the size of the interconnection network grows accordingly, which renders longer memory access latency. The performance of microprocessors is very sensitive to this factor. If the memory-access latency exceeds one instruction time, the processor may idle until the storage cycle completes. A popular solution to this problem is to have cache memory with each processor. However, the use of caches requires a mechanism to ensure cache coherency (i.e., ensure that all cached copies of the same data item have the same value). As we increase the number of processors, the number of messages caused by cache coherency control (i.e., cross interrogation) increases. Unless this problem can be solved, scaling an SE database server into the range of 64 or more processors will be impractical. Commercial DBMSs designed for this architecture include Informix Online Dynamic Server, Oracle Parallel Query Option, and IBM DB2/MVS.

Shared Disk Architecture

To address the memory-access-latency problem encountered in SE systems, each processor is coupled with its private memory in an SD system [see Fig. 1(b)]. The disks are still shared by all processors as in SE. Intel Paragon, nCUBE/2, and Tandem's ServerNet-based machines typify this design. As each processor may cache data pages in its private memory, SD also suffers the high cost of cache coherency control. In fact the interference among processors is even more severe than in SE. As an example, let us

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

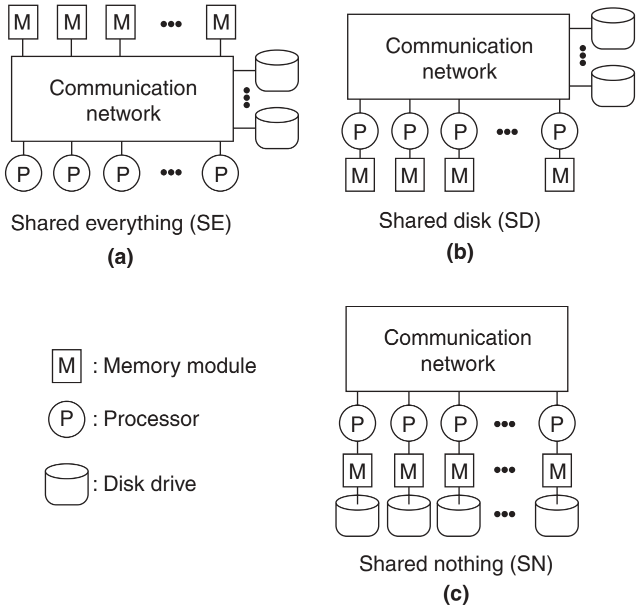

Figure 1. Three basic architectures for parallel database servers. Both disks and memory modules are shared by all processors in SE. Only disks are shared in SD. Neither disks nor memory modules are shared by the processors in SN.

consider a disk page containing 32 cache lines of data. No interference occurs in an SE system as long as the processors update different cache lines of this page. In contrast, an update to any of these cache lines in an SD system will interfere with all processors currently having a copy of this page even when they are actually using different cache lines of the page. Commercial DBMSs designed for this architecture include IBM IMS/VS Data Sharing Product, DEC VAX DBMS and Rdb products, and Oracle on DEC's VAXcluster and Ncube Computers.

Shared Nothing Architecture

To improve scalability, SN systems are designed to overcome the drawbacks of SE and SD systems [see Fig. 1(c)]. In this configuration, a message-passing network is used to interconnect a large number of processing nodes (PNs). Each PN is an autonomous computer consisting of a processor, a local private memory, and dedicated disk drives. Memory access latency is no longer a problem. Furthermore, as each processor is only allowed to read and write its local partition of the database, cache coherency is much easier to maintain. However, SN is not a performance panacea. Message passing is significantly more expensive than data sharing through the centralized shared memory as in SE systems. Some examples of this architecture are Teradata's DBC, Tandem NonStopSQL, Intel's Paragon, and IBM 6000 SP. Commercial DBMSs designed for this architecture include Teradata's DBC, Tandem NonStopSQL, and IBM DB2 Parallel Edition.

To combine the advantages of the previously discussed architectures and to compensate for their respective disadvantages, new parallel database servers are converging toward a hybrid architecture (6). In this architecture, SE clusters are interconnected through a communication network to form an SN structure at the intercluster level (see Fig. 2). The motivation is to minimize the communication overhead associated with the SN structure, yet keep each cluster size small within the limitation of the local memory and I/O bandwidth. Examples of this architecture include new Sequent computers, IBM RS/6000 SP, NCR 5100M, and Bull PowerCluster. Some commercial DBMSs designed for this structure are the Teradata Database System for the NCR WorldMark 5100 computer, Sybase MPP, and Informix-Online Extended Parallel Server.

DATA PARTITIONING TECHNIQUES

Traditional use of parallel computers is to speed up the complex computation of scientific and engineering applications. In contrast, database applications use parallelism primarily to increase the disk-I/O bandwidth. The level of achievable I/O concurrency determines the degree of parallelism that can be attained. If each relation (i.e., dataset) is divided into partitions, each stored on a distinct disk, a database operator can often be decomposed into many independent operators, each working on one partition. To maximize parallelism, several data partitioning techniques have been used (7).

Round-Robin Partitioning

The tuples (i.e., data records) of a relation are distributed among the disks in a round-robin fashion. The advantages of this approach are simplicity and the balanced data load among the disks. The drawback of this scheme is that it does not support associative search (i.e., search for tuples with the desired attribute values). Any search operations would require searching all disks in the system. Typically, local indices must be created for each data partition to speed up the local search operations.

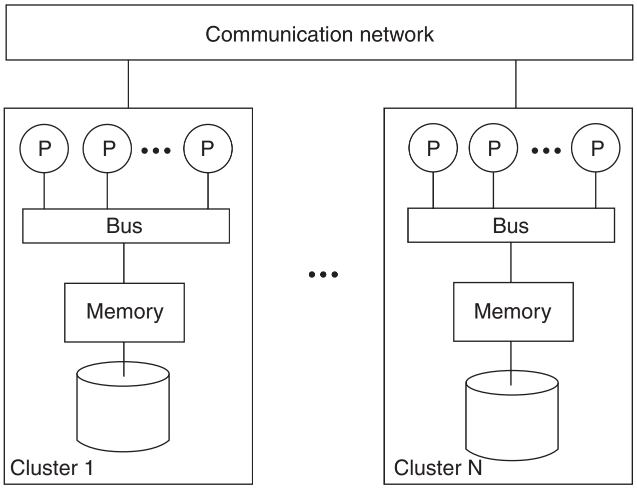

Figure 2. A hybrid architecture for parallel database servers. SE clusters are interconnected to form an SN structure at the intercluster level.

Hash Partitioning

A randomizing hash function is applied to the partitioning attribute (i.e., key field) of each tuple to determine the disk to store the tuple. Like round-robin partitioning, hash partitioning usually provides an even distribution of data across the disks. However, unlike round-robin partitioning, the same hash function can be employed at run time to support associative searches. A drawback of hash partitioning is its inability to support range queries. A range query retrieves tuples that have the value of the specified attribute falling within a given range. This type of query is common in many applications.

Range Partitioning

This approach maps contiguous key ranges of a relation to various disks. This strategy is useful for range queries because it helps to identify data partitions relevant to the query, skipping all uninvolved partitions. The disadvantage of this scheme is that data processing can be concentrated on a few disks, which leaves most computing resources underused. This phenomenon is also known as *access skew*. To minimize this effect, the relation can be divided into a large number of fragments using very small ranges. These fragments are distributed among the disks in a round-robin fashion.

Multidimensional Partitioning

Range partitioning cannot support range queries expressed on nonpartitioning attributes. To address this problem, multidimensional partitioning declusters a relation based on multiple attributes. As an example, let us consider the case of partitioning a relation using two attributes, say age and salary (see Fig. 3). Each data fragment is characterized by a unique combination of the age and salary ranges. For instance, tuples in the fragment [8,7] in Fig. 3 have the age values in range 8 and the salary values in salary range 7. These data fragments can be assigned to the disks in various ways (8–11). As an example, the following function can be used to assign a fragment $[X_1, X_2, \ldots, X_n]$ to a disk:

$$\mathit{DISK\_ID}(X_1, X_2, \ldots, X_n) = \left[\sum_{i=2}^{d} \left[\frac{X_i \cdot \mathit{GCD}_i}{N} \right] + \sum_{i=1}^{d} (X_i \cdot \mathit{Shf\_dist}_i) \right] \bmod N \qquad (1)$$

where N is the number of disks and d is the number of partitioning attributes;

$\mathit{Shf\_dist}_i = [\sqrt{N}]^{i-1}$ and $\mathit{GCD}_i = \gcd(\mathit{Shf\_dist}_i, N)$. A data placement example using this mapping function is illustrated in Fig. 3. Visually, the data fragments represented by the two-dimensional grid are assigned to the nine disks as follows:

1. Compute the shift distance *Shf_dist*. For this example, $\mathit{Shf\_dist} = [\sqrt{N}] = 3$.
2. Mark the top-most row as the check row.
3. Disks 0, 1, . . ., 8 are assigned to the nine fragments in this row from left to right. Make the next row the current row.
4. The allocation pattern for the current row is determined by circularly left-shifting the pattern of the row above it by three (i.e., *Shf_dist*) positions.
5. If the allocation pattern of the current row is identical to that of the check row, we perform a circular left-shift on the current row one more position and mark the current row as the new check row.
6. If there are more rows to consider, make the next row the current row and repeat steps 4, 5, and 6.

Assuming that nine had been determined to be the optimal degree of I/O-parallelism for the given relation, this data placement scheme allows as many types of range queries to take full advantage of the I/O concurrency as possible. Range queries expressed on either age or salary or both can be supported effectively. The optimal degree of I/O parallelism is known as the degree of declustering (DoD), which defines the number of partitions a relation should have. For clarity, we assume in this example that the number of intervals on each dimension is the same as the DoD. The mapping function Eq. (1), however, can be used without this restriction.

Many studies have observed that linear speed-up for smaller numbers of processors could not always be extrapolated to larger numbers of processors. Although increasing the DoD improves the performance of a system, excessive declustering will reduce throughput caused by overhead associated with parallel execution (12). Full declustering should not be used for very large parallel systems. The DoDs should be carefully determined to maximize the system throughput. A good approach is to evenly divide the disks into several groups and to assign relations that are frequently used together as operands of database operators (e.g., join) to the same disk group. Having different DoDs for various relations is not a good approach because the set of disks used by each relation would usually overlap with many sets of disks used for other relations. Under the circumstances, scheduling one operator for execution will cause most other concurrent queries to wait because of disk contention. This approach generally results in very poor system utilization.

PARALLEL EXECUTION

Today, essentially all parallel database servers support the relational data model and its standard query language: SQL (structured query language). SQL applications written for uniprocessor systems can be executed in these parallel servers without needing to modify the code. In a multiuser environment, queries submitted to the server are queued up and are processed in two steps:

- During compile time, each query is translated into a query tree that specifies the optimized order for executing the necessary database operators.
- During execution time, the operators on these query trees are scheduled to execute in such a way to maximize system throughput while ensuring good response times.

	Range 0	Range 1	Range 2	Range 3	Range 4	Range 5	Range 6	Range 7	Range 8
Range 0	0	1	2	3	4	5	6	7	8
Range 1	3	4	5	6	7	8	0	1	2
Range 2	6	7	8	0	1	2	3	4	5
Range 3	1	2	3	4	5	6	7	8	0
Range 4	4	5	6	7	8	0	1	2	3
Range 5	7	8	0	1	2	3	4	5	6
Range 6	2	3	4	5	6	7	8	0	1
Range 7	5	6	7	8	0	1	2	3	4
Range 8	8	0	1	2	3	4	5	6	7

A check row

This fragment is assigned to disk 3.

Tuples in this fragment have age in range 8 and salary in range 7.

Figure 3. Two-dimensional data partitioning based on age and salary. The 9 × 9 data fragments are assigned to nine processing nodes. Range queries based on age, salary, or both can be supported effectively.

Three types of parallelism can be exploited: intra-operator parallelism, intraquery parallelism, and interquery parallelism.

Intra-operator parallelism is achieved by executing a single database operator using several processors. This result is possible if the operand relations are already partitioned and distributed across multiple disks. For instance, a scan process can be precreated in each processor at system start-up time. To use a set of processors to scan a relation in parallel, we need only to request the scan processes residing in these processors to carry out the local scans in parallel. To effectively support various types of queries, it is desirable to create at least one process in each processor for each type of primitive database operator. These processes are referred to as *operator servers*. They behave as a logical server specializing in a particular database operation. Once an operator server completes its work for a query, the logical server is returned to the free pool awaiting another service request to come from some pending query. By having queries share the operator servers, this approach avoids the overhead associated with process creation. Intraquery parallelism is realized by arranging query operators in a query tree to allow several database operators to run concurrently without changing the query result. On the other hand, interquery parallelism is realized by scheduling database operators from different queries for concurrent execution. Two scheduling approaches have been used as follows.

Competition-Based Scheduling

In this scheme, a set of coordinator processes is precreated at system start-up time. They are assigned to the queries by a dispatcher process according to some queuing discipline, say, first come first serve. The coordinator that is assigned the query becomes responsible for scheduling the operators in the corresponding query tree. For each operator in the tree, the coordinator competes with other coordinators for the required operator servers. When the coordinator has successfully acquired all operator servers needed for the task, the coordinator coordinates these servers to execute the operation in parallel. An obvious advantage of this approach is its simplicity. It assumes that the number of coordinators has been optimally set by the system administrator and deals only with ways to reduce service times. The scheduling strategy is fair in the sense that each query is given the same opportunity to compete for the computing resources.

Planning-Based Scheduling

In this approach, all active queries share a single scheduler. As this scheduler knows the resource requirements of all active queries, it can schedule the operators of these queries based on how well their requirements match the current condition of the parallel system. For instance, a best-fit strategy can be used to select from the pending operators the one that can make the maximum use of currently available operator servers to execute first. The motivation is to maximize the resource utilization. This approach, however, is not as fair as the competition-based technique. Queries that involve very small or very large relations can experience starvation. The scheduler can also become a bottleneck. To ameliorate the latter problem, a parallel search algorithm can be used to determine the best fit.

We note that the scheduling techniques discussed previously do not preclude the possibility of executing two or more operators of the same query simultaneously (intraquery parallelism). Both scheduling techniques try to maximize the system performance by strategically mixing all three forms of parallelism discussed herein.

LOAD BALANCING

As each PN in an SN system processes the portion of the database on its local disks, the degree of parallelism is dictated by the placement of the data across the PNs. When the distribution is seriously skewed, balancing the load on these PNs is essential to good system performance

(12,13). Although SE systems allow the collaborating processors to share the workload more easily, load balancing is still needed in such systems to maximize processor utilization (14). More specifically, the load balancing task should equalize the load on each disk, in addition to evenly dividing the data-processing tasks among the processors. As an example, let us consider an extreme scenario in which a large portion of the data that needs to be processed happens to reside on a single disk. As little I/O parallelism can be exploited in this case, the storage subsystem cannot deliver a level of I/O performance commensurate with the computational capabilities of the SE system. Although the data-processing tasks can still be perfectly balanced among the processors by sharing the workload stored on that one disk, the overall performance of the system is deteriorated because of poor utilization of the available I/O bandwidth. Similarly, balancing the data load among the disks is essential to the performance of SD systems. In summary, no architecture is immune to the skew effect. We shall see shortly that similar techniques can be used to address this problem in all three types of systems.

SE and SD systems, however, do have the advantage under the following circumstances. Let us consider a transaction-processing environment in which frequently accessed data are localized to only a few disks. Furthermore, the system memory is large enough to keep these frequently used data in the memory buffer most of the time. In this case, it is very easy for the processors of an SE or SD system to share the workload because each processor is allowed to access the shared disks. In contrast, when an SN system is faced with this situation, only a couple of the PNs that own the disks with the frequently used data are overly busy. The remaining PNs are idle most of the time. This phenomenon, however, is most likely from bad data placement and usually can be rectified by redistributing the tuples.

Many load-balancing techniques have been developed for parallel database systems. Let us first examine techniques designed for SN systems. Several parallel join algorithms have been proposed. Among them, hash-based algorithms are particularly suitable for SN systems. In these strategies, the operand relations are partitioned into buckets in the hashing phase by applying the same randomizing hash function to the join key value, e.g., the join key value modulo the desired number of buckets. The buckets of the two relations, which correspond to the same hash value, are assigned to the same PN. These matching bucket pairs are evenly distributed among the PNs. Once the buckets have been assigned, each processor joins its local matching bucket pairs independently of the other PNs in the joining phase. This strategy is very effective unless there is a skew in the tuple distribution; i.e., some buckets are substantially larger than the remaining buckets. When severe fluctuations occur among the bucket sizes, some processors are assigned significantly more tuples on which to perform the local join operation. As the computation time of the join operation is determined by the slowest PN, skew in the tuple distribution seriously affects the overall performance of the system.

To minimize the skew effect, the buckets can be redistributed among the PNs as follows. At the end of the hashing phase, each PN keeps as many of the larger local buckets as possible; however, the total number of tuples retained should not exceed the ideal size each PN would have if the load were uniformly distributed. The excessive buckets are made available for redistribution among the PNs, using some bin-packing technique (e.g., largest processing time first), so as to balance the workload. This strategy is referred to as *partition tuning* (12). It handles severe skew conditions very well. However, when the skew condition is mild, the overhead associated with load balancing outweighs its benefits, which causes this technique to perform slightly worse than methods that do not perform load balancing at all, because this load balancing scheme scans the entire operand relations to determine the redistribution strategy. To reduce this overhead, the distribution of the tuples among the buckets can be estimated in the early stage of the bucket formation process as follows (15):

- *Sampling Phase:* Each PN independently takes a sample of both operand relations from its disk. The size of the sample is chosen such that the entire sample can fit in the memory capacity. As the sampling tuples are brought into memory, they are declustered into several in-memory buckets by hashing on the join attributes.
- *Partition Tuning Phase:* A predetermined coordinating processor computes the sizes of the sampling buckets by adding up the sizes of the corresponding local buckets. It then determines how the sampling buckets should be assigned among the PNs, using some bin-packing technique, so as to evenly distribute the sampling tuples among the PNs.
- *Split Phase:* Each processor collects the assigned local sampling buckets to form the corresponding sampling join buckets on its disk. When all sampling tuples have been stored to disks, each PN continues to load the remaining tuples from the relations and redistribute them among the same buckets on disks. We note that tuples are not written to disk one at a time. Instead, each processor maintains a page buffer for each hash value. Tuples having the same hash values piggyback to the same page buffer, and the buffer is sent to its disk destination when it is full.
- *Join Phase:* Each PN performs the local joins of respectively matching buckets.

The sampling-based load balancing technique has the following advantages. First, the sampling and load balancing processes are blended with the normal join operation. As a result, the sampling phase incurs essentially no overhead. Second, as the sample is a byproduct of the normal join operation and therefore is free, the system can afford to use a large sample whose size is limited only by the memory capacity. Although the technique must rely on page-level sampling to keep the I/O cost low, studies show that a sample size as small as 5% of the size of the two operand relations is sufficient to accurately estimate the tuple distribution under practical conditions. With the capacity of today's memory technology, this scheme is effective for a wide range of database applications.

We note that although we focus our discussion on the join operation, the same technique can also be used for other relational operators. For instance, load balancing for the union operation can be implemented as follows. First, each PN hashes its portion of each operand relation (using an attribute with a large number of distinct values) into local buckets and stores them back on the local disks. A predetermined coordinating PN then assigns the respectively matching bucket-pairs to the PNs using the partition tuning technique. Once the distribution of the bucket pairs has been completed, each PN independently processes its local bucket pairs as follows. For each bucket pair, one bucket is first loaded to build an in-memory hash table. The tuples of the other bucket are then brought into memory to probe the hash table. When a match is found for a given tuple, it is discarded; otherwise, it is inserted into the hash table. At the end of this process, the hash tables located across the PNs contain the results of the union operation. Obviously, the sampling-based technique can also be adapted for this and other relational operators.

Partition tuning can also be used to balance workload in SE and SD systems. Let us consider an SE system, in which the operand relations are evenly distributed among n disks. A parallel join algorithm which uses n processors is given below.

- *Sampling Phase:* Each processor is associated with a distinct disk. Each processor independently takes a local sample of both operand relations from its disk. The size of the local samples is chosen such that the entire sample can fit in the available memory. As the sampling tuples are brought into memory, they are declustered into several in-memory local buckets by hashing on the join attributes. Each processor also counts the number of tuples in each of its local buckets.
- *Partition Tuning Phase:* A predetermined coordinating processor computes the sizes of the sampling buckets by adding up the sizes of the corresponding local buckets. It then determines how the sampling buckets should be assigned among the disks, using some bin-packing technique, so as to distribute the sampling tuples evenly among the disks.
- *Split Phase:* Each processor collects the assigned local sampling buckets to form the corresponding sampling join buckets on its disk. When all sampling tuples have been collected to disks, each PN continues to load from its disk the remaining tuples of the two relations and redistribute them among the same buckets.
- *Join Phase:* Each PN joins the matching buckets located on its disk independently of the other PNs.

We observe in this algorithm that each disk performs the same number of read-and-write operations assuming the operand relations were evenly distributed across the disks. Furthermore, each processor processes the same number of tuples. The workload is perfectly balanced among the computing resources. An important advantage of associating a processor with a distinct disk unit is to avoid contention and to allow sequential access of the local partitions. Alternatively, the load can be evenly distributed by spreading each bucket across all disks. This approach, however, requires each disk to serve all processors at once during the join phase, causing the read head to move in an anarchic way. On another issue, each processor using its local buckets and page buffers during the sampling phase and split phase, respectively, also avoids contention. If the processors were allowed to write to a set of shared buckets as determined by the hash values, some mechanism would have been necessary to synchronize the write conflicts. This approach is not good because the contention for some buckets would be very severe under a skew condition.

FUTURE DIRECTIONS AND RESEARCH PROBLEMS

Traditional parallel computers were designed to support computation-intensive scientific and engineering applications. As the processing power of inexpensive workstations has doubled every two years over the past decade, it has become feasible to run many of these applications on workstations. As a result, the market for parallel scientific and engineering applications has shrunk rapidly over the same period. A few major parallel computer manufacturers having financial difficulties in recent years are evidence of this phenomenon. Fortunately, a new and much stronger market has emerged for those manufacturers that could make the transition to adapt their machines to database applications. This time, business is much more profitable for the following reasons. First, the database market is much larger than that of scientific and engineering applications. In fact, significantly more than half of the computing resources in the world today are used for data-processing-related tasks. Second, advances in microprocessor technology do not make workstations more suitable for handling database management tasks, which are known to be I/O intensive. It would be impractical to pack a workstation with a very large number of disks. Third, managing a large amount of multimedia data has become a necessity for many business sectors. Only parallel database servers can have the scalable bandwidth to support such applications.

As parallel database systems displaced scientific and engineering applications as the primary applications for parallel computers, manufacturers put a great deal of attention in improving the I/O capabilities of their machines. With the emergence of multimedia applications, however, a new hurdle, the network-I/O bottleneck (16–18), has developed for the database community. Essentially all of today's parallel database servers are designed for conventional database applications. They are not suitable for applications that involve multimedia data. For conventional database applications, the server requires a lot of storage-I/O bandwidth to support query processing. On the other hand, the demand on the network-I/O bandwidth is minimal because the results returned to the clients are typically a very small fraction of the data examined by the query. In contrast, the database server must deliver very large multimedia objects as query results to the clients in a multimedia application. As an example, the network-I/O bottleneck is encountered in Time Warner Cable's *Full Service Network* project in Orlando. Although each SGI Challenge server used in this project can sustain thousands of storage-I/O streams, the network-I/O bottleneck limits its performance to less than 120 MPEG-1 video streams. This poor performance is reminiscent of a large crowd funneling out of the gates after a football match. To address this bottleneck, eight servers had to be used at Time Warner Cable to serve the 4000 homes, which significantly increased the hardware cost and the costs of hiring additional system administrators. It is essential that future-generation servers have sufficient network-I/O bandwidth to make their storage bandwidth available to clients for retrieving large multimedia data.

Today's parallel database systems use only sequential algorithms to perform query optimization despite the large number of processors available in the system. Under time constraints, no optimizer can consider all parallel algorithms for each operator and all possible query tree organizations. A parallel query optimizer is highly desirable because it would have the leeway to examine many more possibilities. A potential solution is to divide the possible plans among several optimizer instances running on different processors. The costs of various plans can be estimated in parallel. At the end, a coordinating optimizer compares the best candidates nominated by the participating optimizers and selects the best plan. With the additional resources, it also becomes feasible to optimize multiple queries together to allow sharing of intermediate results. Considering the fact that most applications access 20% of their data 80% of the time, this approach could be a major improvement. More work is needed in this area.

Parallel database systems offer parallelism within the database system. On the other hand, existing parallel programming languages are not designed to take advantage of parallel database systems. A mismatch occurs between the two technologies. To address this issue, two strategies can be considered. One approach is to introduce new constructs in the parallel programming language to allow computer programs to be structured in a way to exploit database parallelism. Alternatively, one can consider implementing a persistent parallel programming language by extending SQL with general-purpose parallel programming functionality. Several companies have extended SQL with procedural programming constructs such as sequencing, conditionals, and loops. However, no parallel processing constructs have been proposed. Such a language is critical to applications that are both I/O intensive and computationally intensive.

As the object-oriented paradigm becomes a new standard for software development, SQL has been extended with object functionality. The ability to process rules is also being incorporated to support a wider range of applications. How to enhance existing parallel database server technology to support the extended data model is a great challenge facing the database community. For instance, SQL3 supports sequence and graph structures. We need new data placement techniques and parallel algorithms for these nonrelational data objects. Perhaps, techniques developed in the parallel programming language community can be adapted for this purpose.

PEER-TO-PEER COMMUNICATION

INTRODUCTION

A *peer-to-peer (P2P) system* is a type of distributed system constructed at the application level and running at the edge of the Internet, usually on personal computers such as desktops and laptops of millions of users. Each end point in a P2P system is called a *peer*. Peers communicate through *peer-to-peer protocols,* which are on top of the Transmission Control Protocol and Internet Protocol. *Peer-to-peer communication* mainly refers to the communication protocols of peer-to-peer systems.

Peer-to-peer communication is different from a traditional *client–server model*. In peer-to-peer communication, peers in the system are symmetric: Each peer is both a *client* that requests information and services and a *server* that produces and/or provides information and services. A peer in peer-to-peer systems is also known as a *servent,* abbreviated from the combination of the words "*serv*er" and "cli*ent*." P2P systems aim to use the information and resources among end users of the Internet, which complements existing client–server systems.

A peer-to-peer system is an autonomous system in which peers are self-organized into an *overlay network*. Thus, peer-to-peer systems are often called *peer-to-peer networks*. No strict central control exists over all peers in the system (although there may be some kinds of centralized coordination mechanisms), and peers are free to come and go at any time. That is, P2P systems are highly transient. A major and important peer-to-peer application is file sharing among peers. The representative P2P file-sharing systems are Napster (1), Gnutella (2), KaZaa (3), eDonkey/eMule/Overnet (4), and BitTorrent (5).

The Basic Facilities of P2P Systems

The main facilities that P2P systems provide to peers are the content location, file downloading facilities, and incentive for service contributions. By organizing the index of the content that is shared by peers in the system into a uniform structure (centralized or decentralized), a P2P system can provide a hash table-like interface, where the content location and the content ID map are one-to-one. By performing a content search at each peer locally in parallel, a P2P system can support advanced search facilities such as a keyword search and a full-text search. By using some advanced techniques such as *Latent Semantic Indexing*, a hash table-like interface can also support a keyword search in P2P networks. Some P2P systems have no search facility and rely on users employing Web-based search engines to search the desired content manually.

Some P2P systems use the HTTP protocol for file downloading, such as Napster, Gnutella, and KaZaa. BitTorrent and eDonkey/eMule/Overnet use their own file downloading protocols so that the server can control the data sending rate. BitTorrent and eDonkey/eMule/Overnet support parallel downloading, in which each peer can download different parts of the file from multiple peers simultaneously.

KaZaa also supports parallel downloading by using the range request in the HTTP protocol. The advantage of parallel downloading is that it can reduce downloading time on the client side, and thus, it improves the user experience significantly. Another advantage is that peers do not need to wait for the complete downloading of the file to serve for other peers. Once the peer has downloaded a chunk of the file completely, it can serve other peers and continue to download other chunks simultaneously.

Early P2P systems such as Napster and Gnutella have no incentive mechanism for peers to contribute their service. Instead, they rely on the altruism of peers to support the file-sharing service. As a result, *free riding* is very common in such systems (6); many peers called *free riders* receive services without making any contribution. KaZaa provides a credit-based system to encourage peers to contribute, but it is difficult to prevent collusion on the contribution each peer makes. BitTorrent uses a "tit-for-tat" mechanism to restrain free riding and to prevent collusion effectively.

The Classification of P2P Systems

In general, peer-to-peer file-sharing systems can be classified as *centralized*, in which a central server hosts the indices of the content shared by peers in the system or *decentralized*, in which the indices of the content are distributed among peers in the system. Decentralized peer-to-peer systems can be further classified into *unstructured* and *structured* systems, based on the mechanisms of overlay organization and index search. A structured peer-to-peer system has global coordination on the overlay structure and the datasets in the system, whereas an unstructured system does not. Furthermore, according to the methodology of file sharing, peer-to-peer systems can be classified as *exchange-based*, where peers exchange different files with each other by their interests, or *swarming-based*, where peers download the same content by exchanging small chunks of a large file.

In addition to being used for file sharing, peer-to-peer systems have also been used for Internet telephony, also known as voice over IP (VoIP), and live media streaming on the Internet, also known as IPTV. Skype (7,8) is a peer-to-peer VoIP system, in which peers are used for both searching clients and relaying voice packets. PPLive (9,10) is a peer-to-peer streaming video system, which uses peer-to-peer collaboration to distribute online and live media among users.

CENTRALIZED P2P SYSTEM

The first generation of peer-to-peer file-sharing systems is centralized and index-based, such as Napster. In *centralized peer-to-peer systems*, a central index server maintains

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

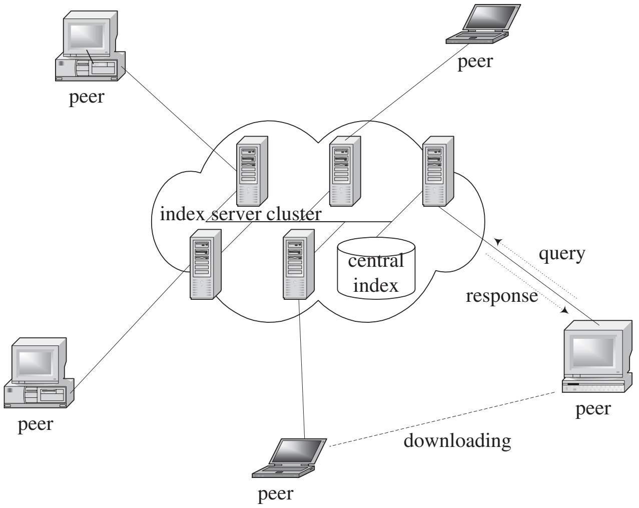

Figure 1. Index-based P2P system.

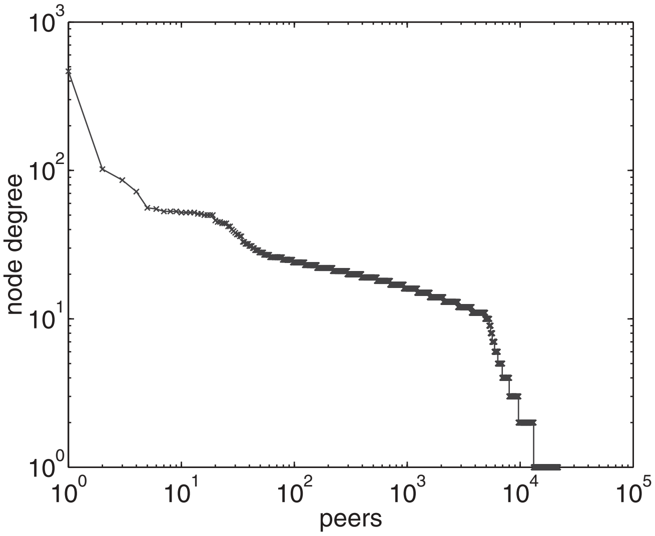

Figure 2. The connectivity degree of an unstructured P2P network.

the directory of files that all peers are sharing, and peers send queries to the server to search the content they want. In Napster, a large cluster of dedicated central servers is used to maintain the indices of the shared files. Each peer connects to one of these servers when it joins the system, uploads the index of its shared files to the server, and sends queries to the server. The server responds with a list of matched files with the location of these files to the peer. Upon receiving the response, the peer selects one file from the return list and initiates a file downloading. The server also monitors the state of peers through the connection and sends related information within the response message. The file transmission is between the clients without passing through the server. Fig. 1 shows the architecture of a centralized, index-based P2P system.

Napster was closed in 2002 due to legal issues. Open-Napster (OpenNap) (11) is an open source project that extends the Napster protocol for file sharing.

Index-based peer-to-peer systems are not scalable and are prone to a single point of failure, which can be overloaded due to flash crowd or attacked by malicious users.

DECENTRALIZED AND UNSTRUCTURED P2P SYSTEMS

To circumvent the limitations of centralized peer-to-peer systems, the P2P community has developed decentralized peer-to-peer systems. Instead of maintaining a huge index in a central server or server cluster for the search service, a decentralized system distributes searching and locating loads across the participating peers. In such systems, peers self-organize into an overlay network to communicate with each other.

The *overlay network* of a peer-to-peer system is a logical network on top of the Internet. Each peer selects a number of peers as its neighbors to connect to in order that the departure of a single peer cannot disconnect the peer from the overlay network. A *host-cache site*, which maintains a list of active peers in the system, works as the *bootstrap site* of the P2P system, which provides an entry for new peers to join the system. When a peer wants to join the system, it connects to the host-cache site to get a list of peers and randomly selects a number of peers to connect to. A peer may try to connect to other peers when some of its neighbors leave or may accept connection requests from other peers. We call such a P2P overlay an unstructured P2P network because the connections of peers are random and do not follow any rules. However, in practice the connectivity of peers in the overlay is not randomly distributed. Instead, the node degree of the overlay topology graph is heavily skewed due to the heterogeneity of the lifetime and computing capacity of peers. Research has shown that the node connectivity of many unstructured P2P networks follows a two-phrase Zipf-like distribution, as shown in Fig. 2. This kind of overlay is highly resilient to random node breakdowns but is vulnerable to attacks that target those highly connected nodes.

Each peer in a P2P overlay network is not only a servent but also a *router* that forwards messages it receives to its neighboring peers. In this way, a message can travel the network to reach the destination peer whose location is unknown to the sender. Message forwarding enables content search over the P2P overlay network. We briefly introduce three well-known peer-to-peer search algorithms for unstructured P2P networks, namely, flooding, super node, and random walk.

Flooding is a broadcast mechanism for the P2P system, such as Gnutella. In the flooding algorithm, a peer sends a message to its neighbors, which in turn forward the message to all their neighbors except the message sender. Each message has a unique message ID. A message received by a peer that has the same message ID as the one received previously is considered a redundant message and will be discarded. Flooding is conducted in a hop by hop fashion counted by Time-to-Live (TTL). A message starts off with its initial TTL, which is decremented by one when it travels

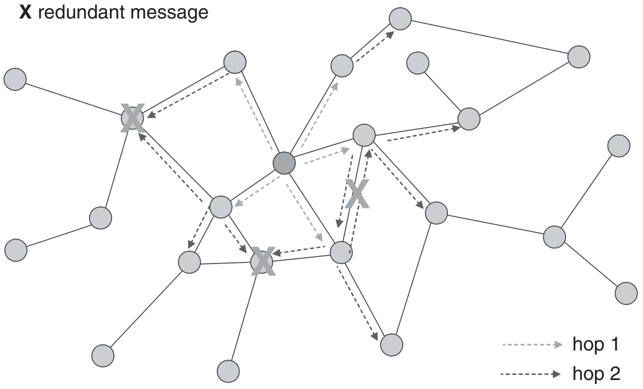

Figure 3. A two-hop flooding in an unstructured P2P network.

across one hop. A message comes to its end either because it becomes a redundant message or because its TTL is decremented to 0. The default initial TTL value is 7 since 7-hop flooding can cover more than 90% of the nodes in the P2P network. Fig. 3 shows the message flooding on the P2P overlay network.

Flooding is very simple and very effective. However, it may cause a great amount of redundant or unnecessary traffic. It has been estimated that routing traffic for the Gnutella network was about 1.7% of the total traffic in the U.S. Internet backbones in December 2000. To reduce the flooding traffic in a P2P overlay, many P2P systems, such as KaZaA, Morpheus, and current Gnutella, adopt a *super node* architecture. A super node is a proxy and index server of a number of leaf nodes. A peer connects to one or several super nodes to join the overlay network. The super node maintains the indices of its leaf nodes, and queries are only flooded in the super node network, in order to limit the flooding scope. Although a super node may leave the system at any time, a peer can still maintain the connection to the overlay network by connecting to several super nodes simultaneously. Fig. 4 shows the super node of the P2P overlay network.

Random walk is another approach to reduce search traffic. The content distribution in the system is heavily skewed, and popular objects have more copies in the system than unpopular ones. Most queries in P2P systems are for popular objects, which are distributed redundantly in the system. Thus, it is unnecessary to travel every node in the overlay to find the information a peer needs. In the random walk search approach, several walkers randomly travel the network in parallel and forward the query initiated by the sender along the travel path. An improved random walk algorithm is the *biased random walk*, in which each peer maintains the indices of its one-hop neighbors, and in which the query is routed to the node with higher connectivity randomly. Thus, the query is routed to the nodes with highest connectivity quickly, and the indices in these highly connective nodes can satisfy the query with high probability. Although random walk has the least communication traffic for message routing, it may result in a long response time. As a result, it has not been practically implemented so far. By constructing a content abundant cluster (CAC) on top of the entire P2P network, which consists of those peers with more objects than other peers, CAC can also reduce the search scope without increasing the average query response time (12).

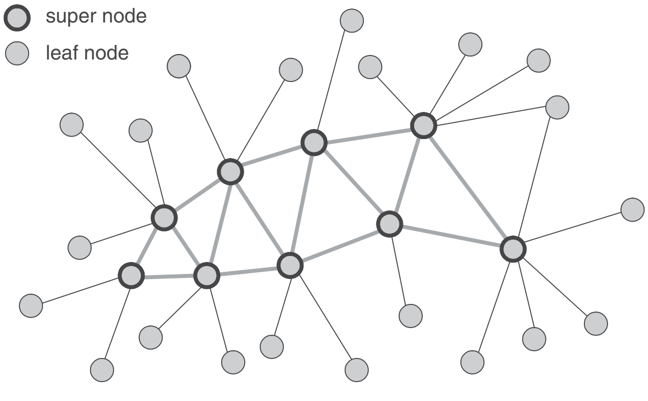

Figure 4. The super node architecture for an unstructured P2P network.

DECENTRALIZED STRUCTURED P2P SYSTEMS

The lack of global data management in unstructured P2P systems makes content locating inefficient and expensive. Decentralized structured P2P systems organize peers in the system into a *distributed hash table* (DHT), which supports hash table-like operations in the overlay network. In structured P2P systems, each node maintains a routing table that is determined by the overlay structure of the distributed hash table. Each object is placed in a unique location in the system based on its key value and can be reached by routing query between nodes, according to the DHT routing rules. The object and its key can be maintained by different peers. The key idea is that the key space is organized as a hierarchical structure so that the key search can be conducted efficiently. A one-dimensional distributed hash table, such as Chord, Pastry, and Tapestry, uses skiplist-like routing or tree-like routing to pass the query to the destination node. Such distributed hash tables can provide $O(\log n)$ lookup with each node maintaining $O(\log n)$ routing table entries. The content addressable network (CAN) uses a multi dimensional mapping mechanism that can provide $O(dN^{1/d})$ lookup with each peer maintaining $O(d)$ routing table entries, where d is the dimension of the system coordination space and N is the number of nodes in the system.

Fig. 5 shows a two-dimensional CAN structure. Keys are mapped into a two-dimensional Cartesian space, with each rectangle of the coordination zone representing a fraction of the entire key space. Each object is mapped into a key in the two-dimensional Cartesian space one-to-one. Each rectanglular zone in the key space is assigned to a peer, which maintains the objects mapped to the keys in this rectangle. The figure shows how a message is routed from coordinate (0.4,0.1) to (0.9,0.7) in the overlay network. Each node maintains a routing table, where each entry corresponds to the coordination zones of one of its neighbors. Intuitively, routing in a CAN overlay is performed by following a

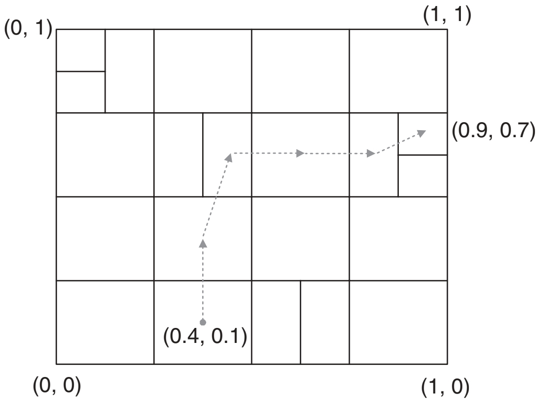

Figure 5. The content addressable network.

straight line in the vertical dimension and then a straight line in the horizontal dimension from the source node to destination node in a decentralized way.

The typical popular distributed hash tables are Tapestry (13), Pastry (14), CAN (15), and Chord (16). Distributed hash tables are often used as an infrastructure to construct large-scale distributed file systems or storage systems. Although early P2P file-sharing systems were usually unstructured, recently distributed hash tables have also been used in P2P file sharing; for example, Overnet uses Kademlia (17) for content search.

BITTORRENT: A SWARMING-BASED P2P SYSTEM

Early P2P file-sharing systems, for example, Napster, Gnutella, KaZza, and eDonkey/eMule/Overnet are basically exchange-based. In exchange-based P2P systems, peers share and exchange different files with each other.

BitTorrent is a swarming-based of P2P system that has become very popular recently. As reported by CacheLogic, BitTorrent traffic represented 53% of all P2P traffic on the Internet in June 2004 (18). Unlike traditional P2P systems such as Napster (1), Gnutella (2), and KaZaa (3), which use various search protocols to find a target file, BitTorrent organizes peers that share the same file into a P2P network and focuses on an efficient replication mechanism to distribute the file among them.

BitTorrent uses parallel downloading techniques to speed up content distribution. By dividing a file into small chunks, a peer can download multiple parts of the file in parallel, which enhances the efficiency of file distribution. Once a peer completes downloading, it becomes a *seed* of the system. BitTorrent uses a "tit-for-tat" incentive mechanism, which enables peers with high uploading bandwidth to have correspondingly high downloading bandwidth. The incentive mechanism of the BitTorrent system effectively prevents free riding, which is the most important difference between BitTorrent systems and other systems. In practice, BitTorrent-like systems scale fairly well during flash crowds and are now widely used for various purposes, such as for distributing large software packages (19).

In a BitTorrent system, a content provider creates a *meta file* (with the torrent suffix name) for the *data file* it wants to share and publishes the meta file on a website. Then the content provider starts a BitTorrent client with a full copy of the torrent file as the original *seed*. For each data file, a *tracker site* is used to help peers find each other to exchange the file chunks. A user starts a BitTorrent client as a *downloader* at the beginning in order to download file chunks from other peers or seeds in parallel. A peer that has downloaded the file completely also becomes a seed that could, in turn provide a downloading service to other peers. All peers in the system, including both downloaders and seeds, self-organize into a P2P network, known as a *torrent* (or a swarm). The initial seed can leave the torrent when other seeds are available; the content availability and system performance in the future depend on the arrival and departure of downloaders and seeds. With the decrease of content popularity over time, the downloading speed of the file may become poor or even unavailable because of the decrease of the number of peers sharing the file (20).

SUMMARY

Peer-to-peer communications are applications that use a self-organized protocol to connect a large number of end machines to share resources among them, where each peer is both a client and a server. The applications of peer-to-peer communications have expanded from initial music file exchanges to large software distribution, live streaming video, and VoIP. Traditional media and movie industries are also considering using peer-to-peer techniques to distribute their content with the protection of copyrights. We believe that peer-to-peer communication represents a common and cost-effective trend on the Internet.

PROGRAMMING MODELS: CLIENT–SERVER, PROCESS GROUPS, AND PEER-TO-PEER

INTRODUCTION

Programming a distributed application is often significantly different from programming an application intended for a single machine. Accessing a remote object may require locating the object first. The object may not currently be available, and even if it is, access latency may be high or unpredictable in case of slow or overloaded network connections. The rate of access to an object may grow unreasonably high as the number of clients in the network grows, overrunning the physical resources that implement the object. Security may be an additional issue, as the network is easily accessed by unrelated third parties. As a result, programming a distributed application is often significantly harder than programming a centralized one, and thus, much thought has been given to how to make distributed programming easier.

The most popular approach to achieving this simplicity is to make distributed programming similar to centralized programming, which is also known as transparency. For the execution of any kind of program, there are two basic ingredients: memory and processing. The memory contains the data structures that are used by the program, whereas the processing implements the program's algorithms. In this essay we focus on memory and the complications of distributing this memory to a set of machines connected only by a network.

Perhaps the most obvious approach is to implement a shared virtual memory address space that can be used by all processes involved in the distributed application. Indeed, this approach exists and is known both as shared virtual memory and distributed shared memory (1). It is typically implemented using hardware page protection bits and intercepting memory locking operations. The approach is valid for homogeneous sets of mutually trusting processes and thus best applied in parallel applications running on CPU clusters.

Instead, we will be focusing on the more general case of sharing arbitrary storage objects among a distributed set of processes. In our terminology, an object has state and a set of operations or methods that operate on the state. Distributed shared memory then is a special case, in which the object is a memory page and the methods are read, write, lock, and unlock operations on the page.

An object is implemented by one or more servers and accessed by one or more clients. Clients send requests for operations to servers, and servers return results to the clients, which is called the client–server model. Typically, servers run on different machines than clients, but this is not a requirement. However, remote access is sometimes necessitated by geographic, reliability, and/or security considerations.

The client–server model is ubiquitous in today's distributed systems. Examples include shared file systems, shared database systems, e-mail, domain name resolution, and of course the World Wide Web. In each of these cases, the specific network protocols are different, but they all involve client–server interactions and allow a set of clients to share and access storage resources.

THE CLIENT–SERVER PARADIGM

The most prominent implementation of the client–server model today is the one where individual server processes implement services. Each server may have many clients. Perhaps the best known example is the Web server, but other examples include FTP, TELNET, SMTP, and shared databases. The server maintains one or more resources or objects. Clients send requests to access or modify the objects or even to have the server do some processing on behalf of the clients.

A server may be also be a client to another server. For example, a Web server may need to access a remote database in order to retrieve data for one of its Web clients. In the case of e-mail, a client sends a request to post an e-mail message to an SMTP server. The server, in turn, has to send a request to the recipient's POP server to deliver the message. In the case of domain name resolution, one domain name service (DNS) server may need to ask another server for the information it needs to satisfy the request of a client, and this can continue recursively.

In Fig. 1, we show a typical example of client–server interactions. A Web browser first looks up a DNS name by sending a request to a DNS server. The DNS server then recursively may use another DNS server. After receiving a response containing an address, the Web browser sends a request to the corresponding Web server. The Web server may in turn invoke several application servers, which may in turn interact with a set of databases. In all of these cases, a specific protocol has been developed for the interactions between a client and a server.

In 1984, Andrew Birrell and Bruce Nelson developed a paradigm called remote procedure call (RPC) (2), which makes these interactions look like normal procedure calls from a client's code into the server's code. To the client, the only difference is that a new exception may be raised such as that the server is not available. To the server, each client's invocation typically looks like a separate thread that is spawned within the server's address space.

The way this process works is quite simple. On the client end, a stub procedure is created for each of the procedures that the server exports. The stub collects all arguments into a request message and sends this message to the server. The stub procedure now blocks the client process while awaiting the reply. At the server, the message is unpacked and the procedure is invoked. The result is placed into a reply message that is sent back to the client. On receipt, the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

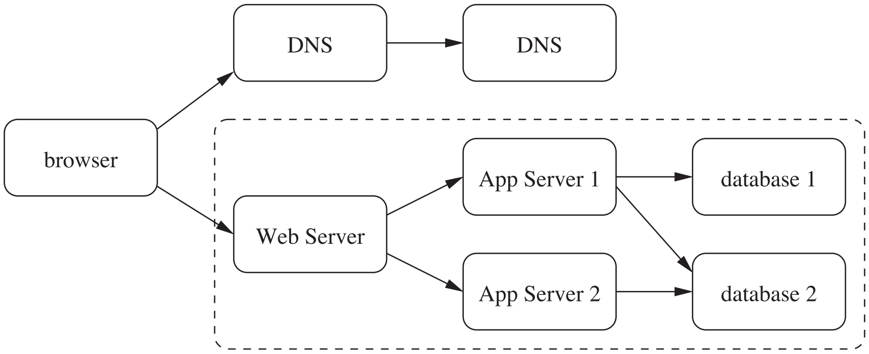

Figure 1. Typical client–server interactions when accessing the WWW. Arrows point from clients to servers.

stub retrieves the result from the message and resumes the client process.

Despite its simplicity, often some issues are tricky to resolve. For example, how does the client's stub procedure determine to which server to send the request? What if the client wants to operate on two different objects stored at two different servers? What if the client specifies as its argument a reference to a very large object within its address space? How are unreferenced objects released (distributed garbage collection)?

Many RPC platforms have been developed over the years. Currently, the best known are Web Services, Java Remote Method Invocation (RMI), and CORBA. Web Services builds on top of the HTTP protocol used to access Web servers and uses XML for data representation within the messages. RMI uses Java's automatic serialization of Java objects to create request and response messages. CORBA (3) is a language-independent framework that uses an Interface Description Language (IDL) to describe a server's methods and its parameters. An Object Request Broker (ORB) automatically locates objects and activates servers if necessary.

Besides RPC, another common form of communication is the one in which a server communicates a stream of events to its clients. Rather than polling a server for updates to objects, a client can be notified at the time such updates occur. A popular form of such event notification is known as publish/subscribe and is treated in more detail below.

PROCESS GROUPS

Although the client–server paradigm simplifies the structuring of distributed applications, it does little to deal with the realities of scale. Servers are centralized processes that can easily become bottlenecks and are also single points of failures. Many clients may not get the service they require if a server becomes overloaded or crashes. Both problems can be addressed by using a collection of machines to implement a service.

A process group is a set of processes cooperating on a common task, such as the maintenance of one or more shared objects. The processes are commonly called the members of the group. The notion of process group was first introduced in the V system (4). The V system supported an unreliable multicast mechanism by which one member could send a message to all members of a group. More recent process group implementations support various forms of reliable communication.

Process groups can be created for a variety of purposes. For example, a service could be made fault tolerant by creating multiple copies of the server. By grouping the servers into a process group, the reliable communication properties can be exploited to keep the servers in sync with one another. For dealing with high load, a service can be partitioned so that each server is responsible for a subset of objects. Process groups can also be used for clients. An example is an event notification service, in which the multicast capabilities of a process group can be used to disseminate events to a group of clients. Below we look at two popular incarnations of process groups, namely Virtual Synchrony and Publish/Subscribe.

Virtual Synchrony

Virtual Synchrony (VSync) was introduced in the Isis system (5). VSync presents a model of a distributed computation in which an execution of a program is divided into self-contained failure-free epochs. At the beginning of an epoch, each process is notified about the current membership or view of the epoch, that is, the set of processes that participate in the computation and are alive and reachable during the epoch. The only messages that may be delivered during an epoch are messages that were sent in that epoch by the initial members of that epoch. Processes may only fail by crashing at the end of an epoch; in which case, they will not participate in the next epoch. Finally, no message loss occurs in an epoch, and all messages sent in an epoch must be delivered before the end of the epoch.

In asynchronous distributed environments, messages may be arbitrarily delayed, lost, reordered, or duplicated; processes may crash or become arbitrarily slow or otherwise unavailable at any given moment; and the network may even partition. Clearly, the pure model as stated above cannot be implemented in these environments. However, it is possible to implement a non-blocking emulation, in which a process cannot tell the difference between the observed execution and an execution in which no failures occur.

In Fig. 2, we show an example of an epoch with five processes A through E. Time is from left to right. The actual

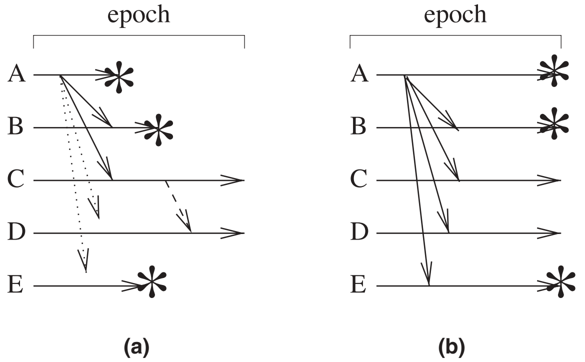

Figure 2. (a) Actual execution. (b) VSync execution. Arrows indicate messages. "*" indicates a process crash. Dotted arrows indicate lost messages, whereas the dashed arrow indicates a message retransmission.

execution is shown in Fig. 2(a). Process A sends a message. Only processes B and C receive the message. Processes A, B, and E crash soon afterward. The VSync protocol will detect the crashes and end the epoch but not before sending a copy of the message from C to D. As a result, C and D cannot distinguish the execution from that of Fig. 2(b), in which no failures occurred. This behavior allows considerably simplified algorithms of several important distributed paradigms, such as replication, leader election, and voting.

One of the most prevalent uses of VSync is replicating objects, in which the state of an object is copied among a set of servers. To keep the replicas consistent with one another, they have to start in the same state and execute updates in the same order (6). Most VSync implementations therefore support state transfer and totally ordered multicast. State transfer mechanisms allow newly joined members to receive a copy of the state at the beginning of an epoch. Totally ordered multicasts allow the members of the group to apply all updates in the same order.

Although simple, VSync has significant scalability problems, as both the rate of failures and the recovery time grow with the size of the membership of the group.

Publish/Subscribe

Another popular paradigm for building distributed applications is publish/subscribe (Pub-sub) (7). In this paradigm, publishers post messages, whereas subscribers specify what messages they are interested in. The pubsub system is responsible for routing the publisher's messages to the corresponding subscribers. Pubsub can be broadly classified into two types. In topic-based pubsub (TPS), subscribers specify what topics they are interested in. Topics are typically indicated by a string name. A publisher specifies a topic for each message that it sends. TPS is essentially a multicast mechanism, in which the multicast address is the topic.

In content-based pubsub (CPS), each message contains a set of attributes. By specifying a predicate over such attributes, a subscriber indicates which messages it is interested in. Note that TPS is easily implemented over CPS by having each message contain an attribute that indicates the topic. CPS is capable of much more precise addressing than TPS but often at much increased routing overhead.

Pubsub has become the backbone of many datacenters. It has gained its popularity because little structure is imposed on the applications. Subscribers can come and go, and the publisher does not need to be aware of the set of subscribers or where they reside. Similarly, publishers can migrate from one machine to another without having to notify the subscribers. A publisher simply posts messages and subsequently can forget about them. This lack of structure makes it very easy to glue together various applications within a datacenter and to scale the system up to virtually any size.

For these reasons, datacenters use pubsub not only as a multicast communication mechanism to keep distributed data such as caches and configuration files up to date but also for point-to-point communication between services. Besides the flexibility afforded by not specifying explicit network addresses, pubsub makes it easy to listen in on point-to-point communication for the purposes of monitoring and debugging.

Essentially, pubsub is a shared object paradigm, in which an object is some implicit state that is shared among a set of processes. Either this state is updated by publishing a request message that specifies the update to be performed on the state or the result of an update is notified after the fact by publishing an update notification message. Subscribers specify which state changes they are interested in, either by noting the topic (TPS) or by using a predicate (CPS).

Herein lie some problems with the pubsub paradigm. As the publisher does not know the set of receivers for any particular message, it cannot guarantee that the message is delivered to all receivers. Even it it did, the publisher could crash before it can ensure that the message is received by all subscribers. For the same reasons, no ordering can be guaranteed among the set of subscribers, and so the shared state may be observed differently by different subscribers. Such problems can lead to rare, unexpected executions that are hard to track down and debug.

PEER-TO-PEER (P2P)

The proliferation of home computers and home Internet connections has made an enormous number of connected storage and computing resources available. Peer-to-peer techniques aim to exploit this availability by providing mechanisms to harness all these resources. P2P intends to provide global services to any client anywhere at any time. This goal is complicated because the resources provided by home computers and home Internet connections are often highly unreliable, highly heterogeneous, and highly susceptible to malicious exploitation. Building a large reliable system out of such components is a significant challenge, but one in which significant progress has been made.

In pure P2P systems, hosts that traditionally are exclusively clients also become servers. Together, they provide a large storage and/or execution facility. Again, we will focus on storage, but projects that focus on computing exist as well, such as SETI@HOME, which harvests unused home computer cycles to search for signs of extraterrestial intelligence in radio telescope data. P2P techniques have become highly popular for sharing music and video, and this has driven much of the initial P2P protocol development. Other drivers include censorship concerns and anonymity. Today, one of the most popular P2P applications is Skype, which provides Internet telephony.

The first widely used P2P protocols, such as Gnutella, are simple. As a distinction between clients and servers no longer exists, we will call the processes that execute the P2P protocol agents. Each agent connects to a small, more or less random set of other agents, and thus a graph of agents emerges. To search for a file, a request is flooded from one agent up to a certain depth in this graph. Any successful matches are returned to the originating agent. By caching results, the most popular files will be found easily. But the flooding protocol is inefficient both in terms of resources used and in how long it can take to obtain a result, and rare files can be very hard to find.

The first more structured approaches were actually proposed before the development of Gnutella. The most famous result is that of Plaxton et al. (8), which presents a technique for finding nearby replicas of objects. The basic idea is to create a user-level routing framework for messages. Messages are addressed to objects' identifiers. Each agent is set up with a routing table that allows it to forward incoming messages to other agents if it does not store the requested object itself.

Peer-to-peer protocols come in various shapes. They can be roughly classified as

- Resource sharing, location, and search
- Application-level routing
- Monitoring and aggregation

SETI@HOME is a resource-sharing protocol in which clients contribute their CPU resources to a public cause. Various large-scale P2P storage services have been proposed as well, in which clients offer capacity on their disks that can be used for cheap backup or caching of public data. Such services could also be used to make censorship-sensitive material available in an anonymous and reliable way. Other P2P services, like Gnutella and BitTorrent, make clients' resources available for public access without offering public storage. Such services focus on location and search, and many audio and video sharing facilities are good examples.

Application-level routing is another interesting area for P2P protocols. Although the Internet essentially supports only unicast routing between hosts, P2P protocols can provide both unicast and multicast routing with a rich set of addressing and routing options not found in the Internet. Many such protocols have been developed, specializing in such features as location-independent routing, optimizing latency or bandwidth, fault-tolerance, security, and anonymity.

Although multicast and pubsub protocols disseminate data from a sender to a set of receivers, it is often required to retrieve information from a set of processes or objects and to return the result to a single process. For example, in a sensor network, it may be necessary to calculate the average temperature in a particular geographical area. For such applications, P2P protocols have been developed that allow clients to query a set of objects and aggregate the results. Such systems often support standing queries that report updates of aggregates.

Programmers can use the sharing, location, routing, and aggregation paradigms to build various distributed, collaborative services. Unfortunately, so far only preliminary proposals have been made toward standardizing the interfaces to these P2P paradigms, which complicates widespread adoption.

CONCLUSION

Whether you use client–server, process groups, or P2P techniques, distributed programming revolves around the maintenance of shared objects. An object can be low level such as a CPU, memory, or any hardware device or high level such as a spreadsheet, a Web page, or an entire running application. The objects have a state that can be centralized in one location, copied in various locations (replication), or partitioned across various locations. The state in turn is manipulated through procedure calls.

Depending on your performance and reliability requirements, either RPC, process groups, or P2P, or some combination, may be the best approach to implementing your application. Client–server style request–response interactions such as RPC are routinely used, for example, in the implementation of the World Wide Web and for the resolution of domain names using DNS.

Process groups are used within datacenters for the management of replicated services and in the implementation of publish/subscribe. P2P techniques are popular among home Internet users for file sharing and Internet telephony. A developer of distributed applications needs a thorough understanding of each of these techniques.

QUEUEING THEORY

INTRODUCTION

Waiting is a common phenomenon in our daily lives. People wait in a post office, at an elevator, at traffic lights, and so on. Airplanes wait to take off. Parts wait to be assembled. Data wait to be transmitted. Taxis wait for passengers, and passengers wait for taxis.

A system in which waiting phenomena exist is called a queueing system. (The word "queueing" is probably the only American English word that contains five vowels in a row). Queueing theory is an academic discipline that studies queueing phenomena in a systematic way.

A queueing system is composed of a set of customers, a set of server(s), and a service discipline (also called an order of service). A doctor is a server, and patients are customers. Failed machines are customers, and a repairman is a server. Data packets are customers, and the router is a server.

The first systematic treatment of a queueing system was carried out by A. K. Erlang (1878–1929) in early 1900s when he studied the congestion phenomena in a telephone exchange (1-3). See also Ref. (4).

In computer science, queueing theory is at the heart of analyzing the performance of several systems such as a router that routes data packets in a computer network (5), a communication switch that switches data or voice packets in a computer or telecom network, a data storage system (such as a hard disk) that serves requests for data access, a file server that serves user requests for access to files, a web server that serves requests for web content, and so on.

Queueing theory is critical to analyze these and other computer systems to ensure efficient resource usage. The arrival pattern of requests for service (be it any service) is rarely deterministic; it is mostly a random process. Eliminating wait time (when there will be no need to use queueing theory to analyze the performance) will in most cases require provisioning the resource for peak usage. However, in such a design, the system will be idle most of the time (except during peak times) and, hence, it will lead to a waste of resources. In several systems, introducing even a small amount of wait period (using buffers), can significantly bring down the amount of resources needed to serve the user requests. This resource efficiency is one primary reason for the prevalence of queueing theory in analyzing the performance of computer systems.

Another reason for the prevalence of queueing theory in computer system analysis is the need to make quality-of-service (QoS) guarantees (or to provide guidance on expected performance) to users. QoS can include a guarantee on the response time, a guarantee on the minimum throughput, and a guarantee on the minimum availability, among others. Making any of these guarantees for a given design typically involves analyzing the system for its queueing behavior.

In summary, queueing theory is an important analytical tool in computer science that has a wide variety of applications. In this article, we provide an introduction to queueing theory. We discuss key concepts and major results for the M/M/1, M/M/1/K, M/M/c, M/M/c/c, M/G/1, closed queueing networks, and open queueing networks. We conclude with a brief discussion of current research interests in this area.

A QUEUEING SYSTEM

A system is an organization in which entities interact with each other. A queueing system is a system in which customers arrive, wait, receive service, and leave. Customers and servers interact with each other in such a way that if the service time of a customer is delayed, other customers end up waiting longer, and if the server momentarily stops serving customers, the number of waiting customers may increase.

Characteristics of a Queueing System

The distinguishing characteristics of a queueing system are as follows:

Customer Classification. In many cases, customers form a single class. But, if there are multiple types of services, or if the customers have priorities, then customers may be classified according to their types of service and/or priorities.

Population Types. Customers can be from a finite population or an infinite population. As an example of a finite population, consider a factory where there are three machines. As soon as the machines break down, they are sent to the repair shop. Then, the repair shop becomes a queueing system and the broken machines are customers. In this system, only three machines can be customers.

No definite distinction is made between finite and infinite populations. The customers to a hardware store in a town are from a finite population to be exact. But if the population size is large, they can be thought of as the customers from an infinite population. In general, a queueing system with a finite population is more difficult to analyze.

The Arrival Process. When the interarrival periods are independent and identically distributed (i.e., a renewal process), the arrival process is represented by the interarrival time distribution. The arrival rate is defined as the average number of arriving customers per unit time. This rate is the reciprocal of the average interarrival time. In some special cases, arrival rates may vary depending on the number of customers in the system. This rate is called the state-dependent arrival rate (or load-dependent arrival rate). Arrival rate can vary as a function of time, as well. This arrival process is called nonstationary. Restaurants are a good example.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

In some cases, customers arrive in groups (batch arrival).

All arriving customers may not enter the system, and some may leave without receiving service. The average number of customers that enter the system (i.e., receive service) per unit time is called the input rate or effective arrival rate. If all arriving customers enter the system, the arrival rate is equal to the input rate. One rich application area of queueing theory is computer networks. In many cases, arrival processes in the communication systems are not renewal processes; i.e., interarrival times are neither independent nor identically distributed.

The Service Process. In many cases, service times of customers are assumed to be independent and identically distributed. In this case, as soon as a customer arrives, a random sample is generated from the service time distribution and the sampled value is assigned to the customer as its service time. This service time is independent of his waiting time or the number of customers in the system.

The service rate is defined as the average number of customers that can be served per unit time, which is the reciprocal of the average service time. The service rate can vary as a function of the number of customers in the system (state-dependent service rate or load-dependent service rate).

The service times of customers may be determined by the customers or by the servers. From the modeling point of view, we do not need to differentiate between these two. The service times may not be identically distributed for all customers. In this case, the complexity of analysis increases.

In many systems, customers depart the system as soon as they have received service. But, in some systems, the serviced customers may return to the queue (are fed back) for another round of service. A good example is the inspection system in which defects are returned for reprocessing.

Customers may be served one at a time (single-unit service) or in batches (batch service, bulk service).

Usually, one server is dedicated to one customer or one customer group. But, there are some cases where more than one server is assigned to serve a customer.

Number of Servers. There are cases of a single server, multiple servers, and an infinite number of servers. In many multiple-server systems, the servers are identical. In a queueing system with an infinite number of servers, customers are served immediately on arrival.

Service Discipline. A service discipline is a rule that stipulates how the next customer is selected at a service completion or in the middle of a service. Typical service disciplines are FCFS (first come, first served), LCFS (last come, first served), RSS (random selection for service), and PR (priority). Other service disciplines are SJF (shortest job first), LJF (longest job first), SRPT (shortest remaining processing time), and so on.

Customer Behavior. Customers may not enter the system for some reason (balk). They may even renege from the system (i.e., leave without receiving service). In the case of forced balking, we say that the customers are *blocked* or *lost*. If multiple waiting lines exist, customers may move from one to another (*jockeying*). Sometimes, blocked customers may retry to enter the system. For example, when a telephone line is busy, customers may hang up and try again.

Queue Structure. In most queueing systems, customers form one waiting line (single-queue system). However, multi-queue systems (i.e., one line for each server) do exist, as in some fast food restaurants. Also, situations exist where a single server serves multiple queues, in turn. A single-lane bridge is a good example. This bridge is analogous to the token-ring system.

Sometimes, the input/output of several queueing systems is interconnected to form a *queueing network*. If the queueing systems are connected in series, the network is called a *tandem queue*.

Performance Measures. Some important performance measures are as follows:

Queue length (system size, queue size). This is the number of customers in the system, including the one(s) in service, if any.

Waiting Time. The waiting time of a customer is the time from its arrival until it begins to be served. To obtain the waiting time distribution, we need to keep track of all the possibilities that the *test customer* (an arbitrarily selected customer) experiences.

Sojourn Time. Sojourn time is the time from the arrival until the customer departs the system. Usually, this time is the sum of waiting time and the service time. It is sometimes also called the *response time*.

Busy period. This period is the time when the server begins to be busy until it becomes idle.

KENDALL'S NOTATION

Until the 1950s, the authors had to list all the characteristics to explain a queueing system and a lot of confusion often ensued. Kendall suggested that a queueing system be specified by the notation (6):

arrival process/service process/number of servers

But the inconsistent notation among authors still caused a lot of problems. Several technical societies whose journals contained such articles recognized the problem and held a joint conference at Northeastern University in May 1971 to discuss the standardization of terminology and notation. The Operations Research Society of America recommended that the queueing systems be specified in the following notation:

(***arrival process/service process/number of servers***)

When necessary an appendage may be added of the form

(/***system capacity/size of calling population/service discipline***)

When the appendage is omitted, the infinite system capacity, the infinite size of the calling population, and the service discipline FCFS is assumed. The system capacity refers to the maximum number of customers that can exist in the system (usually including the one(s) in service). Calling population refers to the group of potential customers. The following notation is recommended.

M	Markovian. It denotes Poisson arrivals, exponential interarrival time, or exponential service time
E_k	Erlang distribution of order k
PH	Phase-type distribution
D	Deterministic (constant)
G	General (sometimes *GI* (General and Independent) is used instead)
Geo	Geometric
B	Bernoulli
MAP	Markovian arrival process
MMPP	Markov modulated poisson process
FCFS	First-come–first-served
LCFS	Last-come–first-served
RSS	Random selection for service

Sometimes FIFO (first in–first out) is used in place of FCFS, LIFO (last in–first out) in place of LCFS, and SIRO (selection in random order) in place of RSS.

Batch arrivals and batch services are denoted by superscripts.

Many queueing systems exist that cannot be described by the above notation. In these cases, authors invent their own notation.

As examples of the above notation, M/M/1 is a queueing system in which customers arrive according to the Poisson process, the service times are exponential, and there is one server. System capacity (∞), the size of the calling population (∞), and FCFS service discipline are omitted. For another example, M/G/1 is a queueing system in which customers arrive according to the Poisson process, the service times are general (i.e., not necessarily exponential), and one server exists. $M^X/G/1$ is an M/G/1 queueing system in which customers arrive in groups. (X denotes a group size. For example, customers arrive in taxis where the taxis arrive according to a Poisson process).

LITTLE'S FORMULA

Consider some "system" in which customers arrive, get served, and depart. Let $A(t)$ be the number of entering customers during t and $D(t)$ be the number of departing customers during t. The ith customer enters the system at a_i and departs the system at d_i. Let $A_a(t)$ and $D_a(t)$ be the average arrival and departure processes. If we assume that all entering customers depart the system only after their service is finished, we have a situation as shown in Fig. 1, where W is the mean time a customer stays in the system and L is the mean number of customers in the system at an arbitrary time. Then, we have

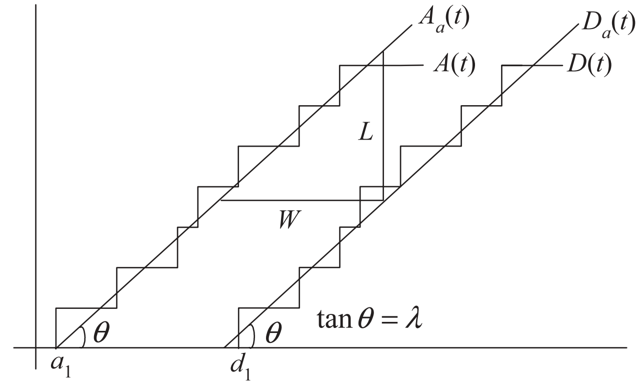

Figure 1. Little's formula $L = \lambda W$.

$$L = \lambda W \tag{1}$$

Equation (1) is called *Little's formula* in the queueing literature (7). We note that in Equation (1), λ is the *entering rate*, not the arrival rate (in some queueing systems, not all arriving customers enter the system).

THE EXPONENTIAL DISTRIBUTION

Let X be a random variable with the following distribution function (DF)

$$F(x) = Pr(X \le x) = 1 - e^{-\lambda x} \tag{2}$$

Then, X is said to be *exponentially* distributed. Its probability density function (pdf) becomes

$$f(x) = \frac{d}{dx}F(x) = \lambda e^{-\lambda x}, (x \ge 0) \tag{3}$$

The nth moment of X is given by

$$E(X^n) = \int_0^\infty x^n \lambda e^{-\lambda x} dx = \frac{n!}{\lambda^n} \tag{4}$$

Thus, the mean and variance become

$$E(X) = \frac{1}{\lambda} \tag{5}$$

and

$$\mathrm{Var}(X) = E(X^2) - E^2(x) = \frac{1}{\lambda^2} \tag{6}$$

The Momoryless Property

Let us assume that the lifetime of a light bulb follows exponential distribution. Let the bulb begin to operate at time 0. Knowing that the bulb has not failed until time t, the probability that it will not fail during the next s time units is given by

$$Pr(X > t + s|X > t) = \frac{Pr(X > t + s, X > t)}{Pr(X > t)}$$
$$= \frac{Pr(X > t + s}{Pr(X > t)} = \frac{e^{-\lambda(t+s)}}{e^{-\lambda t}} = e^{-\lambda s} \qquad (7)$$

From Equation (2), we know that $e^{-\lambda s} = Pr(X > s)$ is the probability that the bulb does not fail during (0, s). Thus, the fact that the bulb has not failed until t does not affect the future life of the bulb. In other words, as long as the bulb is working, it is just like the new one at every moment. This property is called the *memoryless property* of exponential distribution. It can be proved (mathematically) that the exponential distribution is the unique continuous probability distribution with the memoryless property.

THE POISSON PROCESS

If the interarrival times of the customers follow independent and identically distributed (iid) exponential distribution with mean $1/\lambda$, then we say that the customers arrive according to the Poisson process with rate λ. If we define $N(t)$ to be the number of such customers arriving in t time units, then we can show that

$$Pr[N(t) = n] = \frac{e^{-\lambda t}(\lambda t)^n}{n!}, \ (n = 0, 1, 2, \ldots) \qquad (8)$$

The Poisson arrival process is a completely random process, which means that customers arrive in a random way. This is similar to the memoryless property of the exponential distribution.

PASTA (POISSON ARRIVALS SEE TIME AVERAGES)

Suppose that customers arrive in a queueing system according to a Poisson process. Consider an arbitrarily arriving customer A. Also consider an outsider B who passes by the queueing system at an arbitrary time. PASTA (8) says that what is observed by A (arriving customer's distribution) is *stochastically equivalent* to what is observed by B (outsider's distribution). Thus, if we denote P_n as the probability that B observes n customers (this is equal to the probability that there are n customers at an arbitrary point of time) and $\bar{\pi}_n$ as the probability that A observes n customers just before its arrival, then,

$$\bar{\pi}_n = P_n \qquad (9)$$

Equation (9) is not guaranteed if arrivals do not follow a Poisson process.

For a more detailed discussion of the PASTA property, we refer the readers to Ref. (9).

M/M/1 QUEUEING SYSTEM

In an M/M/1 queueing system, customers arrive according to a Poisson process and the service times follow an exponential distribution. If we define λ to be the arrival rate, $\mu = 1/E(S)$ to be the service rate, and $X(t)$ to be the number of customers in the queueing system at time t, the stochastic process $\{X(t), t \geq 0\}$ becomes the birth–death process and we obtain a rate-flow diagram as shown in Fig. 2.

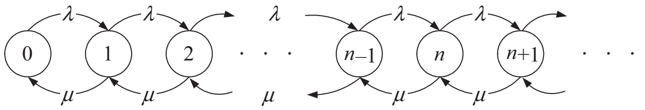

Figure 2. The rate-flow diagram of the queue length process of M/M/1.

Defining $P_n(t) = Pr[X(t) = n]$ to be the probability that there are n customers in the system at time t, we obtain the following system equations:

$$\frac{d}{dt}P_0(t) = -\lambda P_0(t) + \mu P_1(t)$$
$$\frac{d}{dt}P_n(t) = \lambda P_{n-1}(t) - (\lambda + \mu)P_n(t) + \mu P_{n+1}(t), (n = 1, 2, \ldots)$$
$$(10)$$

In the steady state, $\frac{d}{dt}P_n(t) \to 0$ and $P_n(t) \to P_n$. Thus, the steady-state system equations are

$$\begin{aligned} 0 &= -\lambda P_0 + \mu P_1, \\ 0 &= \lambda P_{n-1} - (\lambda + \mu)P_n + \mu P_{n+1}, (n = 1, 2, \ldots). \end{aligned} \qquad (11)$$

Interpretations of the system equations in Equation (11) are as follows:

First equation: λP_0 is the rate out of state 0 and μP_1 is the rate into state 0. These two rates should be equal in steady state.

Second equation: $(\lambda + \mu)P_n$ is the rate out of state n. $\lambda P_{n-1} + \mu P_{n+1}$ is the rate into state n. These two rates should be equal in steady state.

The solution to Equation (11) becomes

$$P_n = (1 - \rho)\rho^n, (n = 0, 1, \ldots), (\rho = \lambda/\mu) \qquad (12)$$

It is observed from Equation (12) that for the system to be stable, it is necessary to have

$$\rho < 1 \qquad (13)$$

Interpretation of Equation (13) is obvious if we note that $\rho = \lambda/\mu = \lambda E(S)$ is the average amount of work that is brought into the system per unit time and that 1 is the maximum amount of load that can be reduced per unit time by the server. We note that ρ also is the probability that the server is busy in steady state.

Performance Measures

Some performance measures of the M/M/1 queueing system are as follows:

Mean Queue Length.

$$L = \sum_{n=0}^{\infty} nP_n = \frac{\rho}{1-\rho} \tag{14}$$

Mean Number of Waiting Customers.

$$\begin{aligned} L_q &= \sum_{n=1}^{\infty}(n-1)P_n = \frac{\rho^2}{1-\rho} = \frac{\rho}{1-\rho} - \rho \\ &= L - L_{\text{in service}} \end{aligned} \tag{15}$$

In Equation (15), $L_{\text{in service}}$ is the mean number of customers being served at an arbitrary time; i.e.,

$$L_{\text{in service}} = (1)P_{\text{busy}} + (0)P_{\text{idle}} = P_{\text{busy}} = \rho \tag{16}$$

Mean System Sojourn Time.

$$W = \frac{L}{\lambda} = \frac{1}{\mu - \lambda} \quad \text{(Little's law)} \tag{17}$$

Mean Waiting Time.

$$W_q = \frac{L_q}{\lambda} = \frac{\rho}{\mu - \lambda} \quad \text{(Little's law)} \tag{18}$$

Alternatively,

$$W_q = W - E(S) = \frac{1}{\mu - \lambda} - \frac{1}{\mu} = \frac{\rho}{\mu - \lambda} \tag{19}$$

Behavior of the Mean Waiting Time

Figure 3 shows the mean waiting time as ρ varies (for simplicity, μ is fixed at 1). Notice that the mean waiting time increases sharply as ρ approaches 1, which means that when ρ is close to 1 (this function is called the *heavy traffic*), even a small increase in the arriving traffic results in an enormous amount of increased waiting time. From Little's law, we can make a similar conclusion regarding the mean number of waiting customers, the mean queue length, and the mean system sojourn time. This type of queueing behavior is typical of queueing systems and can be observed in many real-world systems.

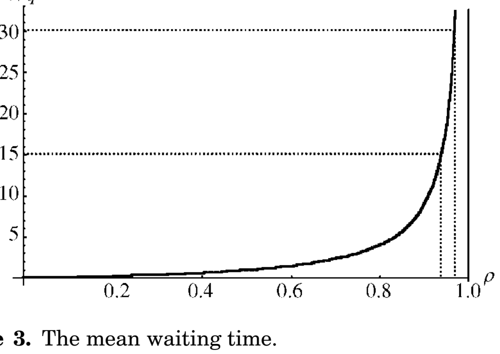

Figure 3. The mean waiting time.

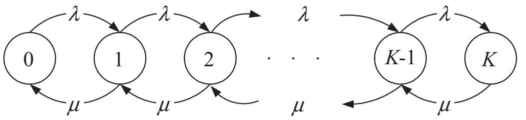

Figure 4. The rate-flow diagram of M/M/1/K.

For a more elementary introduction of the M/M-type queueing systems, we refer the readers to Refs. (10–12).

M/M/1/K QUEUEING SYSTEM

The M/M/1/K queueing system is the same as M/M/1 except that the maximum number of customers that can exist in the system is limited by K (including the one in service). Thus the customers who arrive when K customers are in the system are lost. The rate-flow diagram is as shown in Fig. 4.

In this system, the steady-state exists even when $\rho > 1$. Arriving customers cannot enter the system with probability P_k according to PASTA. Thus the entrance rate (effective arrival rate) becomes

$$\lambda_e = \lambda(1 - P_K) \tag{20}$$

Thus, the Little's formula in this case becomes

$$L = \lambda_e W = \lambda(1 - P_K)W \tag{21}$$

From the rate-flow diagram and using the approach of Equation (11), we can set up the steady-state system of equations as follows:

$$\begin{aligned} 0 &= -\lambda P_0 + \mu P \\ 0 &= \lambda P_{n-1} - (\lambda + \mu)P_n + \mu P_{n+1}, (n = 1, 2, \ldots, K-1) \\ 0 &= \lambda P_{K-1} - \mu P_K \end{aligned} \tag{22}$$

By solving Equation (22), we obtain

$$P_n = \begin{cases} \dfrac{(1-\rho)\rho^n}{1-\rho^{K+1}}, (\rho \neq 1) \\ \dfrac{1}{K+1}, (\rho = 1) \end{cases} \tag{23}$$

Mean Performance Measures

From Equation (23), we can derive the performance measures as follows:

Mean Queue Length.

$$L = \sum_{n=0}^{K} nP_n = \begin{cases} \dfrac{\rho}{1-\rho} - \dfrac{(K+1)\rho^{K+1}}{1-\rho^{K+1}}, (\rho \neq 1) \\ \dfrac{K}{2}, (\rho = 1). \end{cases} \tag{24}$$

Mean System Sojourn Time.

$$W = \frac{L}{\lambda(1-P_K)} \quad \text{(Little's law)} \tag{25}$$

Mean Number of Customers in Service.

$$L_{\text{in service}} = (0)P_0 + (1)(1-P_0) = \frac{(1-\rho^K)\rho}{1-\rho^{K+1}} \tag{26}$$

Mean Number of Waiting Customers.

$$L_q = L - L_{\text{in service}} \tag{27}$$

Mean Waiting Time.

$$W_q = \frac{L_q}{\lambda(1-P_K)} \quad \text{(Little's law)} \tag{28}$$

M/M/c QUEUEING SYSTEM

Customers arrive according to a Poisson process with rate λ. c identical servers exist, and the service times follow the exponential distribution with mean $E(S) = 1/\mu$. All customers wait in a single line. If an arriving customer observes multiple idle servers, it "randomly" chooses one server with equal probability. It is known that the departure process from the steady-state M/M/c queueing system is again a Poisson process with rate λ.

Figure 5 shows the rate-flow diagram for the queue length process of the M/M/c queueing system.

The system equations can be set up as in Equations (10) and (11). The steady-state queue length probability becomes

$$P_n = \begin{cases} \dfrac{\lambda^n}{n!\mu^n}P_0, (1 \le n \le c-1) \\ \dfrac{\lambda^n}{c^{n-c}c!\mu^n}P_0, (n \ge c) \end{cases} \tag{29}$$

where

$$P_0 = \left[\sum_{k=0}^{c-1}\frac{(\lambda/\mu)^k}{k!} + \frac{(\lambda/\mu)^c}{c!(1-\rho)}\right]^{-1}, \left(\rho = \frac{\lambda}{c\mu}\right) \tag{30}$$

The stability condition becomes

$$\rho = \frac{\lambda}{c\mu} < 1 \tag{31}$$

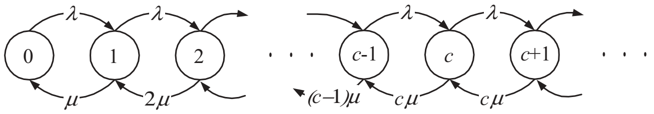

Figure 5. The rate-flow of M/M/c.

It is to be noted that ρ is the probability that server-i is busy at an arbitrary time for all i.

Erlang Delay Formula (Erlang C Formula)

From Equation (29) and from PASTA, the probability that an arbitrary arriving customer waits becomes

$$C(c,a) = \sum_{j=c}^{\infty}P_j = \frac{\dfrac{a^c}{c!(1-\frac{a}{c})}}{\displaystyle\sum_{k=0}^{c-1}\frac{a^k}{k!} + \frac{a^c}{c!(1-\frac{a}{c})}} \tag{32}$$

where

$$a = \lambda E(S) = \lambda/\mu \tag{33}$$

is called the *offered load*, which is the average amount of work offered to the servers per unit time. $C(c,a)$ is determined by the offered load. $C(c,a)$ is called the *Erlang delay formula* or *Erlang C formula*.

Mean Performance Measures

From Equation (29), we can derive the performance measures as follows:

Mean Number of Waiting Customers.

$$L_q = \sum_{n=c}^{\infty}(n-c)P_n = \frac{a^c}{c!(1-\rho^2)}P_0 \tag{34}$$

Probability that an Arbitrary Server is Busy.

$$P_{\text{busy}} = \frac{a}{c} = \rho \tag{35}$$

Mean Number of Customers in Service.

$$L_{\text{in service}} = P_{\text{busy}}c = \lambda E(S) = \lambda/\mu = a \tag{36}$$

Mean Queue Length.

$$L = L_q + L_{\text{in service}} \tag{37}$$

Mean Waiting Time.

$$W_q = \frac{L_q}{\lambda} \text{ (Little's law)} \tag{38}$$

Mean Sojourn Time.

$$W = \frac{L}{\lambda} \quad \text{(Little's law)} \tag{39}$$

Or

$$W = W_q + E(S) = W_q + \frac{1}{\mu} \tag{40}$$

M/M/c/c QUEUEING SYSTEM

In M/M/c/c queueing systems, arriving customers cannot enter the system if all servers are busy. A typical example is the telephone exchange system. If all lines are busy, arriving calls are blocked.

The steady-state system equations can be set up as in M/M/1. The queue length probabilities in this case are as follows:

$$P_0 = \left[\sum_{k=0}^{c} \frac{a^k}{k!}\right]^{-1} \quad (a = \lambda E(S)) \tag{41}$$

$$P_n = \frac{a^n/n!}{\sum_{k=0}^{c} a^k/k!} \quad (n = 0, 1, 2, \ldots c) \tag{42}$$

Erlang Loss Formula (Erlang B formula)

The probability that an arriving customer is blocked is given by

$$B(c, a) = P_c = \frac{a^c/c!}{\sum_{k=0}^{c} a^k/k!} \tag{43}$$

B(c,a) is called the *Erlang loss formula* or *Erlang B formula*.

Some Useful Relations

(i) $$B(c, a) = \frac{aB(c-1, a)}{c + aB(c-1, a)}, \quad (B(0, a) = 1) \tag{44}$$

Note that Equation (44) can be used to compute the loss probability recursively.

(ii) $$C(c, a) = \frac{cB(c, a)}{c - a[1 - B(c, a)]} \tag{45}$$

(iii) $$B(c, a) < C(c, a). \tag{46}$$

(iv) $$C(c, a) = \frac{1}{1 + \frac{c-a}{aB(c-1, a)}}, \quad (c > a, B(0, a) = 1) \tag{47}$$

(v) $$C(c, a) = \frac{1}{1 + \frac{c-a}{a} \frac{c - 1 - aC(c-1, a)}{(c - 1 - a)C(c-1, a)}}, \ (c > a + 1) \tag{48}$$

Note that Equation (48) can be used to compute the delay probability recursively.

An Application of the Erlang B Formula

Consider a small telephone exchange system with c = 10 lines. The current QoS is 99%; i.e., 1% of arriving calls are blocked. It is expected that the number of arriving calls will double next year. To maintain the same QoS, how many more lines are needed?

(i) From $B(10, a) = P_{10} = \frac{a^{10}/10!}{\sum_{k=0}^{10} a^k/k!} = 0.01$, we derive the offered load $a = \lambda E(S) = 4.461$.

(ii) If arrival rate doubles, the offered load doubles to 8.922.

(iii) So, we need to determine a value for c such that
$$B(c, 8.922) = P_c = \frac{8.922^c/c!}{\sum_{k=0}^{c} 8.922^k/k!} \leq 0.01.$$

(iv) Because $B(16, 8.922) = 0.0104$ and $B(17, 8.922) = 0.0054$, we conclude that at least 17 lines are needed to maintain 99% QoS.

Notice that even though the arrival rate doubles, only 70% of additional lines are needed to maintain the same QoS.

M/G/1 QUEUEING SYSTEM

So far we dealt with queueing systems in which the service times follow iid exponential distribution. Now, let us consider a queueing system in which customers arrive according to a Poisson process but the service times are not necessarily exponentially distributed. If we let $X(t)$ to be the queue length at time t, the stochastic process $\{X(t), t \geq 0\}$ is no longer a Markov process because the service time does not possess the memoryless property. Thus, the system equations as in the M/M/1 queueing system are not possible for the M/G/1 queueing system, which means that we need a completely new method to analyze the M/G/1 queueing system. This goal can be accomplished by analyzing the queue length just after service completions (i.e., customer departures).

Let us define the probabilities as follows:

P_n probability that there are n customers at an arbitrary time,

$\overline{\pi}_n$ probability that an arbitrary arriving customer observes n customers,

π_n probability that an arbitrary departing customer leaves n customers behind in the system.

Then, for an M/G/1 queueing system, we have

$$\overline{\pi}_n = P_n = \pi_n \tag{49}$$

Equation (49) comes from PASTA. $\overline{\pi}_n = \pi_n$ comes from the fact that in an M/G/1 queueing system, the number of customers increases by one and decreases by one. Equation (50) implies that the mean queue length L at an arbitrary time is equal to the mean queue length L^+ just after an arbitrary departure and the mean queue length L^- just before an arbitrary arrival

$$L = L^- = L^+ \tag{50}$$

Thus, we will derive L^+ instead of L.

Let us define the random variables as follows:

N_n^+ the number of customers just after the departure of the nth customer,

A_{n+1} the number of customers that arrive during the service of the $(n+1)$st customer.

Then, we obtain

$$N^+_{n+1} = \begin{cases} N^+_n - 1 + A_{n+1}, & (N^+_n \geq 1) \\ A_{n+1}, & (N^+_n = 0) \end{cases} \tag{51}$$

We note that the service times are iid and that customer arrivals are independent of what is happening in the system. Thus, the number A_n is independent of n, and without loss of generality we can use the generic notation A.

Let us define $U(N^+_n)$ as

$$U(N^+_n) = \begin{cases} 1, (N^+_n \geq 1) \\ 0, (N^+_n = 0) \end{cases} \tag{52}$$

Using Equation (52), we can express Equation (51) as follows:

$$N^+_{n+1} = N^+_n - U(N^+_n) + A_{n+1} \tag{53}$$

In steady state, we obtain

$$\lim_{n\to\infty} E(N^+_{n+1}) = \lim_{n\to\infty} E(N^+_n) = L^+ \tag{54}$$

If we take an expectation and let $n \to \infty$ on Equation (53), we obtain

$$L^+ = L^+ - \lim_{n\to\infty} E[U(N^+_{n+1})] + \lim_{n\to\infty} E(A_{n+1}) \tag{55}$$

which implies that

$$\lim_{n\to\infty} E[U(N^+_{n+1})] = \lim_{n\to\infty} E(A_{n+1}). \tag{56}$$

$E(A_{n+1})$ can then be computed as follows:

$$\begin{aligned} E(A_{n+1}) = E(A) &= \int_0^\infty E(A|S = x)s(x)dx \\ &= \int_0^\infty \lambda x \cdot s(x)dx = \lambda E(S) = \rho \end{aligned} \tag{57}$$

where $s(x)$ is the pdf of the service time.

Squaring Equation (53), we get

$$\begin{aligned} (N^+_{n+1})^2 = {} & (N^+_n)^2 + [U(N^+_n)]^2 + (A_{n+1})^2 \\ & - 2N^+_n U(N^+_n) - 2A_{n+1}U(N^+_n) + 2N^+_n A_{n+1} \end{aligned} \tag{58}$$

The following identities can be shown to hold:

$$\lim_{n\to\infty} E[(N^+_{n+1})^2] = \lim_{n\to\infty} E[(N^+_n)^2] \tag{59}$$

$$\lim_{n\to\infty} E[(U(N^+_{n+1}))^2] = \lim_{n\to\infty} E[(U(N^+_{n+1})] = \rho \tag{60}$$

$$\lim_{n\to\infty} E[N^+_n \cdot U(N^+_n)] = \lim_{n\to\infty} E(N^+_n) = L^+ \tag{61}$$

Taking expectation, letting $n \to \infty$ on both sides of Equation (58), and using Equation (57) together with Equations (59), (60), and (61), we obtain

$$L^+ = \frac{\rho - 2\rho^2 + E(A^2)}{2(1-\rho)} \tag{62}$$

$E(A^2)$ can be obtained as follows:

$$E(A^2) = \mathrm{Var}(A) + E^2(A) = \mathrm{Var}(A) + \rho^2 \tag{63}$$

where, by using the mean and variance of the Poisson random variable,

$$\begin{aligned} \mathrm{Var}(A) &= E[\mathrm{Var}(A|S)] + \mathrm{Var}[E(A|S)] \\ &= E(\lambda S) + \mathrm{Var}(\lambda S) = \rho + \lambda^2 \mathrm{Var}(S) \end{aligned} \tag{64}$$

Using Equations (63) and (64) in Equation (62) yields

$$L^+ = L^- = L = \rho + \frac{\lambda^2 E(S^2)}{2(1-\rho)} \tag{65}$$

From Little's law, the mean sojourn time becomes

$$W = \frac{L}{\lambda} = E(S) + \frac{\lambda E(S^2)}{2(1-\rho)} \tag{66}$$

Since the sojourn time is the sum of the waiting time and the service time, it can be shown using Equation (66) that the mean waiting time becomes

$$W_q = \frac{\lambda E(S^2)}{2(1-\rho)} \tag{67}$$

Then, from Little's law,

$$L_q = \lambda W_q = \frac{\lambda^2 E(S^2)}{2(1-\rho)} = \frac{\rho^2}{2(1-\rho)} + \frac{\lambda^2 \mathrm{Var}(S)}{2(1-\rho)} \tag{68}$$

which can alternatively be derived from

$$L_q = L - \rho \tag{69}$$

Significance of Variance of the Service Time

As Equation (68), the variance of the service time affects the system performance significantly. Table 1 shows the mean queue length of five different M/G/1 systems with the same arrival rate and mean service times, but with different variances of the service times (M/D/1 is a queueing system with deterministic (constant) service time).

Notice the differences in the mean queue lengths ranging from 0.25 to ∞ (the Pareto distribution is an example of probability distributions with finite mean but with infinite variance). This distribution is possible because the mean queue length depends heavily on the variance of the service time [see Equation (68)]. Note that the mean queue length of system 2 is 33 times larger than that of the M/D/1 queue. The difference is more spectacular in system 3.

Table 1. Mean queue lengths for different variances of the service times

	M/D/1	M/M/1	System 1	System 2	System 3
λ	2	2	2	2	2
$E(S)$	0.25	0.25	0.25	0.25	0.25
Var(S)	0	1/16	1	2	∞
L_q	0.25	0.5	4.25	8.25	∞

But, it should be noted that the server is idle 50% of its time in all five systems since we have the same $\rho = \lambda E(S) = 0.5$. It is hard to imagine a queueing system in which an average of 10,000 customers are waiting, but the server is idle 50% of its time.

It is important to appreciate, from this example, the effect of the variance on the system performances. In general, if one wants to reduce the mean queue length and the mean waiting time, the variance is the first thing to check.

For an analysis of the variants of the M/G/1 queueing system, including vacation systems and server controls, we refer the readers to Ref. (9).

QUEUEING NETWORKS

A queueing network is composed of several queueing systems connected to each other. Many computer systems, communication systems, and production systems can be modeled by a queueing network.

Classification by Network Structure

Each queueing system that comprises a queueing network is called a node. Multiple servers can exist in a node.

A queueing network can be classified as an open network, a closed network, or a mixed network. One might add a tandem queue as a special case of an open network.

OQN (Open Queueing Network). In an open queueing network, customers can enter the system and leave the system. An arrival to a node can be from either outside (external arrival) or inside (internal arrival). Figure 6 shows an OQN in which the finished customers at node-1 leave the system with probability p_1 and join node-i with probability $p_i, (i = 2, \ldots m)$.

CQN (Closed Queueing Network). In a CQN, a fixed number of customers circulate (existing customers cannot leave the system, and new customers cannot enter the system). Figure 7 shows a CQN model in which there are three nodes and N customers are circulating in the system.

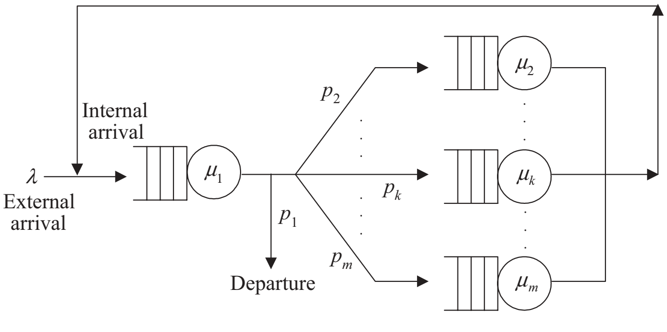

Figure 6. An open queueing network.

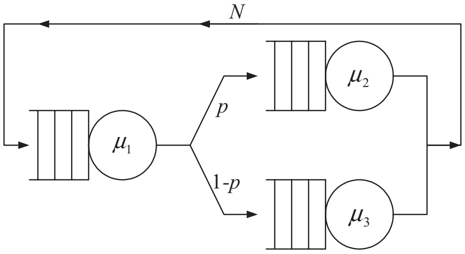

Figure 7. A closed queueing network.

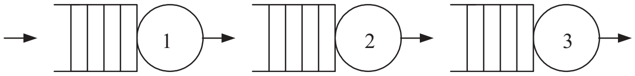

Figure 8. A tandem queue.

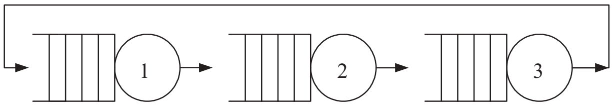

Figure 9. A cyclic queue.

Mixed-Type Queueing Network. This network is a mixture of OQN and CQN. Some classes of customers are free to leave or enter the system, where as others are not allowed to do so.

Tandem Queue (Series Queue). In a tandem queue, multiple nodes are connected in a series (Fig. 8). If it is closed, it is called a cyclic queue (Fig. 9).

MARKOVIAN OPEN QUEUEING NETWORKS (JACKSON NETWORKS)

A Jackson network is an open Markovian queueing network in which external customers arrive according to Poisson processes and service times follow exponential distributions. This network was first studied by Jackson (13,14) and is named after him.

The Jackson network is an open queueing network with the following specifications (13). Let K be the number of nodes.

(i) External arrivals to node-i occur according to a Poisson process with rate λ_i. External arrival processes are independent.

(ii) The service time at node-i is load-dependent exponential: When n customers are at the node, the service rate is $\mu_i(n)$. The case of identical multiple servers can be viewed as a single-server node with load-dependent service rate.

(iii) The customer whose service is completed at node-i goes to node-j with a routing probability of γ_{ij} or departs the system with a probability of $\gamma_{i0} = 1 - \sum_{j=1}^{K} \gamma_{ij}$.

(iv) The buffer size at each node is infinity.

System Equations

Consider a simple case of $K = 2$ nodes with a single server at each node (Fig. 10). More complex systems can be analyzed in an analogous way.

Let us define $P(n_1, n_2)$ as the probability that there are n_1 customers at node-1 and n_2 customers at node-2. Then, the steady-state system equations can be written as follows:

$$\begin{aligned}(\mu_1 + \mu_2 + \lambda_1 + \lambda_2)P(n_1, n_2) \\ = \lambda_1 P(n_1 - 1, n_2) + \lambda_2 P(n_1, n_2 - 1) \\ + \mu_1 \gamma_{12} P(n_1 + 1, n_2 - 1) + \mu_2 \gamma_{21} P(n_1 - 1, n_2 + 1) \\ + \mu_1 \gamma_{10} P(n_1 + 1, n_2) + \mu_2 \gamma_{20} P(n_1, n_2 + 1)\end{aligned} \tag{70}$$

The left-hand side of the above equation is the rate out of state (n_1, n_2), and the right-hand side is the rate into state (n_1, n_2). In Ref. (13), Jackson showed that the following "product-form" solution satisfies Equation (70).

$$P(n_1, n_2) = (1 - \rho_1)\rho_1^{n_1} \cdot (1 - \rho_2)\rho_2^{n_2} \tag{71}$$

where

$$\rho_i = \frac{\Lambda_i}{\mu_i} \tag{72}$$

In Equation (72), Λ_1 is the aggregate arrival rate into note-1 and is given by

$$\Lambda_1 = \lambda_1 + \sum_{j=1}^{2} \Lambda_j \gamma_{j1} \tag{73}$$

Note that λ_1 is the external input rate into node-1 and $\sum_{j=1}^{2} \Lambda_j \gamma_{j1}$ is the internal input rate into node-1. Likewise, we get

$$\Lambda_2 = \lambda_2 + \sum_{j=1}^{2} \Lambda_j \gamma_{j2} \tag{74}$$

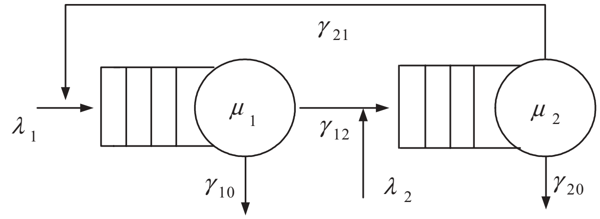

Figure 10. A Jackson network with two nodes (each node has a single server).

From Equation (71), we see that the marginal queue length distribution at node-1 is $P(n_1) = (1 - \rho_1)\rho_1^{n_1}$ and $P(n_2) = (1 - \rho_2)\rho_2^{n_2}$ at node-2. Observe that each node behaves as if it were an M/M/1 queue with arrival rate Λ_i and service rate μ_i. But these queues are not actually M/M/1 queues because the aggregate arrival process (i.e., superposition of the internal and external arrival processes) at each node is not a Poisson process. The aggregate arrival process is not even a renewal process. In general, the aggregate arrival process, into a node at which customers visit more than once is not a Poisson process.

If there exists more than one identical server at a node, we can use the M/M/c results from Equations (41) and (42). That is, the probability $P(n_1, n_2, \ldots n_K)$ that there are n_1 customers at node-1, n_2 customers at node-2,... and n_K customers at node-K is given by the product-form probability as follows:

$$P(n_1, n_2, \ldots n_K) = \prod_{j=1}^{K} P_j(n_j) \tag{75}$$

where

$$P_i(k) = \begin{cases} \dfrac{\Lambda_i^k}{k! \mu_i^k} P_i(0), (1 \le k \le c_i - 1) \\ \dfrac{\Lambda_i^k}{c_i^{k-c_i} c_i! \mu_i^k} P_i(0), (n \ge c_i) \end{cases} \tag{76}$$

and

$$P_i(0) = \left[\sum_{k=0}^{c_i - 1} \frac{(\Lambda_i / \mu_i)^k}{k!} + \frac{(\Lambda_i / \mu_i)^{c_i}}{c_i! (1 - \rho_i)} \right]^{-1}, (\rho_i = \frac{\Lambda_i}{c_i \mu_i}) \tag{77}$$

Λ_i can be computed using

$$\Lambda_i = \lambda_i + \sum_{j=1}^{K} \Lambda_j \gamma_{ji} \tag{78}$$

Equation (78) is called the *traffic equation*.

Mean Performance Measures

From Equations (75), (76) and (77), we can derive the following performance measures.

Mean Number of Waiting Customers at Node-i.

$$L_{q_i} = \frac{(\Lambda_i / \mu_i)^{c_i}}{c_i! (1 - \rho_i^2)} P_i(0) \tag{79}$$

Mean Queue Length at Node-i.

$$L_i = L_{q_i} + \frac{\Lambda_i}{\mu_i} \tag{80}$$

One-Time Mean Waiting Time at Node-i.

$$W_{q_i} = \frac{L_{q_i}}{\Lambda_i} \text{ (Little's law)} \tag{81}$$

One-Time Mean Sojourn Time at Node-i.

$$W_i = \frac{L_i}{\Lambda_i} \text{ (Little's law)} \tag{82}$$

Total Mean Time a Customer Spends in the Network. Let W_T be the total mean time a customer spends in the network. Let R_i be the mean time an arriving customer (internal or external) to node-i spends in the system until it departs the network. The customer has to spend W_i time at node-i first. Then, it goes to node-j with probability γ_{ij} and spend R_j time starting all over again from node-j until it departs the network. Thus, we obtain

$$R_i = W_i + \sum_{j=1}^{K} R_j \gamma_{ji} \tag{83}$$

An arbitrary external customer enters the network through node-i with probability

$$\alpha_i = \frac{\lambda_i}{\sum_{j=1}^{K} \lambda_j} \tag{84}$$

Thus, we get

$$W_T = \sum_{j=1}^{K} \alpha_i R_i \tag{85}$$

Total Mean Number of Customers in the Network at an Arbitrary Time. From Little's law, the total mean number L_T of the customers in the network can be obtained using

$$L_T = \left(\sum_{j=i}^{K} \lambda_j \right) W_T \tag{86}$$

which is equal to

$$L_T = \sum_{j=1}^{K} L_i \tag{87}$$

Total Mean Service Time Received. Let v_i be the mean number of times an external customer visits node-i before it departs the network. Then, v_i can be computed using

$$v_i = \alpha_i + \sum_{j=1}^{K} v_j \gamma_{ji} \tag{88}$$

The total mean service time received at node-i is

$$D_i = \frac{v_i}{\mu_i} \tag{89}$$

The total mean service time received by a customer in the network is

$$D_T = \sum_{j=1}^{K} D_j \tag{90}$$

MARKOVIAN CQN (GORDON-NEWELL NETWORK)

The Gordon-Newell network is a Markovian CQN (15). In a CQN, a fixed number of customers circulate the system. We use an example for illustration; see Fig. 11.

Suppose a fixed number of N customers circulate in the network of Fig. 11. Let $P(k, N-k)$ be the probability that k customers at node-1 exist and $N-k$ customers exist at node-2. In steady-state, we obtain the following set of system equations,

$$\begin{aligned}(\mu_1 + \mu_2)P(k, N-k) = \mu_1 P(k+1, N-k-1) + \mu_2 P \\ \times (k-1, N-k+1), \\ \times (k \neq 0, k \neq N)\end{aligned} \tag{91}$$

$$\mu_1 P(1, N-1) = \mu_2 P(0, N) \text{ and} \tag{92}$$

$$\mu_1 P(N, 0) = \mu_2 P(N-1, 1) \tag{93}$$

In steady-state, if a customers enter node-1 per unit time, the same number of customers enter node-2 per unit time. Let us define $\rho_1 = \frac{a}{\mu_1}$ and $\rho_2 = \frac{a}{\mu_2}$, where a is an arbitrary constant. Thus, ρ_1 and ρ_2 are not the probability that the servers are busy. The reason why ρ_1 and ρ_2 are not unique will be discussed subsequently. If we use $\mu_1 = \frac{a}{\rho_1}$ and $\mu_2 = \frac{a}{\rho_2}$ in the above equations, we get the product-form probability as follows:

$$P(k, N-k) = \frac{1}{C(2, N)} \rho_1^k \rho_2^{(N-k)} \tag{94}$$

Note that $C(2, N)$ is a normalization constant that is determined using

$$\sum_{k=0}^{N} P(k, N-k) = 1 \tag{95}$$

Also, note that $C(2, N)$ changes if a changes (and thus ρ_1 and ρ_2 change). But the effect of a is absorbed into $C(2, N)$ and therefore $P(k, N-k)$ does not change. For convenience, if we let $a = \mu_1$, we get $\rho_1 = 1, \rho_2 = \mu_1/\mu_2$, and

$$P(k, N-k) = \frac{1}{C(2, N)} \rho_2^{(N-k)} \tag{96}$$

Using $\sum_{k=0}^{N} P(k, N-k) = 1$, we get

$$C(2, N) = \begin{cases} \dfrac{1 - \rho_2^{N+1}}{1 - \rho_2}, (\mu_1 \neq \mu_2) \\ N + 1, (\mu_1 = \mu_2) \end{cases} \tag{97}$$

where $\rho_2 = \mu_1/\mu_2$.

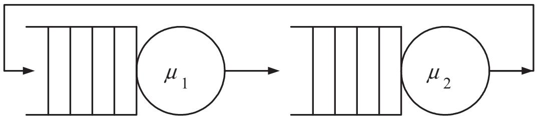

Figure 11. A closed queueing network with feedback.

In general, because the entrance and exit to and from the network is impossible, the traffic equation becomes

$$\Lambda_i = \sum_{j=1}^{K} \Lambda_j \gamma_{ji} \tag{98}$$

This equation does not have a unique solution because

$$\sum_{j=1}^{K} \gamma_{ij} = 1 \tag{99}$$

Thus, $\{\Lambda_i, (i = 1, 2, \ldots, K)\}$ obtained from the traffic equation are not unique. If we let $\{e_i, (i = 1, 2, \ldots, K)\}$ be a solution to Equation (98), then e_i is proportional to Λ_i. One simple way is to let $e_1 = 1$, which means that a customer visits note-1 once while he visits node-i for e_i times.

For the general CQN with K nodes and N circulating customers, according to Gordon and Newell (15)

$$P(n_1, n_2, \ldots n_K) = \frac{1}{C(K,N)} \prod_{i=1}^{K} f_i(n_i) \tag{100}$$

where

$$f_i(n_i) = \frac{e_i^{n_i}}{\prod_{j=1}^{n_i} \mu_i(j)} \tag{101}$$

$$f_i(0) = 0 \tag{102}$$

$C(K,N)$ is a normalization constant that is be determined using

$$C(K,N) = \sum_{\text{for all system states}} \prod_{i=1}^{K} f_i(n_i) \tag{103}$$

As in the preceding example, the biggest problem with a CQN is how to determine the normalization constant. In the preceding example, we had only two nodes and it was not a problem. But we have $\binom{N+K-1}{K-1}$ different system states in general. If we have $K = 8$ nodes and $N = 20$ customers circulating in the network, the number of different system states becomes $\binom{N+K-1}{K-1} = 888,030$. Computing that many probabilities to determine the normalization constant $C(K,N)$ is almost impossible even for the closed network of moderate size. Buzen (16) presents an efficient algorithm to compute the normalization constant.

CURRENT RESEARCH ISSUES

The research area of queueing theory is mature by now. However, several research issues are still being investigated actively. One such area is that of self-similar traffic models. Traditionally, the traffic models assumed in queueing theory were assumed to be Markovian, which was true of telephone network traffic. Subsequently, as queueing theory began seeing applications in other disciplines, other models of traffic were added. In the early 1990s research revealed that the traffic in computer networks did not follow the traffic models assumed in the literature. Rather, the traffic model exhibited a self-similarity behavior where the traffic pattern observed at different time scales had the same bursty pattern. This observation led to a spur in the research activity on the impact of this traffic model in the design of computer systems. This research area continues to be active today. For an overview of traffic patterns and optimal scheduling, we refer the reader to Refs. (17), (18), and (21).

Another rich research area is the discrete-time queueing system. In the discrete-time queueing systems, the time is expressed in multiples of slots and services can start only at slot boundaries. Because information in communication systems is transmitted by means of discrete units of cells, discrete-time models are believed to be more suitable to represent the modern telecommunication systems. Readers are referred to Refs. (19) and (20).

SERVICE-ORIENTED ARCHITECTURE AND WEB SERVICES

INTRODUCTION

Service-oriented architecture (SOA) (1,2) is a software paradigm that enables large applications to be created in an ad hoc, loosely coupled manner from smaller modules called services. SOA defines a methodology for the reuse and interoperability of software components and business processes within and between enterprises over the Internet and, thus, promises to achieve flexibility, agility, and cost savings for enterprises.

In the past, enterprises integrated their silo systems using a point-to-point or enterprise application integration (EAI) approach for each project. That approach resulted in systems that are complex, difficult-to-modify, and expensive-to-maintain. Today, an enterprise must be able to do business with many other enterprises, and it must be able to respond rapidly to changes and challenges, such as competitive pricing and offshoring to compete in the global economy.

SOA enables enterprises to develop and deploy applications more rapidly. It supports modularity of design, facilitates software reuse, promotes standardization, and supports interoperability across diverse hardware platforms, operating systems, and programming languages. Software reuse spreads the costs of software development over many customers. Interoperability allows software services to be accessed without having to know their underlying implementations or the computing platforms on which they run.

SOA offers the promise of reduced time and costs in software development, and reduced application and infrastructure complexity. It aims to promote business between enterprises, increase profits, improve product quality, increase customer satisfaction and achieve operation agility.

Web services (3) are the most common implementation of the service-oriented architecture. However, some SOA implementations do not use Web services but provide similar benefits.

SERVICE-ORIENTED ARCHITECTURE

SOA (1,2) is an architecture definition and process that enables large applications to be created in an ad hoc, loosely coupled manner from modular services. A service is a unit of work performed by a service provider to achieve desired end results for a service consumer. SOA has the following requirements:

- Interoperability of services regardless of the hardware platforms and operating systems on which they are deployed or the programming languages in which they are written.
- Description of services in a clear and unambiguous manner that allows a potential consumer to find and use a service offered by a provider.
- Access to services by means of a standard communication protocol and a common format for messages and the data that they contain, so that a consumer can access and use a service offered by a provider.

SOA consists of multiple layers and components, as shown in Fig. 1. The top layer provides the Services Interface, which allows the clients to invoke the services, and the bottom layer contains the Application Services. The middle layer contains the Services Coordinator, which controls the flow of messages from the Services Interface to the Application Services. SOA may also contain application-neutral Service Management components and Quality of Service components, as shown in Fig. 1.

The essence of SOA is independent services that can be called in a standard way to perform their tasks, without a service needing to know about a client and without a client needing to know how a service actually performs its tasks. Each service interaction is self-contained, and different service interactions are coupled loosely, so that each service interaction is independent of other service interactions. SOA supports communication between services using standard protocols and enables one application to perform a service on behalf of another service.

In SOA, a service represents a larger unit of functionality than a traditional function or class. Unlike a function, the software providing a service must not interact internally with the software of other services. In SOA, services are coupled loosely, in contrast to the functions that a linker binds together to form an executable or a dynamically linked library.

Underlying SOA is metadata that are used to describe not only the characteristics of the services but also the data that the services exchange. The metadata must be in a form that system designers can understand and in a form that software systems can use dynamically and automatically.

In SOA, services work together based on a formal definition or contract (e.g., WSDL description) that is independent of the underlying hardware platform and operating system on which the services are deployed and the programming language in which they are written.

As shown in Fig. 2, a service can assume one or more of three roles: service provider, service broker, or service requester.

A service provider creates a service and defines an interface for invoking that service. The service provider also creates a service description for the service and makes the service available to potential consumers through a service broker by publishing the service description in a service registry.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

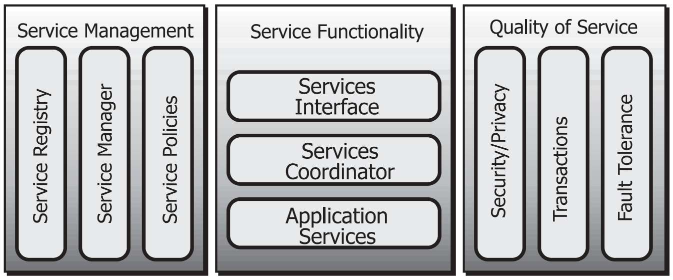

Figure 1. Service-Oriented Architecture. SOA consists of multiple layers and components and promotes modularity of design and software reuse.

A service broker uses the information in the service description to catalog the service and to search for the service when it receives a request for information about the service. The service broker provides a service, the address, and the interface are known a priori to the service requester.

A service requester that is trying to find a service queries the service broker. The service broker replies with a service description that indicates where to find the service and how to invoke it. The service requester can then bind to the service provider by invoking the service.

The basic service concept is extended by orchestration of fine-grained services into more coarse-grained business services, which in turn can be incorporated into business processes and workflows.

SOA can be implemented using a variety of technologies, including Web Services, RPC, Java RMI, CORBA, and DCOM. Typically, the services run in Java Enterprise Edition or .NET environments that manage memory allocation and deallocation, allow ad hoc and late bindings and perform type checking. Services written in Java for Java Enterprise Edition environments and services written in C# for .NET environments can be used by a client, and can use each other. Legacy systems, written in COBOL, can be wrapped and presented as services.

WEB SERVICES

SOA is typically implemented using Web services (3), although that is not required. The World Wide Web Consortium (W3C) defines a Web service as:

> A software application identified by a URI, whose interfaces and bindings are capable of being defined, described, and discovered as XML artifacts. A Web Service supports direct interactions with other software agents using XML-based messages exchanged via Internet-based protocols.

This definition states explicitly that a Web service is based on XML. It emphasizes that a Web service must be capable of being defined, described, and discovered, to enable creation of client software that binds to, and interacts with, the Web service using the defined interfaces.

XML

The eXtensible Markup Language (XML) (4) provides a common syntax for Web services documents, so that the information in those documents is self-describing. It defines the rules that a document must follow to be well-formed. XML aims to achieve interoperability, portability, and automatic processing with data independence for different programming languages, middleware systems, and database management systems.

Like the HyperText Markup Language (HTML), XML has elements, attributes, values, and tags. XML elements and attributes provide type and structure information for the data values. XML element tags describe the data values that they enclose. For example:

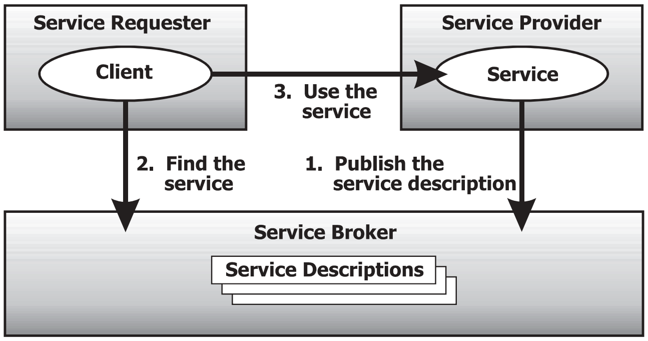

Figure 2. Service-oriented architecture. The service provider creates a service and publishes a service description at the service broker. The service consumer finds the service description at the service broker and then uses the service provided by the service provider.

```
 <Service provider>
    <Name>Enterprise</Name>
    <PhysicalAddress>3210 State Street, Santa Barbara,
     CA 93101<\PhysicalAddress>
    <PhoneNumber>805-569-6222<\PhoneNumber>
     <URL>www.enterprise.com<\URL>
<\ServiceProvider>
```

XML provides a standard way to define the structure of documents so that they are suitable for automatic processing. An XML parser can determine that a document contains a certain element and can extract the content associated with that element.

XML schemas and document type definitions are used to specify document types and to state that a document is of a certain document type. An XML document verifier can be used to check whether the structure and content of a document are consistent with the prescribed type. Currently, XML schemas and document type definitions do not provide semantic information about the document or the elements contained within the document.

More precise tagging instructions have been defined for various vertical business sectors. In particular, the Organization for the Advancement of Structured Information Standards (OASIS) and the United Nations Center for Trade Facilitation and Electronic Business (UN/CEFACT) have developed the electronic business XML (ebXML) standard (5) as a successor to the Electronic Data Interchange (EDI) standard. The ebXML standard defines an architecture and a specification that are designed to automate business process interactions among trading partners.

Web services are classified into two categories: Representational (REST) Web services or Simple Object Access Protocol (SOAP) Web services. Both kinds of Web services use XML for formatting the data so that they are self-describing. These two categories of Web services are discussed below.

REST Web Services

REST Web services (6,7) are based on the concept of a resource, which has a Uniform Resource Identifier (URI). A resource may have zero or more representations. If no representations for the resource exist, the resource is said not to exist. A REST Web service has the following additional requirements:

- Interfaces are limited to HTTP, namely:
  - GET is used for obtaining a representation of a resource. A consumer uses it to retrieve a representation from a URI.
  - DELETE is used for removing a representation of a resource.
  - POST is used for updating or creating a representation of a resource.
  - PUT is used for creating a representation of a resource.
- Messages are in XML, which are confined by a schema written in a schema language such as RELAX NG (8) or XML Schema (9).
- Messages can be encoded with URL encoding.
- Services and service providers must be resources, whereas a consumer may be a resource but is not required to be a resource.

REST Web services require little infrastructure support other than standard HTTP and XML. They are simple and effective, because HTTP is available widely and works for most applications.

As interest in REST Web services has grown, so has the scope and size of business applications that it supports. The input parameters to the HTTP methods have grown in size and number. Structured response values have also grown in complexity, ranging from customer XML namespaces to JavaScript Object Notation (JSON) (10). These trends have made descriptors a natural addition to REST Web Services.

The newly proposed Web Application Description Language (WADL) (11) provides standard descriptors for REST Web services just as the Web Services Description Language (WSDL) provides standard descriptors for SOAP Web services (see the section on WSDL below). A WADL descriptor not only describes the service, including the grammars, resources, and methods of the service, but also aids in the creation of stubs that are used to build service clients. Currently, tools for WADL that create stubs from descriptors are available only for Java environments.

IBM has initiated a project, named Project Zero (12), for REST Web services that aims to extend the Service Oriented Architecture for enterprises to the Web Oriented Architecture. The Zero platform is a Java runtime environment that is optimized to run script and REST Web services. It uses PHP and Groovy for producing REST Web Services and Ajax for building interactive clients. It allows enterprise services to be transformed and exposed as RSS/Atom feeds, which are easy to consume using feed readers.

REST Web services are growing in popularity, perhaps because they are lighter weight than SOAP Web services and because they can achieve a higher level of interoperability more easily.

SOAP Web Services

Today, most people think of Web services as SOAP Web services, rather than as REST Web services. (See the section on SOAP below.) SOAP Web services are based on the following core specifications and standards:

- SOAP (13), which is an XML-based protocol for accessing a Web service using HTTP or SMTP.
- WSDL (14), which is an XML-based language for describing Web services and the means to access them.
- Universal Description Discovery and Integration (UDDI) (15,16), which is used by the service broker (registry).

Some industry organizations, such as the Web Services Interoperability (WS-I) organization (17), mandate the use of both SOAP and WSDL in their definition of a Web service.

SOAP Web services are classified into two categories: SOAP Document-Centric Web services and SOAP Remote Procedure Call (RPC) Web services. These two categories of SOAP Web services are discussed below.

SOAP Document-Centric Web Services

In SOAP document-centric Web services, the service requester and service provider exchange XML documents. They must agree on the structures of the documents to be exchanged. The documents are transported between them in SOAP messages.

As an example of a SOAP document-centric Web service, consider a service for reserving a rental car from a car rental agency.

The service requester creates a rental car reservation document, which contains the kind of car requested, city, and date. The service requester then sends the rental car reservation document to the car rental agency in a SOAP message. The body of the SOAP message contains the rental car reservation document, and the header includes information that identifies the service requester to the car rental agency, as shown at the left in Fig. 3.

The service provider (the car rental agency) creates a reservation confirmation document, which contains the cost of the car rental and the reservation Id for the service requester, and then sends it to the service requester in a SOAP message. The body of the SOAP message contains the reservation confirmation document, and the header includes information that identifies the car rental agency, as shown at the right in Fig. 3.

SOAP RPC Web Services

In SOAP RPC Web services, the service requester encapsulates a remote procedure Call (RPC) in a SOAP message and sends the request message to the service provider. The body of the SOAP request message contains the procedure call, including the name of the procedure being invoked and the input parameters. The service provider processes the RPC and returns the results and output parameters in a SOAP response message to the service requester. The body of the SOAP response message contains the result and the output parameters of the RPC. The service requester and service provider must agree on the RPC signature rather than on the document structures.

As an example of a SOAP RPC Web service, again consider a service for reserving a rental car from a car rental agency.

The service requester creates a SOAP message and sends it to the car rental agency as a request. The body of the SOAP message contains the procedure name reserveRentalCar, as well as the city, date, and kind of car parameters, as shown at the left in Fig. 4.

The service provider (the car rental agency) processes the RPC and returns a SOAP message to the service requester as a response. The body of the SOAP message contains the reservation Id and the cost of the rental car as the return values of the RPC, as shown at the right in Fig. 4.

Any additional properties associated with the RPC are included in the header of the SOAP message. For example, for a transactional RPC, the request header includes the transaction context, which enables the receiver to process the request as a transaction.

The SOAP RPC Web service tunnels application-specific RPC interfaces through the generic SOAP interface. Effectively, it prescribes both system behavior and application semantics, and is imperative rather than descriptive, which is contrary to the spirit of SOA. Procedural interfaces require more complete and rigorous specification, and greater prior agreement, than do document interfaces. Consequently, some people consider applications created with SOAP RPC Web services not as interoperable as SOAP document-centric Web services. Both the WS-I Basic Profile and the SOAP 1.2 Specification consider support for SOAP RPC optional.

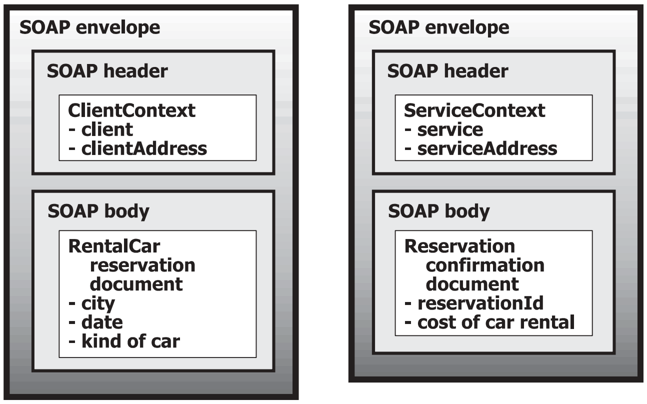

Figure 3. SOAP document-centric Web service. The SOAP message communicated by the service requester contains a reservation request document, and the SOAP message communicated by the service provider contains a reservation confirmation document.

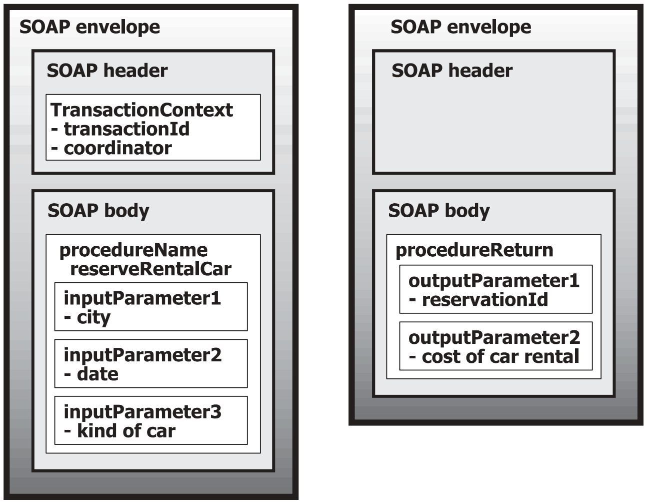

Figure 4. SOAP RPC Web service. The SOAP message from the service requester contains a RPC, and the SOAP message from the service provider contains the results from execution of the RPC.

SOAP

SOAP (13) defines how to organize information and messages using XML, so that the information can be exchanged among service requesters, service providers, and service brokers.

SOAP is an application-layer protocol that operates on top of other protocols, most commonly the HyperText Transfer Protocol (HTTP) but also the Simple Mail Transfer Protocol (SMTP).

SOAP supports applications that interact via one-way asynchronous messages as for SOAP document-centric Web services and also applications that interact via two-way synchronous request-response messages as for SOAP RPC Web services.

SOAP messages are used as envelopes that enclose the data that the application wants to send. An envelope consists of two parts: a header and a body. The header is optional, and the body is mandatory. Both the header and the body can have multiple subparts in the form of header blocks and body blocks, as shown in Figs. 3 and 4 for SOAP Web services.

A SOAP message has a sender, a receiver, and an arbitrary number of intermediaries (nodes) that process the message and route it to the receiver. The information that the sender wants to transmit to the receiver is in the message body. Additional information needed for intermediate processing or for value-added services (such as security or transactions) is included in the message header.

SOAP incurs processing overhead for parsing and serializing the XML messages, and communication overhead for the extra XML tags, but it promotes interoperability among the interacting service requesters, service providers, and service brokers.

WSDL

WSDL (14) provides descriptors for SOAP Web Services in a standard way. A WSDL descriptor specifies how to interact with the Web service, the data that are to be sent, the operations that are involved, the protocol that is to be used to invoke the service, and the data that can be expected in return. A WSDL descriptor can be used as input to a tool that generates stubs and can be used to capture information that allows reasoning about semantics. Thus, it is similar in purpose to the Interface Definition Language (IDL) of other middleware platforms, such as the Common Object Request Broker Architecture (CORBA).

A WSDL descriptor consists of an abstract part and a concrete part, as shown in Fig. 5. The abstract part is analogous to conventional IDL and uses type, message, operation, and port type constructs. These four constructs are called abstract because they do not have a concrete binding, a specific encoding, or a definition of a service that implements them.

Types allow the exchanged data to be interpreted correctly at both endpoints of the communication. By default, WSDL uses the same basic and structured types as XML schemas.

Messages are typed documents that are divided into parts, each of which has a name and a type. For example, a message for a procedure call with integer and string parameters has a part that contains the integer and a part that contains the string.

Operations are classified as one-way, notification, request-response, and solicit-response. One-way and notification operations involve a single message, whereas request-response and solicit-response operations involve two messages. One-way and request-response operations are initiated by the client, whereas notification and solicit-response operations are initiated by the service.

A port type in WSDL is analogous to an interface in IDL. A port type consists of a set of related operations.

The concrete part of a WSDL description defines an instance of a service and uses interface bindings, ports, and service constructs.

An interface binding specifies the message encoding and protocol bindings for all operations and messages defined in a port type. In particular, it specifies the encoding rules to be used in serializing the parts of a message into XML. It can also be used to specify that an operation is either SOAP document-centric or SOAP RPC style, or that the messages of the operation must be communicated using SOAP with HTTP or SMTP bindings.

A port combines the interface binding information with the network address, specified as URIs, where the implementation of the port type can be accessed.

A service is a logical grouping of ports, which are typically related ports at the same address.

UDDI

The UDDI specification (15,16) defines a mechanism for clients to find Web services dynamically. UDDI is based on the notion of a business registry (essentially, a naming or directory service). UDDI defines data structures and application programming interfaces for publishing service descriptions in the business registry and for querying the registry to look for published descriptions.

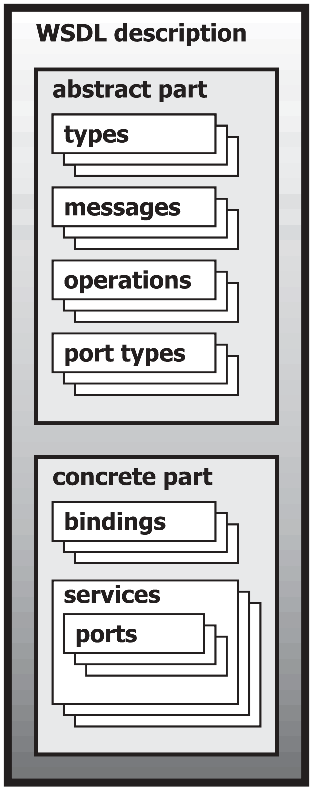

Figure 5. Web Service Description Language. The WSDL descriptor not only describes a service but also allows client stubs to be created from the descriptor.

UDDI registries have three types of users to which they expose their application programming interfaces: service providers that want to publish a service (and its usage interfaces), service requesters that want to obtain services of a certain kind and bind programmatically to those services, and other registries (service brokers) that need to exchange information. Interaction with a UDDI registry takes place as a sequence of exchanges of XML documents, typically using SOAP.

UDDI supports application developers in finding information about Web services, so that they know how to write clients that can interact with those services. It also enables dynamic binding by allowing clients to query the registry and obtain references to services in which they are interested. In addition, it supports the idea of a Universal Business Registry (UBR), where anyone can publish service descriptions and can query the registry for services of interest.

The information within a UDDI registry can be categorized as follows:

- Listings of organizations, contact information, and services that those organizations provide.
- Classifications of companies and Web services according to taxonomies that are either standardized or user-defined.
- Descriptions of how to invoke Web services, by means of pointers to service description documents, stored outside the registry, for example, at a service provider's site.

As yet, few applications use a UDDI registry to discover a Web service and then invoke that Web service dynamically using its WSDL interface. Rather, in current practice, client applications are designed explicitly to invoke Web services with known WSDL interfaces and Uniform Resource Identifiers (URIs). Currently, some Web services can be found on publicly available Web sites, such as the XMethods Website (18), but it is also possible to find Web Services using Google or Amazon as described in Ref. 19.

In addition to the core specifications (XML, SOAP, WSDL, UDDI), many other SOAP Web Services specifications, exist which are general in referred to as WS-*. These specifications include:

- WS-AtomicTransaction, WS-Coordination, WS-BusinessActivity–Specifications that define mechanisms and interfaces for transactions in a distributed environment (20).
- WS-ReliableMessaging–A protocol, issued by IBM, BEA, Microsoft, TIBCO, and currently being standardized by OASIS, for reliable messaging between two Web Services (21).
- WS-Reliability–An OASIS protocol for reliable messaging between two Web services (22).
- WS-Security–A specification that defines how to use XML encryption and XML signatures in SOAP messages to secure message exchange as an alternative or extension to HTTPS (23).

The growing numbers of these SOAP Web services specifications increase the complexity of the systems being built from SOAP Web services and increase the difficulty of achieving interoperability.

CHALLENGES FOR SERVICE-ORIENTED ARCHITECTURE AND WEB SERVICES

One of the primary challenges for SOA and Web Services is achieving interoperability across diverse hardware platforms, operating systems, programming languages, and data representations. The Web Services Interoperability (WS-I) organization (24) has developed the Basic Profile and the Basic Security Profile to improve interoperability. A profile is a set of core specifications (SOAP, WSDL, etc.) in a specific version (SOAP 1.1, UDDI 2, etc.) with additional requirements to restrict the use of the core specifications. The WS-I has also published use cases and tools to assess whether a Web service is conformant with the WS-I profile guidelines.

Related to the challenge of interoperability is ensuring that the XML data are interpreted in the same way by both the service requester and the service provider. Each well-defined data item, such as a date, can be represented in multiple ways. Many data items used in business interactions are much less well defined. Web services, and the

Web in general, currently focus on syntactic aspects of representing and communicating information. In contrast, semantic Web services (25) aim for automation of Web services by standardizing the representation and handling of semantic metadata to describe the services and how to use them. Semantics are difficult even for humans, and initial use of semantic Web services will be restricted to narrow, well-defined domains. The ability to locate an appropriate Web service, based on semantics, and to choose among alternative Web services, requires major advances in automated analysis of semantic information.

Another major challenge for SOA and Web services is the orchestration of services into complex applications and the management of how they interact. Metalanguages, such as the Business Process Execution Language (BPEL) (5), and specifications, such as the Web Services Choreography Description Language (WS-CDL) (26), provide a means of orchestrating fine-grained services into more coarse-grained business services, which in turn can be incorporated into business processes and workflows. As more enterprises use Web services for business interactions, more coordination between service requesters and service providers will be required. Such coordination will, in turn, require more coordination between business partners, rather than simply interfaces between service requesters and service providers.

Also a major challenge for SOA and Web services is the management of change. New services are introduced, and old services are discontinued. Data items acquire new attributes and even new meanings. Operation with multiple interfaces or multiple data representations to achieve interoperability for legacy relationships adds considerable programming complexity and a high rate of errors. SOA and Web services communities have yet to address the topic of change management.

SOA supports services on both sides of the firewall and, thus, opens up the most critical business processes and data to security and privacy risks. WS-Security (23) offers a solution for SOAP Web services, but REST Web services need to use SSL or define their own security protocols. Security appliances that parse XML messages, ensuring that known business partners originated them, can help to address the security and privacy issues, as can HTTPS and IP filtering.

Reliability is also a challenge for SOA and Web services. No guarantee exists that SOAP messages sent over HTTP or SMTP will be delivered reliably to the applications exactly once and in the correct order. The competing WS-ReliableMessaging (21) and WS-Reliability (22) specifications address this issue for SOAP Web services. However, without agreement on a single standard, reliable messaging will be implemented in an ad hoc manner, which unnecessarily complicates interoperability, portability, and extensibility.

Critics of SOA and Web services claim that they result in additional XML layers with applications running slower and consuming more processing power as a consequence. Performance is an issue because XML documents are text-based (rather than binary-based), self-describing, and interpreted. Consequently, they consume more network bandwidth, memory space, and processing cycles. However, new XML parsing and indexing technologies are available, such as VTD-XML (17), that promise to improve the performance of SOA and Web services significantly. Moreover, SOA can be implemented using technologies, such as Java Business Integration (JBI) (27), that do not depend on XML or RPC.

CONCLUSION

SOA aims to promote modularity and reuse of software components. It also aims to maintain interoperability between software applications within a single enterprise and between enterprises that operate across diverse computing platforms over the Internet. SOA can be implemented using Web services, although that is not required.

Web services depend on the use of XML to structure and tag information so that it is self-describing. Web services can be categorized as REST Web services and SOAP Web services. REST Web services currently rely only on XML and HTTP, but soon they might also depend on WADL for describing Web services. SOAP Web services use SOAP to convey XML documents and RPCs in messages between service requesters and service providers, WSDL to describe Web services so that they can be easily accessed, and UDDI to publish and discover Web services.

The potential widespread use and benefits of SOA and Web services are compelling. By supporting modularity of design and maintaining interoperability, they enable enterprises to streamline and automate their business processes and allow diverse computer systems applications to be coupled together. They offer the promise of reduced application development time and cost, increased business agility, and increased business profits.

SHARED MEMORY MULTIPROCESSORS

INTRODUCTION

Shared memory multiprocessors are multiprocessor systems that logically implement a single global address space. The model for parallel programming based on such systems, the shared address space model, is straightforward and frees programmers from the tedious and sometimes complicated task of orchestrating all communication and synchronization through explicit message passing to access remote data. As a result, this class of multiprocessor systems has received much commercial as well as research interest. The effectiveness of shared memory systems as a cost-effective option for high-performance parallel and distributed computing is quantified by four key characteristics: *simplicity, portability, efficiency*, and *scalability*.

Simplicity: Shared memory systems provide a uniform and easy-to-use model for accessing all shared data, whether local or remote. Beyond such uniformity and ease of use, shared memory systems should provide simple programming interfaces that allow them to be platform and language independent.

Portability: The portability of the shared memory programming environment across a wide range of platforms is important as it obviates the labor of rewriting codes for large complex applications. In addition to being able to be portable across "space," good shared memory systems should also be portable across "time," i.e., be able to run on future systems, to enable system stability.

Efficiency: For shared memory systems to achieve widespread acceptance, they should be capable of providing high efficiency over a wide range of applications without requiring much programming effort, especially applications with irregular and/or unpredictable communication patterns.

Scalability: To support high-performance computing, shared memory systems should be able to run efficiently on systems with hundreds (or potentially thousands) of processors. Scalability offers end users yet another form of stability—knowing that applications running on small-to-medium systems could run unchanged and still deliver good performance on large systems.

Most existing shared memory multiprocessor systems represent a practical balance of these properties. The shared memory abstraction in existing systems is supported either in hardware or in software or using a hybrid approach. Figure 1 illustrates the spectrum of shared memory multiprocessor systems. Based on the underlying architectural approach, the current systems can be broadly grouped into two categories: (*1*) physically shared memory (PSM) multiprocessors and (*2*) distributed shared memory (DSM) multiprocessors. However, irrespective of their architectures, shared memory systems must address two critical issues, cache coherence and memory consistency.

Cache Coherence

Although the shared memory abstraction enables global accesses to remote data in a straightforward manner, the difference in access time between local and remote memory accesses in some of these architectures is significant (access times may differ by a factor of 10 or higher). Local caches can be used to hide long remote memory access times. However, ensuring coherence of cached data across the multiprocessor system with (possibly remote) memory is a challenging problem (Fig. 2). Two key approaches have been used to maintain cache coherence.

Snoopy Cache Coherence Protocols. Small shared memory multiprocessor systems that are based on a shared bus implement *snoopy protocols* to maintain cache coherence. In this approach, all caches snoop on the shared "snoopy" bus. When a processor writes into a shared cache block, the write request is transmitted on the bus. All caches snooping on the bus read the address associated with every read/write request and check whether they are currently caching that address. If a cache contains the address, the corresponding entry in the cache is invalidated in case of a write request, or it is used to satisfy the read request. For write-through caches, where data are simultaneously written to main memory and cache, the snoopy protocol is only an incremental addition to the normal cache protocol and the memory is always up-to-date. Write-back caches, which copy modified data to the source memory only when a cache block is replaced, require extra work to implement the protocol. In this type of cache, the most recently modified copy of the data may be in some processor's cache, and on a read miss, the coherence protocol has to retrieve these data by snooping all the caches.

Snoopy protocols require all read and write requests to be broadcast on the bus. As the bus processes only one request at a time, concurrent writes to the same cache are automatically serialized. This serialization of requests by the bus imposes an ordering on all writes, which is critical to maintaining coherence. For small multiprocessor systems (up to 64 processors), snoopy cache coherence protocols work well. The use of caches reduces bandwidth requirements for the bus and main memory. Furthermore, as the caches are kept functionally transparent, the shared-memory programming model is preserved. For larger systems, however, the bus becomes a communication bottleneck.

Directory-Based Cache Coherence. Directory-based cache coherence protocols use a directory to keep track of the caches that share the same cache line. The individual caches are inserted into and deleted from the directory to reflect the

use or rollout of shared cache lines. This directory is also used to purge (invalidate) a cached line because of a remote write to that line.

The directory can either be centralized or distributed among nodes of the shared memory multiprocessor system. Generally, a centralized directory is implemented as a bit map of the individual caches, where each bit set represents a shared copy of a particular cache line. The advantage of this type of implementation is that the entire sharing list can be found by simply examining the appropriate bitmap. However, each potential reader and writer has to access the centralized directory, which becomes a bottleneck. Additionally, the reliability of the scheme is a serious issue as a fault in the bit map would result in an incorrect sharing list.

The bottleneck and single point of failure resulting from a centralized directory is alleviated by distributing the directory. The distributed directory scheme (also called the distributed pointer protocol) implements the sharing list as a distributed linked list. In this implementation, each directory entry (corresponding to a cache line) points to the next member of the sharing list. Cache lines are inserted into and deleted from the linked list as necessary.

Shared Memory Consistency Models

In addition to the use of caches, scalable-shared memory multiprocessor systems migrate or replicate data to local processors. Most scalable systems choose to replicate (rather than migrate) data as this gives the best performance for a wide range of application parameters. With replicated data, maintaining *memory consistency* becomes an important issue. The shared memory scheme (hardware or software) must control replication in a manner that preserves the abstraction of a single address-space shared memory.

The shared memory consistency model refers to how local updates to shared memory are communicated to the processors in the system. The most intuitive model is that a read should always return the last value written. However, the idea of "the last value written" is not well defined in multiprocessor environments, and its different interpretations have given rise to a variety of memory consistency models such as sequential consistency (1), processor consistency, release consistency (2), entry consistency (3), scope consistency (4), and variations of these.

"Sequential consistency" requires that the result of any execution is the same as if the operations of all processors were executed in some sequential order, and the operations of each individual processor appear in this sequence in the order specified by its program. This definition implies (*1*) maintaining program order among operations from individual processors and (*2*) maintaining a single sequential order among operations from all processors. The second aspect makes it appear as if a memory operation executes atomically or instantaneously with respect to other memory operations (5). The simplicity of this model, however, exacts a high price because sequentially consistent memory systems preclude many optimizations, such as reordering, batching, or coalescing, which are feasible in uniprocessor system. These optimizations reduce the performance

Time	Processor P1	Processor P2
↓	x = 0	y = 0
	x = a	y = b
	y = c	
		x = d

Figure 2. Coherence problem when shared data are cached by multiple processors. Suppose initially x = y = 0 and both P1 and P2 have cached copies of x and y. If coherence is not maintained, P1 does not get the changed value of y and P2 does not get the changed value of x.

Table 1. Relaxations in Program Order Allowed by Different Memory Consistency Models

Model	Program Order Relaxation
Sequential consistency	None
Processor consistency	Write->Read
Weak ordering	Data->Data
Release consistency*	Data->Data, Data->Acquire, Release->Data, Release->Acquire

*Release consistency categorizes synchronization operations into acquires and releases.

Note: Only the program order between memory operations to different locations is considered.

impact of having distributed memories and have led to a class of weakly consistent models.

A weaker memory consistency model offers fewer guarantees about memory consistency, but it ensures that a "well-behaved" program executes as though it were running on a sequentially consistent memory system. Once again the definition of "well behaved" varies according to the model. Relaxed memory consistency models can be categorized based on two key characteristics: (*1*) how is the program order requirement relaxed and (*2*) how is the write atomicity requirement relaxed. Program order relaxations include relaxing the order from a write to a following read, between two writes, and from a read to a following read or write. Atomicity relaxations differ in whether they allow a read to return the value of another processor's write before the write is made visible to all other processors. Table 1 summarizes hardware-centric relaxations in program order allowed by the various memory consistency models commonly supported in commercial systems.

Some researchers have proposed DSM systems that support a family of consistency protocols or application-specific protocols, and programmers are allowed to choose any one of them for each memory object (or page) or each stage of an application. Although this scheme might be able to achieve optimal performance, it does impose undue burden on the programmer. Another suggestion is to implement adaptive schemes that automatically choose the appropriate memory consistency protocol to trade off between performance and programming ease.

As many recent high-performance computing platforms have been built by loosely connecting a constellation of clusters, each of them being made of a set of tightly connected nodes, hierarchy-aware consistency protocols have been proposed. At first such protocols have focused on improving locality in data management by caching remote data within clusters. Later studies have addressed locality in synchronization management, which is also a major source of inefficiency.

Programs with good behavior do not assume a stronger consistency guarantee from the memory system than is actually provided. For each model, the definition of "good behavior" places demands on the programmer to ensure that a program's access to the shared data conforms to that model's consistency rules. These rules add an additional dimension of complexity to the already difficult task of writing new parallel programs and porting old ones. But the additional programming complexity provides greater control over communication and may result in higher performance. For example, with entry consistency, communication between processors occurs only when a processor acquires a synchronization object.

PHYSICALLY SHARED MEMORY (PSM) MULTIPROCESSORS

The structure of a physically shared memory multiprocessor system is illustrated in Fig. 3. A small number of microprocessors (typically less than 64) is integrated with a common memory using a shared bus or a crossbar interconnect, that allows all processors to have roughly equal access time to the centralized main memory, i.e., uniform memory access (UMA). Physically shared memory multiprocessors are also termed as *symmetric multiprocessors* (SMPs) or *centralized shared memory processors*. PSM multiprocessors using a shared bus interconnect are called *bus-based symmetric multiprocessors*.

The primary strengths of PSM systems include uniform memory access and a single address space offering the ease of programmability. These systems do not need explicit data placement, as memory is equally accessible by all processors. The PSM design approach is used in commercially successful machines such as the Compaq PentiumPro and Sun UltraEnterprise.

Bus-Based Systems

Early PSM machines, including many desktop PCs and workstations, used a shared serial bus with an address cycle for every transaction. This tied the bus during each

Three Ultra Port Architecture Implementations: (a) small system consisting of a single board with four processors, I/O interfaces, and memory; (b) a medium-sized system with one address bus and a wide data bus between boards; and (c) a large system with four address buses and a data crossbar between boards. [Source: A. Charlesworth (6).]

access for the needed data to arrive. An example is the Sun Microsystems Mbus (6) used in SparcStations. This shared bus, in addition to allowing access to the common memory, is used as a broadcast medium to implement the *snoopy cache coherence protocol*.

Subsequent PSM designs used the *Split-Transaction Bus* (7), with separate buses for address and data. It allows an address cycle to overlap with a data transfer cycle. Split-Transaction buses were used in Sun Microsystems' original Gigaplane (7), in the Ultra-Enterprise 3000-6000. The split-transaction bus also allowed overlapping of snooping and data transfer activities, thereby increasing bandwidth. However, this overlapping needed handshaking during data transfer. The *Pipelined Bus*, used as the PentiumPro System Bus, is a special case of split-transaction bus wherein the address and data cycles are pipelined and devices can respond only in specific cycles, obviating the need for the data handshake. This scheme, however, requires the data cycle to correspond to the slowest device.

Crossbar-Based PSM Systems

In crossbar-based systems, the data bus is replaced with a crossbar switch to provide high-performance UMA. The address bus is also replicated by a factor of four. Point-to-point routers and an active center-plane with four address routers are the key components of the larger UMA symmetric multiprocessors such as the Sun Ultra Enterprise series (6).

Although physically shared memory multiprocessor architectures are used in most commercially successful machines, these systems have relatively high minimum memory access latency as compared with high-performance uniprocessor systems. Furthermore, the inherent memory contention in these systems limits their scalability.

Example System—Sun Ultra-Port Architecture

Figure 4 illustrates the family of SUN Ultra Port Architectures (6) used in their workstations. These systems use a combination of bus and crossbar to implement shared memory. In the smaller Ultra 450 system (1–4 processors), illustrated in Fig. 4(a), a centralized coherency controller and a crossbar is used to connect the processors directly to the shared memory. This system is a relatively low-cost single-board configuration. The intermediate-sized Ultra 6000 system has a Gigaplane bus that interconnects multiple system boards and is designed to provide a broad range of expandability with the lowest possible memory latency, typically (216 ns for a load miss). This scheme supports systems with 6 to 30 processors and is shown in Fig. 4(b). For large systems with 24 to 64 processors, the address bus is replicated by a factor of four. The scheme is illustrated in Fig. 4(c). These four address buses are interleaved so that memory addresses are statically divided among the four buses; i.e., each address bus covers one quarter of the physical address space. A 16 × 16 crossbar is chosen to match the quadrupled snoop rate. To avoid failures on one system board from affecting other boards, and to electrically isolate the boards, point-to-point router application-specific integrated circuits (ASICs) are used for the entire interconnect, i.e., for the data crossbar, the arbitration interconnect, and the four address buses. The ASICs are mounted on a centraplane, which is physically and electrically in the middle of the system.

PHYSICALLY DISTRIBUTED MEMORY ARCHITECTURES

The structure of a typical distributed memory multiprocessor system is shown in Fig. 5. This architecture enables scalability by distributing the memory throughout the machine and by using a scalable interconnect to enable processors to communicate with the memory modules. Based on the communication mechanism provided, these architectures are classified as multicomputer/message passing architectures and DSM architectures. The multicomputers use a software *Message Passing* layer to communicate among themselves, and they are called message passing architectures. In these systems, programmers are required to explicitly send messages to request/send remote data. As these systems connect multiple computing nodes sharing only the scalable interconnect, they are also referred to as multicomputers.

DSM machines logically implement a single global address space although the memory is physically distributed. The memory access times in these systems depended

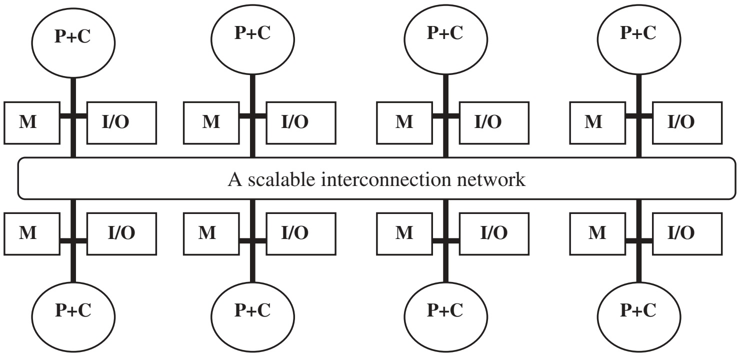

Figure 5. Distributed memory multiprocessors (P+C: Processor + Cache, M: Memory). Both message-passing systems and DSM systems have the same basic organization. The key distinction is that the DSMs implement a single shared address space.

on the physical location of the processors and are no longer uniform. As a result, these systems are also termed as nonuniform memory access (NUMA) systems.

Classification of Distributed Shared Memory (DSM) Systems

Providing DSM functionality on physically distributed memory requires the implementation of three basic mechanisms.

Processor side hit/miss check: This operation, on the processor side, is used to determine whether a particular data request is satisfied in the processor's local cache. A "hit" is a data request satisfied in the local cache, whereas a "miss" requires the data to be fetched from the main memory or the cache of another processor.

Processor side request send: This operation is used on processor side in response to a "miss," to send a request to another processor or the main memory for the latest copy of a data item and wait for a response.

Memory side operations: These operations enable the memory to receive a request from a processor, perform any necessary coherence actions, and send its response typically in the form of the requested data.

Based on how these mechanisms are implemented in hardware/software, various DSM systems can be classified as list in Table 2.

Almost all DSM models employ a directory-based cache coherence mechanism implemented either in hardware or software, which makes these systems highly scalable. DSM systems have demonstrated the potential to meet the objectives of scalability, programmability, and cost-effectiveness (8, 9). In general, hardware DSM systems provide excellent performance without sacrificing programmability. Software DSM systems typically provide a similar level of programmability while trading some performance for reduced hardware complexity and cost.

Hardware-Based DSM Systems

Hardware-based DSM systems implement the coherence and consistency mechanisms in hardware, which makes these systems faster but more complex. Clusters of symmetric multiprocessors, or SMPs, with hardware support for shared memory, have emerged as a promising approach to building large-scale DSM parallel machines. Each node in these systems is an SMP with multiple processors. The relatively high volumes of these small-scale parallel servers make them extremely cost-effective as building blocks.

Hardware-Based DSM System Classification. In hardware-based DSM systems, software compatibility is preserved using a directory-based cache coherence protocol. This protocol supports a shared-memory abstraction despite having memory physically distributed across the nodes. Several cache coherence protocols have been proposed for these systems. These protocols include (*1*) cache-coherent nonuniform memory access (CC-NUMA), (*2*) cache-only memory access (COMA), (*3*) simple cache-only memory access (S-COMA), (*4*) reactive-NUMA, and (*5*) adaptive S-COMA. Figure 6 illustrates the processor memory hierarchies for CC-NUMA, COMA, and S-COMA architectures.

Cache Coherent Nonuniform Memory Access (CC-NUMA). Figure 6(a) shows the processor memory hierarchy in a

Table 2. DSM Systems Classification

System Type	Hardware-implemented	Software-implemented	Sample Systems
Hardware-based DSM	All processor side mechanism	Some part of memory side support	SGI Origin (8), HP/Convex Exemplar (9), IBM RP3 (10), MIT Alewife (11), and Stanford FLASH (12)
Mostly software-based DSM	Hit/miss check based on virtual memory protection mechanism	All other support Coherence unit is virtual memory page	TreadMarks (2), Brazos (4), and Mirage+ (13)
Software-based DSM	None	All three mechanisms mentioned above	Orca (1), SAM (14), CRL (15), Midway (3), and Shasta (16)

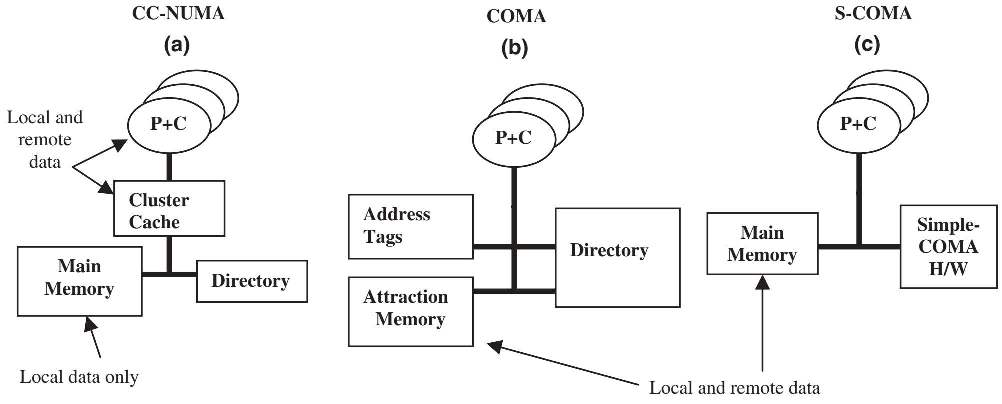

Figure 6. Processor memory hierarchies in CC-NUMA, COMA, and S-COMA (P–C: Processor – Cache, H/W: Hardware).

CC-NUMA system. In this system, a per-node cluster cache lies next to the processor cache in the hierarchy. Remote data may be cached in a processor's cache or the per-node cluster cache. Memory references not satisfied by these hardware caches must be sent to the referenced page's home node to obtain the requested data and perform necessary coherence actions. The first processor to access a remote page within each node results in a software page-fault. The operating system's page fault handler maps the page to a CC-NUMA global physical address and updates the node's page table. The Stanford DASH (17) and SGI Origin (8) systems implement the CC-NUMA protocol.

Cache-Only Memory Access (COMA). The key idea behind the COMA architecture is to use the memory within each node of the multiprocessor as a giant cache (also termed as attraction memory), which this is shown in Fig. 6(b). Data migration and replication is the same as in regular caches. The advantage of this scheme is the ability to capture remote capacity misses as hits in local memory; i.e., if a data item is initially allocated in a remote memory and is frequently used by a processor, it can be replicated in the local memory of the node where it is being frequently referenced. The attraction memory maintains both the address tags as well as the state of data. The COMA implementation requires a customized hardware and hence has not become a popular design choice. The Kendall Square Research KSR1 (18) machine implemented the COMA architecture.

Simple Cache Only Memory Access (S-COMA). A S-COMA system [shown in Fig. 6(c)] uses the same coherence protocol as CC-NUMA, but it allocates part of the local node's main memory to act as a large cache for remote pages. S-COMA systems are simpler and much cheaper to implement than COMA, as they can be built with off-the-shelf hardware building blocks. They also use standard address translation hardware. On the first reference to a remote page from any node, a software page fault occurs, which is handled by the operating system. It initializes the page table and maps the page in the part of main memory being used as cache. The essential extra hardware required in S-COMA is a set of fine-grain access control bits (1 or 2 per block) and an auxiliary translation table. The S-COMA page cache, being part of main memory, is much larger than the CC-NUMA cluster cache. As a result, S-COMA can outperform CC-NUMA for many applications. However, S-COMA incurs substantial page overhead as it invokes the operating system for local address translation. Additionally, programs with large sparse data sets suffer from severe internal fragmentation resulting in frequent mapping and replacement (or swapping) of the S-COMA page caches, which is a phenomenon called thrashing. In such applications, CC-NUMA may perform better. As S-COMA requires only incrementally more hardware than CC-NUMA, some systems have proposed providing support for both protocols. For example, the S3.mp (19) project at Sun Microsystems supports both S-COMA and CC-NUMA protocols.

Hybrid Schemes—Reactive-NUMA and ADAPTIVE-SCOMA. Given the diversity of application requirements, hybrid schemes such as reactive-NUMA (R-NUMA) (20) and adaptive-SCOMA (ASCOMA) (21) have been proposed. These techniques combine CC-NUMA and S-COMA to get the best of both with incrementally more hardware. These schemes have not yet been implemented in commercial systems.

Example Systems. Table 3 presents several research/commercial hardware-based DSM systems.

Recent Advances. Sequential consistency imposes more restrictions than simply preserving data and control dependences at each processor. It can restrict several common hardware and compiler optimizations used in uniprocessors. Relaxed consistency models allow optimization to some extent by permitting relaxations of some program ordering. As it is sufficient to only appear as if the ordering rules of the consistency model are obeyed (22), some researchers have proposed deploying features, such as out-of-order scheduling, non-blocking loads, speculation, and prefetching, into recent processors to improve the performance of consistency models. Three such hardware techniques are described below.

Hardware Prefetching: The instruction window is used to maintain several decoded memory instructions. In existing hardware-based DSM implementations,

Table 3. Hardware-Based DSM Systems

System Name	System Features
SGI Origin (8) (Fig. 7)	The Origin adopts the directory-based cache coherence protocol. Its primary design goal is to minimize the latency difference between remote and local memory, and it includes hardware and software support to ensure that most memory references are local. It primarily supports the shared-memory programming model.
HP/CONVEX Exemplar (Fig. 8) (9)	The Exemplar adopts the two-tiered directory-based cache-coherence protocol. Its primary design goal is to combine the parallel scalability of message-passing architectures with hardware support for distributed shared memory, global synchronization, and cache-based latency management. It supports shared-memory and message-passing programming models.
IBM RP3 (10) (Fig. 9)	The RP3 adopts the directory-based cache coherence protocol. Its primary design goal is to evenly distribute the global address space across all modules to balance access requests across the modules. It supports the shared-memory programming model.
The MIT Alewife Machine (11) (Fig. 10)	The Alewife machine adopts a software-extended cache coherence scheme called LimitLESS (23,24), which implements a full-map directory protocol. Its primary design goal is to combine several mechanisms, including software-extended coherent shared memory, integrated message passing, support for fine-grain computation, and latency tolerance, to enable parallel systems to be both scalable and programmable. It supports shared-memory and message-passing programming models.
The Stanford FLASH Multiprocessor (12) (Fig. 11)	FLASH adopts the directory-based cache coherence protocol. Its primary design goal is to efficiently integrate cache coherent shared memory and low overhead user-level message passing. It supports shared-memory and message-passing programming models.

these instructions may not be issued to the memory because of consistency constraints. With hardware prefetching, the processor can issue nonbinding prefetches for these instructions without violating the consistency model, thus hiding some memory latency.

Speculative Load Execution: This technique speculatively consumes the value of loads brought into the cache, regardless of consistency constraints. In case consistency is violated, the processor rolls back its execution to the incorrect load.

Cross-Window Prefetching: Instructions currently not in instruction window but expected to be executed in the future can also be prefetched. This technique alleviates the limitations imposed by a small instruction window size.

At the processor level, the above techniques narrow the performance gap between consistency models. Other design decisions below the processor level, such as cache write policy and cache coherence protocol, can also affect the performance of the consistency model.

Software-Based DSM Systems

These systems use software to, either partially or completely, implement shared memory. This alternative approach has been used by several DSM systems. Based on their design, these DSM systems can be classified as *mostly software-based systems* and *all software systems*.

Mostly DSM systems are page-based systems. They make use of the virtual memory hardware in the underlying system to implement shared memory consistency

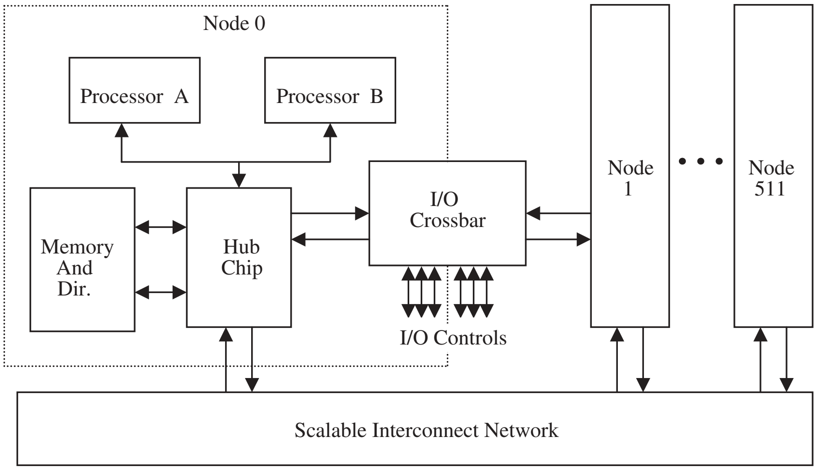

Figure 7. Origin block diagram. [Source: J. Laudon et. al. (8).]

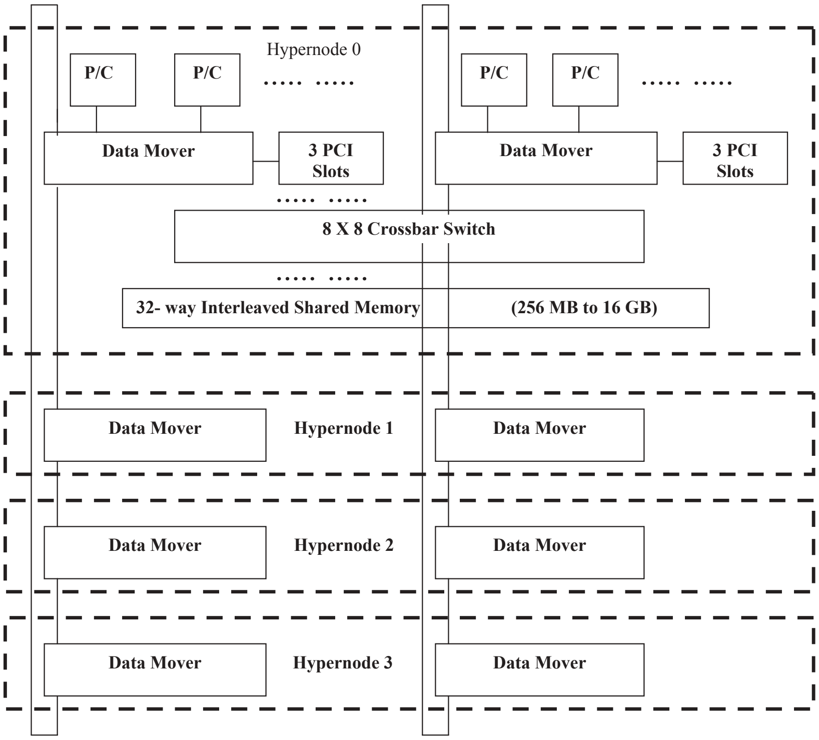

Figure 8. Architecture of the HP/Convex Exemplar X-Class SPP. [P/C: Processor/ Cache, CTI: Coherent Toroidal Interconnect, PCI: Peripheral component interconnect. Source: T. Brewer et. al. (9).]

models in software and to resolve conflicting memory accesses (memory accesses to the same location by different processors, at least one of which is a write access). Examples of mostly software page-based DSM systems include TreadMarks (2), Brazos (4) and Mirage+ (13).

The advantage of page-based DSM systems is that they eliminate the shared-memory hardware requirement, which makes them inexpensive and readily implementable. These systems have been found to work well for certain applications classes, e.g., dense matrix codes (2). As the coherence policy is implemented in software, it can be optimized to make use of the operating system to implement coherence mechanisms. The use of the operating system, however, makes it slow as compared with hardware coherence mechanisms. Additionally, the coarse sharing granularity (i.e., large page size) results in false sharing and relatively higher communication time per page. One solution is to have multigrain systems, e.g., using fine-grain shared memory within an SMP and page-based distributed-shared memory across SMPs.

All-software DSM systems are typically object-based systems. The virtual view of a shared address space is implemented entirely in software in these systems. Examples for DSM systems in this category include Orca (1), SAM (14), Midway (3), CRL (15) and Shasta (16).

Write-Update and Write-Invalidate Protocols. A key issue in software-based DSM systems is the *write protocol.* Two approaches maintain the memory coherence requirement for a write operation. One approach is to ensure that a processor has an exclusive access to a data item before it writes to it, which is the *write invalidate* protocol because it invalidates all other copies on a write. It is by far the most common protocol. The other alternative is to update all the cached copies of a data item when it is written, which is the *write update* protocol.

Single- and Multiple-Writer Protocols. Most DSM systems (and hardware caches) use single-writer protocols.

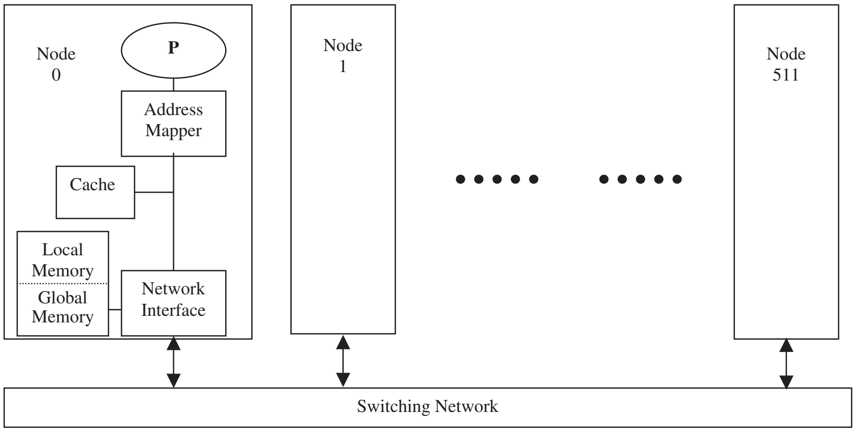

Figure 9. IBM RP3 block diagram.

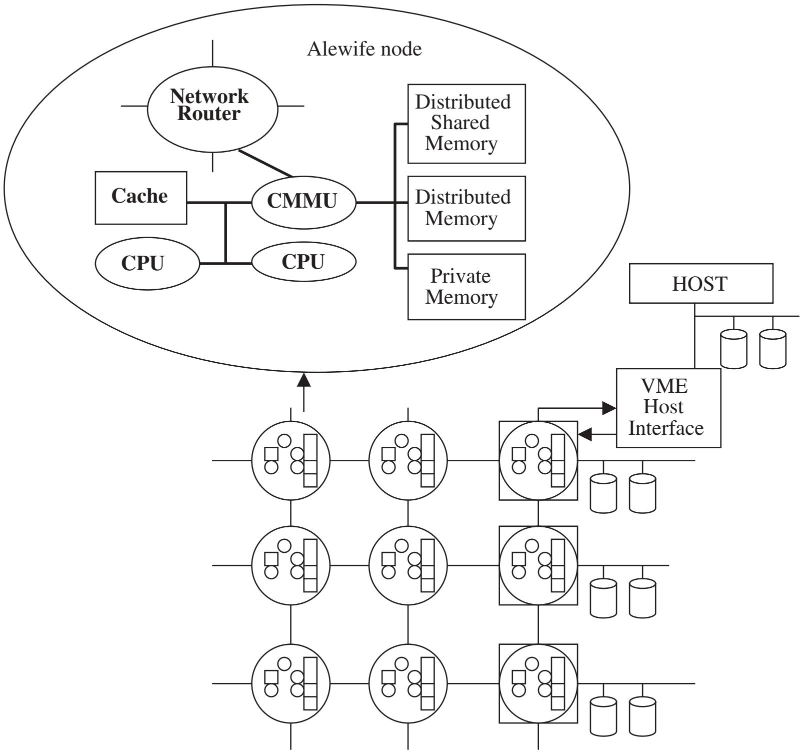

Figure 10. The Alewife architecture (CMMU: Communication and Memory Management Unit, FPU: Floating-point Unit).

These protocols allow multiple readers to access a given page simultaneously, but a writer is required to have exclusive access to a page before making any modifications. Single-writer protocols are easy to implement because all copies of a given page are always identical, and page-fault can always be satisfied by retrieving a valid copy of the page. This simplicity often comes at the expense of high message traffic. Before a page can be written, all other copies must be invalidated. These invalidations can then cause subsequent access misses, if the processors whose pages have been invalidated are still accessing the page's data. *False sharing* occurs when two or more unrelated data objects are located in the same shared page and are written concurrently by separate processors. As the consistency unit (usually a virtual memory page) is large in size, *false sharing* is a potentially serious problem. It causes the performance of the single-writer protocol to further deteriorate because of interference between unrelated accesses. Multiple-writer protocols allow multiple processors to simultaneously modify their local copy of a shared page. The modifications are then merged at certain points of execution.

Example Systems. Table 4 presents several software-based DSM systems.

EMERGING ENABLING TECHNOLOGIES FOR SHARED MEMORY SYSTEM

Recent years have seen the emergence of hardware devices customized to support certain types of shared memory system implementations. Furthermore, standards and technologies have emerged that have the potential to facilitate shared memory system implementations in a broader way.

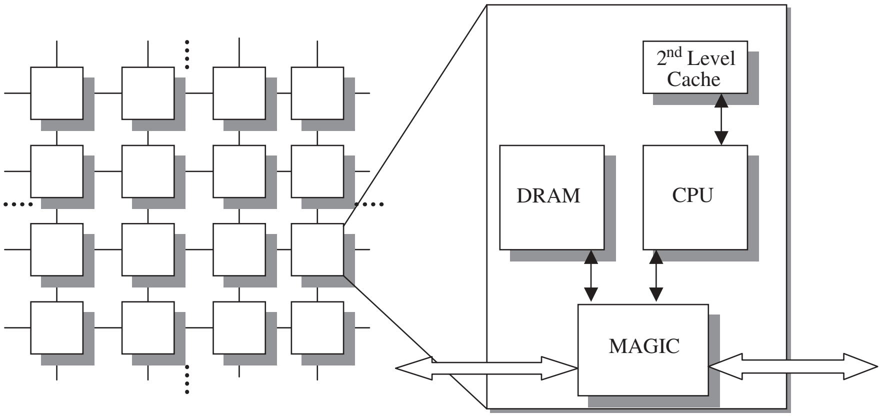

Figure 11. FLASH system architecture. [Source: J. Kuskin et al. (12).]

Table 4. Software-Based DSM Systems

System Name	System Features
	Page-based DSM systems
TreadMarks (2)	TreadMarks is a mostly software-page-based DSM system. It uses lazy release consistency as its memory consistency protocol and adopts the multiple-writer protocol to reduce false-sharing effect. TreadMarks is implemented on a network of workstations.
Brazos (4)	Brazos is a mostly software page-based DSM system. The Brazos implements a scope consistency model, which is a bridge between the release consistency and entry consistency models. Brazos is implemented on network of workstations.
Mirage+ (13)	Mirage+ is a mostly-software page-based DSM system. It extends the strict coherence protocol of the IVY system (25). It also allocates a time window during which nodes possess a page, which provides some degree of control over processor locality. Mirage+ is implemented on a network of personal computers.
	Object-based DSM systems
Orca (1)	Orca is an all-software object-based DSM system. It implements sequential consistency and adopts the write-update coherence protocol with function shipping and totally ordered group communication to achieve competitive performance.
SAM (14)	SAM is an all-software object-based DSM system. Its design ties synchronization with data access and avoids the need for coherence communication. It is implemented as a portable C library and supports user-defined data types.
Midway (3)	Midway is an all-software object-based DSM system. It supports multiple consistency models within a single parallel program and requires a small amount of compile time support to implement its consistency protocols.
CRL (15)	CRL is an all-software DSM system. It employs a fixed-home, directory-based write-invalidate protocol and provides memory coherence through entry or release consistency. It is implemented as a library.
Shasta DSM (16)	Shasta is a fine-grained all-software DSM system. It supports coherence at fine-granularity, and coherence is maintained using a directory-based invalidation protocol. A key design goal of Shasta is to overcome both the false sharing and the unnecessary data transmission.
DSM Using. NET (26)	This is an all-software object-based DSM system. It follows a Multiple Readers Multiple Writers (MRMW) memory model. Its implementation is based on the Microsoft .NET framework adding facilities for object sharing and replication and relies on the availability of IPv4 or IPv6 (unreliable) multicast.
Orion (27)	Orion is an all-software DSM system. It implements the home-based eager release consistency model. Adaptive schemes for the home-based model are also proposed to provide good performance with minimal user intervention. A POSIX-thread-like interface is provided.
DSZOOM-WF (28)	DSZOOM-WF is an all-software DSM system. It implements the sequential consistency model. It assumes basic low-level primitives provided by the cluster interconnect and the operating system bypass functionality to avoid the overhead caused by interrupt- and/or poll-based asynchronous protocol processing, which affects the performance of most software-based DSM systems.

SCI: Scalable Coherent Interface

Scalable Coherent Interface (SCI) is an ANSI/IEEE 1596-1992 standard that defines a point-to-point interface and a set of packet protocols. The SCI protocols use packets with a 16-byte header and 16, 64, or 256 bytes of data. Each packet is protected by a 16-bit CRC code. The standard defines 1-Gbit/second serial fiber-optic links and 1-Gbyte/second parallel copper links. SCI has two unidirectional links that operate concurrently. The SCI protocols support shared memory by encapsulating bus requests and responses into SCI request and response packets. Packet-based handshake protocols guarantee reliable data delivery. A set of cache coherence protocols is defined to maintain cache coherence in a shared memory system. SCI technology has been used to implement DSM systems, e.g., the hardware-based DSM system HP/CONVEX Exemplar. Recently it has also been adopted to build software-based DSM systems, e.g., a cluster of PCs interconnected by a SCI network providing a memory-mapped file abstraction (29).

Active Memory Techniques for CCNUMA Multiprocessors

Active memory systems provide a promising approach to overcome the memory wall (30) for applications with irregular access patterns that are not amenable to techniques like prefetching or improvements in the cache hierarchy. The central idea in this approach is to perform data-parallel computations or scatter/gather operations, via address remapping techniques in the memory system, to either offload computation directly or to reduce the number of processor cache misses. This technique is expanded to multinode hardware DSM systems (31) using the same active memory controller with an integrated commodity network interface and without any hardware modifications, by designing appropriate extensions to the DSM cache coherence protocol.

APPLICATIONS OF SHARED MEMORY MULTIPROCESSOR SYSTEM

Shared memory multiprocessor systems are traditionally used to provide an intuitive programming model for parallel programs based on shared memory. Memory sharing technology is also viewed as a building block for constructing a Single System Image (SSI). It can also be used for code coupling or for realizing shared data repositories.

Single System Image (SSI)

The computing trend is moving from clustering high-end mainframes to clustering desktop computers, triggered by widespread use of PCs, workstations, gigabyte networks, and middleware support for clustering (32). Future clusters will offer increased SSI support with better transparency, for which a single memory space is a fundamental building block.

Code Coupling/Shared Data Repository

Mome (33), a user-level DSM, is designed to provide a shared segment space for parallel programs running on distributed memory computers or clusters. Besides supporting high-performance SPMD applications, the system also targets coupling of parallel applications using an MIMD model. The Mome DSM allows heterogeneous processes running on distributed memory architectures and clusters to share data by mapping the shared memory segments into their address space. A persistent data repository for parallel applications is enabled by allowing programs to dynamically connect to the DSM, map existing segments on their memory, read and modify the data, and leave this data in the repository for further use by other programs.

CONCLUDING REMARKS

Shared-memory machines built with symmetric multiprocessors and clusters of distributed multiprocessors are becoming widespread, both commercially and in academia (1,3,4,6,8,9,11–13,15,19,20,34). Shared memory multiprocessors provide ease of programming while exploiting the scalability of distributed-memory architectures and the cost-effectiveness of SMPs. They provide a shared memory abstraction even though memory is physically distributed across nodes. Key issues in the design of the shared memory multiprocessors are cache coherence protocols and shared memory consistency models, as discussed in this article. Symmetric multiprocessors (SMPs) typically use snoopy cache coherence protocols, whereas, the DSM systems are converging toward directory-based cache coherence. More popular consistency models include sequential consistency, release consistency, and scope consistency.

High-level optimizations in the programming model, such as single global address space and low latency access to remote data, are critical to the usability of shared memory multiprocessors. However, these optimizations directly trade off with system scalability and operating system performance. Current shared memory multiprocessors are built to achieve very high memory performance in bandwidth and latency (6,8). An important issue that needs to be addressed is the input/output behavior of these machines. The performance of distributed input/outputs and the distributed file system on a shared memory abstraction need to be addressed in the future designs.

SOFTWARE ENGINEERING FOR TELECOMMUNICATIONS SYSTEMS

INTRODUCTION

Since the construction of the worldwide telephone network started more than a century ago, advances in communication systems and their widespread availability have been a source of profound change in societies and are an important part of what we call the "information society." Today, communication systems allow people to talk, see, and exchange data with each other almost independently of their physical location in the world. In the so-called developed countries, telephones are in virtually every household, cell phones are omnipresent, and half a billion computers are part of the Internet—together, these technologies form a gigantic network that allows anyone easy access to an enormous amount of information and to communicate easily with each other.

According to a broad definition, any system that makes communication over long distances (tele = distant) possible is a telecommunication system. Historically however, the term refers primarily to telephony networks for fixed and mobile communication. For the Internet and other interconnections of computers, the term computer network is used. The term communication system can refer to both computer networks and telecommunication systems. Because of the convergence of telecommunication and Internet technology, the once sharp line between computer networks and telecommunication systems has, however, been blurred in recent years. End users engaged in distant communication are indifferent as to whether their voice is transported via traditional telecommunication networks or over the Internet—as long as the service preserves high-quality demands expected from telecommunication systems: lost calls, too much delay in voice transmission, echoes, and so on are not tolerated.

Although from today's point of view many commonalities seem to exist between the two, the telephone system and the Internet were historically created with different aims and design philosophies in mind and are based on different technologies. The telephone system was designed primarily for voice communication between humans; even data services like transmission of facsimiles (fax) used tone modulation techniques over the voice channel. The telephone system uses circuit and packet switching to establish a dedicated connection with guaranteed quality of service (QoS) for the duration of a call. The Internet, on the other hand, was designed for flexible data exchange between computers with the capability to compensate single points of failure—it was intended as a network for military purposes in the first place. The Internet uses packet switching for efficient communications with best effort QoS.

Many definitions for software engineering exist in the literature. One definition that we feel is particularly suitable in the context of telecommunication systems is "the application of engineering to software" (1). In fact, (electrical) engineers built the first telecommunication systems. The key challenges for software engineering telecommunication systems developed from several aspects that make telecommunication systems special. These aspects relate to the system in general and the software components in particular and can be subdivided into industry practices, general technical challenges, and quality demands. Important industry practices in the telecommunications domain include the definitions of standards and protocols, the layering of systems, and intensive testing. General technical challenges develop mainly from the distribution aspect of telecommunication systems and the large amount of communication that these systems need to handle simultaneously in real time. For example, modern switching systems can handle several ten thousands of calls simultaneously. Thereby, high-quality demands must be fulfilled.

From a user's perspective, telecommunication systems must provide a high quality of service, namely the fulfillment of real-time and lossless requirements. In addition to that, they must satisfy high availability, reliability, and robustness demands. For example, delays greater than a tenth of a second or lost words in a telephone conversation are unacceptable; the expectation of users is that the telephone system "always works" and that especially emergency calls always go through, no matter the amount of traffic. From the perspective of software engineers, telecommunication systems must be scalable, extensible, and portable. Scalability means that the code basis can be used for different traffic demands. For example, it is desirable that the same switching software can be used in a system that handles an average of 1000 simultaneous calls as well as in a system that handles 100,000 calls simultaneously. Scalability is especially important as the demand for telecommunication services is steadily increasing. Extensibility is important because the services that must be provided by telecommunication systems are constantly subject to enhancements. Portability has to do with the long lifetime of telecommunication software and the rapid advances in hardware platforms; one cannot afford to throw away the software developed for two decades just because of a switch to new hardware.

The next section provides an overview of relevant historic developments and crucial design decisions that led to today's telecommunication systems; important background information for understanding what makes software engineering for telecommunication systems special is given. The section entitled System Design in the Large describes fundamental telecommunication concepts that are encountered when designing systems in the large. The basic notions of distribution and communication, as well as layering, planes and resource control are discussed. Systems Design in the Small is the topic of the section that follows. The last section surveys a selection of the literature on modeling telecommunication systems and introduces

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

the Real-Time Object-Oriented Modeling (ROOM) language as an example of a modeling language for telecommunication systems.

BACKGROUND AND RATIONALE

Modern telecommunication systems were developed in the early 1960s. The new technology of computer control, called stored program control (SPC), started to substitute electromechanical systems (2). One of the main advantages introducing SPC was flexible systems, in which additions and changes could be introduced primarily through program modifications rather than through changes in the hardware (3). However, by the late 1960s, it was time for a review. At Ericsson, one had learned that the current generation of SPC, as it existed in the late 1960s, was expensive and way too complex, with hindsight, for widespread use, except, to some extent, in the American Bell companies. The disadvantages were above all in the high costs of handling—design, testing, modification, fault-correction, production, installation, and operation and maintenance (4). What was needed was a new approach to structure and organize these complex systems. With the engineering techniques available at that time—“Structured Programming” is in the air (5), the principle of functional modularity was a promising approach. Within Ericsson, it was Ivar Jacobson who made the important contribution of the “block concept” in 1967 (6), which included the structuring of the system into self-contained functional modules (blocks), with all interworking between blocks performed by software signals (7). The development of Ericsson’s AXE switching system was based on these principles; it went into trial service late in 1976 and became and still is one of the most successful switching systems worldwide (4).

Hand in hand with this development, the study of new languages was initiated. The industry was in need of languages highly adapted to the demands of programming and designing telecommunication systems. The outcome of these efforts were Specification and Description Language (8) (SDL), Message Sequence Chart (9) (MSC), CHILL CCITT High Level Language (CHILL) (10), and Man-Machine Language (MML) (11). All three languages have been standardized by Consultatif International de Télégraphique et Téléphonique) (CCITT) and are still in use today. In the early 1980s, SDL and MSCs were intended for system specification and design, CHILL for detailed design, coding and testing, MML primarily for operation and maintenance. Especially for coding, many companies developed their own variant of a programming language. For example, Ericsson developed the Programming Language for EXchanges (PLEX) (7), and Northern Telecom developed the Procedure Oriented Type Enforcing Language (PROTEL) (12); both languages are block structured. More recently, new languages and paradigms have become part of the toolset of software engineers in the telecommunication domain. An example of a modern programming language for telecommunication systems is Erlang (13); Erlang can be classified as a functional programming language. It was developed at the Ericsson Computer Science Laboratory in the late 1980s and was released as open source in 1998. It has been used in industrial projects for the production of highly reliable and fault-tolerant telecommunication systems. For example, Ericsson’s AXD301 switching system handles 30–40 million calls per week and node, and its reliability is measured at 31 milliseconds downtime per year. It contains 1.7 million lines of Erlang code (14).

In 1994, the ROOM language appeared. ROOM blends object-oriented and real-time concepts and techniques and is thus particularly well suited for modeling telecommunication systems. Elements of ROOM were added to the Unified Modeling Language (UML) (15,16) version 2.0 that was released in 2004. In 2006, the Object Management Group (OMG) released the specification for the Systems Modeling Language (SysML) (17), which is a modeling language for systems engineering that seems to be a promising addition to the toolset of software engineers in the telecommunications domain. A good chance exists that telecommunication systems engineering might benefit from the recent research and commercial interest in generative (18) and model-driven development (19). Domain-specific notations have been used by telecommunication engineers for a long time, and new technologies might enable the generation of systems based on descriptions using these notations.

The complexity of switching systems by sheer size of code is impressive. Already around 1980, several hundred programmers had produced over one million lines of code over a five-year period for the DMS-100 switching system family of Northern Telecom. The source code was organized into 15,000 procedures in 1500 modules (12). The systems of today are even more complex. A code base of several million lines of code is not unusual. Still, these systems fulfill high-quality demands on availability, reliability, fault tolerance, and so on. Such systems can be upgraded and maintained while being in operation! A downtime of some few minutes per year is already perceived as “bad quality.”

Considering their complexity, it may come as no surprise that *architecture* is and always has been an important issue in telecommunication systems design. Architecture is and was a means to deal with complexity. Of course, the term “architecture” was not defined clearly, but it is absolutely in line with the design paradigm of the 1970s: The modularization of a system is regarded as its architecture. Architectures were not modeled, as we tend to say today, but rather described either informally, usually in some sort of box-line diagrams, or formally with SDL. It is interesting to read which design conceptions were identified for new software architectures in the 1980s: independent subsystems for call control (features), signaling, and hardware control; data abstractions partitioned for each subsystem; formal communication protocols; concurrent and asynchronous operation of each subsystem; terminal-oriented control; layered virtual machines; finite state machine specifications; application programs; and systems programs (20)—the topicality of the list is astonishing.

Before “software engineering” was an established field, telecommunication engineers had already established a discipline of engineering highly reliable, scalable, and robust real-time systems, which are open and standardized—and it included software. When the telecommunication engineers included programmable devices into their systems, they integrated these devices into a hardware-driven environment. Thus, they applied a lot of their hardware principles to software. In effect, they made it transparent to the system, whether an entity is realized in hardware or software. Simply speaking, the software was and still is developed as seriously and effortful like hardware. Because failures and downtimes of telecommunication components are not an option, much energy is put into the design and architecture of those systems. The engineering aspect of the software part of telecommunication systems resembles many qualities of systems engineering: standardized interfaces, message-orientation, cascading, and composition as main design principles; exhaustive testing routines including load and stress testing, configuration management, process driven development—to name just a few—are best practices in the telecommunication domain.

The concepts, techniques, and requirements we describe in the historic overview above are still relevant to software engineering for telecommunication systems today. It is the way telecommunication engineers design their systems in the large and in the small that is special. That is why we put our focus on these two topics in the following sections. Other software engineering issues like requirements engineering and traceability, configuration and product management, software product lines and families, testing, project management and so on do not differ that much from software development practices in other domains such as large enterprise information systems.

Regarding software engineering for telecommunication systems, no established body of literature exists yet, which reflects a commonly agreed viewpoint on how telecommunication systems are (to be) designed in the large and in the small. However, if you spend some years in the telecommunication industry among systems designers and software developers and study existing publications, then you will notice that they somehow speak "one language" and design their software in similar ways. This article is an attempt to uncover the elements of design of telecommunication system engineers to provide valuable input for the interested reader. A more elaborated version of the systematics presented here can be found in Ref. 21.

SYSTEMS DESIGN IN THE LARGE

In telecommunications, systems design in the large must deal with the notion of distribution, layering, planes, and resource control. We will discuss each issue in turn.

Distribution

A telecommunication system is made up of entities like switching systems, radio base stations, and mobile phones. These entities are physically distributed in space; they are either located in a fixed place (like switching systems) or are mobile (like mobile phones). These entities collaborate with each other to provide a service to end users. Thus, the most obvious characteristic of a communication system is its aspect of distribution. If two or more devices, processes, users or—more abstractly—entities are physically spread in space but want to collaborate, they somehow have to bridge spatial distribution and establish communication. We will give rather informal definitions of the concepts related to distribution in the following sections. Formal definitions of these concepts can be found in Ref. 22.

Communication. "It is all about communication"—this slogan characterizes concisely the motto of telecommunications. We can classify three types of communication used in telecommunications. The classification scheme bases on the question "Who controls whom?" We can distinguish three basic combinations of the exertion of control between two communicating parties: (*1*) no side exerts control, that is no side has a state model of the other side to influence the other side's behavior in a controlled way, which we call *data-oriented* communication; (*2*) only one side exerts control, which we call *control-oriented* communication; (*3*) both sides exert control, which we call *protocol-oriented* communication.

Any communication type can be realized in a connection-oriented mode, a connectionless mode, or even other kinds of communications styles. We will come back to this in the discussion of communication services. Note that communication in telecommunications is message-oriented and that communication relations are strictly specified in form of protocols.

Decomposition and Remote Communication. What is distribution? With the eyes of software engineers, we tackle the notion of distribution in two steps: First, distribution is an issue of logical *decomposition*. Second, we need to consider the effects of *remote communication*.

We can view a telecommunication system as a logical entity that encapsulates some functionality and offers interfaces (often called "ports") for message-based communication with the environment. We assume that the behavior of the system is given, meaning that we know the set of allowed messages per interface, their format, how the system reacts on messages delivered to the interfaces and which messages it emits to the environment. The behavior of a telecommunication system is often said to provide services to its environment, usually its end users.

A first step toward distribution is that the entity under consideration can be logically split up ("decomposed") into separate parts, each part representing a new entity. The parts also communicate to each other via messages through their interfaces. The interfaces are connected via so-called channels, which are sometimes also called connectors. A channel is an idealized communication medium, which transfers messages faultless and in an instant. In other words, a logical entity gets refined by a network of separated but cooperating parts. From an outer perspective, the conglomerate of parts preserves the behavior that can be experienced at the interfaces of the single entity. The decomposition process is recursive.

The second step is to take into account that the communication over a channel is not ideal but suffers from the real-world effects of remote communication. When the decomposed parts get spread over, say, hosts or physical nodes, they require some sort of communication means to bridge the spatial separation. The interaction of the decomposed parts in a distribution network is *not* fault-free per se; it is sensitive to disturbances on the communication medium and dependent on the properties of the connection. We condense the whole communication medium in a model of a nonideal channel, which we call complex connector. The complex connector is a component that represents the properties of the communication channel and its effects on the transmission of messages. These properties are called QoS attributes and include all relevant characteristics, such as reliability, throughput, jitter, and delay (21,22).

To summarize: A telecommunication system is a distributed system. To its end users, a telecommunication system appears as a single, coherent, service-provisioning system. As a matter of fact, the system is decomposed into a number of physically separated but interacting parts, called nodes, which constitute a communication network. The effects of remote communication are captured by the notion of a complex connector.

Network Topology and Communication Services. Readers might be familiar with the fact that communication systems are composed of a stack of layers. We will come back to layering in a subsequent section entitled Layering. In this section we view each layer in a communication system as a self-contained unit without any dependencies to other layers. Each layer unit consists of distributed entities communicating remotely to each other via a network that interconnects the entities. In short, we treat a layer as a distributed network in its own right.

Here, we are concerned with what kind of communication services and communication resources the distributed entities use to bridge their spatial distance; for the time being we are not interested in how it is achieved via a lower layer. That means our understanding of a network is an abstract model of distribution, which includes a *network topology* (who is permitted to communicate with whom) and the used *communication services*. A communication service can offer connection-oriented or connectionless communication means.

Connection-Oriented Communication Services. With the help of the complex connector, we can describe *static* configurations of distant connection-oriented communication. The complex connector concentrates all impacts that the transmission may have on the messages to be conveyed. In reality, connections are rarely static; they are rather a form of a long-lasting, dynamically created connection. Normally, connections are set-up and released on demand. Thus, we need something; we can ask for inserting and removing a complex connector between any two ports at some point in time. The connection-oriented communication service fulfills this role. In a telecommunication system, circuit switching is a connection-oriented communication services.

Connectionless Communication Services. A style of communication exists that requires no connection. Instead, messages include the address of the receiver. The sender hands the message over to a connectionless communication service, which distributes the message according to the address to a destination. If the sender wants to get a response on a delivered message from the receiver, then the sender has to include its source address in the message as well. In a telecommunication system, packet switching is a connectionless communication service.

Addressing. Addressing is crucial for communication systems in general and telecommunication systems in particular. In the following, we focus on addressing in the context of telecommunication systems. Generally speaking, an *address* denotes a concept to identify and locate objects in a defined scope. The scope is the so-called *address space* (or name space), which is an assembly of addresses with each address being unique in the assembly. An *address association* relates two addresses to each other; the association is directed pointing from one address (the source address) to another address (the destination address). Source and destination address may or may not belong to the same address spaces; we must make a difference between external address associations and internal address associations. External address associations relate addresses of different address spaces, internal address associations relate addresses of the same address space.

For example, the difference between connection-oriented communication and connectionless communication is basically different ways of working with address spaces. In connection-oriented communication, communication interfaces are associated with a fixed (better: temporarily fixed) communication partner. Information that is pushed to the interface is conveyed to the communication partner; reversely, information the communication partner wants us to notice, pops up at the interface. In that sense, the interface is a sort of representation of the other party, and the interface identifier is an internal address denoting the other party. So, to talk to another party it is necessary to either use another interface (that is bound to the other party) or to newly bind the interface with the other communication party.

For connectionless communication, the general addressing structure looks different. The arrangement of associations is so that two communication partners do not maintain direct relations between their address spaces. Instead, local addresses are associated to a third party, which is an external address space. Consequently, users who communicate connectionless need to have an internal representation of the address space outside their locally addressable scope. They need to specify the destination of their messages. Users who communicate connection-oriented do not have to do that.

Remarks. Definitions on distribution to be found in literature suffer preciseness on the one hand and generality on the other hand. We think that at an abstract-level distribution is primarily a logical conception and that it is adequate to give a formal definition based on a proper model. Secondary, distribution has a technical dimension. A formal definition of distribution is given in Ref. 22.

No notion exists of a complex connector in Open Systems Interconnection (OSI), but in practice, telecommunication engineers work with this concept. As an evidence for that statement, have a look at channel substructures in SDL (23, p.121), which basically captures the same intention as complex connectors.

Addressing is a delicate issue in modeling and an neglected issue in software engineering.

Layering

Layering is one of the oldest techniques in software engineering to structure a system. Possibly the first, who made systematically use of layering was Dijkstra, he used layering for the design of the THE operating system (24). Layering is also a key structuring principle in the design of communications systems, be they telecommunications or computer networks. In the previous section, we intentionally left out the issue of layering. We simply said that one can look at each layer of a distributed communication system individually. Now it is time to explain, how several layers of communication networks are interconnected and make up a layered system.

In the next section, we will briefly outline the seven layer reference model (RM) of open systems interconnection(25) (OSI). We will then distill the key idea that underlies layering. This progression will naturally lead us to two viewpoints one can have on a communication network: a network-centric or a node-centric perspective. Finally, we discuss the concept of planes.

The OSI Reference Model. Layering is a means to stepwise provide higher-level services to a user or the next "upper" layer, and to separate levels of services by precisely defined interfaces. This overall design principle is reflected by the use of protocol stacks. The OSI RM is the most prominent framework for a layered communication architecture. We do not repeat OSI RM to the full extent, we just would like to remind the reader of the basic outlook, see Fig. 1: Several network layers are stacked on each other, each layer realizing a complete network of its own. Higher-layer network services rely on lower layer services until a physical layer is reached. Additional introductory information can be either retrieved from the X-Series of the ITU-T recommendations or from textbooks. Almost any textbook on computer networks and/or data communications gives an introduction into OSI RM, for example Ref. 26.

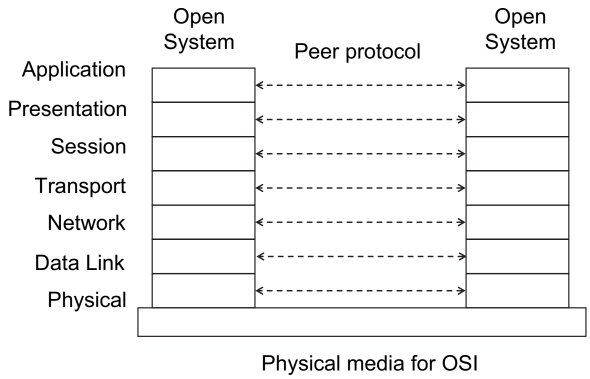

Figure 1. OSI seven layer reference model; see Ref. 25, p. 31.

We wish to highlight one important point. OSI RM clearly distinguishes two communication relations: layer-to-layer ("vertical") communication from peer-to-peer ("horizontal") communication. "Vertical" communication refers to the exchange of information between layers (that is levels of services usually within the same physical entity) in the form of *Service Data Units* (SDU). "Horizontal" communication refers to the exchange of information between remote peers. Remote peers are physically distributed and communicate with each other according to a protocol in the form of protocol messages, also called *Protocol Data Units* (PDU), thereby sharing the same level of protocol conventions. PDUs are the vehicles for SDUs. A single SDU may be packaged into one or more PDUs. Such PDUs are also called *data* PDUs. Nondata PDUs are called *control* PDUs. In a multilayer communication architecture, a service provisioning layer becomes the service user of the next lower layer.

Communication Refinement. To understand how two different networks of service levels are connected through layering, one has to know that Fig. 1 unveils only half the truth. The dotted lines labeled with "Peer protocol" do not represent protocol relations only. Each double-headed arrow "hides" a complete infrastructure of a communication service for this specific layer. The communication service per layer is an abstract model of the style of communication (connection-oriented, connectionless), properties (delay, reliability, etc.), topology, and addressing schema. This abstract model can be refined into a more concrete model, which is in effect the next lower layer of the protocol stack. The next lower layer includes the communicating entities (the boxes next to the double-headed arrow) and the communication service of that layer. In essence, layering is the result of refining communication services; we call this *communication refinement*.

Communication refinement leads to two different viewpoints on distributed layered communication systems. Both viewpoints are important for systems modeling in software.

Network-Centric Viewpoint. If we regard the communication service as an abstract model of the means of communications, suppressing all the details of lower layers, then we just observe a network of communicating entities of one layer using the communication service. This view is the network-centric viewpoint on communication systems. This view allows one to look onto a network as a distributed system ignoring layering. We made use of this technique in the section about distribution.

Node-Centric Viewpoint. If all communication services are resolved by a refinement, which represents the next lower layer, we end up with a situation similar to Fig. 1: We have a communication service at the very bottom, a physical media, which cannot be resolved more. The pile of boxes labeled "Open System" on the left and on the right represent the entities that, together, make up the software or hardware, which resides on a physical node in a network. This view is the node-centric viewpoint on communication systems.

Planes

One concept that has turned out to be extremely useful is the concept of *planes*. The concept was introduced in Integrated Services Digital Network (ISDN) (27), taken over in Global System for Mobile communication (28), and currently shapes the network architecture of Universal Mobile Telecommunication System (UMTS) (29). The distinction is usually in three planes, namely the control plane, the user plane, and the management plane.

A plane encapsulates service functionality and may have internally a layered (protocol) structure. Planes are an organizational means on top of layering and communication refinement, respectively. In telecommunications, the user plane provides for user information flow transfer (data PDUs), along with associated controls (e.g., flow control, recovery from errors); the control plane performs call and connection control functions (control PDUs), dealing with the necessary signaling to set up, supervise, and release calls and connections; the management plane takes care of (*1*) plane management functions related to the system as a whole including plane coordination and (*2*) functions related to resources and parameters residing in the layers of the control and/or user plane (30).

OSI RM is not prepared to handle planes (nor is the Internet architecture), which is also one of its major deficiencies. The control and user plane are not separated. In software engineering, the organization of a system in planes is almost unknown. On a case-by-case basis, designers had and still have to invent individual solutions to handle planes in their models. For example, in ISDN the engineers introduced a synchronization and coordination function (SCF) as a major component of the management plane. The SCF is connected to the highest layer of the user plane and to the highest layer of the control plane to coordinate and synchronize the required collaboration of planes (27).

Resource Control

A field that is largely ignored in computer networks but is of importance in telecommunications is the issue of resource control—most popular textbooks on computer networks and distributed systems do not touch on the subject at all. The term *resource* does not only include physical resources such as adaptors, switchboards, echo cancellers, codec converters, and so on, but also resources implemented in software. On a software level, resources can be combined, added by some functionality, and offer value added services that make a user believe to access a “new” kind of resource that is more than the sum of its physical components. Take for example an alarm clock and a radio, add a composing layer, and you will get a clock radio. The new feature, that the radio turns on at a certain alarm time, is more than any of the resources could provide in isolation.

We recognize a need to pay some special attention to resource control. As was mentioned previously, telecommunication systems are sliced in a control and a user plane; basically, it is the control plane that controls the user plane. In most cases this control relationship breaks down to resource control. The control plane controls resources of the user plane. Although the control plane and the user plane may operate as largely independent networks, the combining spots are locations of resource control. Usually, the node hosting the resource brings together the control and the user plane. Traditionally, the aspect of resource control has been a local, internal issue. Often, inside such a node, the border between controlling and controlled behavior is blurred and not fully separable. At best, the designers define a proprietary application programming interface (API) for the resource.

One of the intentions of UMTS has been to clearly separate the control and the user plane and to avoid the blur of the control/user plane inside nodes hosting resources; this idea is the so-called *architectural split* introduced with UMTS. As a result of that, the telecommunication sector of the International Telecommunication Union (ITU-T) defined a protocol, a control-oriented protocol in our terminology, that describes how a user can control a switching center. This protocol is called media gateway control protocol, it is specified in H.248 (31) and has been taken over as a standard by IETF as well, see RFC 3015 (32). With the definition of a protocol and the separation in a resource user and a resource provider all prerequisites are given to aim for physical separation of both roles. In the UMTS architecture, these two roles are logically fulfilled by the media gateway controller and the media gateway. It is up to a manufacturer to produce two individual nodes or a single combined node. Important is that the distinction has been made logically.

Remarks

We mentioned the OSI RM. The reference model of the Internet Architecture, is related loosely to OSI RM, see Ref. 26. Other frameworks exist that address the topic of distributed communication system and propose a terminology, a set of conceptions, and a system architecture organization. The most important frameworks to mention are the Reference Model for Open Distributed Processing (33,34) (RM-ODP), the Telecommunications Information Networking Architecture (35) (TINA), and the object management architecture (36,37), (OMA), which is the basis for the Common Object Request Broker Architecture (38,39) (CORBA). Basically, all three frameworks specify an environment to develop, install, and maintain distributed applications.

SYSTEMS DESIGN IN THE SMALL

When it comes to systems design in the small, the most apparent issue a software engineer is confronted with is that telecommunication systems are real-time systems. An understanding of real-time systems and a suitable approach for designing such systems is required. The use and the understanding of the term “real-time system” is not consistent in the literature. It is a mixture of characterizing attributes and structural properties of a system. For example: On one hand, it is said that a real-time system fulfills timing constraints, (i.e., a real-time system has to react to a stimulus in a certain time frame); in this example the guaranteed response time is an attribute, which characterizes a real-time system. On the other hand, real-time systems are often classified as “embedded systems.” An embedded system can be seen as a specific part of a larger system, which is a structural aspect. Besides this lack of clarity in terminology, there is not even common agreement on the word “real-time.” The following paragraphs summarize findings from studying the literature.

What is a Real-Time System?

Real-time systems are defined as those systems in which the correctness of the system depends not only on the logical result of computation, but also on the time in which the results are produced (40). After more than a decade this definition still seems to be the greatest common denominator. Here, “real-time” is an attribute to “system.” Because of their specific field of application, additional attributes are usually associated with real-time systems. Included in this category are e.g., reliability, fault tolerance, adaptability, and speed (41).

Hard versus Soft Real-Time

The most popular classification is the distinction in *hard* and *soft* real-time systems. Hard real-time systems are under deadline constraints. Passing a deadline is considered unacceptable. A soft real-time system retains some tasks that are still valuable for execution even if they miss their deadlines (41). Telephony systems belong to the class of soft real-time systems (42): Passing of deadlines is accepted as long as the number of failures is below a defined threshold. Although this categorization might be true in general, some components in telecommunication networks, have to fulfill hard real-time constraints. For example, the time delay perceived as acceptable for voice transmission in a speech conversation places tough time limitations on a mobile phone for speech encoding- and decoding including cyphering and channel coding.

Rough Structure

A very rudimentary structure of the basic elements of a real-time system is given by Ref. 42: It consists of hardware, *sensors* and *effectors*, the environment, and software. The sensors and effectors interact with the environment; the software controls the actions of the hardware via a hardware interface. A similar description using different terminology can be found in Ref. 43: A real-time system consists of a controlling and a controlled system. The controlling system interacts with its environment using information about the environment available from various sensors and activating elements in the environment through “actuators.” The controlled system can be viewed as the environment with which the computer interacts.

A loose reasoning describes why timing aspects and structural issues of a real-time system are related: Timing correctness requirements arise because of the physical impact of the controlling systems’ activities on its environment. That means that the environment needs to be monitored periodically and sensed information needs to be processed in time (41). This finding implies that we have to distinguish the environment from a controlling part, and detecting and acting devices are needed.

What is an Embedded System?

The definition of an embedded system is vague; it mainly describes a structural aspect. In its most general form, an embedded system is simply a computer system hidden in a technical product (44). A more concrete definition is that most embedded systems consist of a small microcontroller, and limited software situated within (e.g., an automobile or a video recorder) (45). Three issues seem to be important here: (*1*) size matters, (*2*) an embedded system is part of a technical system, and (*3*) it serves the purpose of the technical system and not vice versa. Issue (*3*) especially helps delimitate nonembedded systems from embedded systems. A Personal Computer (PC) for instance is a general purpose computing machine, the software and the central processing unit (CPU) are an integral part of it. This eliminates a PC from being an embedded system. A counterexample might be a mobile phone. The digital signal processing chip and its software serve a single purpose: to offer phone functionality. Embedded systems may or may not have real-time constraints (43), but many real-time systems are embedded systems (45).

To summarize: The special character of systems, that have a physical impact on the “real” world by means of reactiveness is most significantly described by the requirement on the timing constraints to be met by the system. Such systems are called *real-time systems*. Additional properties, which reflect other aspects of the physical impact character, include reliability, fault tolerance, stability, safety and so on. As yet no commonly agreed list of properties exists that constitutes a real-time system. Moreover, the physical impact nature of such systems implies a rough structure: a controlling part interacting with the environment (the controlled part) through sensors and effectors. The hardware mediates between the sensors/effectors and the software of the system. Many real-time systems are embedded systems, which means they serve a specific purpose in a technical system, which is actually the case for all nodes in a telecommunication system.

Despite these various aspects of real-time systems and partly confusing definitions from the literature, designing real-time systems is a well-established domain. When designing telecommunication systems in the small, it becomes obvious that just a few key design concepts are required, such as active objects for modeling threads and message-orientation for modeling asynchronous communication. Interestingly, these concepts can also be used for systems design in the large. This statement means that one can use the same language for both systems design in the small and in the large. In the section on Real-Time Object-Oriented Modeling, we describe a language that can be used for both tasks.

MODELING TELECOMMUNICATION SYSTEMS

In this section, we describe different modeling approaches by surveying the available literature. We then go on to describe ROOM, which is a language in widespread use in the telecommunications domain. ROOM can be used for both systems design in the large and in the small.

Modeling Approaches

Since the UML has been standardized by the Object Management Group (OMG) and published in many books, *modeling* is on everybody's lips. Also, the importance of the architecture level in software systems is more and more respected, see for example OMG's initiative on Model Driven Architecture (46). However, when it comes to modeling telecommunication systems the fundus of literature is even smaller.

In some books, the object-oriented paradigm has been used to model communication systems. One example is "Object-Oriented Networks: Models for Architecture, Operations, and Management" (47). The book uses not only conventional object-oriented modeling concepts but also advanced concepts from specialization theory. The syntax used to capture the semantics of models is the Abstract Syntax Notation One (see Ref. 48). The author develops a classification scheme adapted to the needs of communication networks that enables a designer to develop understandable and meaningful object and class diagrams. The approach is descriptive and the techniques presented seem to be suited for modeling product architectures. The risk is that given "facts" are just schematically modeled (it is relatively easy to note down an object diagram for almost anything) without any reflection about the actual functioning and the actual meaning for the architecture.

Another example is "Object-Oriented Network Protocols" (49). The book's intention is to provide a foundation for the object-oriented design and implementation of network communication protocols. Although modeling of communication systems is not the topic of the book, it is worth to have a look at the modular communication system framework developed by the author. It gives an insight how protocols could be modeled and that object-orientation is a practical approach in protocol design.

A completely different approach is taken by "Modeling Telecom Networks and Systems Architecture: Conceptual Tools and Formal Methods" (50). This book condenses more than 20 years of experience gained on the subject within Ericsson. It presents a method and a language for modeling telecommunication system and is based on the processing system paradigm (51). The whole field of communication systems is covered, and a stringent methodology and classification scheme is discussed. The interested reader might also look at Ref. 52.

Real-Time Object-Oriented Modeling

Subsequently, we briefly present the ROOM language to give the reader a notion of what kind of concepts software engineers in the telecommunication system domain work with. Even though the publication of ROOM dates back to 1994, it is still modern and a rare example of a well-documented design language, see Ref. 42. Many features of the ROOM language have been incorporated into the UML (15,16). Nonetheless, we have chosen to describe ROOM, because it represents a coherent set of features required for designing (embedded) real-time systems in the telecommunication domain; the UML is just a rich set of modeling concepts a designer can choose from. In this section we will briefly discuss structural elements of ROOM, behavioral elements and mention model execution.

Structural Elements. ***Actor, Port, Message, Protocol.*** The ROOM language is built on the notion of an *actor*. An actor represents a physical device or a software unit; it is a sort of active object that clearly separates its internals from the environment. Everything inside the actor, meaning the actor's structure and behavior, is not visible to the environment. Only at distinct points of interaction, so-called *ports*, the actor interfaces the environment. A port is somewhat comparable to an interface as known for example, in the UML but the comparison blurs two important facts. First, ports in ROOM are not method interfaces but message interfaces. A *message* consists of a message name, priority, and data. Messages may be incoming and/or outgoing at a port (the direction is always defined from the viewpoint of the actor). So, ports are message exchange points between the actor and its environment. Secondly, a port is not only an interface that tells the environment how to use the actor but also is a definition of the actor's expectations on the environment. Therefore, a *protocol* is always associated with a port, which defines the set of incoming and outgoing messages that may pass the port. An actor is specified by means of an *actor class*. An actor class is symbolized by a rectangular box with a thick black border. A port is figured by a small squared box that appears on the border of an actor class symbol. An example is shown in Fig. 2.

Actor References. An actor can be composed of other actors. In ROOM, references describe compositions. That means, an actor class specification may reference zero or more other actor class specifications. Such a reference is called *actor reference*; it is a way to include other actors into the name space and life-time context of an actor. Per actor reference, a *replication factor* determines the maximum number of valid actors of the referenced actor class that can be put in context. By default, the replication factor is set to one. The following types of references can be distinguished: an actor reference may be fixed, optional, imported or substitutable. These types specify run-time relations. For a *fixed* actor reference, actors of the referenced actor class are incarnated along with the incarnation of the composing actor. If the actor reference is declared as *optional*, then actors of the referenced actor class can be

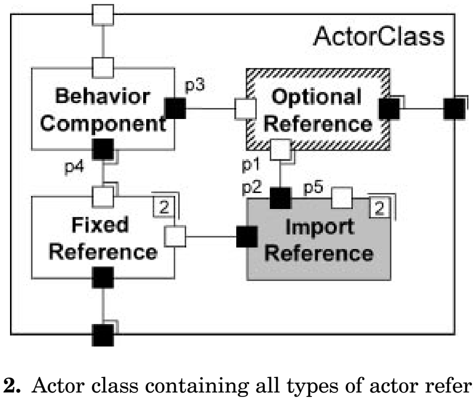

Figure 2. Actor class containing all types of actor references.

dynamically created and destroyed during the life time of the composing actor. The maximum number of allowed actors (given by the replication factor of the actor reference) may not be exceeded. If declared as *imported*, then an actor that already exists in another context of another composing actor is plugged-in at incarnation of the composing actor. That means a single actor instance may act in two or more contexts of a composing actor: in the context of the "original" composing actor that created the actor and owns the permission to destroy it and in the context of one or more other composing actors which imported that specific actor. Imported actor references are a powerful tool to define different roles for different contexts of an actor and thereby to define patterns of collaboration. A *substitutable* actor reference means that any actor instance of that actor reference can be replaced by another actor, provided that the other actor's class specification is compatible with the referenced actor class of the actor reference. Here, compatibility means that the other class specification supports at least the same set of ports (with the same message schema).

Binding, Contract. To build up complete structures of actor references, some means to interconnect their ports must exist. This connection is done by so-called *bindings*, sometimes also referred to as *connectors*. A binding connects a port of an actor reference either with the port of another actor reference or with a port of the composing actor class. Bindings define communication relationships on class level. The auxiliary concept of a *contract* consists of a binding and the two interface components (ports) that the binding connects.

Example. An example of an actor class specification that encompasses all the discussed modifications of an actor reference is shown in Fig. 2. Actor references are symbolized by a rectangular box with a thinner black border and can only appear "inside" the context (also called *decomposition frame*) of an actor class specification. Names for actor references begin with a small letter. Names for bindings begin with a small letter by convention. Sometimes, to avoid visual clutter, the names of bindings and ports are not displayed in the diagram. The replication factor of a replicated actor reference is displayed inside a box in the upper right-hand corner. Optionality is indicated by stripes. If imported, the actor reference is colored grey. Substitutability is indicated by a "+" symbol in the upper left-hand corner.

The Behavior Component. A component specifies the actor class' behavior. In fact, the behavior component is invisible; the behavior component's border is colored in grey just for demonstration purposes. Thus, all ports of an actor class specification that are not connected somewhere else are actually connected to the actor's behavior component; they are called *end ports*. Otherwise, they are called *relay ports*. All other ports (p3, p4) that "hang around" are also implicitly connected to the behavior component. *Reference ports* (the name for ports of actor references) that are not involved in a contract are actually not in use, see p5.

Layer Connection, Service Provision Point, Service Access Point. The notion of layers is a built-in concept in ROOM. Layering is a form of abstraction that is used to define "islands" of self-contained functionality that provide services to another "island" of functionality. In contrast to the *horizontal* structure of peer-to-peer communication between ports, layers represent a *vertical* organization of a system. The terms "horizontal" and "vertical" are apparently vague and indicate the difficulty for giving a precise definition of layers. Actually, the sort of interfaces used to describe layers are very close to ports. The interface of an actor that provides (layer) *services* towards another actor is called service provision point (SPP). The SPP may be replicated; the number of replications is given by a replication factor. Its counterpart, the interface that accesses services of an SPP is called service access point (SAP). SAPs can be replicated as well but they rarely need to. The SPP and the SAP each have a protocol associated with it that determines the interface type. Similar to a binding, a SPP and a SAP are connected to each other by a *layer connection*.

Behavioral Elements. *ROOMcharts, Scheduler.* We already mentioned the behavior component of an actor. In ROOM, behavior is specified in form of state machines, so-called *ROOMcharts*, a variant of Harel's statechart formalism (53). Actors in ROOM are reactive objects with their own thread of execution, which is a typical characteristic for real-time systems. All incoming messages at the behavior component are *events* that may trigger a *transition* to leave a *state*, to perform some *action* and enter the same or another state. For a state, entry and exit actions can be specified. Actions are specified in a detail level language such as C, C++, or Java. A *guard* (a boolean condition) can be attached to a transition, which prevents the transition from firing if the condition evaluates to false. The concept of *composite states* enables the modeler to nest states within states. Once all actions have been executed (ROOM follows the "run-to-completion" processing model), the actor "falls asleep" waiting for additional events to process. Because incoming events are queued, the actor may immediately become busy again until the event queue is empty. Events can also be deferred (i.e., the processing is postponed). Message priorities change the order of event processing usually to "the more important, the more up front in the event queue." In principle, the scheduling semantics of the *scheduler* can be adapted to any other scheme. ROOM is flexible in that respect to cover a wide range of real-time applications. For example, time-based scheduling ("the more urgent, the more up front in the queue") may be an alternative.

Data Classes. Complex data structures can be modeled using the concept of *data classes*. Data classes correspond to traditional classes: they define data and methods that operate on them. In contrast to actors, data objects do not have their own thread of control; they are extended state variables that are encapsulated within the actor and are accessible by the behavior component. Typically, data classes are based on classes provided by the detail-level programming language. That means within an actor the modeler can use and stick to a traditional object-oriented design paradigm. In addition to their role as variables, data classes are used to define the data carried in messages. Remember that a message consists of a name, a priority, and data, or more precisely, a data object. This single data object is an instance of a predefined or user defined data class. The basic requirement put on data objects is that they must be serializable for message transfer by the ROOM virtual machine.

Model Execution. In principle, two possible methods exist to execute ROOM models: (*1*) the model is accompanied by an interpreter called the *ROOM virtual machine*, which is a hypothetical platform implemented in software that interprets ROOM models; and (*2*) the elements of the model are mapped to their functional equivalents in the target environment, which usually is a real-time operating system.

TIME AND STATE IN ASYNCHRONOUS DISTRIBUTED SYSTEMS

INTRODUCTION

A distributed system is characterized by multiple processes that are spatially separated and are running independently. As processes run, they change their *states* by executing *events*. Processes communicate with each other by exchanging messages over a set of communication channels. However, message delays are arbitrary and may be unbounded.

Two inherent limitations of distributed systems are as follows: *lack of global clock* and *lack of shared memory*. Two important implications exist. First, due to the absence of any system-wide clock that is equally accessible to all processes, the notion of common time does not exist in a distributed system, and different processes may have different notions of time. As a result, it is not always possible to determine the order in which two events on different processes were executed. Second, since processes in a distributed system do not share common memory, it is not possible for an individual process to obtain an up-to-date state of the entire system. In addition, because of the absence of a global clock, obtaining a meaningful state of the system, in which states of different processes are consistent with each other, is difficult.

We describe different schemes that implement an abstract notion of time and can be used to order events in a distributed system. We also discuss ways to obtain a consistent state of the system possibly satisfying certain desirable property.

CLOCKS AND ORDERING OF EVENTS

For many distributed applications such as distributed scheduling and distributed mutual exclusion, it is important to determine the order in which various events were executed. If the system has a shared global clock, then time-stamping each event with the global clock would be sufficient to determine the order. However, if such a clock is not available, then it becomes impossible to determine the actual execution order of events. A natural question to ask is as follows: What kind of ordering information can be ascertained in the absence of a global clock?

Each process in the system generates a sequence of events. Therefore it is clear how to order events within a single process. If event *e* occurred before *f* on a process, then *e* is ordered before *f*. But, how do we order events across processes? If *e* is the send event of a message and *f* is the receive event of the same message, then *e* is ordered before *f*. Combining these two ideas, we obtain the following definition:

Definition 1 (Happened-Before Relation). *The happened-before relation, denoted by* $\rightarrow$, *is the smallest transitive relation that satisfies the following:*

(1) *If e occurred before f on the same process, then* $e \rightarrow f$.

(2) *If e is the send event of a message and f is the receive event of the same message, then* $e \rightarrow f$.

As an example, consider a distributed computation involving three processes, namely P_1, P_2, and P_3, shown in Fig. 1. In the figure, time progresses from left to right. Moreover, circles denote events and arrows between processes denote messages. Clearly, $e_2 \rightarrow e_4$, $e_3 \rightarrow f_3$, and $e_1 \rightarrow g_4$.. Also, events e_2 and f_2 are not related by happened-before relation and therefore could have been executed in any order.

The concept of happened-before relation was proposed by Lamport (1). The happened-before relation imposes a *partial order* on the set of events. Any extension of the happened-before relation to a total order gives a possible ordering in which events could have been executed.

The happened-before relationship also captures the causality between events. If an event *e* happened-before an event *f*, then *e* could have caused *f*. In other words, if *e* had not occured, then *f* may not have occurred as well. Events *e* and *f* are said to be *causally related*.

For some distributed applications such as distributed mutual exclusion, it is sufficient to know *some total order* in which events *could have* been executed. The total order may or may not correspond to the actual order of execution of events. However, all processes must agree on the same total order. Furthermore, the total order must respect the happened-before relation. We next describe a mechanism to determine such an ordering at runtime.

Ordering Events Totally: Logical Clocks

A logical clock time-stamps each event with an integer value such that the resulting order of events is consistent with the happened-before relation (Fig. 2). Formally,

Definition 2 (Logical Clock). *A* logical clock *C is a map from the set of events E to the set of natural numbers N with the following constraint:*

$$\forall e, f \in E : e \rightarrow f \Rightarrow C(e) < C(f)$$

The implementation of logical clock, first proposed by Lamport (1), uses an integer variable to simulate local clock on a process. On sending a message, the value of the local clock is incremented and then sent with the message. On receiving a message, a process takes the maximum of its own clock value and the value is received with the message. After

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

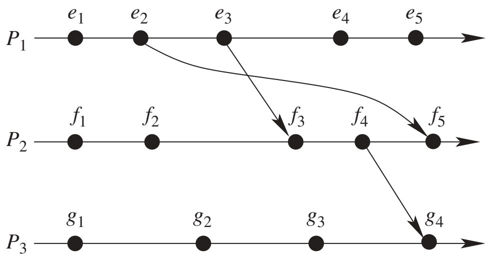

Figure 1. An example of a distributed computation.

taking the maximum, the process increments the clock value. On executing an internal event, a process simply increments its clock. The algorithm can be used even when message communication is unreliable and unordered.

A logical clock has been used to devise efficient distributed algorithms for solving many problems in distributed computing such as mutual exclusion, causal message ordering, and termination detection. For example, in many mutual exclusion algorithms, a logical clock is used to time-stamp requests for critical section. Requests will smaller time-stamps are given priority over requests with larger time-stamps.

Ordering Events Partially: Vector Clocks

A logical clock establishes a total order on all events, even when two events are incomparable with respect to the happened-before relation. For many problems such as distributed debugging and distributed checkpointing and recovery, it is important to determine whether two given events are ordered using the happened-before relation or are incomparable.

The set of events E are partially ordered with respect to $\rightarrow$, but the domain of logical clock values, which is the set of natural numbers, is a total order with respect to $<$. Thus, logical clocks do not provide complete information about the *happened-before* relation. We describe a mechanism called a *vector clock* that allows us to infer the happened-before relation completely.

Definition 3 (Vector Clock). *A* vector clock V *is a map from the set of events E to* N^N *(vectors of natural numbers) with the following constraint:*

$$\forall e, f \in E : e \rightarrow f \Leftrightarrow V(e) < V(f)$$

```
Process $P_i$::
var
    $c$: integer initially 0;

send event :
    $c := c + 1$;
    send $c$ along with the message;

receive event with $d$ as the received timestamp:
    $c := max(c,d) + 1$;

internal event :
    $c := c + 1$;
```

Figure 2. A logical clock algorithm.

```
Process $P_i$:
1   var
2       $\upsilon$ :array[1..$N$] of integer
            initially$(\forall j : j \neq i : \upsilon[j] = 0)$;

3   send event :
4       $\upsilon[i] := \upsilon[i] + 1$;
5       send $\upsilon$ along with the message;

6   receive event of a message tagged with vector $u$:
7       for $j := 1$ to $N$ do
8           $\upsilon[j] := \max(\upsilon[j], u[j])$;
9       $\upsilon[i] := \upsilon[i] + 1$;

10  internal event :
11      $\upsilon[i] := \upsilon[i] + 1$;
```

Figure 3. A vector clock algorithm.

Because $\rightarrow$ is a partial order, it is clear that the time-stamping mechanism should also result in a partial order. Thus, the range of the time-stamping function cannot be a total order like the set of natural numbers used for logical clocks. Instead, we use vectors of natural numbers. Given two vectors x and y of dimension N, we compare them as follows:

$$\begin{aligned} x \leq y &= (\forall k : 1 \leq k \leq N : x[k] \leq y[k]) \\ x < y &= (x \leq y) \vee (x \neq y) \end{aligned}$$

For example, [1,2,1] < [2,2,3] but [2,3,0] and [0,4,1] are incomparable. The vector clock mechanism was proposed independently by Fidge (2) and Mattern (3). Figure 3 shows an implementation of vector clock using vectors of size N, where N is the number of processes in the system.

The algorithm presented in Fig. 3 is described by the initial conditions and by the actions taken for each event type. A process increments its own component of the vector clock after each event (lines 4, 9, and 11). Furthermore, it includes a copy of its vector clock in every outgoing message (line 5). On receiving a message, it updates its vector clock by taking a component-wise maximum with the vector clock included in the message (lines 7 and 8). It is not required that message communication be ordered or reliable. A sample execution of the algorithm is given in Fig. 4.

A vector clock is useful when it is important to determine the *exact relationship* between two events. For example, when *debugging a distributed program*, the programmer may want to find out whether two events are causally related. A potential race condition exists if there is no causal relationship between two events. (This relationship can be detected by comparing the vector time-stamps of the two events.) Likewise, the knowledge that an event could not have caused another event can be used to locate a bug more efficiently. Another application of vector clock arises when *simulating a system in a distributed manner*. In a distributed simulation system, a process needs to know the clock of other processes in order to safely advance its own clock. The notion of a vector clock applies naturally in such a system. The jth entry of a vector clock at process P_i can be interpreted as P_i's knowledge about the (virtual) time at process P_j.

$\begin{bmatrix}0\\0\\2\end{bmatrix}$
$\begin{bmatrix}1\\3\\3\end{bmatrix}$

Figure 4. A sample execution of the vector clock algorithm.

As it can be observed, when capturing the happened-before relationship between events, we use a vector containing N entries, where N is the number of processes in the system. Each process has to maintain a vector of size N and each message has to carry a vector of size N, which is expensive when N is large. A question that arises is as follows: Is it possible to capture the happened-before using a vector of smaller size? The answer is in general "no". It can be shown that there are distributed computations for which a vector of size at least N is required to faithfully capture the happened-before relationship (4).

Higher Dimensional Clocks

It is natural to ask whether two or more dimensional clocks can give processes additional knowledge. The answer is "yes." For an event e, let $e.v$ denote the value of the local clock immediately after executing e. A vector clock can be viewed as a knowledge vector. In this interpretation, for an event e on process P_k, $e.v[i]$ denotes what process P_k knows about process P_i after executing event e. In some application, it may be important for the process to have even more *fine-grained* knowledge about its causal past. The value $e.v[i, j]$ could represent what process P_k knows about what process P_i knows about process P_j. For example, if $e.v[i,k] \geq m$ for all i, then process P_k can conclude that everybody knows that it has executed at least m events.

Physical Clocks

Until now, we assumed that message delays are arbitrary and unbounded. However, if message delays are bounded (but still arbitrary), then another way to time-stamp events is to equip each process with a physical clock. Due to limitations in technology, it is possible for physical clocks on different processes to drift apart from each other. Therefore, different physical clocks have to be synchronized with each other at a regular interval. Clocks are synchronized in a manner such that a sufficiently small constant ε exists satisfying the following:

$$\forall i, j : |C_i(t) - C_j(t)| < \varepsilon \tag{1}$$

where $C_i(t)$ denotes the value of the physical clock on process P_i at time t. Let $dC_i(t)/dt$ denote the rate at which the clock on process P_i is running at time t. Clearly, if C_i is an ideal clock, then $dC_i(t)/dt = 1$. Even if C_i is not an ideal clock, we assume that its rate of drift is bounded. Specifically, let κ be the maximum rate at which a clock can drift away from the actual time. Therefore for all i:

$$1 - \kappa < dC_i(t)/dt < 1 + \kappa \tag{2}$$

Clearly, to avoid anomalous behavior, the time-stamp of a receive event should be greater than the time-stamp of the corresponding send event. Therefore, for all i, j, and t:

$$C_i(t + \mu) > C_j(t) \tag{3}$$

where μ is the transmission time. To achieve synchronization of physical clocks that satisfies Equations (1), (2), and (3), the following algorithm proposed by Lamport (1) can be used:

1. Each process sends a synchronization message to all its neighboring processes after every τ units of time. A process includes its value of local physical clock along with the message.
2. A process, on receiving a synchronization message with time-stamp T_m, sets its physical clock value to the maximum of its current value and $T_m + \mu_m$, where μ_m is the minimum amount of time required for message transmission.

GLOBAL STATE

To solve many problems in distributed systems such as termination detection, we need to examine the state of the entire system, which is also referred to as *global state* or *global snapshot*. (In contrast, state of a process is referred to as *local state* or *local snapshot.*) A simple collection of local states, one from each process, may not correspond to a meaningful system state. To appreciate this, consider a distributed database for a banking application. Assume for simplicity that only two sites keep the accounts for a customer. Also assume that the customer has \$500 at the first site and \$300 at the second site. In the absence of any communication between these sites, the total money of the customer can be easily computed to be \$800. However, if there is a transfer of \$200 from site A to site B, and a simple procedure is used to add up the accounts, we may falsely report that the customer has a total of \$1000 in his or her accounts (to the chagrin of the bank). This happens when the value at the first site is used before the transfer and the value at the second site after the transfer. Clearly, the two values are not consistent with each other. Note that \$1000 cannot be justified even by the messages in transit (or that "the check is in the mail"). We now describe what it means for a global state to be meaningful or consistent.

Consistent Global State

Intuitively, a global state captures the set of events that have been executed so far. For a global state G to be consistent, it should satisfy the following condition:

$$\forall e, f : (e \rightarrow f) \wedge (f \in G) \Rightarrow e \in G$$

Sometimes, it is more convenient to describe a global state in terms of local states instead of events. For a local state s, let $s.p$ denote the process to which s belongs. We can extend the definition of the happened-before relation, which was defined on events, to local states as follows: $s \rightarrow t$ if $s.p$ executed an event e after s and $t.p$ executed an event f before t such that either $e = f$ or $e \rightarrow f$. Two local states s and t are *concurrent*, which is denoted by $s \| t$, if $s \nrightarrow t$ and $t \nrightarrow s$. For a global state G, let $G[i]$ refer to the local state of process P_i in G. We now define what it means for a global state to be consistent, when the global state is expressed as a collection of local states.

Definition 4 (Consistent Global State). *A global state G is consistent if it satisfies*

$$\forall i, j : G[i] \| G[j]$$

In general, a global state can be used to deduce meaningful conclusions about the state of the system only if it is consistent.

Finding a Consistent Global State

We discuss how to obtain a consistent view of the entire system. The algorithm, which was proposed by Chandy and Lamport (5), assumes that all channels satisfy the first-in–first-out (FIFO) property. Moreover, it also records the state of all communication channels, which is given by the set of messages in transit. The computation of the snapshot is initiated by one or more processes. We associate with each process a variable called *color* that is either white or red. All processes are initially white and turn red eventually. Intuitively, the computed global snapshot corresponds to the state of the system just before processes turn red. After recording its local state, a process turns red. Thus, the local snapshot of a process is simply the state just before it turned red. The algorithm relies on a special message called a marker. The consistent global snapshot algorithm is given by the following rules:

(1) **(Turning Red Rule):** When a process records its local state, it turns from white to red. On turning red, it sends out a marker on every outgoing channel before sending any application message on that channel. It also starts recording messages on all incoming channels.

(2) **(Marker Receiving Rule):** On receiving a marker, a white process turns red. The process also stops recording messages along that channel.

A process has finished its local snapshot when it has received a marker on each of its incoming channel. The algorithm requires that a marker be sent along all channels. Thus, it has an overhead of one message per channel in the system. We have not discussed how to combine local snapshots into a global snapshot. A simple method would be for all processes to send their local snapshots to a predetermined process. This color-based description of Chandy and Lamport's algorithm for recording a consistent global state of the system was proposed by Dijkstra.

One advantage of Chandy and Lamport's snapshot algorithm is that it is not necessary to "freeze" the computation when recording a global state. However, it is possible that the global state recorded by the algorithm is such that the system never actually passes through the (recorded) state during its execution. But, Chandy and Lamport show that it is possible to reorder the events (while still respecting the happened-before relation) in such a way that the system indeed passes through the recorded global state (5).

Finding a Consistent Global State Satisfying the Given Property

Sometimes it is not sufficient to find just any consistent global state. Rather, we may want to find a consistent global state that satisfies certain global property (6–8). If the global property is stable, that is, it stays true once it becomes true, then repeated invocations of the Chandy and Lamport's algorithm for taking a consistent global snapshot can be used to find the required global state.

We discuss an algorithm that can be used to find a consistent global state satisfying an unstable property. We will assume that the given global property, say B, is constructed from local predicates using Boolean connectives. We first show that B can be detected using an algorithm that can detect q, where q is a pure conjunction of local predicates. The predicate B can be rewritten in its disjunctive normal form as

$$B = q_1 \vee \ldots \vee q_k \qquad k \geq 1$$

where each q_i is a pure conjunction of local predicates. Next, observe that a global state satisfies B if and only if it satisfies at least one of the q_i's. Thus, the problem of detecting B is reduced to solving k problems of detecting q, where q is a pure conjunction of local predicates.

Formally, we define a *weak conjunctive predicate (WCP)* to be true for a given computation if and only if a consistent global state exists in the computation for which all conjuncts are true (7). Intuitively, detecting a WCP is useful generally when one is interested in detecting a combination of states that is unsafe. For example, violation of mutual exclusion for a two-process system can be written as "P_1 is in the critical section and P_2 is in the critical section." To detect a weak conjunctive predicate, it is necessary and sufficient to find a set of concurrent local states, one on each process, in which all local predicates are true. We now present an algorithm to do so.

In this algorithm, one process serves as a checker. All other processes involved in detecting the WCP are referred to as *application processes*. Each application process maintains a vector clock. It also checks for the respective local

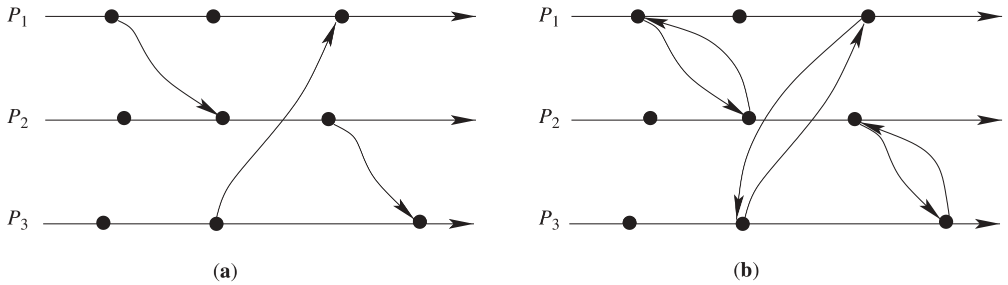

Figure 5. (a) A distributed computation and (b) its slice with respect to the property "all channels are empty."

predicate. Whenever the local predicate of a process becomes true for the *first* time since the most recently sent message (or the beginning of the trace), it generates a debug message containing its local time-stamp vector and sends it to the checker process.

Note that a process is not required to send its vector clock every time the local predicate is detected. If two local states, say s and t, on the same process are separated only by internal events, then they are indistinguishable to other processes so far as consistency is concerned; that is, if u is a local state on some other process, then $s \| u$ if and only if $t \| u$. Thus, it is sufficient to consider at most one local state between two external events and the vector clock need not be sent if no message activity has occurred since the last time the vector clock was sent.

The checker process is responsible for searching for a consistent global state that satisfies the WCP by considering a sequence of candidate global states. If the candidate global state either is not consistent or does not satisfy some term of the WCP, the checker can efficiently eliminate one of the local states in the global state. The eliminated state can never be part of a consistent global state that satisfies the WCP. The checker can then advance the global state by considering the successor to one of the eliminated states. If the checker finds a global state for which no state can be eliminated, then that global state satisfies the WCP and the detection algorithm halts.

Finding All Consistent Global States Satisfying the Given Property

In debugging applications, it is sometimes useful to record all consistent global states that satisfy the given property. A computation slice is a concise representation of all such global states. A slice of a distributed computation with respect to a given property B is a concise representation of all the global states that satisfy B(8).

To understand the principle behind slicing, one needs to note that a computation (an acyclic directed graph on set of events) can be viewed as a generator of all consistent global states. A subset of vertices H of a directed graph is a *consistent global state* if it satisfies the following condition: If H contains a vertex v and *(u, v)* is an edge in the graph, then H also contains u. Given a computation, if one adds additional edges to the computation, the number of consistent possible global state can only decrease. The goal of slicing is to determine the maximum set of edges to add to the graph such that the resulting graph continues to contain all consistent global states of the computation that satisfy the given property. Note that when an edge is added to the original graph, the resulting graph may not be acyclic anymore.

As an example, consider the distributed computation shown in Fig. 5(a). Its slice with respect to the global property "all channels are empty" is depicted in Fig. 5(b).

Three main motivations for computing all the global states satisfy a given property. First, for debugging applications, the programmer may not know the exact condition under which a bug occurs, but only that whenever the bug occurs B is true. Therefore we have to record all global states that satisfy B. Based on slicing, one can provide a "fast-forward" utility in debuggers where the system only goes through global states satisfying B. The second motivation comes from detecting predicates of the form $B_1 \wedge B_2$ in which the programmer knows an efficient detection algorithm for B_1 but not B_2. Instead of searching the set of all global states for a global state that satisfies $B_1 \wedge B_2$, slicing allows the programmer to restrict the search to only those global states that satisfy B_1. This set of global states may be exponentially smaller than the original set of global states.

The reader is referred to Ref. 9 for a more detailed description of slicing and associated algorithms.

TRANSPORT LAYER

INTRODUCTION

The Internet has evolved into an extremely large complex system and has changed many important aspects of our lives. Like any complex engineering system, the design of the Internet is carried out in a modular way, where each main functional module is called a "layer." One of the layering structures often used is the five-layer model consisting of the physical layer, the link layer, the network layer, the transport layer, and the application layer.[1] See Fig. 1 for a simple illustration.

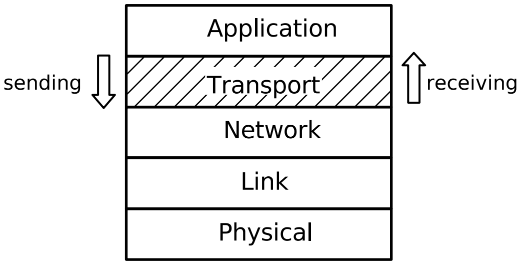

Figure 1. Internet protocol stack.

The sending and receiving computers each run analogous stacks, with data being passed down the stack from the sending application, and then up the receiver's stack to the receiving application. The physical layer is the part that actually moves information from one place to another, such as by varying voltages on wires or generating electromagnetic waves. The application layer is the part with which users interact, such as the hypertext transport protocol (HTTP) used to browse the Web, or the simple mail transfer protocol (SMTP) used to send e-mail.

Each layer consists of *protocols* to specify such things as the data format, the procedure for exchanging data, the allocation of resources, and the actions that need to be taken in different circumstances. This protocol can be implemented in either software or hardware or both. This article concerns transport layer protocols and their associated algorithms, mainly focusing on the wireline Internet but also discussing some other types of networks such as wireless ones.

The transport layer manages the end-to-end transportation of packets across a network. Its role is to connect application processes running on end hosts as seamlessly as possible, as if the two end applications were connected by a reliable dedicated link, thus making the network "invisible." To do this, it must manage several nonidealities of real networks: shared links, data loss and duplication, contention for resources, and variability of delay. By examining these functionalities in turn, we will provide a brief introduction to this important layer, including its functions and implementation, with an emphasis on the underlying ideas and fundamentals. We will also discuss possible directions for the future evolution of the transport layer and suggest some further reading.

MULTIPLEXING: MANAGING LINK SHARING

One basic function of the transport layer is *multiplexing* and *demultiplexing*. Usually there are multiple application processes running on one host. For example, a computer may be sending several files generated by filling in web forms, while at the same time sending e-mails. The network layer only cares about sending a stream of data out of the computer. Therefore, the transport layer needs to aggregate data from different applications into a single stream before passing it to the network layer. This is called multiplexing. Similarly, when the computer receives data from the outside, the transport layer is again responsible for distributing that data to different applications—such as a web browser or e-mail client—in a process called demultiplexing. Figure 1 also shows the data directions for multiplexing (sending) and demultiplexing (receiving).

Multiplexing is achieved by dividing flows of data from the application into (one or more) short *packets*, also called *segments*. Packets from different flows can then be interleaved as they are sent to the network layer. Demultiplexing is achieved by allocating each communication flow a unique identifier. The sender marks each packet with its flow's identifier, and the receiver separates incoming packets into flows based on their identifiers. In the Internet, these identifiers consist of transport layer *port* numbers, and additionally the network layer addresses of the sender and receiver and a number identifying the transport layer protocol being used. Even before a flow is started, a "well-known" port number can be used to identify which process on the receiver the sender is attempting to contact; for example, Web servers are "well known" to use port 80.

Multiplexing and demultiplexing is one of the most fundamental tasks of the transport layer. Other functions are required by some applications but not by all, and so different transport layer protocols provide different subsets of the possible services. However, essentially all transport layer protocols perform at least multiplexing and demultiplexing.

There are two dominant types of transport layer protocol used in the Internet. One is UDP (User Datagram Protocol), and the other is TCP (Transmission Control Protocol). The former provides unreliable and connectionless service to the upper layers, whereas the latter generates reliable and connection-based service.

[1] There are also some other ways of defining these layers; e.g., the standard OSI (open systems interconnection) reference model defines seven layers with the session layer and the presentation layer added.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

UDP: Multiplexing Only

UDP is a very simple protocol. It is called connectionless because all UDP packets are treated independently by the transport layer, rather than being part of an ongoing flow.[2] Besides minor error checking, UDP essentially only does multiplexing and demultiplexing. It does not provide any guarantee that packets will be received in the order they are sent, or even that they will be received at all. It also does not control its transmission rate. In fact, the rationale behind the design of UDP is to let applications have more control over the data sending process and to reduce the delay associated with setting up a connection. These features are desirable for certain delay-sensitive applications such as streaming video and Internet telephony. In general, applications that can tolerate certain data loss/corruption but are sensitive to delay would choose to use UDP.

TCP: Reliable Connection-Oriented Transport

In contrast to UDP, TCP provides a connection-oriented service, which means that it sends data as a stream of related packets, making concepts such as the order of packets meaningful. In particular, TCP provides reliable service to upper layer applications, ensuring that the packets are correctly received and in the order in which they are sent.

At the start of a connection, TCP uses a *three-way handshake* to establish a connection between sender and receiver, in which they agree on what protocol parameters to use. This process takes 1.5 round-trip times (one side sends a SYNchronize packet, the other replies with a SYN and an ACKnowledge packet, and the first confirms with an ACK), which is an overhead avoided by UDP.

TCP receives data from the application as a single stream, e.g., a large file, and segments it into a sequence of packets. It tries to use large packets to minimize overhead, but there is a maximum size that the network can carry efficiently, called the MTU (maximum transfer unit). TCP is responsible for choosing the correct size, in a process called *path MTU discovery*. In contrast, UDP is given data already segmented into packets, and so it is the application's responsibility to observe MTU restrictions.

TCP is the most common transport protocol in the Internet; measurements show that it accounds for about 80% of the traffic (1). Applications such as file transmission, Web browsing, and e-mail use it partly because of its ability to transfer continuous streams of data reliably, and partly because many firewalls do not correctly pass other protocols. The following two sections, on *reliable transmission* and *congestion control*, describe in greater detail the main features of TCP.

RELIABLE TRANSMISSION: MANAGING LOSS, DUPLICATION, AND REORDERING

When the underlying network layer does not guarantee to deliver all packets, achieving reliable transmission on top of this unreliable service becomes an important task. Reasons for packet loss include transient routing loops, congestion of a resource, or physical errors that were not successfully corrected by the physical or link layer.

This problem is very similar to that faced by the link layer. The difference is that the link layer operates over a single unreliable physical link to make it appear reliable to the network layer, whereas the transport layer operates over an entire unreliable network to make it appear reliable to the application. For this reason, the algorithms employed at the transport layer are very similar to those employed at the link layer, and they will be reviewed briefly here.

ARQ (Automatic Repeat-reQuest) is the basic mechanism to deal with data corruption. When the receiver receives a correct data packet, it will send out a positive acknowledgment (ACK); when it detects an error, it will send out a negative acknowledgment (NAK).

Because physically corrupted packets are usually discarded by the link layer, the transport layer will not directly observe that a packet has been lost, and hence, many transport layer protocols do not explicitly implement NAKs. A notable exception is multicast transport protocols. Multicast protocols allow the sender to send a single packet, which is replicated inside the network to reach multiple receivers, possibly numbering in the thousands. If each sent an ACK for every packet, the receiver would be flooded. If instead receivers send NAKs only when they believe packets are missing, the network load is greatly reduced. TCP implicitly regards ACKs for three or more out-of-order packets (resulting in "duplicate ACKs") as forming a NAK.

An interesting problem immediately develops. If the sender only sends the next packet when it is sure the first one is received correctly, the system will be very inefficient. In that case, the sender would only be able to send one packet every round-trip time (the time it takes for a packet to reach the destination and the ACK to return), whereas the time taken to send a packet is usually much smaller than the round-trip time. This is especially true for today's high-speed networks. For example, consider a 1 Gbit/s (1,000,000,000 bits per second) connection between two hosts that are separated by 1500 km and therefore have a round-trip distance of 3000 km. Sending a packet of size 10 kbit takes only 10 μs (ten microseconds), whereas the round-trip time cannot be smaller than the physical distance divided by the light of speed (300,000 km per second), which in this case is 10 ms. In other words, in this case, the utilization of the sender is about 0.1%, which is clearly not acceptable. This is the motivation for the general sliding window algorithm that will be discussed in the following subsection.

Sliding Window Transmission Control

The basic idea here is again simple. The sender sends more packets into the network while it is waiting for the acknowledgment of the first packet. This certainly increases the utilization. On the other hand, it cannot send too much before receiving ACKs as that may heavily congest the network or overflow the receiver. In general, the sender is allowed to send no more than W packets into the network before receiving an acknowledgment. Here W is called the *window* size. If $W = 1$, it reverts to the inefficient transmission previously discussed. Since the sender can send W

[2] It is common for the application layer to implement flows on top of UDP, but that is not provided by UDP itself.

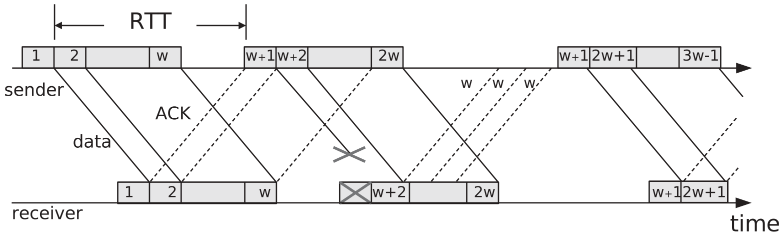

Figure 2. Sliding window flow control, with packet $W + 1$ being lost.

packets every round-trip time, the utilization is increased by a factor of W if the network and receiver can handle the packets. If not, then there will be congestion and the value of W must be reduced, which is the topic of the next section. The left of Fig. 2 shows the case when packets are successfully received. It shows that using $W > 1$ allows more than one packet to be sent per round-trip time (RTT), increasing the throughput of the connection.

However, things become a little more complex when $W > 1$ as now the sender needs to keep track of acknowledgments from more than one packet in one round-trip time. This is done by giving every packet a *sequence number*. When a packet is received, the receiver sends back an ACK carrying the appropriate sequence number.

When packets are received out of order, the receiver has three options, depending on the protocol. It may simply discard packets that are received out of order, it may forward them immediately to the application, or it may store them so that it can deliver them in the correct order once the missing packet has been received, possibly after being resent. Finally, if the sender has not received an ACK for a particular packet for a certain amount of time, a *timeout* event occurs. After that, the sender resends all packets that are sent out but have not yet been acknowledged.

Realization

The following example presents a simplified example of how the above ideas are realized by TCP, which is currently the most widespread example of sliding window transmission control.

Example 1. Rather than acknowledging each packet, TCP ACKs cumulatively acknowledge all data up until the specified packet. This increases the robustness to the loss of ACKs. Figure. 2 shows the operation of TCP when packet $W + 1$ is lost. Initially, the window spans from 1 to W, allowing the first W packets to be sent. The sender then waits for the first packet to be acknowledged, causing the window to slide to span packets 2 to $W + 1$, allowing the $W + 1$st packet to be sent. This continues until the second window is sent, and after sending the $2W$th packet, the sender again must pause for an ACK to slide the window along. However, this time, the $W + 1$st packet was lost, and so no ACK is received. When packet $W + 2$ is received, the receiver cannot acknowledge it, since that would implicitly acknowledge packet $W + 1$, which has not yet arrived. Instead, it sends another ACK for the most recently received packet, W. This is repeated for all subsequent arrivals, until $W + 1$ is received. When the sender receives the third duplicate ACK for W, it assumes that $W + 1$ was lost, and retransmits it. It then continues transmitting from where it left off, with packet $2W + 1$.

The precise response to packet loss of current TCP is more complex than in this example, because packet loss is treated as a signal that a link in the network is overloaded, which triggers a congestion control response, as described in the following section.

CONGESTION CONTROL: MANAGING RESOURCE CONTENTION

When transport layer protocols were first designed, they were intended to operate as fast as the receiver could process the data. The transport layer provided “flow control” to slow the sender down when the receiver could not keep up. However, in the 1980s, the Internet suffered from several famous *congestion collapses*, in which the sliding window mechanism was resending so many packets that the network itself because overloaded to the point of inoperability, even when the receivers were not overloaded.

Recall from the previous section that senders use $W > 1$ to increase the utilization of the network. Congestion occurred because flows sought to use more than 100% of the network capacity. As a result, a set of rules were proposed (2) for how senders should set their windows to limit their aggregate sending rate while maintaining an approximately fair allocation of rates.

Congestion control considers two important topics: what rates would we ideally like to allocate to each flow in a given network, and how can we achieve that in practice using only distributed control. The latter is made difficult because of the decentralized nature of the Internet: senders do not know the capacity of the links they are using, how many other flows share them, or how long those flows will last; links do not know what other links are being used by the flows they are carrying; and nobody knows when a new flow will arrive. Figure 3 shows an example in which two flows each use three links, of which they share one.

Let us now consider the current solutions to the problem of implementing congestion control in a scalable way, and then examine the other problem of deciding what rate allocation is more desirable.

Existing Algorithms

There are two main phases of a congestion control algorithm: *slow start* and *congestion avoidance*, punctuated by

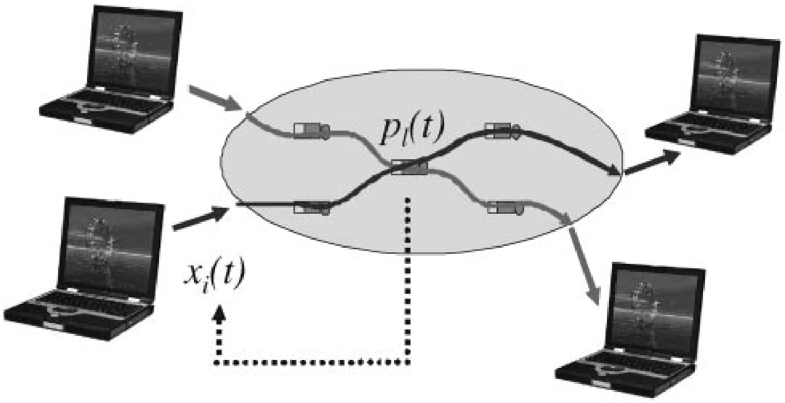

Figure 3. Two flows sharing a link, and also using nonshared links.

short periods of retransmission and loss recovery. We now introduce both using the standard TCP congestion control algorithm, commonly called TCP Reno.[3]

When a TCP connection begins, it starts in the slow start phase with an initial window size of two packets. This results in a slow initial transmission, giving rise to the name. It then rapidly increases its sending rate. It doubles its window every round-trip time until it observes a packet loss, or the window reaches a threshold called the "slow start threshold." If a loss occurs, the window is then halved, and in either case, the system enters the congestion avoidance phase. Note that the sender increases its transmission rate exponentially during the slow start.

In the congestion avoidance phase, the sender does what is known as Additive Increase Multiplicative Decrease (AIMD) adjustment. This was first proposed by Chiu and Jain (3) as a means to obtain fair allocation, and implemented in the Internet by Jacobson (2). Every round-trip time, if all packets are successfully received, the window is increased by one packet. However, when there is a loss event, then the sender will halve its window. Because large windows are reduced by more than small windows, AIMD tends to equalize the size of windows of flows sharing a congested link (3). Finally, if a timeout occurs, the sender will start from slow start again. Figure 4 shows how the window evolves along time in TCP Reno. Importantly, TCP Reno uses packet loss as congestion indication.

In summary, the basic engineering intuition behind most congestion control protocols is to start probing the network with a low transmission rate, quickly ramp up initially, then slow down the pace of increase, until an indicator of congestion occurs and transmission rate is reduced. Often packet loss or queueing delay (4) are used as congestion indicators, and packet loss events are in turn inferred from local measurements such as three duplicated acknowledgments or timeout. These design choices are clearly influenced by the views of wireline packet-switched networks, in which congestion is the dominant cause of packet loss. The choice of the ramp-up speed and congestion indicators have mostly been based on engineering intuition until recent developments in predictive models of congestion control have helped with a more systematic design and tuning of the protocols.

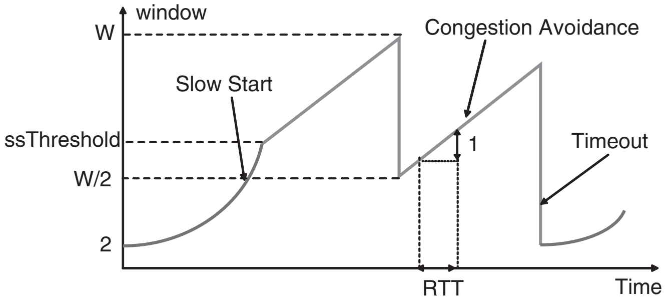

Figure 4. TCP Reno Window Trajectory.

This window adaptation algorithm is combined with the sliding window transmission control, to form the whole window-based congestion control mechanism, as illustrated in Fig. 5. The transmission control takes two inputs, the window size and the acknowledgments from the network. The window size is controlled by the congestion control algorithm such as TCP Reno, which updates the window based on the estimated congestion level in the network. In summary, with window-based algorithms, each sender controls its window size—an upper bound on the number of packets that have been sent but not acknowledged. As pointed out by Jacobson (2), the actual rate of transmission is controlled or "clocked" by the stream of received acknowledgments (ACKs). A new packet is

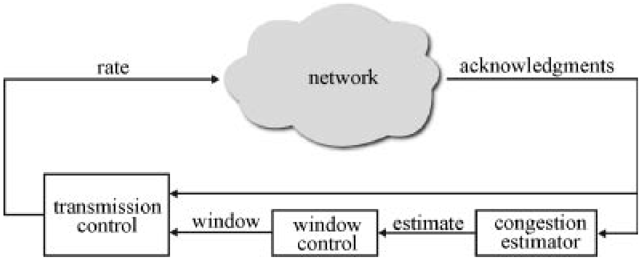

Figure 5. Window-based congestion control.

[3] Most systems actually implement a variant of Reno, typically NewReno, since Reno performs poorly when two packets are lost in a single round trip. However, the differences do not affect the descriptions in this section, and so we use the term "Reno."

transmitted only when an ACK is received, thereby ideally keeping the number of outstanding packets constant and equal to the window size.

Theoretical Foundation

As mentioned, congestion control is essentially a resource allocation scheme that allocates the capacities of links to TCP flows. It is desirable to be able to calculate the share of the capacity and discuss its properties, such as the fairness of the allocation.

Many valuable models of TCP have been proposed. Since Kelly's work in the late 1990s, generic congestion control protocols have been modeled as distributed algorithms maximizing the total benefit obtained by the applications (5–8). This "reverse-engineering" approach shows that existing TCP congestion control mechanisms are implicitly solving an underlying global optimization, with an interpretation of link-price-based balancing of bandwidth demand by the end users. Following economic terminology, the user objective being maximized is called the *utility*, and the utility that the ith flow obtains by sending at a rate x_i is denoted $U_i(x_i)$. If each flow i uses a set of links $L(i)$ and link $l \in L(i)$ has capacity c_l, then the problem of maximizing the utility can be expressed as follows:

$$\max_{x \geq 0} \sum_i U_i(x_i)$$

$$\text{subject to} \sum_{i:l \in L(i)} x_i \leq c_l$$

This is a convex optimization problem provided that the utility functions follow the usual "law of diminishing returns," that is, the utility increases as the rate received increases, but the incremental benefit becomes smaller. Such problems have a very rich mathematical structure.

The theory of Lagrange duality for convex optimization allows the problem to be decomposed into subproblems in which each flow *independently* chooses its rate based on congestion signals from the links, such as packet loss or queueing delay, which are computed based only on local information. Again following economic terminology, these congestion signals are sometimes referred to as *prices*.

The strict convexity structure also implies that the optimal rates are unique, and that those rates are independent of many properties of the links, such as their buffer sizes. In particular, as long as the congestion signal is zero when the sum of the rates through the link is less than its capacity, it does not matter how the congestion signals are calculated; the equilibrium rates will depend only on the utility functions, which are in turn determined by the TCP algorithm at the sender.

The choice of utility function determines the notion of fairness implemented by the network (9). If the utility function is almost linear, it reflects only slightly diminishing returns as the transmission rate is increased, and the network will seek to maximize the sum of the rates of all flows, with no regard to fairness. At the opposite extreme, if the incremental benefit decreases rapidly, the utility function will be very concave and *max–min* sharing is achieved. The max–min rate allocation is the one in which no flow can increase its rate, except by reducing the rate of a flow that already has a lower rate. This is often seen as the fairest way to allocate rates.

A logarithmic utility function results in a compromise between fairness and throughput known as proportional fairness. Similarly, to a first approximation, the utility of the AIMD algorithm used by TCP Reno is as follows:

$$U_i(x_i) = -\frac{1}{x_i \tau_i^2}$$

where τ_i is the round-trip time of the flow i. This is similar to proportional fairness, but it tends slightly toward improving fairness at the expense of throughput, as will be seen in the following example.

Example 2. Consider a network with two congested links, each with a capacity of c. One flow uses both links, and each link also carries a single-link flow, as shown in Fig. 6.

The maximum sum of rates is achieved when $x_1 = x_2 = c$ and $x_3 = 0$, which maximizes the sum of utilities if $u_i(x_i)$ is approximately proportional to x_i. This is clearly unfair since the two-link flow cannot transmit at all. In contrast, the max–min rates are $x_1 = x_2 = x_3 = c/2$, which maximizes the sum of utilities if $u_i(x_i)$ rises very sharply for $x_i < c/2$, and rises only very slightly for $x_i > c/2$. This is completely fair in that all flows receive the same rate, but it is unfair in the sense that the long flow causes twice as much congestion but still achieves the same rate. In this case, the total rate has reduced from $c + c = 2c$ to $c/2 + c/2 + c/2 = 1.5c$.

The proportional-fair rates, which maximize logarithmic utilities, are $x_1 = x_2 = 2c/3$ and $x_3 = c/3$. These rates are in the ratio 2:1 because the resources consumed are in the ratio 1:2, and they give a total rate of around 1.67c. If all flows have equal round-trip times τ_i, TCP Reno will give average rates in ratio $1 : \sqrt{2}$, namely $x_1 = x_2 = \sqrt{2}c/(1 + \sqrt{2})$ and $x_3 = c/(1 + \sqrt{2})$, with a total throughput of 1.59c. The fact that the rates are more similar for Reno than for proportional fairness, but the sum of rates is lower, supports the statement that Reno is a compromise between proportional fairness and max–min fairness.

In concluding this subsection, we mention that there has been a lot of recent research on both reverse-engineering and forward-engineering congestion control protocols, based on the above mathematical model and its variants. Some of the ongoing research issues will be briefly presented toward the end of this entry.

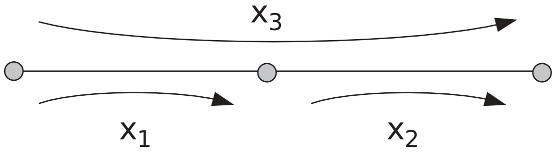

Figure 6. A two-link network shared by three flows.

TIMING RESTORATION: MANAGING DELAY VARIATION

In most cases, it is desirable for the transport layer to pass data to the receiving application as soon as possible. The notable exception to this is streaming audio and video. For these applications, the temporal spacing between packets is important; if audio packets are processed too early, the sound becomes distorted. However, the spacing between packets gets modified when packets encounter network queueing, which fluctuates in time. In its role of hiding lower layer imperfections from the upper layers, it is up to the transport layer to reestablish the timing relations between packets before sending them to the application.

Specialist transport protocols such as the Real Time Protocol (RTP) are used by flows requiring such timing information. RTP operates on top of traditional transport layer protocols such as UDP and provides each packet with a timestamp. At the receiver, packets are inserted as soon as they arrive into a special buffer known as a jitter buffer, or playout buffer. They are then extracted from the jitter buffer in the order in which they were sent and at intervals exactly equal to the interval between their timestamps. Jitter buffers can only add delay to packets, not remove delay; if a packet is received with excessive delay, it must simply be discarded by the jitter buffer. The size of the jitter buffer determines the tradeoff between the delay and packet loss experienced by the application.

TCP can itself cause delay fluctuation, both through ACK-clocking and the fluctuation in rate induced by Reno-like congestion control. When transmitting video and other streaming data, it is sometimes desirable to have packets sent with more uniform spacing. The burstiness caused to ACK-clocking can be avoided by *paced* TCP. Rather than sending packets exactly when acknowledgments are received, paced TCP sends one window's worth of packets uniformly spaced throughout a round-trip time. Many congestion control algorithms have been proposed that dispense with Reno's AIMD, reducing burstiness on longer timescales; notable examples include TCP Vegas and TCP Friendly Rate Control (TFRC).

RECENT AND FUTURE EVOLUTION

With the Internet expanding to global scale and becoming ubiquitous, it is encountering more and more new environments. On the one hand, the TCP/IP "hourglass model"[4] has been very successful at separating applications from the underlying physical networks and enabling the Internet's rapid growth. On the other hand, some basic assumptions are becoming inaccurate or totally invalid, which therefore imposes new challenges. This section describes some of the hot issues in both the Internet Engineering Task Force (IETF, the primary Internet standards body) and the broad research community. Many topics touch on both implementation issues and fundamental questions. We will start with the most implementation related ones and then progress to the more theoretical ones. It is certainly clear that the list below cannot be exhaustive and instead reflects the authors' taste and expertise. For example, many more variants of TCP congestion control are proposed in the last few years than can be surveyed within an encycopedia. In addition to the rest of this section, there are many other exciting developments in the theory and practice of transport layer design for future networks.

Protocol Enhancement

1) Datagram Congestion Control Protocol: Although TCP provides reliable in-order data transfer and congestion control, UDP provides neither. However, applications such as video transmission should implement congestion control, but they do not need guaranteed transmission. Moreover, they cannot tolerate the delay caused by retransmission and in-order delivery. Consequently, the IETF has developed a new protocol called DCCP (Datagram Congestion Control Protocol), which can be viewed either as UDP with congestion control or as TCP without the reliability guarantees. Because many firewalls block unknown protocols, DCCP has not yet been widely used, although it is implemented in many operating systems.

2) Multiple indicators of congestion: The current TCP NewReno relies primarily on detection of packet loss to determine its window size. Other proposals have been made that rely primarily on estimates of the queueing delay. The utility maximization theory applies to networks in which all flows are of the same "family." For example, all flows in the network may respond solely to loss; different flows may respond differently to loss, provided that loss is the only congestion signal they use. However, when a single network carries flows from both the "loss" and "delay" families, or flows responding to other "price" signals such as explicit congestion signals, the standard theory fails to predict how the network behaves.

Unlike networks carrying a single family of algorithms, the equilibrium rates now depend on router parameters, such as buffer sizes, and flow arrival patterns. The equilibrium can be nonunique, inefficient, and unfair. The situation is even more complicated when some individual flows respond to multiple congestion signals, such as adjusting AIMD parameters based on estimates of queueing delay. This has motivated recent efforts to construct a more general framework, which includes as a special case the theory for networks using congestion signals from a single family (10).

Applications

1) Delay-tolerant networks: Sliding window protocols rely on feedback from the receiver to the sender. When communicating with spacecraft, the delay between sending and receiving may be minutes or hours, rather than milliseconds, and sliding windows become infeasible. This has lead to research into "interplanetary TCP." Technology called DTN (Delay-Tolerant Networking) is being developed for this, and also for more mundane situations in which messages suffer long delays. One example is in vehicular networks, in which messages are exchanged over short-range links as vehicles pass one another, and

[4] It is called an hourglass because a small number of simple network and transport layer protocols connect a large variety of complex application layer protocols above with a large variety of link and physical layer protocols below.

are physically carried by the motion of the vehicles around a city. In such networks, reliability must typically be achieved by combinations of error correcting codes and multipath delivery (e.g., through flooding).

2) Large bandwidth delay product networks: In the late 1990s, it became clear that TCP NewReno had problems in high speed transcontinental networks, commonly called "large bandwidth-delay product" or "large BDP" networks. The problem is especially severe when a large BDP link carries only a few flows, such as those connecting supercomputer clusters. In these networks, an individual flow must have a window *W* of many thousands of packets. Because AIMD increases the window by a single packet per round trip, the sending rate on a transatlantic link will increase by around 100 kbit/s. It would thus take almost three hours for a single connection to start to use fully a 1 Gbit/s link.

Many solutions have been proposed, typically involving increasing the rate at which the window is increased, or decreasing the amount by which it is decreased. However, these both make the algorithm more "aggressive," which could lead to allocating too much rate to flows using these solutions and not enough to flows using the existing TCP algorithm. As a result, most solutions try to detect whether the network actually is a "large BDP" network, and adjust their aggressiveness accordingly. Another possibility is to avoid dealing with packet loss in large BDP networks. Researchers have developed various congestion control algorithms that use congestion signals other than packet loss, e.g., queueing delay. Many proposals also seek to combine timing information with loss detection. This leads to the complications of multiple indicators of congestion described previously.

An alternative that is often proposed is for the routers on the congested links to send explicit messages indicating the level of congestion. This was an important part of the available bit-rate (ABR) service of asynchronous transport mode (ATM) networks. It may allow more rapid and precise control of rate allocation, such as the elimination of TCP's time-consuming slow start phase. However, it presents significant difficulties for incremental deployment in the current Internet.

3) Wireless networks: Wireless links are less ideal than wired links in many ways. Most importantly, they corrupt packets because of fading and interference, either causing long delays as lower layers try to recover the packets, or causing packets to be lost. The first of these results in unnecessary timeouts, forcing TCP to undergo slow start, where as the latter is mistaken for congestion and causes TCP NewReno to reduce its window. Again, many solutions have been proposed. Some mask the existence of loss, where as others attempt to distinguish wireless loss from congestion loss based on estimates of queueing delay or explicit congestion indication.

The fundamental task of resource allocation is also more challenging in wireless networks, partly because resources are more scarce and users may move, but more importantly because of the interaction between nearby wireless links. Because the capacity of a wireless link depends on the strength of its signal and that of interfering links, it is possible to optimize resource allocation over multiple layers in the protocol stack. This cross-layer optimization generalizes the utility maximization. It provides challenges as well as opportunities to achieve even greater performance, which requires a careful balance between reducing complexity and seeking optimality.

Research Challenges

1) Impact of network topology: Transport layer congestion control and rate allocation algorithms are often studied in very simple settings. Two common test networks are *dumbbell* networks in which many flows share a single congested link, and *parking lot* networks, consisting of several congested links in series with one flow traversing all links, and each link also being the sole congested link for another short flow. Figure 6 shows a two-link parking lot network. These are used partly because they occur frequently in the Internet (such as when a flow is bottlenecked at the ingress and egress access links), and partly because there are intuitive notions of how algorithms "should" behave in these settings. However, these simple topologies often give a misleading sense of confidence in our intuition. For example, in parking lot topologies, algorithms that give a high rate to the single link flows at the expense of the multilink flow achieve higher total throughput, and thus it is widely believed that there is a universal tradeoff between fairness and efficiency. However, networks exist in which increasing the fairness actually increases the efficiency (11). This and other interesting and counter-intuitive phenomena develop only in a network setting where sources interact through shared links in intricate and surprising ways.

2) Stochastic network dynamics: The number of flows sharing a network is continually changing, as new application sessions start, and others finish. Furthermore, packet accumulations at each router is shaped by events in all upstream routers and links, and packet arrivals in each session are shaped by the application layer protocols, including those in emerging multimedia and content distribution protocols. Although it is easy to study the effects of this variation by measuring either real or simulated networks, it is much harder to capture these effects in theoretical models. Although the deterministic models studied to date have been very fruitful in providing fundamental understanding of issues such as fairness, there is an increasing interest in extending the theoretical models to capture the stochastic dynamics occurring in real networks.

As an example of one type of these dynamics, consider a simple case of one long flow using the entire capacity of a given link, and another short flow that starts up using the same link. If the short flow finishes before the long flow does, then the finish time of the long flow will be delayed by the size of the short flow divided by the link capacity, *independent* of the rate allocated to the short flow, provided that the sum of their rates is always the link capacity. In this case, it would be optimal to process the flows in "shortest remaining processing time first" (SRPT) order; that is, to allocate all rate to the short flow and meanwhile totally suspend the long flow. However, as the network does not know in advance that the short flow will finish first, it will instead seek to allocate rates fairly between the two flows. This can cause the number of simultaneous flows to be much larger than the minimum possible, resulting in each flow getting a lower average rate than necessary. The fundamental difficulty is that the optimal strategy is no longer to allocate instantaneous rates fairly based on the existing flows.

FURTHER READING

The transport layer is a main topic in many textbooks on computer networks, which is now a standard course in most universities. This article only seeks to provide a basic understanding of the transport layer. For those who are interested in digging into details and working in related areas, the following references are a useful starting point. For a complete introduction to computer networks including the transport layer, see any of the major networking textbooks such as Ref. 12. The Internet's main transport layer protocol, TCP, is described in detail in Ref. 13, although several details have evolved since that was written. For a general mathematical approach to understanding network layering, see a recent survey (14). Samples of early TCP congestion control analysis include Refs. 15–18. A survey on the mathematical treatment of Internet congestion control can be found in Ref. 19. Enduring issues are also well described in Ref. 20.

VIDEO CONFERENCING AND IP TELEPHONY

INTRODUCTION

In the early 1990s, computer processing power and networking connectivity had advanced enough to allow for the digitizing, compression, and transmission of audio and video. Communicating audio and video over traditional packet-switched networks, however, is harder than traditional data communications for several reasons. First, the amount of data required to transmit video and audio can be significantly higher than their traditional data counterparts. Second, the stream needs to be continuous over time, requiring that the resources be sufficiently allocated to allow for the continuity of the media being delivered. Third, for video conferencing and IP telephony, the end-to-end latency needs to be minimized. This latency includes the capture and compression of the audio and video, compression, transmission, and display on the remote side. Finally, because the data are being streamed, the variation in delay (i.e., jitter) needs to be minimized as well.

Through the 1990s, several efforts focused on standardizing the storage and transmission of digital media emerged. These standards covered a broad range of applications and network assumptions. For example, MPEG-1 was designed for the storage of VHS quality video onto a CD-ROM, whereas MPEG-2 was designed for high-definition digital video applications (1). Other standards such as H.261 and H.263 were designed to enable digital media over telephony-based networks (2). From an internetworking perspective, standards such as Session Initiation Protocol (SIP), H.320, and H.323 were defined to specify how connections for video conferencing and IP telephony were managed.

In the rest of this article, we will provide an overview of digital audio and video formats as well as a discussion of compression algorithms. We will then provide an overview of both video conferencing and IP telephony. Finally, we will summarize where these fields are moving to in the future.

DIGITAL MEDIA BACKGROUND

Sound

Sound is a variation in air pressure that the human ear can detect. The physical parameters of a sound wave involve its frequency and amplitude. The ability to detect such sound depends on the physiology of the ear. For example, humans can typically hear frequencies between 15 Hz and 20 kHz. Cats and dogs, on the other hand, can typically hear frequencies up to 40 or 60 kHz. Sound can be represented digitally through a sampled signal stream. The stream is determined by two primary factors: the sample depth (or the bits required to represent each sample) and the sampling frequency (samples per second). The goal of digitizing sound is to take samples at a rate high enough to capture the highest frequency needing to be represented and to use a large enough sampling depth in order to avoid significant sample distortion. According to Nyquist, the sampling rate needs to be twice the maximum frequency required. As humans are capable of hearing up to about 20 kHz, capturing all audio, a human can hear requires a sampling frequency of at least 40 kHz. For this reason, CD-audio uses a 44.1 kHz with a 16-bit per channel sample.

For computer and telephony applications that require audio, several standards can be used to represent the sound, including the International Telecommunications Union (ITU) G.711 standard and MPEG-audio (from the MPEG-1 audio and video codec). For IP telephony, the primary representation is the G.711 format. G.711 is an international ITU standard for representing sound for a 64-kbps channel. It is a pulse code modulation scheme that uses 8 bits per sample with a sampling frequency of 8 kHz. Thus, the speech signal is limited to a 4-kHz band. Two methods are used. A-law and μ-law differ slightly in their nonlinear transform used to encode the data into 8-bit samples. Both encoding mechanisms use a nonlinear, logarithmic, transform of the input sample space. As a result, the samples are spaced uniformly on a perceptual scale to represent the amplitude.

The compression of audio signals can take several forms. In the G.711 standard, the compression ratio from its samples is fixed to approximately 1.7 to 1. Additional compression algorithms have been developed for telephony applications. These applications include algorithms that perform silence suppression or take advantage of the limitation of human hearing by removing perceptually undetectable sound. In particular, the MPEG audio algorithms (e.g., MPEG audio layer 3, or MP3) remove perceptually undetectable sound and are applicable to a wider range of audio streams, including music.

Video

Digital video consists of a sequence of images, called frames. Digital video can be described by its (*1*) frame rate—the number of frames captured per second and (*2*) the resolution of the images in pixels. Unfortunately, high-quality video requires significant resources. For example, a VHS quality video stream of 352 × 240 pixels at 30 frames per second requires approximately 60 megabits per second to transmit over a network in uncompressed form. Digital video compression algorithms aim to reduce the required bit rate by a factor of 50 to 100.

Digital video compression algorithms take advantage of the redundancy within a frame and between frames of the video. Since the early 1990s, many different video compression algorithms have been developed such as H.261, H.263, Motion JPEG, MPEG-1, and MPEG-2. The ITU and the International Standards Organization (ISO) have standardized the H.26* and the MPEG formats, respectively. In addition, there are proprietary formats such as the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

RealVideo suite from Real Networks, Quicktime from Apple, and the Windows Media Encoding algorithm from Microsoft. For the rest of this article, we will focus on video compression techniques that have been primarily developed and used in video conferencing systems.

Video Compression Standards. Two primary groups are responsible for the development of standardized video compression formats: the ITU and the Motion Pictures Experts Group (MPEG). The ITU is responsible for many of the encoders and decoders (codecs) that are used in the H.320 and H.323 umbrella standards for video conferencing and IP telephony. The ITU group is responsible for the H.261, H.263, and H.264 standards, which we provide brief overviews of here.

- H.261 is a video coding standard for audio and video over multiples of 64 kilobit per second (kbps) channels. The standard, which was intended specifically for interactive video conferencing applications, supports two main resolutions. The Common Interchange Format (CIF) is defined as 352 × 288 pixel video, and quarter CIF (QCIF) is defined for 176 × 144 pixel video. H.261 is intended for communication channels that are multiples of 64 kilobits per second and is sometimes called *p*x64 where *p* runs from 1 to 30. The compression algorithm uses the discrete cosine transform (DCT) as its main compression algorithm. The DCT algorithm transforms small blocks (8 × 8 pixel in size) of the video into the frequency domain, allowing for greater compression efficiency. In H.261, there are two main types of pictures. (*1*) intracoded frames, which are independently coded; and (*2*) predictive coded frames, which are predicted from a previous frame. Finally, block-based motion compensation is used to reduce the bit rate for predictive coded frames.
- H.263 is a video coding format for audio and video that is considered the successor to the H.261 standard. It is similar in format to H.261 but provides better picture quality for the same bandwidth. It was originally intended for bandwidth as low as 20 kbps to 40 kbps but has been applied to larger bandwidth scenarios. It improves the image quality for a given bit rate through half-pixel motion compensation. It also supports additional pixel resolutions, including Sub-Quarter CIF (SQCIF) at 128 × 96 pixel video, 4CIF at 704 × 576 pixels, and 16CIF at 1408 × 1152 pixel resolution. Finally, it provides bidirectionally coded frames, called PB frames, which are similar to MPEG-style P and B frames that we will describe in the compression section.
- H.264 is a newer video compression algorithm from the ITU and MPEG groups. It provides even higher compression efficiency than the H.263 standard through several refinements. Many of these refinements are beyond the scope of this overview.

The MPEG group is a working group of the ISO and the International Electro-Technical Commission (IEC). They are responsible for the MPEG-1, MPEG-2, and MPEG-4 standards. An overview of each is described below.

- MPEG-1 is one of the first standardized video compression formats. In 1988, the Motion Pictures Expert Group gathered a group of companies to standardize the compression of VHS quality video for storage to CD-ROM. The standard, released in 1992, specified the compression of CIF quality video and audio into a 1.5-Mbps stream. As in the ITU video coding standards, the core MPEG algorithms are DCT-based. MPEG has three types of frames (*1*) I-frames that are independently coded frames using a technique similar to the JPEG compression algorithm; (*2*) P-frames that are predictive coded to a previous frame; and (*3*) B-frames that are coded with respect to both a previous and a future reference frame. Compression ratios in the range of 100:1 are possible using MPEG. As an aside, the popular MP3 format is the MPEG-1 Audio Layer-3 compression algorithm.
- MPEG-2 is intended for the compression of TV signals and other applications capable of 4 Mbps and higher data rates, which result in a very high-quality video stream. MPEG-2 is the algorithm that is typically used for DVD format video disks. The underlying algorithms between MPEG-1 and MPEG-2 are very similar. MPEG-2 provides several refinements to deal with the interlaced video signals found in television signals.
- MPEG-4 was originally intended for low-bit-rate applications. One such application is the streaming of video over wireless channels. Through its development, it became a compression format intended for video in general. It has numerous refinements over the previous MPEG formats. It also adds several new features such as primitive media objects that allow for the specification of virtually arbitrary objects, both natural and synthetic.

Fortunately, all of the above compression algorithms from the ISO and the ITU are DCT-based and are fairly similar in their basic structure. In the next section, we will describe a generic DCT-based video compression algorithm. Readers interested in the low-level details of a particular encoding algorithm are referred to the list of references at the end of the article.

A Generic Video Compression Algorithm. In this section, we will describe a basic DCT-based video compression algorithm. The purpose of this discussion is to give an overview of DCT-based video so that we can better describe the issues involved in delivering video over the Internet. We will describe a video compression algorithm that is most similar to the MPEG-1 video standard as it is the most "generic" of the standards above.

The two main areas that compression algorithms can take advantage of are redundancy within a single frame and the redundancy between nearby video frames. I-frames are independently coded video frames. They result in the largest size when compressed but are independently decodable. P-frames are predictive coded from a previous

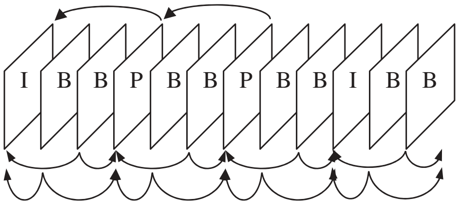

Figure 1. This figure shows the frame dependence and frame pattern that can be found in an MPEG-1 video stream.

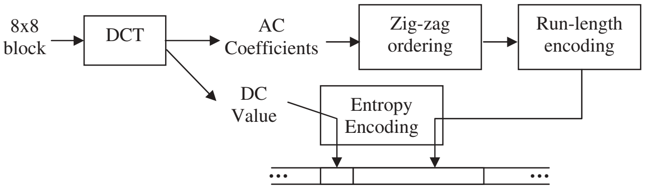

Figure 2. This figure shows the basic steps involve in the coding of each block within a single frame of video.

reference frame. This results in a frame that is considerably smaller than the I-frames but also requires a reference frame to be present in order for it to be decodable. Finally, B-frames are bidirectionally interpolated between two reference frames, one in the past and one in the future. This results in the smallest compressed frames but requires the most computation in order to decode it. The actual ordering of frames depends on the application. For MPEG-1, virtually any ordering of frame types is possible; however, repeated patterns are typically chosen. An example sequence, along with the frame dependence, is shown in Fig. 1.

Within a frame, the data are compressed in several steps. First, the pixels encoded in the red, green, blue (RGB) color space are first converted into the YUV color space, which represents the luminosity channel (grayscale) and two chrominance channels that add color. Next, the frame is split into 16 × 16 pixel regions called macroblocks. Each macroblock is then further subdivided into 8 × 8 blocks. The purpose of this is that the U and V channels are typically further subsampled because the human eye cannot discern small differences in the chrominance channels. In general, each 16 × 16 pixel U and V block is represented by one 8 × 8 pixel subsampled block, respectively. Once the frame is divided into its relevant blocks, the blocks are then compressed.

For each block within a macroblock, several additional steps are taken. An overview of the basic steps is shown in Fig. 2. Each block is transformed into the frequency domain through a DCT. The unique property of this transform is that areas of relatively constant color can be represented by only a few coefficients, rather than the 64 unique pixel values in the spatial domain. After the DCT transform, the DC value (or average value) for the entire block is in the upper left-hand corner. The rest of the coefficients are called the AC coefficients. If all coefficients are 0, then this means the entire block can be represented by a solid 8 × 8 block of a single value. The coefficients are then quantized. Quantization accomplishes two main functions. First, it converts the floating point values back into integers. Second, it reduces the number of nonzero coefficients that need to be represented by dividing each coefficient by a predefined table look-up and a user-defined quantization value. Finally, the coefficients are zigzag ordered, run-length encoded, and then entropy encoded (typically Huffman encoding). The steps for the last part of the compression are shown in Fig. 3.

For coding P- and B-frames, each macroblock has an additional block-based motion compensation algorithm applied to it. The goal of the motion compensation algorithm is to find an area within the reference frame that is the closest match to it. Although a pixel by pixel comparison within the reference frames might be computationally prohibitive, several heuristics have been proposed and put to use that make finding reasonably close matches fairly quick. These heuristics include performing sampled searches and limiting the area that the reference frame is searched for a match. For the P-frames, the previous reference frame (either an I- or P-frame) is searched for the match. The closest match is then used as a prediction for the blocks to be encoded. The goal is to have a prediction that requires very little correction, which results in many coefficients in the transform to be close to 0. For the B-frames, both the previous reference frame and a future reference frame are used to find a match. Furthermore, the B-frame allows for the forward and reverse matches to be interpolated in order to predict the block to be encoded. Clearly, B-frames require the buffering of several frames in order

Entropy Encoding

Figure 3. This figure shows the basic process of quantization and run-length encoding. Coefficients in the upper left are quantized with larger values. For the run-length encoding, the run represents the number of zeros until the next coefficient.

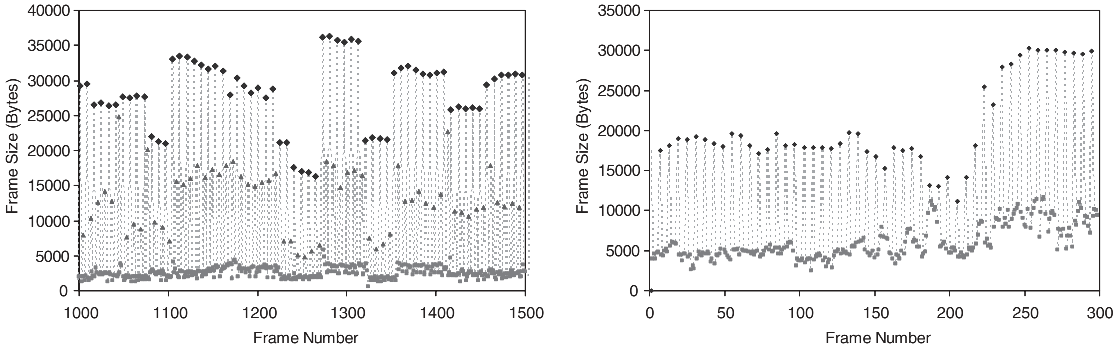

Figure 4. This figure shows the result of compression of video into MPEG and H.263. On the left, in MPEG, there are three distinct frame types (I-frames are diamonds, P-frames are triangles, B-frames are squares). On the right is an H.263 sequence with I-and P-frames (P being smaller in size).

for the forward reference frame to appear at the encoder. This additional delay may not be acceptable for some low-latency applications.

Because the compressed stream is heavily dependent on the data, the actual compressed frame sizes tend to vary considerably over time. As a result, this variability can cause strain on the network that needs to deliver each *frame* of video with low latency as well as fairly constant delay jitter. As an example, we have graphed the result of applying MPEG compression to a sequence of frames. They are shown in Fig. 4 for a constant quality compressed video stream. We will describe the impact of the video requirements later in the chapter.

Basic Multimedia Transport

There are several ways in which video conferencing and IP telephony data can be transmitted between two points. Transmitting data over a telecommunications channel (e.g., ISDN or the plain analog telephone network) is relatively simple, requiring that the application allocate as many channels as necessary. As the network is circuit switched, transmitting data over such networks is relatively easy and has guaranteed service. The main disadvantage of using the telephony network is the high cost associated with using such a service. The alternative to this is to use a data network such as the Internet to transfer the session.

The primary transport mechanisms that are in use for the Internet are the Transmission Control Protocol (TCP) or the User Datagram Protocol (UDP) over the Internet Protocol (IP). TCP provides a congestion-controlled (network-friendly) delivery service that is reliable. Thus, nearly all data traffic such as Web traffic or file transfers occur over the TCP protocol. There are two main disadvantages of using TCP for video conferencing and telephony networks. First, because TCP attempts to fairly share network bandwidth while maximizing throughput, the bandwidth from the application perspective is bursty over time. Second, TCP is a reliable transport protocol. When the network drops a packet because of congestion, an application-layer delay will be induced because TCP will retransmit the lost data. UDP is a lighter weight protocol that simply transmits packets. Whether the packet arrives at the receiving side is left up to the application layer to manage. For video conferencing and IP telephony, this has several implications. First, lost data may impact the ability to display or play-back the data being transmitted. Upon the loss of a packet within a compressed video stream, the application will not be able to display the frame or frames that were in the packet. Furthermore, all other packets will need to be discarded until the application can find an area within the stream to resynchronize itself with the video stream (e.g., the start of new frame). Second, UDP is not sensitive to the load within the network. As a result, it may overrun the network with data. For IP telephony applications, this may not be that large a concern as the data rate for IP telephony is relatively small. For video conferencing, this becomes a larger concern.

For managing the real-time nature of audio and video, the Real-time Transport Protocol (RTP) and the Real-time Transport Control Protocol (RTCP) can be used. Typically, these protocols are used in tandem to deliver streaming data over the best-effort Internet. RTCP is the control part of the protocol that provides feedback information to the applications. For example, it provides feedback on the quality of the data delivered such as packet loss or network jitter. In addition, it provides for intrastream synchronization. RTP is the transport mechanism for real-time data that is typically built on top of the UDP/IP protocols. It provides primitive network information to the application such as sequencing of packets and time-stamps for media synchronization.

MULTIMEDIA CONFERENCING AND TELEPHONY SESSION MANAGEMENT

For interactive conferencing and telephony, there are two primary protocols that are in use for data networks: H.323 and the SIP.

H.323

H.323 is an ITU standard for packet-based multimedia communications that was released in 1996. It is, perhaps, the most widely deployed protocol for video conferencing and IP telephony. The H.323 protocol is used for several interactive applications, including the popular Polycom and Microsoft NetMeeting products. H.323 encompasses several standards, some of which are mandatory in H.323 implementations and others that are optional. For video conferencing and telephony, H.323 must implement H.261 and G.711, for video and audio, respectively. Other standards such as H.263 are optional. H.323 defines several entities that can participate in interactive conferencing and telephony. They are as follows:

- Terminals—Terminals are the end devices that the users use. These devices include telephones, video phones, PCs running video conferencing software, and voice mail systems.
- Multipoint Control Units—Multipoint control units (MCUs) are used to manage multiway video and audio conferences. For video conferencing applications, MCUs take the individual incoming videos from the participants and mix the streams together to create a mosaic of the videos. As a result, MCUs add delay to the video conference and are expensive because of the hardware cost necessary to mix video in real time. MCUs are, however, necessary for low-latency multiway video conferencing.
- Gateways—Gateways are used to allow H.323-compliant systems to interact with other systems. For example, a gateway can be used to cross between H.323- and SIP-based communications. Additionally, they can be used to bridge between an H.323-based network and the regular voice telephony network.
- Gatekeepers—Gatekeepers, although not necessary to use H.323, can act as a manager for H.323 sessions. They can provide address translation from local addresses to IP addresses. Gatekeepers can also perform bandwidth management, authentication, and billing.

For the actual transmission of data, H.323 specifies several standards for the encoding of audio, video, and data. As mentioned, H.323 requires the support of H.261 streams for video and G.711 for audio. In addition, there are many optional components such as having H.263 as a video codec. In more recent versions of H.323, support for H.264 video streams has been added.

Session Initiation Protocol

The SIP is a protocol standardized by the Internet Engineering Task Force (IETF) for the transmission of teleconferencing and multimedia communications over the Internet. SIP was introduced in 1999 in IETF RFC 2543 and later updated in 2002 in IETF RFC 3261 (3). SIP, like H.323, is an umbrella protocol that provides the signaling necessary to bring video, audio, and data communications together for interactive applications (4). SIP is more open in that it does not require any particular media compression format to be implemented. As a result, its use may include other interactive applications beyond audio and video. Its main functions include the negotiation and initiation of sessions between two endpoints as well as connection maintenance and termination. SIP is a text-based protocol allowing for simple debugging and easier interoperability.

SIP is a peer-to-peer architecture, where the endpoints are called user agents. The endpoints can be SIP-enabled telephones or PCs. Gateways can also be used to provide translation between various entities (e.g., format translation or between different types of networks).

MANAGING THE DATA IN VIDEO CONFERENCING AND TELEPHONY

In the rest of this article, we briefly describe some issues with managing the actual compressed data within video conferencing and telephony applications.

Voice Over IP

Although voice can be represented with relatively few bytes when compared with video, it is still possible to reduce the amount of data required to transmit voice over IP further. The Algebraic Code Excited Linear Prediction (ACELP) algorithm can be used to further compress the audio. This has been specified in the G.723.1 standard. Other techniques involve silence suppression, which has been applied in the regular telephony network.

Sending voice over IP requires the management of two key parameters: end-to-end delay and delay jitter. Both of these parameters can impact the ability of two users to interactively carry on a conversation. End-to-end delay is the amount of delay required for the actual transmission of bits across the network (including all queuing delay within the routers of the network). Typically, the delay is correlated to the number of routers that the packets must go through. Overcoming network delay that causes unacceptable application-layer performance requires dedicated network lines, which is typically an expensive operation. Fortunately, the delay within the Internet is typically not that large.

Delay jitter, or the variation in end-to-end delay, is more problematic to handle in general. Buffering can be used to mitigate delay jitter. Unfortunately, the variation in delay continues to vary over time. Tuning the buffer delay to handle the maximum delay jitter will cause unnecessary delay at the other times. Tuning the buffer delay to something too small, however, will cause excessive packet loss and drops in the audio. Techniques like queue management can be used to actively adapt the amount of buffering at the client to mitigate the effects of delay jitter for audio applications (5).

Video Conferencing Over IP

As mentioned, delivering compressed video over packet-switched networks is even more complicated than delivering voice over IP because of (*1*) the variability in frame sizes from the compression algorithms, (*2*) the larger size of the video relative to the audio channel, and (*3*) the variability in both network delay and delay jitter. In the remainder of this section, we will briefly highlight some mechanisms that one can use to deliver high-quality video over the Internet.

Depending on the choice of frame types that are used, a small amount of buffering can be used to smooth the video stream a little so that the extra bandwidth required to deliver I-frames can be amortized across several smaller predictive coded frames. Unfortunately, such smoothing is very sensitive to delay as each frame that is buffered requires an additional one thirtieth of a second. This is partially why there is a noticeable delay in most video conferencing applications.

In addition to buffering of data for video, one can employ techniques that actively manage the video data itself by adapting the video to the underlying network resources. Adaptation can happen either at encode time, where the video codec estimates the available network bandwidth and codes for it, or can be at transmission time, where the sender of the video can drop some data in order to make it fit within the available network resources. For the former, the network bandwidth needs to be actively monitored in order to provide feedback to the encoder. The encoder, in turn, can adjust the quantization value, which forces more coefficients to zero, making the video stream smaller. The net effect, however, is that the quality of the video will be lower. For senders that code the video and drop data in order make it fit within the available network bandwidth, typically layered encoders are used. Standards such as MPEG-2, MPEG-4, and H.264 have been designed to allow for fine-grain scalability on-the-fly. Layered encoders work by encoding the video stream into multiple layers consisting of a “base-layer” and “enhancement layers.” Sending a higher priority “base-layer” that encodes a basic quality video stream first allows a minimum quality of video delivered to the client. The delivery of each enhancement layer after that will gradually continue to raise the quality of the video. Typically, most encoders use no more than four layers.

To support layered transmission, encoders use one of two mechanisms. First, the encoder can use a lower pixel resolution as a base layer and as an enhancement layer, which provides more details that raise the quality of the video. Second, the encoder can split the coefficients between the various layers. For example, the encoder can encode the lowered numbered coefficients in the zigzag ordering in one layer and have the enhancement layer with the remaining coefficients. Thus, the enhancement layer adds the higher frequency details to the image. Finally, the encoder can encode all the higher order bits of the coefficients into the base layer. Each enhancement layer can then add more of the lower order bits in succession. Obviously, using enhancement layers will reduce the coding efficiency of the compression algorithm but, nevertheless, make them more flexible for network adaptation.

Even with buffering and layered coding, it is entirely plausible that packets will be dropped within the network. Removing data from a compressed stream can cause significant artifacts within the display, particularly if data are lost in a reference frame on which other frames will depend. In such an event, error correction techniques can be applied. Several such techniques can be used. First, the frame that has any data lost can just not be displayed. Second, for macroblocks that are lost, the macroblocks from the previous frame can be reused. Third, one can use the previous motion vector to offset a previous macroblock into the new frame. Finally, one could interpolate the data from nearby regions within the current frame. Error recovery techniques, however, are not a replacement for streaming and adaptation algorithms.

WIDE-AREA NETWORKS

INTRODUCTION

Wide-area networks (WANs) can be defined roughly as the computer networks that cover a broad geographical area. These networks may be considered as the opposite of local-area networks (LANs) and metropolitan-area networks (MANs). LANs refers to the networks within a single office, building, or campus, wheres MANs refers to the networks within a single metropolitan area.

Although no specific boundary definition distinguishes MANs from WANs, in the real world a WAN usually covers multiple locations in a country or, in many cases, in multiple countries. WANs are usually used to connect LANs and MANs in different locations. The most typical WAN is the Internet. Another example would be an intranet for a large enterprise that has multiple geographically distributed branches.

The size difference between WANs and LANs/MANs necessitates some fundamental differences in both the network hardware and software. Communications over a WAN travel much longer distances, and, although it is not necessarily true, usually many more hosts and pieces of network equipment comprise WANs. WANs need to use switches and, more importantly, routers to connect different LANs and other networks. In contrast, LANs usually do not need routers. Furthermore, the networks and networking equipment in a WAN can all belong to different organizations; thus, stricter policies may be applied in a WAN.

WANs, like other networks, are usually organized in a layered architecture so that technology changes in one layer will not affect functionalities of other layers. For example, a transport protocol, such as TCP, can work on top of many different physical networks.

In the rest of this article, we will describe WANs in detail for each layer in the five-layer TCP/IP reference model. Brief background knowledge is introduced first.

BACKGROUND

TCP/IP Model

The TCP/IP network reference model, also known as the Internet reference model, is a depiction of the layered model used in the current Internet. Another well-known model is the OSI reference model, which is also a layered architecture, but the OSI model has two additional layers that do not exist in the current Internet.

The TCP/IP model has five layers (Fig. 1). From bottom to top they are the physical layer, data-link layer, network layer, transport layer, and application layer. In network terms, they are also called Layer 1 to Layer 5, respectively.

The physical layer takes care of the encoding and decoding of signals (bits) that represent the data passed down from the upper layers. This layer is responsible for moving the data along the physical network wires and equipment.

The data-link layer transmits packets, or a group of bits, between two hosts. Data are packed by using different schemes, such as Ethernet (1) or ATM (asynchronous transfer mode) (2). Switches work in this layer so that packets can be transferred to different network segments.

The first two layers are often mixed together. Examples of hardware/protocols working in these two layers include Ethernet, SONET (synchronous optical networking), Wi-Fi (3), PPP (point-to-point protocol) (4), and so on. Ethernet and SONET are usually used for high-speed networks, WiFi is used for wireless networks, and PPP is used for home dial-up networks or DSL (digital subscriber line).

The network layer addresses two issues: addressing and routing. In other words, hosts and certain pieces of network equipment are assigned a unique network address; then packets can be routed to a certain destination. Routing allows the network to be extended to a much broader area. Protocols in this layer include communication protocols such as IP (Internet protocol) (5); routing protocols such as OSPF (open shortest path first) (6), IS–IS (intermediate system to intermediate system) (7), and BGP (border gateway protocol) (8); and address-resolution protocols such as ARP (address resolution protocol) (9).

The transport layer is responsible for transferring application data on an end-to-end basis. It provides direct support for application-data transfer. Congestion control is one of the most important schemes in the layers. It allows all connections to coexist and to realize their fair and efficient share of the network bandwidth. The two core transport protocols are TCP (transmission control protocol) (10) and UDP (user datagram protocol) (11); over 90% of the Internet traffic is carried by TCP.

Finally, applications such as worldwide web (WWW), file transfer protocol (FTP), and e-mail work in the application layer. Applications define their own specific protocols and send data using the transport protocols.

At the sender side, applications pass their data down to each lower layer, which adds their own packet header in front of each packet. The data eventually is transmitted to the receiver side via the physical link. At the receiver side, the data packet is passed up, and each layer interprets and removes the proper packet headers.

End-to-End Principle

Another principle that plays a significant role in the Internet design is the end-to-end (E2E) principle (12). It has been applied to the Internet design since the early 1980s. The E2E principle argued that systems tend to require end-to-end processing to operate correctly, in addition to any processing in the intermediate system. It pointed out that most features in the lowest level of a communications system have costs for all higher-layer clients, even if those clients do not need the features, and are redundant if the clients have to reimplement the features on an end-to-end

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

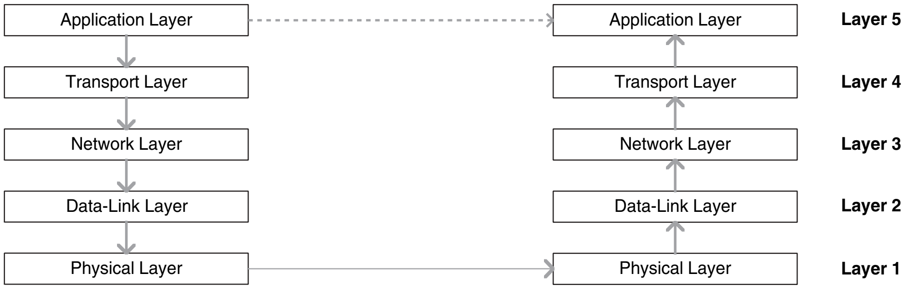

Figure 1. TCP/IP-layered model.

basis. As a result, the Internet can be described as a "dumb, minimal" network with smart terminals.

For example, IP is a very simple protocol that transmits packets only with best-effort delivery, whereas TCP adds reliability control, flow control, and congestion control to the data transfer. All of these schemes are done at the end host.

In addition to the layered architecture and E2E principle, more Internet design guidelines can be found in Ref. 13.

Standardization

For network equipment and software to communicate with each other, the network hardware and software must follow the same standard, usually called a protocol in network terms. Most protocols are formed by two organizations. IEEE (Institute of Electrical and Electronics Engineers) focuses on lower layers (physical and data-link layer), whereas IETF (Internet Engineering Task Force) focuses on network, transport, and application layers. IETF publishes Internet standards as RFCs (Request for Comment). Other standardization committees include ITU (International Telecommunication Union) and ANSI (American National Standards Institute).

INFRASTRUCTURE (LAYER 1/2)

The bottom two layers set up the infrastructure of a computer network. In the real world, they are often treated together as one single layer.

Today, WANs use optical fiber as the major physical signal transfer media. Fiber is less expensive and provides much faster speed (compared with traditional media such as copper). The Internet2 (a WAN that connects most educational institutes in United States) just realized 100 gigabits per second (Gb/s) backbone transfer speed.

Fiber/WDM

Optical fiber is the major physical media used in WANs. The light signal is reflected by the cladding layer outside the fiber core until it reaches the other end (Fig. 2).

The reflection of light within the fiber core is affected by the diameter of the core. The larger the core is, the more reflections are needed for the light to pass through. Fiber with a significant larger core (compared with wavelength) is called multimode fiber; the light may have many different paths because of the input angle.

However, if the core is thin enough (the diameter is less than 10 times that of the wavelength), the above geometric analysis cannot be used, but electromagnetic analysis is in effect. In this case, the light can traverse only one mode in the fiber. Such fibers are called single-mode fibers.

Single-mode fiber is better in conserving the light power and thus can pass the light through a greater length. However, it is also more expensive to make. Overall, fibers are cheaper than traditional media, such as copper, and can transmit signals much farther without the use of relay equipment. For example, 1 Gb/s (1 gigabit = 1,000,000,000 bits) Ethernet copper cable can only extend to 100 meters, whereas 1 Gb/s Ethernet single-mode fiber can extend to 6000 meters.

Signals transmitted in the fiber can be differentiated by the different wavelengths of the light. Therefore, a single fiber can be used to carry multiple signals at the same time. This use is called wavelength-division multiplexing (WDM). WDM significantly increases the capacity of a single fiber. Greater capacity increasing can be done by simply upgrading the WDM equipment at the end of the fiber.

Dense wavelength-division multiplexing, or DWDM, is common today. DWDM can support wavelengths that are closer to each other, thus it supports more data channels. For example, some DWDM equipment can support up to 160 channels (which means up to 160 separate connections can be supported by a single fiber).

Note that computers and switches do not recognize optical signals directly yet. (All-optic switches are in experimental stage.) Light signals have to be converted to electronic signals for processing, which limits the network speed. Currently 100 Gb/s is being deployed, whereas 10 Gb/s is becoming common in WANs.

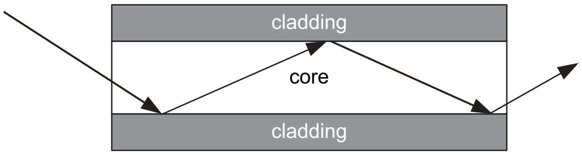

Figure 2. Light passing through optical fiber.

Tiers of Network

A natural question is: Who owns the fiber around the world? Although fiber is a relatively inexpensive solution for a WAN, it is still beyond the financial ability of most single organizations (business or government) to deploy fibers over a wide area. Because WANs usually span international borders, not only economical but also political issues are involved.

In the real world, the hardware infrastructure of WANs is actually maintained in a "tier" hierarchical structure (Fig. 3). The most powerful stakeholders use each other's network by a reciprocal agreement. More precisely, this agreement is a settlement-free peering agreement. The networks owned by such organizations are called Tier 1 networks. Traffic from one Tier 1 network can pass through another Tier 1 network without paying any fee. In return, it allows traffic from other Tier 1 networks to pass through for free. Obviously, not many Tier 1 networks exist in the world. Other smaller and less-powerful networks that own a segment of the network but have to pay some Tier 1 networks to pass their traffic are called Tier 2 networks. Both Tier 1 and Tier 2 networks are usually by large national or international networking companies. In fact, Tier 2 networks may purchase services from multiple Tier 1 networks, and it is possible that some Tier 2 networks are larger than some Tier 1 networks.

Similarly, if a network is operated by solely purchasing services from either Tier 1 or Tier 2 networks, without any settlement-free peering, then it is called a Tier 3 network. Typical Tier 3 networks are those local ISPs (Internet service providers, e.g., DSL, cable, or campus network) that cover a small community.

In network terms, each region in Fig. 3 is also called an autonomous system (AS), defined as a collection of IP networks and routers under the control of one entity.

Switch and VLAN

Above the physical fiber, switches work at Layer 2, and they forward packets to destinations according to the physical MAC (media access control) address.

Note that sometimes the term "switch" is used to name interconnection devices in other layers, too. However, such devices working at Layer 1 are usually called hubs and Layer 3 switches are usually called routers to differentiate them from Layer 2 switches. Hubs, switches, and routers have different functionalities as they work at different layers. In this article, we use the term "switch" only for Layer 2 interconnecting devices.

A switch learns the MAC addresses of those switches and hosts that connect to it and forwards the packets to the destination with the specified MAC address. This method is not a scalable because as the MAC-address table of a switch is limited in size. For the same reason, switches are usually only used in LANs.

In technical terms, a Layer 2 switch covers a broadcast domain. Each switch is capable of broadcasting a packet to every connected switch or host. When the packet reaches a switch, it checks the hardware address (MAC) and either forwards the packet or drops it (if no MAC address is associated with the switch).

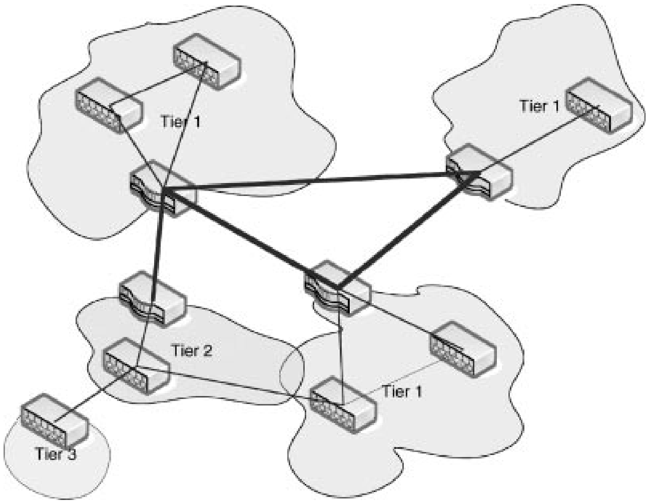

Figure 3. Tier hierarchy of the Internet.

However, the forwarding scheme described above can cause an infinite loop if the switches are connected in a loop. The problem is solved using the spanning tree protocol (STP) (14). STP forms a logical tree structure among all connected switches to avoid loops in the forward path.

An important technology called virtual LAN, or VLAN, allows networks to expand to wide area and to form a WAN by using only switches. VLAN allows multiple network segments to be grouped together even if they are physically located in different places and belong to different LANs.

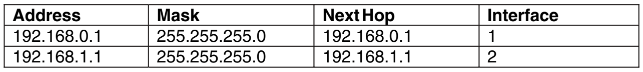
Originally VLANs were created to separate a physically connected network into several independent logical networks to help management and security. For example, the LAN in a campus can be separated into VLANs for different departments (even though offices of the same department may not be physically located together). Without a VLAN, this separation has to be done by routers, with additional cost and performance overhead. This purpose remains the major purpose of the VLAN today.

Although it is possible to use VLAN to construct a WAN, such WANs are small ones and usually only used as an Intranet for a single organization. Wide-area VLANs are usually used inside a single organization to extend the logical network to their branches located in different places. For general public WANs, routers are used for much greater flexibility and scalability.

IP AND ROUTING (LAYER 3)

Routers are usually used to interconnect network segments to construct a WAN, such as the Internet. Whereas Layer 2 switches use a physical address (MAC) to match the destination by broadcasting the message to all adjacent switches or hosts, routers, which are sometimes called Layer 3 switches, use an IP address to locate a single path to the destination by looking up a routing table that is updated by routing protocols.

IP addresses are assigned hierarchically to each organization and its subdepartments; thus, the router knows



Address	Mask	Next Hop	Interface
192.168.0.1	255.255.255.0	192.168.0.1	1
192.168.1.1	255.255.255.0	192.168.1.1	2

Figure 4. Routing table.

that all packets with destinations within a specific IP range can be forwarded to the same next hop. Otherwise the router would need to maintain too many entries for it to handle. Currently, version 4 of IP uses 32-bit addresses, which are usually represented by four numbers between 0 and 255 (*a.b.c.d*). For example, a university uses IP address 192.168.X.X, where X can be any number between 0 and 255. The math department uses 192.168.0.X, the English department uses 192.168.1.X, and so on. For more information about IP addressing, see Ref. 15.

To route a packet, each router maintains a routing table that tells the next hop of a packet which destination falls into a specific IP range. When a packet comes in, it checks the destination address against each entry in the routing table (Fig. 4).

For example, in Fig. 4, all packets sent to the math department 192.168.0.X (192.168.0.1 masked by 255.255.255.0, results which in 192.168.0.X) will be sent to the router in math department 192.168.0.1 via the physical router interface 1.

The algorithm used to update the routing table is called a routing algorithm. Two kinds routing algorithms occur: distance-vector protocol and linked-state protocol. In distance-vector algorithms, each link/hop is assigned a cost. The algorithm computes a route of hops with the smallest sum of cost based on the Bellman–Ford algorithm (16). Each router periodically sends its routing cost information to all of its neighbors; thus, its neighbors can update the routing table according to the new cost information.

In link-state algorithms, each router broadcasts to the whole network its own connectivity information. Thus each node will obtain the map information (a graph) of the whole network. The routing table can be computed from the graph by finding the shortest path, for example, using Dijkstra's algorithm (17).

Because the Internet is organized through many autonomous systems (AS) (Fig. 3), intra-AS and inter-AS routing have different requirements and limitations. Interior gateway protocols (IGPs) are used inside an autonomous system, whereas exterior gateway protocols (EGPs) are used between autonomous systems. Roughly speaking, IGP seeks to optimize a complete autonomous system; thus, its coverage is limited because of the limitation of computation power on the router and the number of messages generated by the protocol. In contrast, EGPs work on only representative nodes from each autonomous system.

Today, the most common routing algorithms are OSPF, IS–IS, and BDP. Both OSPF and IS–IS are link-state algorithms, and both belong to IGP. In contrast, BGP uses a distance-vector algorithm, and it belongs to EGP.

TRANSPORT PROTOCOL (LAYER 4)

Transport protocols provide end-to-end data-transfer service for the applications. They provide data-transfer functionality to applications without knowing the intermediate routers and switches, which are taken care of by Layer 3 and Layer 2, respectively. Transport protocols can be described by the following characteristics:

Connection-oriented or connection-less. Certain transport protocols need to set up a virtual circuit for data transfer between two end hosts. The existence of the connection allows easier control of reliability, security, and traffic. In contrast, some other protocols do not set up a connection, and an end-host entity can send a message to any destination at any time.

Streaming or messaging. Transport protocols also differ at the semantics of data delivery. Some protocols treat the application data as an infinite stream, and the receiver side can read at any length. The other class of protocols, namely messaging, conserves the boundary of each application buffer, and the receiver side will be able to retrieve the original buffer one at a time.

Reliability. Data can be delivered either completely intact or simply in a best-effort manner. Some protocols allows user-defined partial reliability. In this mode, only the data that can be delivered within a specified time are guaranteed full reliability; otherwise, it will be discarded. Note that when data is not delivered reliably, the application messages can be delivered out of order.

Congestion control. Transport protocols usually work on shared networks; therefore, they need to adjust the data sending rate to realize fairness and efficiency of the network bandwidth usage. Different protocols may use different congestion-control algorithms, whereas some protocols do not have any congestion control at all. Recall that transport protocols work in an end-to-end manner, and no single point in the network coordinates traffic from different flows (i.e., flows do not know the existence of each other). This agreements makes congestion control probably the most difficult part in developing transport protocols.

TCP and UDP

TCP and user datagram protocol (UDP) are the two core protocols of the transport layer. Over 90% of Internet traffic is carried by TCP because it is reliable and because it has a congestion-control scheme to use the network efficiently and stably. UDP is used in a certain area only when reliability is not required or when applications have their own reliability control.

TCP is the *de facto* transport protocol on the Internet. It is a connection-oriented, reliable, streaming protocol. TCP is used for WWW/HTTP, e-mail, FTP, and many other Internet applications.

For TCP, a connection needs to be established between two nodes before the data transfer. The user buffers are packed into segments (packets). The receiver sends back acknowledgments for received packets. A loss report is sent back to the sender if packet loss is detected, thus the sender will retransmit the lost packets. In addition, a retransmission timer is used in case no acknowledgments or loss reports are received. In this way, TCP guarantees data reliability. However, TCP does not keep the boundaries of the application buffers (i.e., TCP works in data-streaming mode).

TCP has two important schemes to maintain the stability of the network. Flow control is used to avoid overwhelming packets to overrun the receiver. The receiver acknowledges the flow window size (the available space for incoming data) so that the sender will never send more data than the flow window size.

Whereas flow control is used to maintain the stability of end hosts, congestion control is used to maintain the stability of the complete network. Basically, TCP starts sending data at a low initial rate and slowly increases the sending rate if no packet loss is detected. However, once a packet loss happens, TCP will halve the sending rate and increases again. This scheme is the AIMD (additive increasing multiplicative decreasing) scheme used in TCP congestion control.

Figure 5 depicts the change in sending rate of a single TCP flow. The algorithm had been working fine until recently when the inexpensive optical fiber greatly increased the network bandwidth. The recovery time after a packet loss (during which time the sending rate increases from the lowest point to the highest) depends on the bandwidth-delay product (BDP), which can be very large in WANs (e.g., 10Gb/s network between NYC and Tokyo with more than 200ms round-trip delay). Thus, TCP does not work well on such networks. New TCP algorithms are being investigated, including HighSpeed TCP (18), CUBIC TCP (19), and Compound TCP (20), just to name a few.

UDP is a connectionless, unreliable, messaging protocol. Applications can send data to any destination without setting up a connection. This feature allows UDP to send data simultaneously to multiple destinations, which is described by the term “multicast,” in contrast to the “unicast” mode in which data has a single determined destination. However, multicast in WANs is often limited or blocked by routers to avoid data flooding.

Although data transferred over UDP is unreliable, sometimes it is a desirable feature because reliability requires additional mechanisms such as acknowledging, which leads to additional delay in data transfer. Some applications, like streaming media, can tolerate limited packet loss, but cannot tolerate long delays. Finally, messages transferred over UDP can be conserved so that the receiving side knows the boundaries between messages. Applications will be able to read a whole message each time, which is a convenient feature.

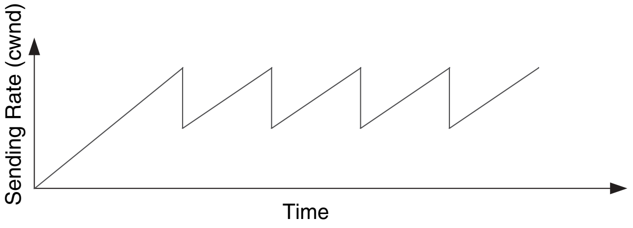


Figure 5. AIMD.

New Transport Protocols

The core transport protocols were designed for general purposes, and both TCP and UDP have been working for several decades. The rapid growth of the Internet has enabled a wide variety of applications (although, it can also be argued that these emerging applications stimulate the Internet expansion), and it is not shocking that neither TCP nor UDP may fit the requirements of some new applications. Therefore, recently several new transport protocols have been proposed.

The datagram congestion control protocol (DCCP) is a message-oriented protocol (21). DCCP can be regarded as a somewhat-enhanced version of UDP. In contrast to UDP, DCCP applies congestion control on the unreliable messaging delivery. Various congestion-control schemes are deployed in DCCP. However, the new feature comes with a cost; DCCP requires connection setup, and hence multicast is not supported, which means that it cannot replace the connection-less UDP. DCCP is designed for certain applications such as streaming media and Internet telephony, which require timed delivery of each message.

Whereas DCCP is somewhat related to UDP, SCTP (stream control transmission protocol) (22) can be compared with TCP. SCTP provides reliable message streaming, instead of the byte streaming of TCP. That is, SCTP is a messaging protocol. In addition, SCTP also supports parallel streams in one single connection. These streams can deliver message independently so that packet loss in one stream will not block others. (In TCP, when packet loss occurs, subsequent data cannot be delivered until the packet loss is recovered.) Furthermore, SCTP also supports multi-homing, and one SCTP socket can be bound to multiple IP addresses of the end which hosts, which enables transparent failover between redundant network paths. Finally, transport protocols can also be built at the application layer on top of UDP. UDT (UDP-based data transfer protocol) (23) is such an example. UDT is a high-speed data-transfer protocol that targets a fair and efficient usage of high-speed long-distance links, a situation that applies to many WANs today. UDT solves TCP’s efficiency problems described in Fig. 5. In addition, because it is at the application level, it does not require changes in operating systems to get deployed.

APPLICATION (LAYER 5)

The application layer hosts most of the Internet applications, including WWW, e-mail, FTP, Telnet, SSH, streaming multimedia, and so forth.

Applications define their own protocols, pack the application data, and pass it into lower layers. Each layer below adds their own packet header and eventually delivers the data at the physical layer (see Fig. 1). At the other end, the data is passed from the lower layers to the upper layers, and each layer's own packet header is removed. The application will receive the data and interpret it according to the application-specific protocol.

Applications on WANs often differ from those usually running in LANs. In addition, WAN applications are usually more difficult to write because WANs are less reliable, are less predictable, and have less available bandwidth.

For example, it is fairly easy to move a 1 Gb file between two hosts in the same LAN, but it may take days to move the same file between Asia and America. Actually, certain applications address such file-transfer problems in WANs. Content distribution network (CDN) (24) is an example.

For similar reasons, other applications that work well in LANs, such as database systems (DBMS), may not have good performance over WANs.

WWW

We describe the most popular application, WWW, as an example of Internet applications. A user usually types a URL into the web browser to go to a website. The URL is translated into IP address by another application-layer service called domain name system or DNS (25). DNS is a hierarchical service that translates domain names (URL) into IP addresses (recall that IP addresses are also assigned to organizations in a hierarchical manner).

After the web browser obtains the IP address of the web server, it sets up a TCP connection to the web server listening on the IP address. The subsequent process is interpreted by HTTP (hypertext transfer protocol) (26).

The web browser first will send out an HTTP request message to the server for a specific page. The server then responds to the request by either sending the requested page back or sending error information (e.g., 404 Page Not Found). Web pages are special text documents written in HTML, or hypertext markup language (27).

After successfully receiving the web page, the browser will parse the HTML web page and render the page within the browser display. The HTML page may contain non-HTML components, such as a flash movie. The web browser will locate the proper local programs to run the components.

Web pages also contain forms and allow uses to submit/upload information. The web browser will send a "PUT" request to the server to upload the user's input. The web server will then process the input and return the result, if necessary.

WWW has evolved considerably since its birth in the early 1980s. Today it has grown far beyond the simple static web page of text. It now serves as a platform for a broad range of complicated applications such as e-commerce, social networking, search engine, online video, and so forth. In recent years, an informal term, Web 2.0, is being used to represent a set of emerging Internet and WWW-based applications that aim to facilitate creativity, collaboration, and sharing between users. Examples of Web 2.0 applications include blogs, wikis, and online communities.

CONCLUDING REMARKS

We have briefly described wide-area networks from the perspective of each layer in the TCP/IP model. In the last four decades or so, computer networks have expanded from a small network with just several nodes connected by 2.4 Kb/s to today's Internet with billions of nodes and backbone speed now at a 100 Gb/s level.

WANs will continue to evolve rapidly, and new transport media, switches, network protocols, and, in particular, applications, will emerge.

WIMAX NETWORKS

IEEE Std 802.16-2004 or Worldwide Interoperability for Microwave Access (WiMAX), is a broadband wireless system that offers packet-switched services for fixed, nomadic, portable, and mobile accesses. WiMAX uses orthogonal frequency division multiplexing (OFDM) and many other advanced technologies in the physical (PHY) and the medium access control (MAC) layers to provide higher spectrum efficiency than a code division multiple access (CDMA) system. Moreover, WiMAX supports scalable channel bandwidths and can be operated over different frequency bands so that operators have the flexibility to deploy a WiMAX network over various radio spectrums. With these important features, WiMAX has become one of the most important technologies for broadband wireless access (BWA) in both fixed and mobile environments.

IEEE Std 802.16-2004 is initially designed as an access technology for a wireless metropolitan area network (WMAN). The first specification ratified by the IEEE in 2004, i.e., IEEE Std 802.16-2004, targets on fixed and nomadic accesses in both line-of-sight (LOS) and non-line-of-sight (NLOS) environments. In the IEEE 802.16e-2005 amendment, the IEEE 802.16e system (also called Mobile WiMAX) further provides handover, sleep-mode, idle-mode, and roaming functions to facilitate mobile accesses. The system also uses scalable orthogonal frequency division multiplexing access (SOFDMA), which is optimized for accessing dynamic mobile radio channels. Besides the PHY and MAC layer specifications, IEEE working groups and technical forums have also defined management and networking protocols for WiMAX. For example, IEEE Std 802.16g standardizes the management plane for both fixed and mobile devices and networks. IEEE Std 802.16f and IEEE Std 802.16i facilitate cross-vendor interoperability for IEEE 802.16 and IEEE 802.16e devices and networks, respectively. To address the requirements for network and service deployment, the WiMAX Forum was thus formed in 2001 to promote and certify WiMAX products. The WiMAX Forum also specifies management plane procedures, an end-to-end network architecture, application and service operations, and conformance test cases for both fixed and mobile WiMAX. With these efforts, WiMAX becomes a complete solution for broadband wireless access beyond 3G.

This article provides an overview to WiMAX from an end-to-end perspective. The next section describes the architecture and entities of a WiMAX network. Then the design of fixed/mobile WiMAX PHY and MAC layers is presented. Then in the subsequent sections, protocols and procedures for the network entry, connection management, mobility management, sleep-mode and idle-mode operations, and security management are introduced.

WIMAX NETWORK ARCHITECTURE

Based on IEEE Std 802.16 and IEEE Std 802.16e, the network group (NWG) under the WiMAX Forum develops network architecture, entities, and protocols for a WiMAX network and defines reference points between the entities. These network entities are logical components and may be integrated in a physical network node. A reference point is a conceptual point between network entities, which associates with a number of protocols. When logical entities colocate in a network node, reference points between the entities are implicit. Figure 1 illustrates the WiMAX network architecture consisting of three major parts: subscriber stations/mobile stations [SSs/MSs; Fig. 1(1)], network access providers [NAPs; Fig. 1(2)], and network service providers [NSPs; Fig. 1(3,4)]. An SS/MS is customer premise equipment (CPE) that is a mobile or a personal device for individual usage or a residential terminal that is shared by a group of users. Subscription, authentication, authorization, and accounting (AAA) of WiMAX services can be applied to either devices or both devices and subscribers. In this architecture, interfaces R1–R8 between network entities are specified. The R1 interface between SSs/MSs and BSs implements control and data planes conformed to IEEE Std 802.16-2004 and IEEE Std 802.16e-2005 specifications, and other management plane standards. R2 logical connection between an SS/MS and the home AAA server is established for authentication and authorization purposes.

An NAP establishes, operates, and maintains several access service networks [ASNs; Fig. 1(8)] deployed in different geographical locations. An ASN consists of base stations [BSs; Fig. 1(5)] controlled by one or more ASN-gateways [ASN-GWs; Fig. 1(6)]. An ASN-GW inter-works an ASN with a connectivity service network [CSN; Fig. 1(7)] operated by a network service provider (NSP). The ASN-GW transmits packets between SSs/MSs and CSNs, handles ASN-anchored mobility, implements a mobile IP foreign agent, and security functions such as authenticator and key distributor. The ASN-GW also manages radio resources of the BSs in an ASN.

The functional partition between BS and ASN-GW is an implementation issue not defined by either IEEE 802.16 or WiMAX Forum. Generally speaking, a BS implements most PHY and MAC functions. On the other hand, an ASN-GW implements data plane functions such as packet classification, and control plane functions such as handover decisions, radio resource control, an address allocation relay, and an AAA proxy. In decentralized ASN implementation, certain functions such as handover decisions and radio resource management are moved from ASN-GW to BS. This approach increases the scalability of an ASN. R4, R6, R7, and R8 reference points are defined in an ASN. R4 is the interface between ASN-GWs. This interface defines control plane for mobility management and data

packet forwarding between ASN-GWs during handover. R6 reference point defines control and data plane packet delivery between BSs and an ASN-GW. R8 is the interface for transferring control plane packets and optionally data packets between BSs. This interface facilitates fast and seamless handover.

An NSP operates a CSN, and the CSN manages subscriber information such as service policies, AAA records, and so on. To provide services to SSs/MSs, an NSP can either establish its own service networks such as IP multimedia core network subsystem (IMS) in a CSN or forwards SSs/MSs' requests to other application service providers [ASPs; Fig. 1(9)]. A user initially subscribes to the services through a contract agreement with an NSP. The NSP then establishes contact agreements with one or more NAPs that offer WiMAX access services. Also, the NSP may have roaming agreements with other NSPs so that a roaming SS/MS can attach to its home NSP [Fig. 1(4)] via visited NSPs [Fig. 1(3)]. In such a case, the SS/MS first associates with an NAP, which only has a contact agreement with a visited NSP. Then, the visited NSP relays authentication messages to the SS/MS's home NSP, and finally the home NSP authenticates and authorizes the SS/MS. To further access Internet or services provided by ASP networks, IP addresses should be assigned to SSs/MSs. An ASN-GW implements DHCP relay functions and forwards SSs/MSs' IP acquisition requests to either visited NSPs or home NSPs to obtain IP addresses. In a CSN, R3 (between an NAP and an NSP) and R5 (between NSPs) are defined. The R3 reference point implements control plane protocols such as AAA, policy enforcement, and mobility management. Data plane packets are tunneled and transferred between an ASN and a CSN over the R3 interface. The R5 reference point consists of a set of control and data plane protocols for interconnecting home NSP with visited NSP.

PHY AND MAC LAYERS

Figure 2 illustrates the control plane and data plane protocols for WiMAX. IEEE Std 802.16 and IEEE Std 802.16e specify control plane messages for network entry, connection management, mobility management, security management, and so on. These messages are carried by either basic, primary management or secondary management connection identifiers (CIDs) [(1) in Fig. 2(a)] and then they are transferred between SSs/MSs and BSs through the MAC layer [(3) in Fig. 2(a)] and the PHY layer [(4) in Fig. 2(a)]. In IEEE Std 802.16, a connection that is numbered by a unique CID in a cell is a unidirectional mapping between BS and MS MAC peers for transferring a service flow's traffic. The WiMAX Forum further defines control protocols [(2) in Fig. 2(a)] between BSs and ASN-GWs over UDP/IP in order to support the control plane procedures in an ASN network.

IEEE Std 802.16 and IEEE Std 802.16e also define the data plane protocols for data packet delivery between SSs/MSs and BSs. The convergence sublayer [CS; (6) in Fig. 2(b)] performs packet classification, header suppression, and converts packets between upper layer and the MAC layer. Currently, two CSs, i.e., the asynchronous transfer mode (ATM) CS and packet CS, are supported [(7) in Fig. 2(b)]. The MAC layer receives service data units (SDUs) from the CS, which may fragment and pack the SDUs, encrypts the packets, generates the MAC protocol data units (PDUs), and then sends the PDUs to the PHY layer [(3) in Fig. 2(a)]. The PHY layer performs the baseband processing on MAC PDUs and transmits the information over the air by using OFDM/OFDMA technologies [(4) in Fig. 2(a)]. A BS or an SS/MS receives the signals and then passes data to the MAC layer after the baseband processing. The receiver MAC needs to reassemble the PDUs,

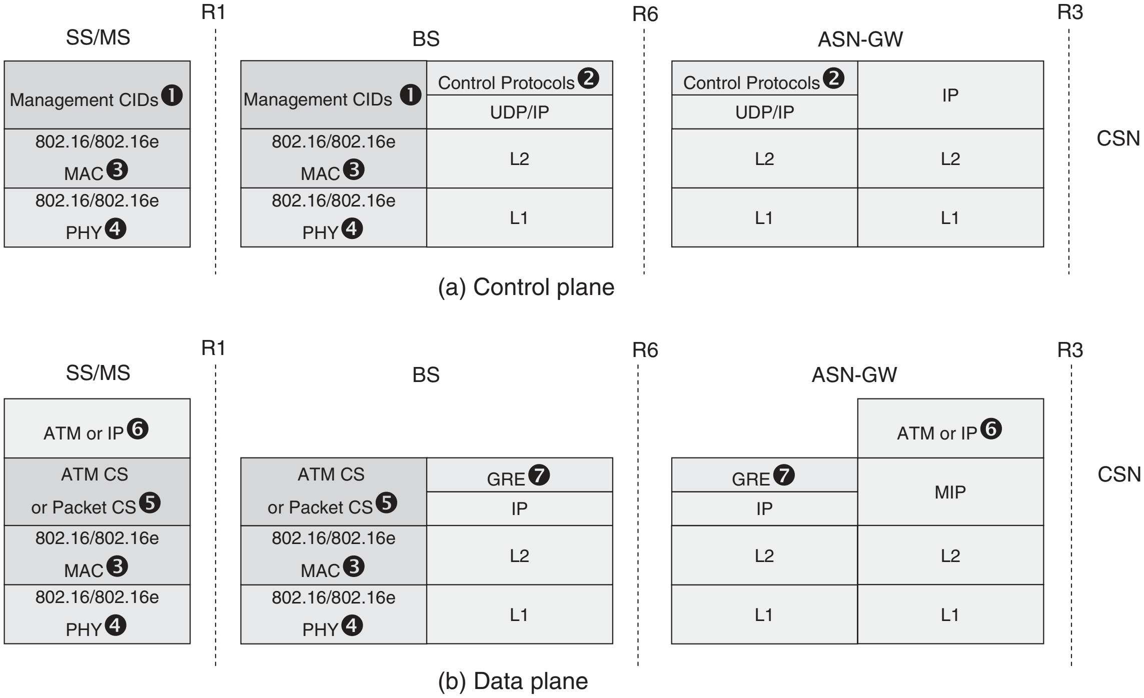

Figure 2. Overview of WiMAX protocol stack.

performs retransmission if necessary, decrypts the packets, and finally forwards the packets to upper layer protocols via the service-specific CSs. To deliver packets between BSs and ASN-GWs, the WiMAX Forum reuses Generic Routing Encapsulation [GRE; (8) in Fig. 2(b)], which is a tunnel protocol over an IP transport infrastructure defined by the Internet Engineering Task Force (IETF).

Figure 3 shows the details of data packet processes for IEEE Std 802.16 and IEEE Std 802.16e. A network-layer connection such as an IP connection has to be mapped to a service flow, which has its own service flow identifier (SFID) in a WiMAX network. The service flow is defined as a unidirectional flow of MAC SDUs and has its own quality-of-service (QoS) requirements. A service flow is a logical entity. During transmission, the service flow must associate with a link-layer connection, i.e., an IEEE 802.16 connection with a CID. One of CS major tasks performs the CID classification while it receives upper layer SDUs such as ATM cells or IP packets [Fig. 3(1)]. The classification for the ATM CS can be done by mapping ATM virtual circuit or virtual path to a specific CID. On the other hand, the packet CS may have to check the IP or TCP/UDP header of the SDU to determine the CID. Besides the CID mapping, the CS may perform the optional payload header suppression (PHS) to eliminate the redundant parts of the SDUs during the transmission over the air interface [Fig. 3(2)]. For example, if the header information of an IP packet is not used during transmission and routing in a WiMAX network, the IP header can be removed by the sender and reconstructed by the receiver to save radio resources. An SS/MS and a BS that activate the PHS function should first negotiate header suppression parameters. For example, the PHS parameters are composed of a classification rule for identifying the packets that should be processed by the header suppression, a payload header suppression mask (PHSM) that indicates the parts of a header should be removed, and a payload header suppression field (PHSF) that tells the receiver the original parts of headers for reconstruction. These PHS-related information are described in a data structure, indexed, and stored on the BS and the corresponding SS/MS. When a BS or an SS/MS sends a packet, the CS matches the PHS rules, finds the PHS index (PHSI), masks the packet using the PHSM, generates the new PDU with the PHSF, and sends the packet to the receiver. The receiver checks the PHSI in the PDU, searches the PHS information, and rebuilds the original packet using the PHSM and PHSF. The PHS is applied to a connection, and each connection may associate with more than one PHS rule and PHS setting.

SDUs are sent to the MAC layer after they are processed by the CS. The MAC layer may perform the block processing of the automatic repeat request (ARQ) on MAC SDUs if the ARQ is enabled for this connection [Fig. 3(3)]. The ARQ mechanisms used for retransmitting lost packets are optional in IEEE Std 802.16 but are mandatory for IEEE Std 802.16e. WiMAX and Mobile WiMAX support several ARQ mechanisms, and their parameters should be negotiated by a BS and an SS/MS. When the ARQ is enabled, SDUs are first segmented into fixed-size ARQ blocks, which are the basic retransmission units defined in the ARQ mechanism. When any ARQ block is lost, the sender needs to retransmit the ARQ block. As an ARQ block is the basic retransmission unit, the following MAC processes such as packet fragmentation and packing must

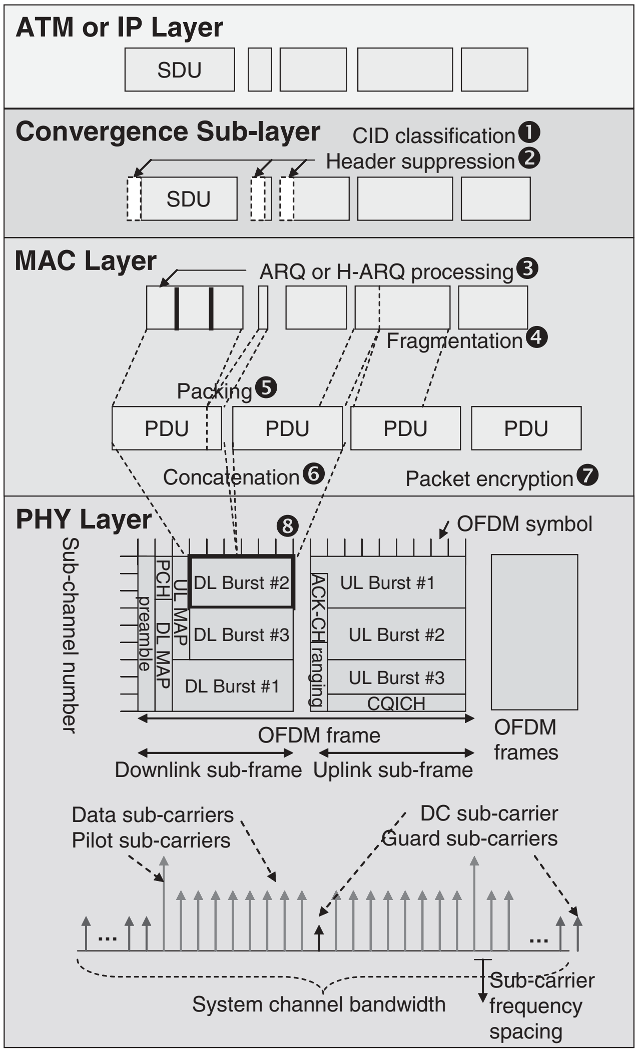

Figure 3. Overview of packet processing in IEEE Std 802.16 and IEEE Std 802.16e.

align with the boundary of an ARQ block. The MAC fragmentation divides an MAC SDU into one or more small PDUs [Fig. 3(4)], and the MAC packing packs multiple MAC SDUs into a single MAC PDU [Fig. 3(6)]. The MAC concatenates multiple MAC PDUs into a single transmission [Fig. 3(7)]. The MAC fragmentation, packing, and concatenation mechanisms are designed for efficient use of the available radio resources to meet the QoS requirements. The MAC layer also encrypts and decrypts MAC PDUs to prevent packet sniffing and modifications [Fig. 3(9)]. To perform packet encryption and decryption, a security association (SA) for a connection contains the security information and settings such as encryption keys. The SA information is negotiated by a BS and an SS/MS during the connection establishment phase. The MAC layer in the sender then encrypts MAC PDUs, and the receiver can decrypt these PDUs according to the information in the SA.

One of the most critical tasks for the MAC layer is the PDU scheduling and radio resource management. IEEE Std 802.16 and IEEE Std 802.16e reuse the data over cable system interface specifications (DOCSIS) MAC, which is a deterministic access method with a limited use of contention for bandwidth requests. All radio resources for downlink (DL) and uplink (UL) accesses are controlled by a BS. An SS/MS receives DL bursts that contain several PDUs to the SS/MS, and sends packets via the UL transmission opportunities, called UL bursts, which are also scheduled by a BS. In WiMAX, each service flow has its own QoS, and a BS uses these QoS information of these service flows to schedule DL/UL bursts. For example, a BS can schedule DL resources to SSs/MSs according to the QoSs associated with service flows. Also, a BS schedules UL resources based on the QoS of UL service flows and the bandwidth requests from SSs/MSs. All DL/UL schedules are decided by a BS, and the scheduling results are embedded in the DL-MAP and UL-MAP in every OFDM frame. SSs/MSs should listen to the DL-MAP and UL-MAP and receive and transmit packets according to the schedule.

For the IEEE 802.16 and IEEE 802.16e PHY layer, a system channel bandwidth must be first allocated. WiMAX supports both frequency division duplex (FDD), which requires two separated spectrums for DL and UL accesses, and time division duplex (TDD) where DL/UL accesses share the same spectrum. FDD may suffer from inefficient channel utilization due to unbalanced UL/DL traffics. TDD, on the other hand, can dynamically change the allocation of the UL and DL resources in each OFDM frame and is more flexible than FDD in terms of radio resource management. Figure 3 also shows a frame structure of a TDD-based OFDMA system. A system channel bandwidth is divided into several subcarriers. The frequencies of subcarriers are all orthogonal. These subcarriers can be categorized into pilot subcarriers that are used for pilot, a DC subcarrier that indicates the center subcarrier, guard subcarriers that serve as the guard band, and data subcarriers that are used to carry data packets. In OFDMA, subcarriers are further divided into groups, and one subcarrier from each group forms a subchannel. Subchannels are the basic unit to schedule DL/UL accesses. As shown in Figure 3, DL/UL bursts are scheduled and transmitted by several subchannels and for several OFDM symbols. A DL/UL burst that may contain several MAC PDUs for the same SS/MS are the basic schedule unit.

An OFDM frame is fixed with lengths such as 2 ms, 5 ms, and 10 ms, and each frame is composed of several OFDM symbols [Fig. 3(8)]. Two consecutive OFDM frames are guarded by a Receive Transition Gap (RTG). In an OFDM frame, a BS further divides a frame into a DL subframe and a UL subframe. An OFDM frame begins with a DL subframe, and a DL subframe has a preamble to identify the start of an OFDM frame. Followed by the preamble, a frame control header (FCH) contains the DL frame prefix and specifies the burst profile and the length of a DL-MAP. After FCH, the first DL burst is a broadcast burst containing many important information such as DL-MAP, UL-MAP, downlink channel describer (DCD), and uplink channel describer (UCD). The DL-MAP indicates the DL burst allocations, and the DCD describes the coding and modulation scheme that each burst uses. On the other hand, UL-MAP and UCD inform SSs/MSs how UL bursts are arranged and how UL bursts should be coded and modulated. OFDM/OFDMA support adaptive modulation and coding (AMC), and each burst can apply different modulation and coding schemes depending on the channel condition between a BS and an SS/MS. In UL subframes, there are several important bursts. The contention ranging period is a period that an SS/MS uses for the initial ranging. The channel quality information channel (CQICH) is a channel for SSs/MSs to report its channel conditions, and it can be used for the AMC. The details will be further elaborated in the next section.

NETWORK ENTRY

An SS/MS has to complete network entry procedures before it can access the Internet. Network entry for an SS/MS begins with a cell selection procedure [Fig. 4(1)]. An SS/MS first searches the cells that it associated before. If the last associated cells cannot be detected, the SS/MS performs a complete search of the spectrum. To locate the boundary of an OFDM frame, an SS/MS seeks for the preambles situated in the beginning of every OFDM/OFDMA frame. Once OFDM frames are synchronized, the SS/MS decodes FCH and the first DL burst containing the broadcast information from the BS [Fig. 4(2)]. The broadcast information composes of a DL-MAP, UL-MAP, DCD, and UCD, which indicate to all SSs/MSs how a DL subframe and UL subframe are organized. Based on the information, an SS/MS locates the contention period for the initial raging [Fig. 4(3)]. The initial ranging synchronizes the time and frequency between a BS and an SS/MS and adjusts the transmission power. The initial ranging is a contention-based ranging, which means that all SSs/MSs

send ranging requests in the same period. If an SS/MS does not receive ranging response from the BS, the SS/MS should increase the transmission power and retransmit the ranging requests in the subsequent contention-based ranging periods with random back-offs. After successfully receiving a ranging response, the initial ranging is complete. The CID of an initial ranging message (RNG-REQ) is zero. When a BS replies to the request, a ranging response message (RNG-RSP) informs the SS/MS of the basic CID and the primary management CID, which are used to carry important management messages between the BS and the SS/MS.

After ranging procedures, an SS/MS negotiates basic capacities of the PHY/MAC layer such as ARQ supports with a BS through SBC-REQ/SBC-RSP messages [Fig. 4(4)]. Following the basic capacity exchanges, authentication and authorization procedures are performed [Fig. 4(6)]. For an SS shared by several users, devices and subscribers might be authenticated and authorized separately. Security management related functions will be discussed below. Once an SS/MS has been authenticated and authorized, an SS/MS sends a registration request message (REG-REQ) to register to a WiMAX network [Fig. 4(7)]. In the registration response message (REG-RSP), the BS provides the SS/MS a new CID called the secondary management CID. The secondary management CID carries management messages forwarded to the network nodes behind a BS/ASN-GW. To access Internet, the SS/MS further acquires an IP address [Fig. 4(8)] either allocated by the visiting NSP or issued by the home NSP.

CONNECTION MANAGEMENT AND QOS

After an SS/MS has successfully attached to a WiMAX network, the home NSP downloads the user's QoS profile and the associated policy rules to the service flow management (SFM) and service flow authorization (SFA) [Fig. 5(1)]. Both SFA/SFM are logical entities implemented in an ASN/NAP. SFM is responsible for the admission control and management such as creation and deletion of service flows. SFA is responsible for evaluating service requests against the user's QoS profile. The establishment of a new service flow is either initiated by the network or by an SS/MS. Figure 5 shows an example where an SS/MS sends a service flow creation message (DSA-REQ) to a BS to initiate a service flow [Fig. 5(2)]. A service flow creation message from an SS/MS contains a service flow identifier (SFID) and may specify the PHS and other MAC parameters. When a BS receives the message, it first checks the integrity of the message and sends an acknowledgment message (DSA-RVD) to the SS/MS. Then the BS determines whether the service flow is accepted according to the QoS profile and available resources of a BS. If so, the BS replies to the SS/MS with a response message (DSA-RSP), and then the service flow is established [Fig. 5(3)]. When a BS or an SS/MS starts to transmit packets, the service flow needs to be activated and associated with a link-layer connection with a unique CID.

A connection for a service flow is associated with a schedule data service that is an unsolicited grant service (UGS), enhanced real-time polling service (ertPS), real-time polling service (rtPS), non-real-time polling service (nrtPS), or best effort service (BE). These data service scheduling are defined by IEEE Std 802.16. IEEE 802.16e further defines ertPS. Characteristics of data connections for these scheduling services are described below.

- **UGS**: For a UGS connection, a BS guarantees a fixed amount of DL or UL transmission bandwidths. UGS is

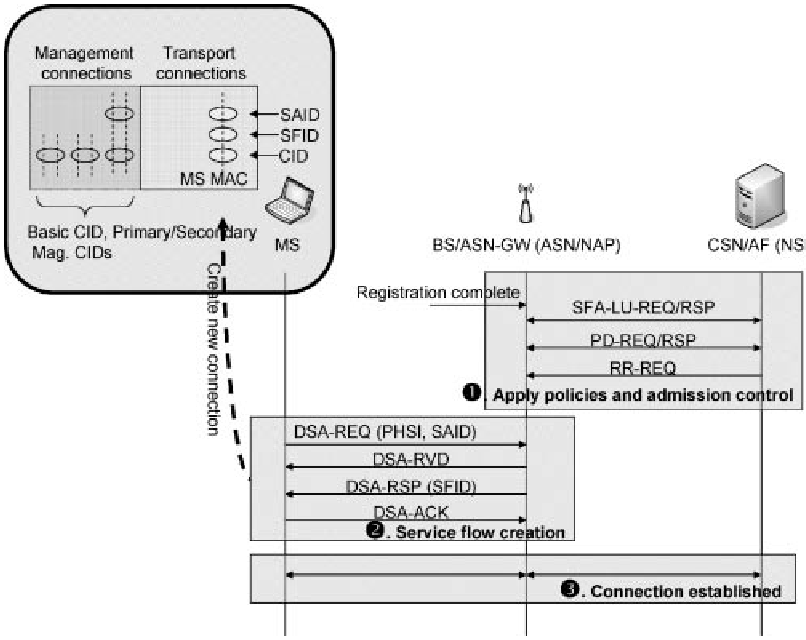

Figure 5. An example of service flow establishment.

suitable for the constant bit rate (CBR) traffic such as voice over IP (VoIP) without silence suppression.

- **ertPS**: Different from a UGS service, ertPS supports VoIP with silence suppression or variable bit rate (VBR) real-time services. In ertPS, a BS not only allocates fixed amount of UL or DL resources to an MS, but also allocates the bandwidth requests in the UL bursts to an MS so that the MS can use the bandwidth requests to change UL allocations. This mechanism allows a BS to save the radio resources if it does not have packets to transmit during silence periods.
- **rtPS**: To support real-time service flows such as video streaming, a BS allocates periodical bandwidth requests in UL bursts to an SS/MS and polls the SS/MS if there is any UL burst need. If an SS/MS has packets to transmit, it can simply use the reserved bandwidth request slots to request UL bursts. Since the requests of UL bursts are done by a periodical polling basis, the response time for a UL packet is fast and the rtPS can support real-time applications.
- **nrtPS**: For non-real-time traffic, such as Web access and Telnet, an nrtPS connection is allocated regular bandwidth request resources to an SS/MS, and an SS/MS that has packets to transmit should use the bandwidth requests to request UL bursts. Since the bandwidth request is not sent periodically, the bandwidth request might not be received by the BS immediately and the delay for UL burst allocations cannot be guaranteed.
- **BE**: A BS allocates resources to BE connections in a best effort manner. Therefore, this type of connection cannot guarantee any QoS.

A BS has to schedule DL and UL resources and guarantees the QoSs of the service flows. It also has to refer to the channel qualities between a BS and each SS/MS to schedule DL/UL bursts, which associate with different modulation and coding schemes in order to maximize the radio utilization.

MOBILITY MANAGEMENT

WiMAX mobility functions can be categorized into ASN-anchored and CSN-anchored mobility management. ASN-anchored handover, also called micro mobility, implies that an MS moves from one BS to another BS without updating its care-of address (CoA). CSN-anchored handover, on the other hand, defines macro mobility where an MS changes its serving ASN-GW/FA and its CoA. In general, the handover procedure includes the following steps. First, an MS performs a cell (re)-selection, which comprises scanning and association procedures to locate candidate BSs to handover. Second, the MS is informed or decides to handover to the target BS. Finally, the MS completes network (re)-entry procedures and performs network-layer handover procedures if necessary.

The scan measures the signal qualities of the neighboring BSs for an MS, and the measurement reports are used for either MSs or BSs to select the target BS during handovers [Fig. 6(1)]. Initially, the serving BS may indicate MSs for the scanning trigger-conditions in DCD and/or neighbor advertisement messages (MOB_NBR-ADV). The MOB_NBR-ADV broadcasting message contains a list of suggested BSs for scanning and the DCD, UCD, and other parameters of the BSs. Therefore, an MS can synchronize with the neighbor BSs. After receiving DCD or MOB_NBR-ADV messages, an MS should measure the signal qualities of the serving BS and other BSs and check whether the measurement results satisfy the trigger criteria. If the scan procedure is triggered, an MS sends a MOB_SCN-REQ message to the serving BS with the MS's preferred scanning and interleaving intervals. Also, the MOB_SCAN-REQ message contains a list of BSs that are selected from the neighbor BSs in the MOB_NBR-ADV message or other BSs, which are not in the neighbor BS list. The serving BS then replies a scan response message (MOB_SCN-RSP), which contains the final list of BSs to scan, the start frame of the scan, the length of a scanning and interleaving interval, and the scan iteration. The start frame of the scan indicates the exact frame for the MS to perform scan, and the scan and interleaving interval are used to determine the length of a scan and normal operation period. The scanning and interleaving intervals are scheduled in a round-robin basis, and the scan iteration controls the number of iterating scanning intervals.

An MS may perform associations with neighbor BSs during scanning intervals. Association helps an MS to establish basic relationships such as ranging for these BSs, which may become potential target BSs for the MS. By conducting associations before handovers, MSs can reduce the time to synchronize and register with the target BS. The scanning type in a MOB_SCN-RSP message indicates whether an MS should perform an association with a neighbor BS, and what association type an MS and a BS should establish. Several scanning types are defined.

- **Without Association**: The MS does not have to perform associations during scanning intervals.
- **Association Level 0** (scan/association without coordination): The MS should perform an association during scanning intervals, but the neighbor BSs do not allocate dedicated ranging regions for the MS. Therefore, the MS must perform ranging procedures such as an initial ranging on a contention basis.
- **Association Level 1** (association with coordination): The serving BS coordinates ranging parameters of the neighbor BSs for the MS. The serving BS sends an association request over the backbone to notify the neighbor BSs, and the neighbor BSs allocate ranging opportunities for the MS and inform the serving BS. Then the serving BS sends the MS the association parameters such as the reserved ranging slots via a MOB_SCN-RSP message. The association parameters assist the MS to send ranging requests to the neighbor BSs in the reserved ranging slots. That reserved-based ranging is faster than the contention-based ranging.
- **Association Level 2** (network assisted association reporting): The MS is not required to wait for ranging

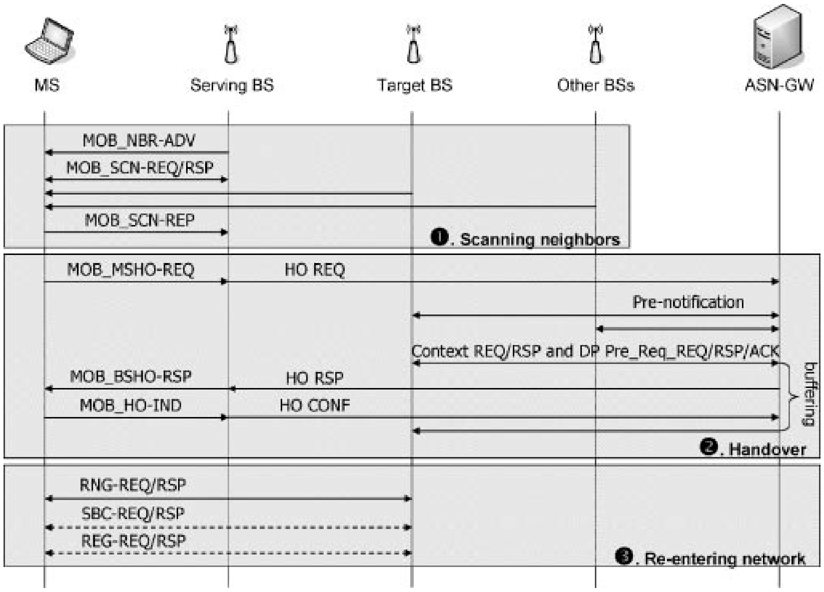

Figure 6. An example of an ASN-anchored handover.

response messages replied by the neighbor BSs after sending ranging requests. The ranging response messages are forwarded to the serving BS over the backbone network and are sent by the serving BS to the MS.

A handover followed by scanning and association procedures can be initiated by an MS or the network. Figure 6 gives an example of an ASN-anchored handover initiated by an MS. After the cell selection [Fig. 6(1)], an MS sends a handover request message (MOB_MSHO_REQ) to the serving BS [Fig. 6(2)]. The handover request message contains a list of candidate BSs and a measurement report of the BSs. Based on this report and some other information on the serving BS, the serving BS sends a handover request message (HO request) to one or several neighbor BSs over the backbone network to identify the possible target BSs. Once the neighbor BSs receive handover requests from the serving BS, the BSs may send a context request to the context server to collect information such as the QoSs of current connections of the MS and check whether they have sufficient resources to support this handover. After the context transfer and data path pre-registration, the neighbor BSs send handover response messages (HO response) to the serving BS. The serving BS summarizes the results from the neighbor BSs and finally decides a new list of recommended BSs and replies a MOB_BSHO-RSP message to the MS. Meanwhile, buffering schemes for queueing incoming packets to the MS should be performed on an ASN-GW and/or BSs to the MS to prevent packet loss.

After receiving a handover response message (MOB_BSHO-RSP), an MS should send a handover indication message (MOB_HO-IND) to confirm or terminate the handover process. In the MOB_HO-IND message, an MS explicitly notifies the target BS of the MS. Finally, an MS disconnects from the serving BS and synchronizes with the target BS. An MS can either perform ranging procedures or directly accesses the target BS if the association has been already established during the scanning phase. After the ranging procedure, an MS needs to perform network (re)-entry procedures [Fig. 6(3)]. To accelerate network (re)-entry, the target BS can obtain the configurations and settings such as service flows, state machines, and service information of an MS from the serving BS via the context server without the MS's involvement.

During handover, an MS may have to disconnect from the serving BS and then attaches to the network again via the target BS. Packets may be lost, and services may be disrupted during handover. To reduce the handover delay and minimize packet loss during handover, two advanced handover mechanisms, i.e., fast BS switching (FBSS) and macro diversity handover (MDHO), are proposed in the IEEE 802.16e-2005 specification. In FBSS and MDHO, an MS maintains a diversity set and an anchor BS. The diversity set is a list of target candidate BSs to handover for an MS. An anchor BS is the serving BS that transmits/receives packets to/from the MS over the air interface for FBSS. For MDHO, an MS receives the same data packets from all BSs in the diversity set, and only monitors the control information from the anchored BS, which may be any BS in the set. An MS must associate with the BSs in the diversity set before handover and should perform a diversity set update to include new neighbor BSs or remove BSs with poor signal qualities from the list. The ASN-GW should multicast incoming packets for an MS to all BSs in the diversity set, and therefore, the BSs in the diversity set are always ready to serve the MS for FBSS and MDHO. For the packet transmission over the air interface, an MS transmits/receives packets to/from the anchored BS only for FBSS. Since packets are ready in the BSs in the diversity set, the packet transmission can be resumed quickly after an MS performs an anchor BS update to change the serving BS. The packet loss and handover delay are reduced by employing the FBSS. On the other hand, in MDHO the BSs in the diversity set transmit the same data packets to the MS simultaneously. In this case, an MS can still receive packets from several BSs during handovers, and the MDHO approach further minimizes the packet loss and handover delay.

CSN-anchored mobility management involves MSs moving from the current FA to another FA. This type of handover requires MSs to change its CoA. Mobile WiMAX supports network-layer handover for both IPv4 and IPv6 networks. For IPv4, client mobile IP (CMIP) and proxy mobile IP (PMIP) are supported. For IPv6, only client mobile IPv6 (CMIPv6) is defined because each MS has its own IP address in an IPv6 network. CMIP integrates the conventional mobile IP (MIP) mechanisms with the designs for an MS and a Mobile WiMAX network to handle network-layer handover. On the other hand, to minimize the development efforts on MSs and to reduce MIP message exchanges over the air interface, PMIP suggests running a PMIP client on the ASN-GW or a dedicated node in the ASN. The PMIP client serves an agent to handle network-layer handover for MSs, and thus, network-layer handover is transparent to the MS.

SLEEP AND IDLE MODE MANAGEMENT

Power consumption might not be a problem for Fixed WiMAX, but it is a critical issue for Mobile WiMAX, which targets on portable devices. IEEE Std 802.16e, therefore, defines sleep-mode operations for MSs that have data connections but does not have a packet to send or receive. Three power-saving classes for sleep-mode operations are defined to accommodate network connections with different characteristics. Each connection on an MS can be associated with a power-saving class, and connections with a common demand property can be grouped into one power-saving class. If an MS establishes multiple connections with different demand properties, the periods that an MS can sleep are determined by the sleep-mode behaviors associated with all connections. The parameters of a power-saving class, i.e., the time to sleep and listen, the length of a sleep period and a listen period are negotiated by a BS and an MS. Then, an MS can sleep during the sleep periods, and can wake up to listen to the incoming packets during listen periods. Once an MS receives DL-MAP, which indicates packets to receive, the MS must return to the normal mode to receive the packets. Three power-saving classes are defined as follows:

- The type-one power-saving class specifies that an MS sleeps for a period and wakes up to listen for incoming packets. If there is no packet to send or receive during a listen period, the MS doubles the period for the next sleep. This power-saving class is suitable for Web browsing or data access services.
- The type-two power-saving class requires an MS to repeat the sleep and listen with fixed periods. This sleep mode is appropriate for real-time connections such as VoIP and video streaming services with periodic packet delivery. In this class, an MS only needs to wake up for packet delivery in those listen periods without violating the QoSs of the real-time connections.
- The type-three power-saving class defines the length of a sleep period, and an MS sleeps for that period and then returns to the normal operation.

On the other hand, if an MS does not have any connection for a period, an MS might want to switch to a deeper sleep state, called the idle mode, to conserve the energy. Mobile WiMAX defines its own idle-mode operations and paging network architecture. Four logical entities, i.e., paging controller (PC), paging group (PG), paging agent (PA), and location register (LR), for idle-mode and paging operations are defined. A PG that comprises one or several PAs in the same NAP is controlled by a PC, and a PC can manage one or more PGs. A PC can access an LR that contains information such as paging parameters for idle-mode MSs, and administers the activities of all idle-mode MSs situated in the PG managed by the PC. A PC can function as an anchor PC that is in charge of the paging and idle-mode management, and/or a relay PC that only forwards paging-related messages between PAs and an anchor PC. A PC could either colocate with a BS or a PC can be implemented on a network node such as an ASN-GW to communicate with its PAs through the R6 interface. PAs that are implemented on BSs interact with the PC to perform paging functions.

Figure 7 illustrates an example for an MS to enter the idle mode, update its location, and to be paged by the network. This example assumes that an LR and PC colocate on an ASN-GW and PAs are implemented on BSs. When an MS decides to switch to the idle mode [Fig. 7(1)], it first sends a de-registration message (DREG-REQ) to the ASN-GW [Fig. 7(2)]. The serving BS/PA and ASN-GW/PC release the resources such as the data path occupied by the MS and update the information of the MS to the LR. Meanwhile, the PA and PC negotiate, configure, and inform the paging parameters such as paging cycle, paging offset, paging interval length, anchor PC identifier, and paging group identifier for the MS. Based on the paging cycle (*PAGING_CYCLE*), paging offset (*PAGING_OFFSET*), and paging interval length, the MS derives the BS paging listening interval. A BS paging listening interval begins from the *PAGING_OFFSET* frame in every paging cycle, and each paging listening interval lasts for paging interval length. The MS has to stay awake during the entire BS paging listening interval in order to receive BS broadcasting paging messages (MOV_PAG-ADV).

The MS should perform a location update (LU) upon LU evaluation conditions [Fig. 7(3)]. For example, the MS performs an LU while the MS detects change of the paging group or when idle-mode timer expires. After a BS receives LU messages, the BS/PA updates the MS information to the PC/LR. When receiving an incoming packet sent to an idle MS, the ASN-GW/FA first obtains the information of the MS from the LR and informs the PC to page the MS. Then, the PC generates a paging announcement message and sends it to the relay PCs or PAs [Fig. 7(4)]. Based on the paging parameters of the MS, PAs/BSs send BS broadcasting paging messages (MOV_PAG-ADV) to the MS.

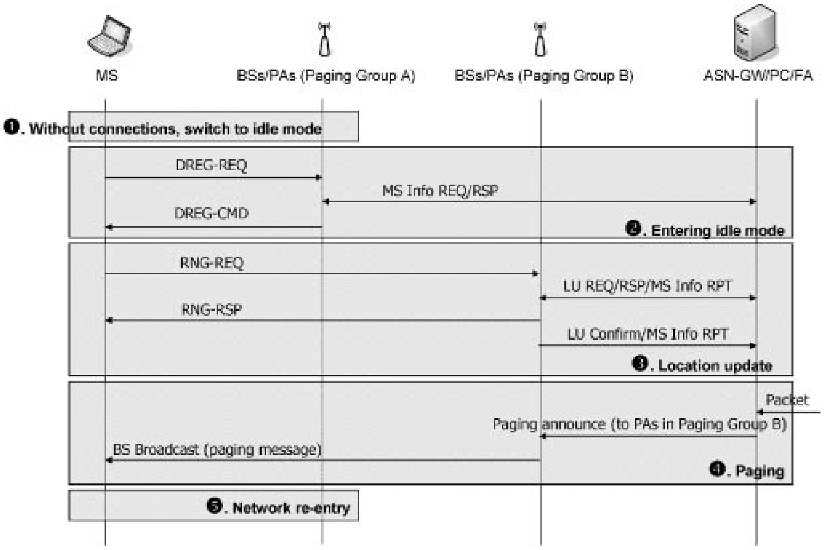

Figure 7. An example of idle-mode operation.

After an MS is paged, the MS shall exit idle mode, perform ranging with the serving BS, and complete the network (re)-entry procedures [Fig. 7(6)].

SECURITY MANAGEMENT

Security management in WiMAX includes authentication, authorization, key management, and encryption functions. When an SS/MS attaches to a WiMAX network, it is requested to perform the authentication and authorization based on X.509 protocol before it can register to a network. In IEEE Std 802.16e, authentication and authorization are enhanced by adopting IEEE Std 802.1X. In IEEE Std 802.16, the authentication and authorization can be applied to both a device and subscribers if an SS serves as a gateway, and it is shared by several users. Figure 8 shows an example for authentication and authorization using IEEE Std 802.1X. The authenticator first sends an identifier request to an SS/MS based on the EAP protocol after the SS/MS finishes the services capacity exchange with a BS during a network entry [Fig. 8(1)]. Depending on the authentication method negotiated by the authenticator and the subscriber, i.e., SS/MS, the message exchange between the authenticator and subscriber may be different [Fig. 8(2)]. After the authentication and authorization procedures, the SS/MS can register to a WiMAX network.

IEEE Std 802.16 uses privacy key management protocol version 1 (PKMv1) to support packet encryption and decryption. IEEE Std 802.16e further enhances the features by supporting PKMv2. In PKMv2, the master session key (MSK) is first established between the AAA server in the home NSP and the SS/MS. The MSK is transferred to the authenticator in the ASN, e.g., ASN-GW, which generates a pairwise master key (PMK) based on the MSK and other information. After the PMK is established, an SS/MS and authenticator further establish the authentication key (AK). The AK is then transferred from an ASN-GW to the

serving BS. Finally the serving BS and SS/MS derive the traffic encryption key (TEK) based on IEEE 802.16 and IEEE 802.16e specifications [Fig. 8(2)]. With TEK, the data packets are encrypted and decryption based on specific algorithms such as the Advanced Encryption Standard (AES). Data encryption and decryption are applied to all data connections and the secondary management connection. Each connection must associate with a security association (SA), which is identified by an SA identifier (SAID). An SA is a data structure shared by a BS and an SS/MS. It is constructed during the connection establishment phase and describes the security information such as keys or other parameters for the connection.

SUMMARY

WiMAX and Mobile WiMAX have become a complete network solution for a broadband wireless and mobile communication system. With a total packet-switched design, the existing all-IP service network, e.g., IP multimedia subsystem (IMS), can be easily integrated with a WiMAX network to offer mobile data services. Although the basic functions and protocols of WiMAX have been established, several challenging issues need to be further investigated. Adaptive Antenna Systems (AAS) and Multiple-Input Multiple-Output (MIMO) are considered as important technologies for an OFDM-based system. They significantly influence MAC and radio resource management (RRM). Cross-layer approaches that consider not only physical behaviors, MAC designs, and upper layer transport and application protocols are important and should be further studied. MAC/RRM scheduling algorithms should be developed to improve the throughput and radio utilization, guarantee QoS, and minimize the power consumption for mobile devices. Mobility management mechanisms such as FBSS and MDHO for Mobile WiMAX and the integration of IEEE Std 802.16e and IEEE Std 802.21 can optimize and support seamless handovers within a Mobile WiMAX network and between WiMAX and other wireless access technologies. Technologies such as Mobile Multi-hop Relay (MMR), i.e., IEEE Std 802.16j, and Advanced IEEE 802.16, i.e., IEEE Std 802.16m, also bring new challenges for MAC, RRM, mobility management, and network architecture designs.

ABSTRACT DATA TYPES

INTRODUCTION TO DATA ABSTRACTION

The tasks involved in the design, development, and maintenance of large software systems are extremely complex because the details that need to be mastered far exceed most programmers' comprehensive ability. Abstraction is a fundamental technique for dealing with comprehension. In addition, abstraction supports reuse of code and flexibility in choosing different implementations.

Abstraction means that one focuses on the essential properties of the software system while ignoring most of the details of the implementation. Well-designed procedures and data types that hide the unnecessary implementation details are the key to abstraction and are discussed in Refs. 1 and 2.

Data abstraction focuses on the types of data and the operations on that data and ignores the complex details of the code. Abstract data types (ADTs) have been devised to support data abstraction.

An initial step toward the notion of using abstract data types (ADTs) was introduced through classes in the programming language Simula (3) in the 1960s. Parnas first discussed the concept of information hiding through modularization (4,5), which formed a basis for ADTs. Subsequent research introduced the notion of programming with ADTs (6). Since then, procedural languages such as ADA (7), CLU (8) and object-oriented languages such as Smalltalk (9), C++ (10), and Java (11) have allowed programmers to implement ADTs.

Early work formalizing ADTs also includes the introduction of procedural abstraction (12) and the use of algebraic methods in semantics (13,14,15). This research evolved into topics such as algebraic specification (16, 17, 18) and type theories (19). Hoare (20) provided an early theoretical treatment of ADTs within procedural languages. Many systems for the formal description of programs such as VDM (21) and Z (22) naturally support ADTs because they allow the description of intentions rather than detailed implementation. One use of VDM in this context can be found in Refs. 23 and 24.

The remainder of this article introduces ADTs for the data types stack, queue, set, and bag by describing their semantics or meaning using a form of mathematical description called algebraic semantics. The article also contains a detailed description of a stack implementation in the procedural programming language C (25). In this way, the reader can observe the details of how a practical ADT implementation might be structured.

INTRODUCTION TO THE CONCEPT OF ABSTRACT DATA TYPES

The term "abstract data type" can be understood based on four related phases; "type," "data type," "data structure," and "abstract." These terms are amplified in the next few paragraphs.

A type is a classification term related to collections of entities with common properties. For example, a type could represent all the people who live in a specific city or all the engineers in a country or state.

A data type is a type in which the classification relates to data values, such as integers, characters, or strings, or structures of data values, such as (string, integer) pairs, which could represent persons and their corresponding ages. A specific data type, such as all the real numbers or all the integers, also has related operations, such as addition and multiplication. A data structure is a specific implementation of a data type. The term abstract is defined later in this section after a brief discussion of some specific data types.

A data type in programming languages such as Pascal or Java is usually defined by:

(i) a collection of data values with similar characteristics (data type),
(ii) the operations on the data type, and
(iii) the implementation of the type and its corresponding operations (data structure).

Many different data types exist. Simple ones in programming languages are integers, reals (real numbers), characters, or strings of characters. Operations on integers or reals can include addition, subtraction, multiplication, or equals, whereas operations on strings could be concatenation, equals, or substring. More complex types can include arrays, tuples (sometimes called records), stacks, and queues.

Arrays are ordered finite sequences of the same data type, so we can have an array of reals. Elements of an array are usually accessed by their position in the sequence, and operations on an array include those to extract an element from a given position or place an element in a given position.

Tuples are ordered finite sequences of different data types and can also be extracted or placed by their position or by the name of the position. A tuple could consist of a name, gender, and age, where the name is a string of alphabetic characters, the age is a non-negative integer, and the gender is a single character, namely, "F" or "M."

Stacks consist of elements of the same data type and operate on the last-in-first-out principle similar to the stack of plates at a buffet table in a restaurant. Stacks have three basic operations, namely, *push*, which puts an item on top of the stack; *popOff*, which removes an item from the top of the stack but does not copy its value; and *top*, which copies the value of an element from the top of the stack but does not remove it. There is also a function *isEmpty* that determines if the stack is empty, because top and popOff can not be applied to an empty stack. From a programming perspective, it is also convenient to have an operation *pop*, which combines the effect of top and popOff.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Queues also consist of elements of the same data type and operate on a first-in-first-out principle in which elements are added at one end of the queue and removed from the other end. A queue is similar to a line waiting at a bus stop. Typical operations on a queue are *add*, which puts an element on a queue; *front*, which provides access to the value of the earliest added item placed on a queue; and *remove*, which removes the earliest added item placed on a queue. A queue also has a function *isEmpty* because front and remove cannot operate on an empty queue. Queues can also have an operation *delete*, which combines the operations front and remove.

Each data type can be implemented in many different ways. For example, integers can use a representation that allows for plus (+) and minus (−) signs or uses a modular or wrap-around approach. Complex data types such as stacks and queues can be implemented as either a fixed-size sequence (often called an array) of memory cells that are contiguous or separate memory cells that are linked together where each cell contains pointers (or the address) to its immediate successor or predecessor. This second implementation is called a linked list and allows a stack or queue or similar data type to grow to the size of available memory rather than be constrained to a fixed size as in an array.

An abstract data type (ADT) is a data type and its related operations, independent of its underlying implementation. Therefore, a change in this implementation should not affect the program that is using abstract data types because it only uses the operations and the data types involved with those operations, thus, following the hiding principle (4). Usually the operations on an ADT are defined by an interface, which cannot change when the ADT implementation changes.

A definition of abstract data type provided by the National Institute of Standards and Technology (NIST) (26) states that an ADT is a set of data values and associated operations that are precisely specified independent of any particular implementation.

To use a data type as an ADT, two specific details must be known:

(i) The meaning of the operations or functions acting on the ADT or operation semantics, that is, the properties of the data objects that the operations require and produce, and

(ii) The form of the operations on an ADT or operations syntax, that is, the program interface to the ADT.

The next two sub-sections contain a general description of how the syntax and semantics can be represented.

Operation Meaning or Semantics

The semantics of the operations or functions acting on an ADT can be described in natural language, mathematics, or programming languages. By using mathematics, it becomes possible to be precise about the semantics of each operation and thus be able to reason about results, such as the effects of an operation, the relationships to other operations and properties of data objects related to other ADTs, and whether a program implements an ADT correctly.

The descriptions of operation semantics in this article will use algebraic semantics. Other mathematical notations such as logic could be used, but algebraic semantics seems to be the easiest to comprehend. In this case, algebraic semantics is simply the definition of the behavior of an ADT using an algebra. An algebra consists of one or more sets of values (called domains or sorts) and a set of operations on these domains. Simply stated:

$$\text{algebra} = <\text{domains, operations}>$$

The algebraic approach uses a set of statements (axioms) in a mathematical format to describe the properties of the operations. Operations in an algebra are usually described in terms of each other. Note that the data representation and implementation are not part of the algebraic specification.

In the description that follows, the algebraic statements that define each operation in terms of the domain will be accompanied by a verbal description to assist the reader in understanding the meaning of the statement.

Operation Form or Syntax

The operation form or syntax describes how the ADT is used, that is, what types of values or parameters are required for the operations and what type of values the operation provides or returns. Programming languages and mathematical descriptions use different approaches to specify the operations or interface to an ADT. We choose the programming language C to illustrate a way of specifying the interface independent of the implementation and an algebraic method to provide a mathematical description.

Now that we have presented a general description of the syntax and semantics of ADTs, in the next part of this article, we will describe the algebraic semantic operations and the syntax of a stack in detail so that the principles involved are clear. The algebraic semantics of the stack are defined first because this specifies the operations needed. Once the stack is thoroughly described, the algebraic semantics for other ADTs, including queue, set, and bag, are presented. The reader should be able to infer the program syntax from these semantic descriptions of operations.

THE STACK ADT

Informal Definition

A stack is a collection of items of the same data type in which only the most recently added item may be examined or removed. For example, the data type could be integers, real numbers, or something more complex, such as a tuple. If the most recently added item is removed, then the second most recently added item becomes the most recently added item and may be examined or removed. The stack is also known as a last-in-first-out data type or LIFO.

The subsequent discussion uses elements from the domain of natural numbers {1, 2, 3, . . .} as the data type to be placed on a stack. The symbol "N" is used to represent this domain. Using only natural numbers as the data type simplifies the discussion without affecting its generality. Changing to a different data type is straightforward as it only requires choosing a new domain such as $X = \{x_1, x_2, x_3, \ldots\}$. For example, if the data type is a tuple that consists of a name and an age, then the domain X would be the domain that consists of all name, age pairs.

Algebraic Semantics of Operations

Operations on a Stack. The normal definition of a stack S has the following basic operations:

- push(v, S) puts item v from N on stack S and returns a stack. Thus, the operation push operates on two domains, the domain N and the domain of all stacks of N, which is designated as S_t. The operation push returns a member of the domain S_t.
- popOff(S) removes the item from N most recently placed on the stack S and returns a stack. The function popOff only operates on the domain S_t returning a member of S_t.
- top(S) provides access to the item v from N, the item most recently placed on the stack S, and returns that value. The function top operates on the domain S_t and returns a value in the domain N.
- isEmpty(S) returns a value true (T) if stack S is empty and false (F) in all other cases. The function isEmpty is necessary to ensure that popOff and top do not try to manipulate an empty stack. The function isEmpty introduces the Boolean domain designated by B, which contains two members true (T) and false (F). The function isEmpty operates on the domain S_t and returns a value in the domain B.
- *new*() returns a new stack. The function new operates on the domain S_t and returns a specific member of S_t, namely, the empty stack.

Related Domains. Based on the previous discussion, it can be seen that the operations on a stack involve three domains:

N—the domain of natural numbers

S_t—the domain of all stacks of natural numbers including the empty stack

B—the domain of Boolean values (true, false)

Elements of the domain N are pushed onto a stack in S_t, and produce a stack in S_t. Elements of the domain N are produced when the top of the stack in S_t is examined, and elements of the domain S_t are produced when the top element in S_t is removed. Thus, elements of the domains N and S_t act as both input and output for the operations push, popOff, and top. Finally, the operation isEmpty acts on an S in S_t to produce elements of the domain B. Elements of B are only outputs of operations.

A domain is often called a sort, and the domain and the operations on the domain are called the signature of the algebra. A many-sorted algebra has operations based on more than one domain. Because an ADT uses values from several different sorts or domains, an ADT can be defined by a many-sorted algebra.

Algebraic Semantics of a Stack. Once the operations for a stack are understood, a set of precise mathematical identities or axioms that describe the behavior of the stack in terms of the operations must be created. These axioms are developed and explained progressively. Note that these identities use the "$\equiv$" sign to indicate that the two sides of the expression are identical.

Axiom 1—popOff(push(v, S)) $\equiv$ S

This axiom says that when an item v from the domain N is pushed onto S and then removed, the stack is the same. For example, if elements 1, 2, and 3 are in stack S with 3[1] at the top of the stack, then popOff(push(300, S)) produces S = (1, 2, 3) because 300 is pushed onto S by the push operation to produce S = (1, 2, 3, 300), and then the element 300 is removed by the popOff operation.

Axiom 2—top(push(v, S)) $\equiv$ v

Here, when an item v is pushed onto S from the domain N, the function top provides access to that item. For example, if a new stack is produced by new(), then top(push(5, push(2, new())) will produce 5 and leave the stack as (2, 5).

Axiom 3 for isEmpty (S):

Axiom 3a—isEmpty(new()) $\equiv$ true

The stack generated by new() is the empty stack. Testing the empty stack with the operation isEmpty produces true.

Axiom 3b—isEmpty(push(v, S)) $\equiv$ false

The push operation puts one element on the stack, so even if S is empty, the stack generated by push is not. Therefore, isEmpty returns false.

These three axioms define the complete behavior of a stack. However, an additional operation can be introduced, namely, the operation pop, because pop is used later in the syntactic description of the stack as a matter of programming convenience. The operation pop is defined in terms of top and popOff. The operation pop returns the value of the top item on the stack, removes the item most recently placed on the stack S, and returns a stack. Thus, pop returns a tuple (v, S) where v belongs to N and S belongs to S_t. Thus, a new domain T has been introduced, namely, all pairs of values from N and S_t. The operation of combining two domains to make tuple is called the Cartesian product, in this case, the Cartesian Product of N and S_t.

Axiom 4—pop(push(v, S))$\equiv$(top(push(v,S)), popOff(push (v,S))) $\equiv$ (v, S)

This axiom defines the pop operation. An item v is placed on the stack with push; top provides access to the data item v, and popOff removes v leaving the stack S. Thus, the result of the pop operation is a tuple that consists of the top element and the remaining stack. In a stack (1, 4 ,8), the operation pop(push(5, (1, 4, 8)) creates a stack (1, 4, 8, 5), and pop(1, 4, 8, 5) produces (5, (1,4,8)) which provides access to 5, removes 5, and leaves the stack (1,4, 8).

[1] Note that stacks are written from left to right and the last added element is the rightmost element in the sequence.

The axioms popOff and top have assumed that the stack always has an entry. We could define a new domain E containing one element, namely, the value "error," and two corresponding axioms for popOff and top acting on an empty stack.

Axiom 5—popOff(new()) ≡ error

This axiom states that removing the top element of an empty stack produces an error.

Axiom 6—top(new()) ≡ error

This axiom states that examining the top element of an empty stack produces an error.

The equations just presented define equivalences between syntactic elements; they specify the transformations that are used to translate from one syntactic form to another. This mathematical description of an axiom for an operation on an ADT is known as a rewrite rule, which means which that any axiom "X ≡ Y" is a statement that any occurrence of an X can be replaced with a Y. For example, whenever the expression or sequence of symbols of the form

popOff(push(v, S))

is encountered, it can be replaced by the symbol S. If

popOff(push(w, T))

is encountered, then, similarly, it can be replaced by the symbol T.

Syntax of Operations

Interface. In this section, several programs for a stack that is written in the programming language C and uses the information-hiding principle are described to show how to produce an ADT in practice. The presentation is based on a calculator program adapted from Ref. 25. Hopefully, the commentary that accompanies the programs is self-explanatory. However, if the reader needs more details about the language C, then Ref. 25 is an excellent reference.

The calculator program, which is shown next, uses reverse polish (also called postfix) notation instead of infix because it makes a simple demonstration of the stack. Some

```
/* Stack example using an array */
#include <stdio.h>
#include <stdlib.h>      /* for atof() */
#define MAXOP     100   /* max size of operand or operator */
#define NUMBER    '0'   /* signal that a number was found */

#define MAXVAL     100   /* max depth of val stack */
int sp;                  /* next free stack position */
double stack[MAXVAL];    /* value stack as an array */
int getop(char[]);
void new();
void push (double);
double pop (void);

/* reverse Polish calculator */

main()
{
          int type;
         double op2;
         char s[MAXOP];
         new();
         while ((type = getop(s)) != EOF)
         {
              switch (type)
              {
        case NUMBER:
              push(atof(s));
              break;
         case'+':
              push(pop() + pop());
              break;
        case '*':
              push(pop() * pop());
              break;
         case'-':
              op2 = pop();
              push(pop() - op2);
              break;
         case'/':
              op2 = pop();
              if(op2!=0.0)
                   push(pop() / op2);
              else
                   printf("error: zero divisor\n");
              break;
         case '\n':
              printf("\t%.8g\n", pop());
              break;
         default:
             printf("error: unknown command %s\n", s);
                   break;
              }
         }
         return 0;
}
 /* new; initialize the stack */
void new()
{

         stack[sp++] = f;
     else
         printf("error: stack full can not push %g\n", f);
}
/* top: return top value from the stack */
double top()
{
           return stack[sp-1];
}
/* popOff: remove top elementof stack */
void popOff()
{
           --sp;
}
/* pop: pop and return top value from stack */
double pop()
{
           double top_value;
           if(!isEmpty())
           {
                 top_value = top();
                 popOff();
                 return top_value;
            }
            else
            {
                 printf("error: stack empty\n");
                 return 0.0;
            }
```

```
#include <ctype.h>
int getch(void);
void ungetch(int);

/* getop: get next operator or numeric operand */
int getop(char s[])
{
          int i, c;
          while ((s[0] = c = getch()) == '' || c == '\t')
                ;
          s[1] = '\0';
          if (!isdigit(c)&& c !='.')
                    return c;           /* not a number */
          i = 0;
          if(isdigit (c))      /* collect integer part */
                   while (isdigit (s[++i] = c = getch ()))
                         ;
          if(c == '.')         /* collect fraction part */
                   while (isdigit (s[++i] = c = getch ()))
                         ;
          s[i] = '\0';
          if(c!=EOF)
                 ungetch (c);
          return NUMBER;
}

#define BUFSIZE 100
char buf[BUFSIZE];    /* buffer for ungetch */
int bufp = 0;         /* next free position in buf */

int getch(void)     /*get a (possibly pushed back) character*/
{
        return (bufp > 0) ? buf[--bufp] : getchar();
}
void ungetch(int c)       /* push character back on input */
{
        if (bufp >= BUFSIZE)
              printf("ungetch: too many characters\n");
        else
            buf[bufp++] = c;
}
```

calculators and programming languages, such as Postscript (27), use reverse polish notation. In reverse polish notation each operator follows its operands; so the familiar infix expression

$$(3+2)*(6-2) \text{ is written as } 3\ 2 + 6\ 2 - *$$

Parentheses are not needed in postfix notation, and it is unambiguous, as long as we know how many operands go with each operator. In this example, each operator expects two operands.

The implementation of the calculator is simple. When each operand is encountered, as the expression is scanned from left to right, the operand is pushed on the stack. When an operator occurs, the stack is popped the correct number of times (in this case, always two), the operator is applied to the operands, and the result is pushed back on the stack.

In the example just described, 3 and 2 would be pushed on the stack, the "+" operator would cause the stack to be popped twice, and the result 5 would be computed and be pushed on the stack. Next, the 6 and 2 would be pushed on the stack, and then the "−" operator would cause the stack to be popped twice with the result 4 being pushed back on the stack. Finally, the operator "∗" would cause the stack to be popped twice (remember 5 and 4 are on the stack), which would produce the final result of 20. Note that the equal sign (=) is used for assignment, whereas the identity operator and its inverse are coded as "==" and "!=", respectively.

Note that the operations described for a stack have been used in this example so that the syntactic form and algebraic semantic form look similar. An actual operational program could be simplified by omitting top, popOff, and ifEmpty and coding them inline.

The algebraic semantics approach always assumes that elements in the domain S_t can grow without bound; in other words, no bound exist on the size of memory available for a stack. Of course, programs run in large, but finite, memory, and a limit to memory size and thus a limit to the size of a stack does exist. Therefore, the function *isFull* is introduced to indicate when no more memory is available so appropriate action can be taken.

The part of the program labeled main{} is the calculator and consists of a loop that "reads" operands (decimal numbers) and operators (+, *, -, and /). Inside the loop is a case statement that pushes numbers on the stack or pops numbers, applies the operator, and pushes the result back on the stack. One or two functions need explaining. The function getop uses other functions to collect the characters comprising an operand or operator from the input, the function atof converts the collection of characters constituting an operand (digits and a decimal point) into a decimal or floating point number.

Notice that the program uses an array for the stack that is defined by the statements:

```
#define MAXVAL 100         /* max depth of val stack */
int sp;                    /* next free stack position */
double stack[MAXVAL];      /* value stack */
```

The stack is an array of 100 elements of floating point numbers (double). To demonstrate data abstraction, the statements that define an array will be replaced by statements that define a linked list, namely:

```
struct stack_element {
        double data;                     /* data value */
        struct stack_element * next;     /* pointer to next
                                            data element */
};
struct stack_element * stack_top;        /* top of stack */
```

The statement "struct stack_element" defines a new data type that contains a number and a pointer to the next stack element. The asterisk (*) indicates that next is a pointer to a data type called stack_element. The definition in this case is recursive. The functions new, isFull, isEmpty, push, top, popOff and pop are replaced by new functions with the same name where the differences between each function is indicated by boldface type.

```
/* new; initialize the stack */
void new()
{
                stack_top = NULL;
}
/* is Full: is stack full? */
int isFull(struct stack_element * s)
{
if (s !=NULL)
                    return 0;
          else
                    return 1;
}
/* isEmpty: is stack empty? */
int isEmpty()
{
if(stack_top !=NULL)
                return 0;
           else
```

```
                    return 1;
/* push: push f onto value stack */
void push (double f)
{
      struct stack_element * p;     /* new stack element */
      p = malloc(sizeof(struct stack_element));
      if(!isFull(p))
      {
          (*p).data = f;
          (*p).next = stack_top;
          stack_top = p;
      }
      else
          printf("error: stack full can not push %g\n", f);
}
/* top: return top value from the stack */
double top()
{
     return (*stack_top).data;
}
/* popOff: remove top elementof stack */
void popOff()
{
     struct stack_element * temp;
     temp = stack_top;
     stack_top = (*stack_top).next;
     free(temp);
}
/* pop: pop and return top value from stack */
double pop(void)
{
     double top_value;
     if(!isEmpty())
     {
           top_value = top();
           popOff();
           return top_value;
     }
     else
     {
           printf("error: stack empty\n");
           return 0.0;
     }
}
```

Notice that substitution of a linked-list implementation for an array implementation does not require a change in the program main{}, that is, the program using these operations. This is what makes this data type abstract; the use of its operations is independent of the underlying implementation, but not of the interface.

The program can be generalized by allowing the push and pop operations to have a stack as an argument, which, thus, allows them to be used in more general situations. A version of the program main{} that uses an array for the stack and the functions new, isFull, isEmpty, push, top, popOff and pop with arguments follows. Programs written in the language C follow the call-by-value convention in which they always pass the values of a parameter. C uses an “asterisk” sign (*) to indicate that a variable is a pointer and the “and” sign (&) to indicate the value associated with a pointer. The function *malloc* creates a block of memory the same size as an element of the data type. Note that the functions for getop are not included because they do not change from implementation to implementation, which is another example of data abstraction.

```
/* Stack example using an array with arguments */
#include <stdio.h>
#include <stdlib.h>    /* for atof() */
#define MAXOP   100    /* max size of operand or operator */
#define NUMBER ’0’    /* signal that a number was found */
#define MAXVAL 100    /* max depth of val stack */
struct stack_type {
    int sp;                  /* next free stack position */
    double array [MAXVAL];  /* value stack */
};
struct stack_type * stack;
int getop(char[]);
void new(struct stack_type **);
void push (double, struct stack_type *);
double pop (struct stack_type *);

/* reverse Polish calculator */
main()
{
      int type;
      double op2;
      char s[MAXOP];
      new(&stack);
      while ((type = getop(s)) != EOF)
{
      switch (type)
      {
      case NUMBER:
            push(atof(s), stack);
            break;
      case’+’:
            push(pop(stack) + pop(stack), stack);
            break;
      case ’*’:
            push(pop(stack) * pop(stack), stack);
            break;
      case’-’:
            op2 = pop(stack);
            push(pop(stack) - op2, stack);
            break;
      case ’/’:
            op2 = pop(stack);
            if(op2!=0.0)
                  push(pop(stack) / op2, stack);
      else
                  printf("error: zero divisor\n");
            break;
      case ’\n’:
            printf("\t%.8g\n", pop(stack));
            break;
      default:
            printf("error: unknown command %s\n", s);
            break;
      }
  }
  return 0;
}
/* new; initialize the stack */
void new(struct stack_type ** s)
{
        *s = malloc(sizeof(struct stack_type));
        (**s).sp = 0;
}
/* is Full: is stack full? */
int isFull(struct stack_type * s)
{
if((*s).sp<MAXVAL)
                return 0;
          else
                return 1;
}
/* isEmpty: is stack empty? */
int isEmpty (struct stack_type * s)
{
if((*s).sp>0)
                return 0;
          else
                return 1;
}
/* push: push f onto value stack */
void push (double f, struct stack_type * s)
{
     if(!isFull(s))
          (*s).array[(*s).sp++] = f;
     else
          printf("error: stack full can not push %g\n", f);
}
/* top: return top value from the stack */
double top(struct stack_type * s)
{
             return (*s).array[(*s).sp-1];
}
 /* popOff: remove top elementof stack */
void popOff( struct stack_type * s)
{
           --(*s).sp;
}
/* pop: pop and return top value from stack */
double pop(struct stack_type * s)
{
          double top_value;
          if (!isEmpty(s))
          {
                 top_value = top(s);
                 popOff(s);
                 return top_value;
          }
          else
          {
                 printf("error: stack empty\n");
                 return 0.0;
          }
}
```

Again, the statements defining the stack as an array, namely,

```
struct stack_type {
     int sp;                /* next free stack position */
     double array[MAXVAL]; /* value stack */
};
struct stack_type * stack;
```

are replaced by the statements defining a list:

```
struct stack_element {
   double data;                  /* data value */
   struct stack_element * next;   /* pointer to next data
element */
};
struct stack_element * stack; /* top of stack */
```

Further more, the functions new, isFull, isEmpty, push, top, popOff and pop are replaced by new functions with the same name where the differences between each function is indicated by boldface type.

```
/* new; initialize the stack */
void new(struct stack_element ** s)
{
                *s = NULL;
}
 /* is Full: is stack full? */
int isFull(struct stack_element * s)
{
if (s !=NULL)
             return 0;
     else
             return 1;
}
/* isEmpty: is stack empty? */
int isEmpty (struct stack_element * s)
{
 if (stack != NULL)
             return 0;
       else
             return 1;
}
/* push: push f onto value stack */
void push (double f, struct stack_element * s)
{
     struct stack_element * p;        /* new stack element */
     p = malloc(sizeof(struct stack_element));
     if(!isFull(p))
     {
           (*p).data = f;
           (*p).next = stack;
           stack = p;
      }
     else
         printf("error: stack full can not push %g\n", f);
}
 /* top: return top value from the stack */
double top(struct stack_element * s)
{
        return (*stack).data;
}
/* popOff: remove top elementof stack */
void popOff( struct stack_element * s)
{
         struct stack_element * temp;

         temp = stack;
         stack = (* stack).next;
         free(temp);

/* pop: pop and return top value from stack */
double pop(struct stack_element * s)
{
         double top_value;
         if (!isEmpty(s))
         {
                 top_value = top(s);
                 popOff(s);
                 return top_value;
          }
          else
          {
                printf("error: stack empty\n");
                return 0.0;
           }
}
```

This section is intended to illustrate how a specific ADT, namely, a stack, may be implemented in practice. Similar techniques apply to all ADTs. The remainder of the article focuses on the definition for several ADTs using algebraic semantics. Included are the abstract data types (ADTs) for queue, set, and bag.

THE QUEUE ADT

The queue is the next ADT to be examined because it is similar to the stack in operation. However, the axioms for the queue involve recursion.

Informal Definition

A queue is a collection of items in which only the earliest added item may be accessed. The queue, just like an orderly line to board a bus or airplane, has a head and a tail. Items at the head are the next to board the bus or plane or to be accessed. Items joining the queue join at the tail. If no other item is added to the tail, then this item would be the last to be accessed. The queue is also known as a first-in-first-out data type or FIFO. Similar to the stack, this presentation about queues only uses elements from the domain of natural numbers as the data type to be placed on a queue. All possible queues of natural numbers themselves form a domain that is named Q_u.

Operations on a Queue

The queue Q has the following basic operations:

- add(v,Q) puts item v from the domain N on a queue Q and returns a new queue Q. The function combines elements from two domains N and the domain of all queues of N that is designated by Q_u, and produces an element from the domain Q_u.
- front(Q) provides access to the value of the earliest added item placed on the queue Q. The operation front

takes an element from the domain Q_u and produces an element from the domain N.

- remove(Q) removes the item placed first on the queue Q. The function or operation remove takes an element from the domain Q_u and produces an element in the domain Q_u.
- isEmpty(Q) returns a value true (T) if Q is empty and false (F) in all other cases. Thus, isEmpty maps an element from the domain $Q_u$to the domain B (Boolean).
- new() returns a new queue. The function new operates on the domain Q_u and returns a specific member of Q_u, namely, the empty queue.

Related Domains

Based on the previous discussion, it can be seen that the operations on a stack involve three domains:

N—the domain of natural numbers

Q_u—the domain of all queues of natural numbers

B—the domain of Boolean values

Note that we could introduce the domain containing "error," but we do not include it in this and subsequent examples.

Algebraic Semantics of Operations

Once the operations are defined for a queue, the axioms that describe their behavior are produced. These axioms are developed and explained progressively. Note that axioms 1 and 2 each have two parts because the axioms are recursive. The first part of the axiom is the result for a queue of length 1, whereas the second part of the axiom deals with the case where the queue has more than one element. An analysis of the recursion shows the operation moving recursively from the tail to the head of the queue to locate the element to be returned and to be removed. In other words, the recursive definition reduces a queue of length greater than 1 one step at a time until the resulting queue is of length 1 and the front element of the queue can be accessed or removed.

Axiom 1 for front(Q):

Axiom 1a—front(add(v, (new())) ≡ v

This axiom states that the front operation on a queue of length 1 returns the single element in the queue. In other words, when an item v is added to an empty queue, then it is the front item on the queue.

Axiom 1b—front(add(v, add(w, Q))) ≡ front(add(w, Q))

This axiom defines the general recursive definition of the front operation. It states that the front of a queue with elements v and w added to a queue Q is the same as the front of the Q with only the element w added. The operation front is applied repeatedly to reduce the length of the queue to a queue of length 1 where Axiom 1a can be applied. For example, if Q has elements 5, 7 and the front is 7, then the front of (v, w, 5, 7) is the same as the front of (w, 5, 7). This queue then is processed by the same expression, namely, Axiom 1b to produce (5, 7) and finally (7). The queue (7) then is processed by Axiom 1a to produce 7 as the front.

Axiom 2 for remove(Q):

Axiom 2a—remove(add(v, new())) ≡ new()

This axiom states that removing a single item from a queue of length 1 produces the empty queue.

Axiom 2b—remove(add(v, add(w, Q))) ≡ add(v, remove (add(w, Q)))

This axiom provides the recursive definition of the remove operation. It states that removing the head of the queue (v, w, Q) is the same as removing the head of the queue (w, Q). Again, the axiom is applied recursively to reduce the queue to a length of 1 where Axiom 2a is applied. If Q has elements 5, 7 and the front is 7, then remove(add(v, add(w, 5, 7))) is the same as add(v, remove (add(w, 5, 7))), which is the same as add(v, add(w, remove(add(5, 7)))), which becomes add(v, add(w, add(5, remove(7, new()))))). Of course, remove(7, new()) is new(), which is the empty stack. Thus, the queue is (v, w, 5) with the 7 removed.

Axiom 3 for isEmpty():

Axiom 3a—isEmpty(new())) ≡ true

A new queue is empty, and therefore isEmpty returns the value true (T).

Axiom 3b—isEmpty(add(v, Q)) ≡ false

For a queue that has at least one element, isEmpty returns the value false (F).

These three axioms define the complete behavior of a queue. However, an additional operation delete could be introduced as a matter of programming convenience. The operation delete is defined in terms of front and remove. The operation delete returns the value of the front item of a queue and removes this front item. Thus, delete returns a tuple (v, Q) where v belongs to N and Q belongs to Q_u. Thus, a new domain T has been introduced, namely, the domain of all pairs of values from N and Q_u.

Axiom 4—delete(add(v, add(w, Q))) ≡ (front(add(v, add(w, Q))), remove(add(v, add(w, Q)))

This axiom states that deleting the item at the head of the queue Q produces a tuple of two elements, namely, the item at the front of the queue and the queue itself. For example, delete operating on the queue (v, w, 3) produces the tuple containing the element 3 and the queue (v, w).

THE SET ADT

Informal Definition

A set is an unordered collection of elements where each element occurs at most once. A set has three properties: (1) All elements belong to a universe or domain, (2) either each element is a member of the set or it is not, and (3) the elements are unordered. The statement "all elements belong to a universe" needs some explanation. A universe encompasses all elements that have at least one common property. For example, the universe of all black chairs encompasses all chairs that are black. They could be made of wood, leather, or other materials. Another example is the universe or domain of all grades in a course where the numeric grades are integers from 0 to 100. A set could be some of these grade values. Because an element of a set can occur only once, if two students receive a grade of 72, the grade 72 only appears once in the set.

Operations on a Set

A set S has the following basic operations:

- add(v, S) adds an element v to a set S if v is not already in the set and returns a set S. The function add operates on the domain N of natural numbers and the domain of all sets of N, which is designated by S_e, and produces a set in the domain S_e.
- isIn(v, S) determines if a set S contains the element v and returns either true (T) or false (F). Thus isIn operates on the domain of all sets of natural numbers S_e and returns a value in the Boolean domain B.
- remove(v, S) removes an element v from the set S if v is in the set. The operation remove operates on the domain N of natural numbers and the domain S_e and produces a set in the domain S_e.
- isEmpty(S) determines if the set has no elements and returns either true or false. Thus isEmpty operates on the domain of all stacks of natural numbers S_e and returns a value in the Boolean domain B.
- new() returns an empty set. The function new operates on the domain S_e and returns a specific member of S_e.

Related Domains

Based on the previous discussion, it can be seen that the operations on a stack involve three domains:

N—the domain of natural numbers

S_e—the domain of all sets of natural numbers

B—the domain of Boolean values

Semantics of Operations

Now that the operations have been defined, we provide their definition through a set of axioms. Axioms for isIn, add, remove, and isEmpty exist where isIn, add, and remove have three parts and isEmpty has two parts. Multiple axioms are required for each of these operations to cover all situations. Note that the operations add, isIn, and remove are recursive.

Axiom 1 for add(v,S):

Axiom 1a—add(v, add(v, S)) ≡ add(v, S)

A set has only one occurrence of an element. Adding an element twice is the same as adding it once.

Axiom 1b—add(v, add(u, S)) ≡ add(u, add(v, S)) v ≠ u

This axiom states that elements that are not the same can be added to a set in either order.

Axiom 2 for isIn(v, S):

This operation has the value true (T) or false (F).

Axiom 2a—isIn(v, new()) ≡ false

An empty set does not contain any elements, so the element v is not in the set. The operation is false.

Axiom 2b—isIn(v, add(v, S)) ≡ true

A set that just has had v added must contain v. If v was already in the set then the new v will not be added. Thus, v is in the set whether it is added by the add operation or not, and so the isIn operation is true.

Axiom 2c—isIn(v, add(u, S)) ≡ isIn(v , S) if v ≠ u

This axiom provides a recursive definition of the isIn operation. The operation states that v is not the most recently added element to S, but it may be in the remainder of S. For example, the elements 5, 4, 3, and 7 can be added to S using the operations add(7, add(3, add(4, add(5, new())))). Then, isIn(4, add(7, add(3, add(4, add(5, new()))))) could be replaced by isIn(4, add(3, add(4, add(5, new())))), which could be replaced by isIn(4, add(4, add(5, new()))), which is true.

Axiom 3 for remove(v, S):

Axiom 3a—remove(v, new()) ≡ new()

Removing the element v from the empty set produces the empty set.

Axiom 3b—remove(v, add(v, S)) ≡ remove(v, S)

The first step in this axiom adds the element v to the set S. If v is already in S, then adding v produces S, which gives the right-hand side of the identity. If v is not in S, then we get S, which can also be written as remove(v, S).

Axiom 3c—remove(v, add(u, S)) ≡ add(u, remove(v, S)) if v ≠ u

This axiom states that removing v from the set that results when u is added to S (v ≠ u) is the same as add u to the set that results when v is removed from S.

Axiom 4 for isEmpty(S):

Axiom 4a—isEmpty(new())) ≡ true

A new set is empty, and therefore isEmpty returns the value true (T).

Axiom 4b—isEmpty(add(v, S)) ≡ false

For a set that has at least one element, isEmpty returns the value false (F).

THE BAG ADT

Informal Definition

A bag is an unordered collection of elements where each element can occur more than once. A bag has three properties: (*1*) All elements belong to a universe or domain, (*2*) either each element of the universe or domain is a member of the bag or it is not, and (*3*) the elements are unordered. The statement "all elements belong to a universe" has already been explained under the discussion of the set ADT. The example of all grades in a course shows how a set and bag differ. For example, if two students receive a grade of 72, then the grade 72 could only appear once in the set of grades but twice in a bag of grades.

Operations on a Bag

A bag S (we use S for sack, a synonym for a bag, as B is already taken as the symbol for the Boolean domain) has the following basic operations:

- add(v, S), which adds an element to the bag.
- isIn(v, S), which tells whether an element is in the bag.

- numberIn(v, S), which tells how many times an element is in the bag.
- remove(v, S), which removes an element from the bag.
- isEmpty(S), which returns true if the bag is empty and false otherwise.
- new(), which returns a new empty bag from the domain of all bags.

Related Domains

Based on the previous discussion, it can be seen that the operations on a stack involve three domains:

N – the domain of natural numbers
S_b – the domain of all bags of natural numbers
B – the domain of Boolean values

Axiom 1—add(v, add(u, S)) $\equiv$ add(u, add(v, S))

This axiom states that the elements can be added in either order and achieve the same result because all elements are added to the bag.

Axiom 2 for isIn(v, S):

Axiom 2a—isIn(v, new()) $\equiv$ false

The element is not in the empty bag, and so the operation is false.

Axiom 2b—isIn(v, add(v, S)) $\equiv$ true

The element is in the bag because it has just been added, and so the operation is true.

Axiom 2c—isIn(v, add(u, S)) $\equiv$ isIn(v, S) if v $\neq$ u

The element v is not in the bag produced by adding u to S, but it could be in S itself.

Axiom 3 for numberIn(v, S):

Axiom 3a—numberIn(v, new()) $\equiv$ 0

The number of times the element v is in the empty bag is zero.

Axiom 3b—numberIn(v, add(v, S)) $\equiv$ 1 + numberIn(v, S)

If the element v is added to S, then the count of v is one more than the number of times v is in S.

Axiom 3c—numberIn(v, add(u, S)) $\equiv$ numberIn(v, S) if v $\neq$ u

If the element u is added to S where v and u are not the same, then the count of v is the same as the number of times v is in S.

Axiom 4 for remove(v, S):

Axiom 4a—remove(v, new()) $\equiv$ new()

Removing v from the empty bag produces the empty bag.

Axiom 4b—remove(v, add(v, S)) $\equiv$ S

Removing v after it has been added to S produces S.

Axiom 4c—remove(v, add(u, S)) $\equiv$ add(u, remove(v, S)) if v $\neq$ u

Removing v from S augmented by u is the same as removing v from S when v and u are not the same.

The axiom isEmpty is not defined because it is similar to the ones for data types previously discussed.

SUMMARY

This article provides a comprehensive introduction to methods for describing and implementing abstract data types (ADTs). Many other ADTs could be described, including maps, which can be used to define dictionaries and priority queues. More information can be found in the references. A very complete formal description of ADTs is contained in Ref. 1, although the mathematical symbolism requires some translation into the notation used in this article.

AGENT-ORIENTED SOFTWARE ENGINEERING

INTRODUCTION

Agent-oriented software engineering (AOSE) is an approach to construct software systems based on the *agent* paradigm.[1] An agent can be thought of as an *autonomous* and *social* entity, which can communicate, coordinate, and cooperate with other agents to achieve goals. This notion of agent offers a higher-level abstraction than the notion of object used in object oriented (OO) software engineering.

AOSE approaches were originally proposed to engineer software agents. However, as soon as heterogeneous, networked software systems began to appear, machine-oriented views of computing appeared to be inappropriate to understand the complexity of these systems and to design them. AOSE is being recognized as a promising approach, offering human-oriented abstractions when designing these software systems (1). Along this view, agents are not only building blocks of a software systems, but also are proposed as design abstractions.

More generally, it can be said that AOSE provides computational abstractions, models, and tools with which to conceptualize and implement distributed software systems, whether they are realized as software agents or not. In the following article we will call them agent-oriented (AO) systems.

To help understanding the complexity of these systems and the type of problems we encounter building them, it can be useful to consider some applications of software agents and of current distributed systems, along with their properties.

Systems that operate in high-risk situations that are unsuitable or impossible for humans, like control systems on board robotic spacecraft for deep space exploration, were initially considered "killer" applications for software agents. For instance, the NASA space exploration mission *Deep Space 1* in 1999 experimented with agent-based software to manage exploration tasks in a flexible way. This software has been named *Remote agent*.[2] The *Remote agent* software could plan and execute many activities on board the spacecraft, being given only general mission goals from ground controllers on the Earth. An example goal might have been to "take asteroid pictures for navigation every 2 days for 2 hours" or "turn off the camera once you are done using it." The *Remote agent* monitored the execution of a plan that had been generated to accomplish a goal, to assess unforeseen failure conditions, and to decide to change a plan accordingly. For instance, it could recognize false information sent by a failed sensor and correctly ignore it. A main feature *of Remote agent* is that of behaving autonomously and in a goal-directed way.

In a domestic scenario, Robot vacuum cleaners are available today that behave autonomously (once switched on), having the ability to perceive their environment and adjusting their actions to achieve their design objectives, such as cleaning a room.

The Internet and the availability of distributed computational resources and services offer tremendous technological challenges and opportunities for AO systems. When planning for a journey or a vacation, we can access a virtual travel agency on the Internet to get an offer for a travel package that consists of flights, hotel rooms, and car rental, taking into account our date constraints and preferences, and we may eventually buy it, paying by credit card, in a secure way.

Current e-commerce applications provide product discovery and packaging (e.g., flight, hotel, car rental). Moreover, they perform simple bidding actions on behalf of a user. Research is progressing toward developing systems that act as brokers, engaging negotiation activities in the context of multiple auctions, taking into account customer preferences and constraints.[3]

The main feature of this type of agent-based system is the ability to interact with other systems following high level protocols, such as electronic auctions, and to decide how to perform a bid according to a specific policy that fit the customer's objectives.

Web 2.0, that is, the second generation of web-based communities and hosted services (such as social-networking sites, wikis, and folksonomies), which aim to facilitate collaboration and sharing between users, is also presenting tough software engineering problems. Complexity here derives from the heterogeneity of the platforms and networks these systems operate on; the diversity of their users, with different needs and preferences that evolve continuously; and the dynamicity of their operating environment.

Intervehicle communications for improving traffic safety and efficiency are also worth mentioning as a challenging application scenario for AO systems. A car can communicate with neighboring vehicles with the aim of coordinating at critical points (e.g., blind crossing, highway entries) or in case of critical events (e.g., accident, fog). These types of functions are particularly useful on secondary roads, which cannot be equipped with an information and warning service infrastructure (such as highways have). Communication between heterogeneous systems is a primary issue to be addressed together with the need of making these systems aware of their local environment, which changes while moving.

Summarizing, AO systems are software systems that behave in a *goal-directed* manner, either recognizing and adopting users' goals or being driven by their own goals. They are *situated*, that is, they are aware of their operational context and are *autonomous,* being requested to

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

respond dynamically to changing circumstances while trying to achieve a goal. They *interact* with other systems using high-level communication protocols. They act on behalf of humans who may have different needs and preferences, which *evolve* continuously. These software systems can be implemented as software agents, using agent programming environments, or as software components deployed in a distributed system platform. The most challenging application areas, accordingly to Luck (2), are *ambient intelligence,* which foresees an environment of potentially thousands of embedded and mobile devices that interact to support user-centred goals and activities. *Grid computing* should enable the efficient use of distributed computational resources, and *Electronic Business* supports the automation of information gathering and purchase transactions over the Internet.

Having to deal with such complex application domains, how can we understand them properly to identify requirements and properties of suitable software systems? That is, how can we design software with properties of autonomy and social interaction? How can we implement and test them? In other words, which type of software engineering methods and tools are appropriate to build such a system?[4]

AOSE aims at addressing these questions. First, it proposes to adopt the notion of *agent* and its related notions as a conceptual paradigm to understand and specify properties of AO systems.

Second, AOSE offers methodologies for analyzing the requirements and the software architecture of these software systems. AOSE methodologies adopt a visual modeling language, based on the agent paradigm, define models to be built during requirements analysis and system-design phases. They often offer specialized techniques for the analysis of these models.

Third, AOSE can offer structured processes that guide the development of the software system from early requirements analysis down to the implementation in terms of agent code or software components of a distributed system platform.

Content

In the following, the agent paradigm and examples of modeling languages based on it will be described. AOSE methodologies and examples of tool-supported software development processes will be also illustrated. Research on challenging issues in the AOSE area is very active. Some of the most promising efforts and trends will be recalled briefly.

THE AGENT-ORIENTED PARADIGM

On Agent Definition

The concept of software agent has evolved from artificial intelligence (AI) research areas, and in particular from distributed AI work, which date back to 1980. Different definitions have been proposed since then (3,4), which show influence from a variety of disciplines, including economics, philosophy, logic, ecology, and social science. This fact also motivates the use of the agent paradigm along different perspectives.

Adopting the software engineering perspective, common properties referred by all the different definitions and that are considered making the agent paradigm disruptive with respect to previously adopted software engineering paradigms (2) are represented by the following:

- *Autonomy and Situatedness.* An agent is a computer program that encapsulates some state (also called mental state) that is not accessible to other agents, and it makes decisions about what to do, based on this state, without the direct intervention of others. An agent can perceive the environment in which it operates, through appropriate sensors, and respond in a timely fashion to changes that occur in it. An agent's environment may be the physical world, the Internet, a collection of other agents, or a combination of them. An agent can exhibit a goal-directed behavior and can select dynamically and autonomously which action to execute, according to its designed objectives.
- *Social Ability.* An agent can interact with other agents (artificial and human) through high-level protocols. It can coordinate and collaborate with other peers for achieving its designed objectives.

Quoting Luck (2), the agent paradigm "causes a re-evaluation of the very nature of computing, computation and computational systems, through concepts such as autonomy, coalitions and ecosystems, which make no sense to earlier paradigms." It can be useful to contrast the definition given above with other widely used abstractions in software engineering, that is, the *object* paradigm and the system *component* abstraction. Worth mentioning is also the difference between software agent and *agent in the world*, as used in requirements engineering approaches.

Agents versus Objects. Objects are defined as computational entities that encapsulate some states, perform actions or *methods* on this state, and communicate by message passing. Agents have goals and skills (services) to achieve them. Agents exploit a symbol-level communication.

Even if objects encapsulate state and behavior realization (method), they do not encapsulate behavior activation (action choice). An object's public method can be invoked by any object, and only once the method has been invoked, the corresponding actions are executed. Objects are passive, they can not refuse to execute them. Objects can be used to enable agent technology. Most currently used agent-programming languages and platforms are built on top of Java (5). More generally, object and methods abstractions are considered too low-level granularity for describing interactions. This motivated the development of more powerful abstraction mechanisms, such as system component.

[4] Herein, see: Software Engineering: Software Life-Cycle Activities and Software Engineering: Software Engineering Tools and Techniques

Agents versus System Components. A software component is a system element that offers a predefined service and communicates with other components. Components are considered to be a higher level of abstraction than objects, and as such they do not share state and communicate by exchanging messages that carry data. A main difference between components and agents is in the mechanism they use to communicate, which is usually referred as imperative versus declarative message passing, and in the purpose of communication. A component communicates with another one to force it to execute the body of a method without saying why. The sender is entirely responsible for such an execution (that is, it is responsible for guaranteeing that preconditions hold and for changes caused in the system). An agent communicates with another one in an attempt to transfer part of its mental state to the receiver. For instance, it can delegate one of its goals to the receiver. It is up to the receiver to accept this delegation. Moreover, the receiver is solely responsible for the outcome of its own actions.

The different communication models determine a major difference in their relationship to the outer world (the environment). Agents execute in the environment (that is the execution of their actions affects the environment); they can perceive it so that changes in the environment reflect into changes of the agent's mental state. Components use interfaces to enumerate what they can do and how clients can get in contact with them. Interfaces can specify postconditions, which define how the state of the component changed on executing an action, but no information on the environment is given (6).

Agents in Requirements Engineering. Requirements engineering provides methods and techniques for supporting the identification of users and stakeholders needs, and for analyzing them in terms of alternative solutions. Its ultimate goal is that of deriving software requirements that fit those needs. In requirements engineering, the agent paradigm is used to analyze the application domain, in which a new software has to be introduced, in terms of agent's intentionality and sociality. Agents here are humans, organizations, and artificial systems; each one has its own goals and mutual dependencies for goal achievement. Introducing a new software system means introducing a new agent in the domain, which will provide alternative ways to achieve the domain agents' goals. Requirements of this software are traced back to domain agents' goals, which provide a rationale for requirements and also a way for detecting reasons for possible conflicts among requirements. As pointed out by Yu (7) despite the fact that "agents-as-software" and "agents-in-the-world" may share conceptual features, important differences must be taken into account when using them. For instance, assigning greater autonomy to software agents means building a more powerful and complex system. When modeling the world instead, the analyst ascribes an increasing level of autonomy to the modeled agent when the implications of a greater level of uncertainty and variability need to be understood. As for sociality, agents in the world engage in complex relationships, which form an unbounded network, so when modeling them the purpose is to provide a means to acknowledge complexity in the world rather then to identify mechanisms to manage it.

Agent-Oriented Modeling Languages

Modeling languages allow one to represent the structure and the properties of a system in an abstract way. The most widely used in software engineering is the Unified Modeling Language (UML) (8), which is the standard language for object-oriented modeling. Besides a specific syntax and semantics, modeling languages usually provide a diagrammatic notation, which allows one to represent a system specification with a set of diagrams.

Visual modeling has been recognized as a powerful support for communication among the stakeholders involved in the development process and for the documentation of a project. It became a popular practice as soon as software tools that provide functions to create models and diagrams started to become available.

Modeling is a core activity in software development processes that follow the model-driven architecture (MDA) approach (9). Indeed, MDA conceives the software development as a modeling process. The basic artifacts in an MDA process are models that are used to specify the software to be built. Two types of models are usually created: (*1*) a model that corresponds to a software specification which is independent from the technology that will be used for its realization, called also platform-independent model; and (*2*) a model specified in a language, which allows it to represent basic construct of the target implementation platform (the platform-specific model). MDA proposes guidelines and standards to automate the mapping from a platform-independent model to a platform-specific model, provided that the syntax and semantics of the modeling languages used to build these models are given in terms of a meta-model. The term meta-model is used to indicate a model of the concepts that can be used to design and describe actual systems. These meta-models are usually specified as UML class diagrams. The models that describe a system contain instances of the meta-model classes. Figure 1(a) sketches the structure of an MDA process (9,10). Mapping between source and target models are obtained through an application of mapping rules defined between the elements of the meta-models of the source and the target modeling languages.

The ultimate goal of MDA is to improve the quality of software products and the development process, by allowing for the reuse of models and mappings between models. Nowadays, lot of effort is required to develop model interoperability standards, as well as model-to-model transformation concepts and techniques for their automation in MDA. The MDA initiative refers mainly to OO software development, but its ideas and standards influenced AO approaches also.

Agent-oriented modeling languages are usually given their own graphical notation and UML meta-models to express their syntax and semantics. In a broad sense, we may consider three main families of AO modeling languages: (*1*) languages that inspired directly from the AO

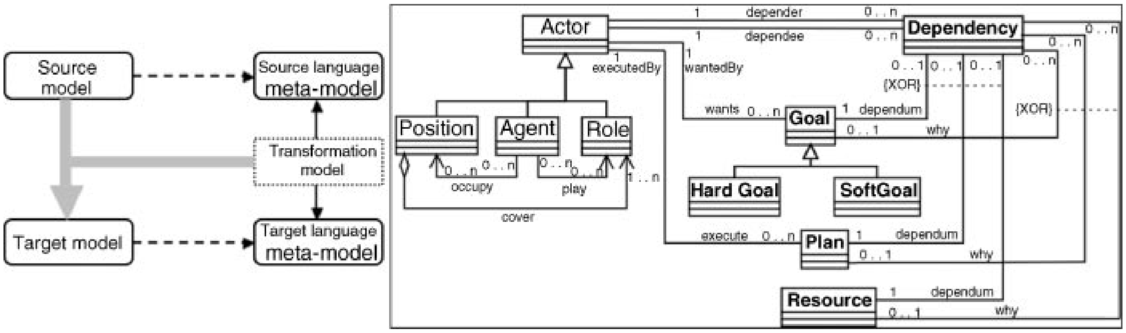

Figure 1. (a) Model to model transformations according to the MDA approach (9). (b) A portion of the meta-model specifying the semantics of the i^* based notation used in the *Tropos* methodology (10).

paradigm. Examples of languages belonging to this family are the agent-object-relationship modeling language (AORML) (11), the i^* framework (12), and Knowledge Acquisition in autOmated Specification (KAOS) (13), which have been initially proposed for modeling and analyzing requirements; (*2*) languages defined by abstracting from specific agent programming languages. Examples include the modeling language used by the *Prometheus* methodology; (*3*) languages that extend UML with agent paradigm notions. Examples are Agent UML (AUML) (14), Agent Modeling Language (AML) (15), and the modeling language used by the *ADELFE* methodology.

Figure 2 illustrates AO modeling languages' genealogy. In the rest of this section, for each family, an example of a modeling language is given in more detail. Some consider the situation at the time of writing analogous to the situation that preceded the agreement, which led to the definition of a unified language for object-orientation, namely UML.

Languages Inspired from the AO Paradigm

The i^* framework (12) proposes an agent-oriented approach to requirements engineering, which focuses on the *intentional* characteristics of agents, such as goals, beliefs, abilities, and commitments. The underlying idea is that agents in organizations depend on each other for goals to be achieved, tasks to be performed, and resources to be furnished, which leads to a network of dependencies. That is, the framework rests on a concept of *distributed* intentionality, from which the name i^* derives.

Primitive concepts of the i^*modeling framework are: the concept of *actor*, which is an entity that has strategic goals and intentionality within the system or the organizational setting. An actor can represent a physical or a software *agent*, a *role* played by an agent in a specific context or a set of roles (*position*). The concept of *goal* represents a strategic interest of an actor. The language distinguishes hard goals from soft goals, which are typically used to model nonfunctional requirements. Task (*plan*) represents, at an abstract level, a way of doing something; *resource* represents a physical or an informational entity. Moreover, the framework supports several primitive relationships, such as strategic *dependencies* between actors where one actor wants something and another is willing and able to deliver it. Additional types of relationships are: goal AND/OR *decompositions, means-end* relationships between a plan (the means) and a goal (the end), as well as positive/negative *contributions* from goals/plans to soft goals.

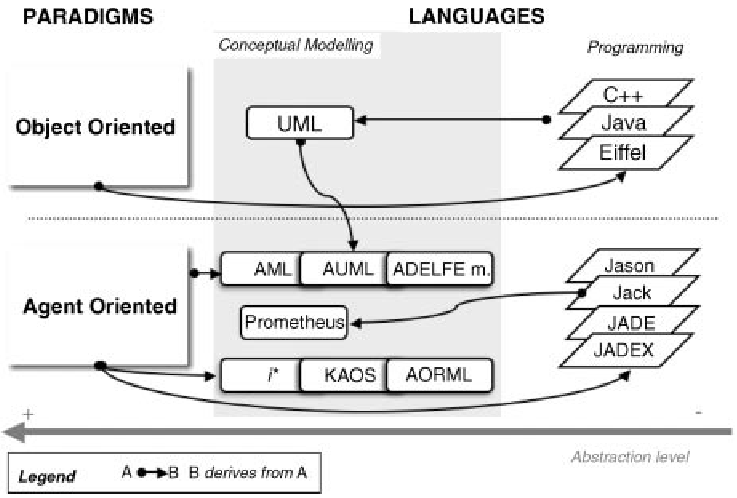

Figure 2. Genealogy of AO modeling languages. The abstraction level increases going from programming languages to paradigms. The UML language for object-oriented analysis and design was defined by abstracting from OO languages. Some AO modeling languages result from an analogous abstraction process from AO programming languages (e.g. Prometheus) whereas others inspire directly from the AO paradigm (e.g. i*, KAOS, AORML), or extend UML with AO concepts (e.g. AHL, AUML, ADELFE).

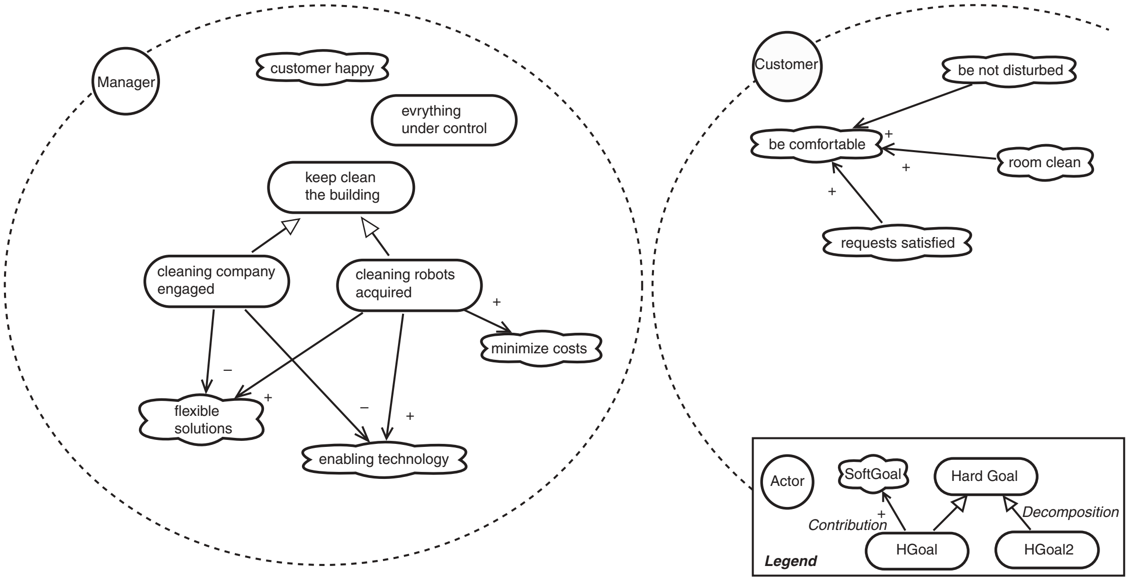

Figure 3. Goal diagrams of the Early Requirements *Tropos* model of the hotel cleaning domain.

These notions are more formally specified in the language meta-model, which is illustrated in Fig. 1(b). For instance, an actor *dependency* is a 4-ary relationship: The first and second arguments are of type actor (depender and dependee), and the third argument is of type goal or plan or resource (dependum). It is also possible to specify a reason for the dependency (labeled as why), which can be a goal or a plan, which is part of a goal/plan decomposition or a resource. A model is an instance of the meta-model and can have a graphical representation in terms of an *actor* diagram that represents strategic dependencies between networks of actors and a *goal* diagram, which depicts how actor goals have been decomposed into subgoals and possibly operationalized through means–end relationships.

An example of *goal* diagram is given in Fig. 3, which illustrates an excerpt from a model of an "hotel cleaning" domain.

> Two stakeholders, the hotel's manager, and the customer are represented as actors, the `Manager` and `Customer` actors respectively, with their goals. The point of view of the actor `Manager` with reference to main goals like `keep clean the building` is analyzed inside the balloon diagram. This top level goal is OR-decomposed into subgoals, which represents alternative ways to achieve it, namely engaging a cleaning company or acquiring a cleaning robot system.

Abstracting from Agent Programming Languages

As soon as agent programming environments were ready to be used outside the academic environment, modeling languages for specifying agent applications started to be proposed. The aim was mainly that of providing a modeling language for a practical methodology that should guide a software engineer during the use of a specific programming environment, which is eventually generalizable to others.

Along this line, we can mention the modeling language used by the *Prometheus* methodology (16). Among the basic concepts of this modeling language are those of *percepts* and *action*, which represent information that the environment provides to an agent and the actions the agent can perform to change the environment, respectively. Moreover, two types of agents can be specified: *proactive* agents, which can pursue goals, and *reactive* agents, which respond to significant occurrences (events). These events may be percepts from the environment, but they may also be messages from another agent or even internal occurrences. In case of proactive agents, the concepts of *belief* and *plan* are used to represent states and library of plans to achieve goals. To model social properties of agents concepts like *commitment, norm*, and *team* are also provided.

A set of diagrams to build views on a model are provided, including goal, scenario, role, system overview, agent overview diagrams. Figure 4, depicts a simple system overview diagram for a cleaning robot agent.

Extending UML

The UML language provides different mechanisms for its extensions, for instance, the stereotype mechanism that extends the UML vocabulary adding new model elements or the profile mechanism for tailoring the language to a specific problem domain. These features of UML were exploited in several AO modeling language proposals, which aimed at capitalizing on the wide use of UML in software engineering and on the availability of a variety of tools supporting UML, to favor the adoption of agent-based technology.

The AUML proponents made explicit their intention to provide minimal extension to UML for supporting the specification of properties peculiar to agents and for reusing UML diagrams as much as possible during AO systems design. The initial work on AUML focused on agent interaction, which is specified through sequence diagrams, that were extended, for instance with AND, OR, XOR operators (14).

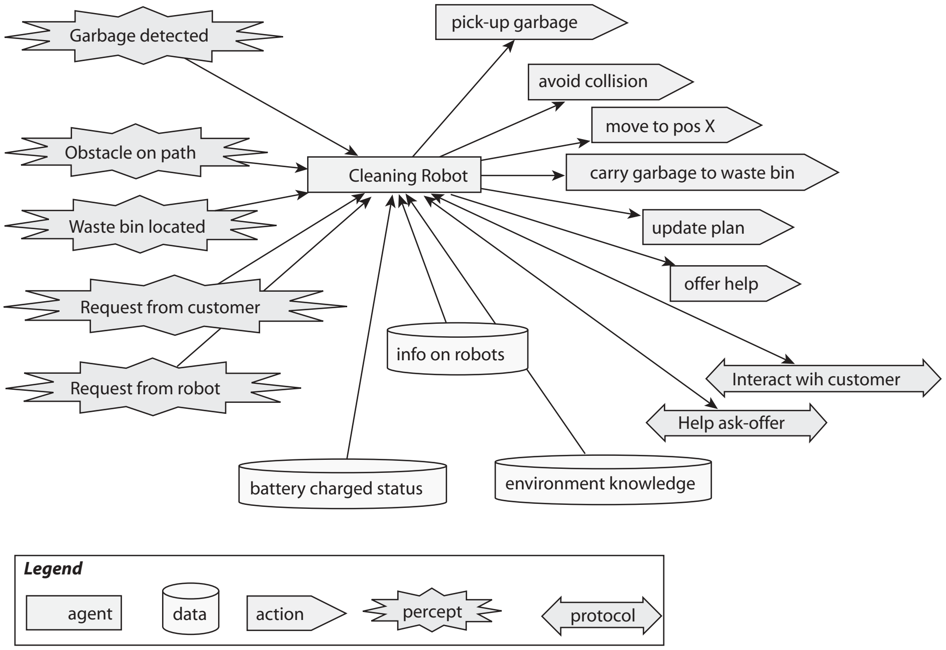

Figure 4. System overview diagram in the *Prometheus* methodology for the cleaning robot agent.

AUML sequence diagrams were adopted by FIPA[5] to express agent interaction protocols and became a reference notation for several methodologies to specify agent protocols. The example in Fig. 5, illustrates an interaction protocol in which an agent (a robot cleaner) requests peers about offering help for cleaning tasks. The protocol admits a set of communicative actions such as refusal to help, acceptance, and inform. Agent class diagrams as well as extensions to other UML elements like package, template, and activity diagrams are also provided. AUML definition is currently a task of the *Agent Platform Special Interest Group* of OMG,[6] whose final objective includes that of promoting a standard agent modeling language.

Based on UML extensions are the modeling language used by the *ADELFE* methodology (17) and the AML (15), which represents an industrial initiative.

AGENT-ORIENTED SOFTWARE ENGINEERING METHODOLOGIES

Software engineering methodologies define a structure for the development process in terms of phases, activities, and work products (artifacts).

Research on AOSE methodologies received a lot of attention in the last 10 years, and currently we may count tens of different proposals. Indeed, on one side, researchers try to analyze and compare them along different criteria, like coverage of the agent abstractions used in modeling, model's completeness, consistency, complexity, re-usability; development life-cycle; availability of tools; and in general usability of the methodology. On the other side, a reciprocal contamination and evolution of some previously proposed methodologies can be observed. Currently few of them provide tool-supported environments. Interesting is also an analysis made by Sellers et al. (18) that identified the roots of state-of-the art methodologies in OO frameworks like RUP and Fusion.

We focus here on AOSE methodologies that adopt a model-based approach. These methodologies define the models to be created, step by step, during the different phases in the development process, and adopt an AO modeling language for their specification.

To give a flavor of what AOSE methodologies offer today, in the following, basic features of the principal methodologies will be recalled along basic phases of the software development process, namely requirements analysis, system design, implementation and testing. Excerpts from the analysis and design of the "cleaner world" scenario, adapted to the problem of room cleaning in a hotel, will be used to exemplify.[7] In particular, room cleaning will be considered as a cooperative task performed by a team of autonomous agents, which have on-board sensors to help moving in the environment avoiding collision with objects or moving entities, and the ability to engage forms of collaborations with the other robots to ask/offer help for cleaning.

[5] The Foundation for Intelligent Physical Agent (FIPA) aims at promoting agent-based technology and the interoperability of its standards with other technologies. Since 2005, it is an IEEE Computer Society standards organization.

[6] The Object Management Group (OMG) is an international consortium aiming at promoting standards for a wide range of technologies. The effort on AUML definition has been first carried out inside FIPA, and since 2005 it is one of the OMG initiatives, http://agent.omg.org/.

[7] The "cleaner world" scenario has been largely used in AI research. A description is given by Firby (19).

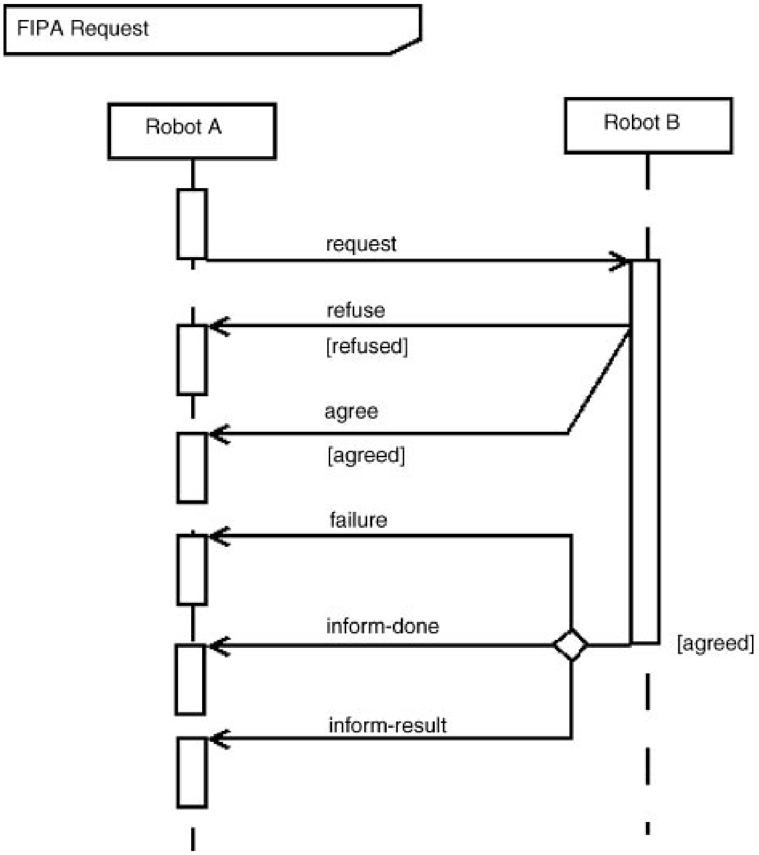

Figure 5. AUML specification of the ask/offer help interaction protocol between cleaning robot agents.

Analysis

The analysis phase aims at understanding the problem domain and the requirements of the software system to be built. These aspects are crucial in developing software because poor understanding of the problem domain and of customer needs is a major reason for software projects failures. This fact motivates the development of a specific discipline inside software engineering, named requirements engineering, which offers methods and techniques to discover and specify requirements, to analyze and verify the consistency of a requirements specification, and to manage requirements changes.

Focusing on AO approaches, the analysis phase will be guided by questions like the following ones. How will the system affect the current domain organization? Which goals will be the system responsible for? How will the system interact with the environment? The resulting models will specify aspects like: the role(s) of the system-to-be with respect to domain stakeholders; its assigned goals (responsibilities); reasoning capabilities, sensors/effectors the system should be provided with; human-system and system-system interaction protocols.

Table 1 recalls specific models to be built in this phase, according to some AOSE methodologies. In particular, the *Tropos*(20) methodology borrows ideas from the i^* framework for requirements engineering and proposes to model the application domain first, using actor and goal diagrams, as those depicted in Fig. 3 and in Fig. 6. In the *Early Requirements* model, the domain stakeholders are represented as *actors* together with their goals and their strategic dependencies for goal achievement. For example, the hotel cleaning scenario is modeled in terms of two main stakeholders: the hotel manager and the customer (Fig. 3).

> The manager goal `keep clean the building` is analyzed along alternative ways to achieve it. Exploiting a cleaning robot system is represented by the subgoal `cleaning robots acquired`. This alternative is considered a more flexible solution with respect to engaging a cleaning company and contributes to reduce costs, this is represented in terms of positive contributions to the soft-goals `flexible solutions` and `minimize costs`.

A deep understanding of the domain is considered a crucial step to understand the role of the software system to be built and to identify the goals the new system should contribute to achieve. This is represented in the *Late Requirements* model, an excerpt from the model of the hotel cleaning scenario is depicted in Fig. 6.

> The `RobotTeam` actor represents the cleaning robot system. The overall objective of the system is that of daily cleaning the building (`clean building` goal). A predefined task allocation is given to the cleaning agents, but dynamic re-planning of the cleaning task is used to manage unforeseen situations like

Table 1. Artefacts by Process Steps, Supporting Tools and Development Process of Some AOSE Methodologies (6, 18).

Process Phase	*Tropos*	*MAS-CommonKADS*	*Gaia*	*o-MaSE*	*Prometheus*

Figure 6. Hotel cleaning scenario: excerpts of Late Requirements and Architectural diagrams in *Tropos*. A fragment of the Jadex code that has been automatically derived from the Architectural diagram is also shown.

> extra effort required to clean a room or robot malfunctions. Re-planning results from agents collaboration (be `cooperative` goal). Of course re-planning can still end up with a failure condition that will be communicated to the hotel manager.

Another methodology, *MAS-CommonKADS* (21) adapts conceptualization techniques, such as *Class-Responsibility-Collaboration* (CRC) cards together with user centred techniques and prescribes a set of models to be built in the analysis phase, including an organization model that describes the agent society, and a communication model that describes the human-software agent interactions.

In other AOSE methodologies the analysis phase focuses directly on the system-to-be and subsequently on the external actors, which interact with it. For instance, *Gaia* (22) assumes that requirements have been identified during a preliminary requirements elicitation activity and prescribes to build role and interaction models for the system. Note that *Gaia* does not commit to any specific notation for its models. Analogously in *o-MaSE* (23) first a goal model of the system is created and refined into an AND/OR goal tree, from which the organizational model is derived. The organizational model points out interfaces with external actors and it will be complemented with a specification of the interaction between those actors and specific roles in the system (Role model).

Other AOSE methodologies, like *Prometheus,* adapt Use Case analysis techniques used also in OO methodologies, which identify the external entities (referred to as actors) that will use or interact in some way with the system-to-be and the key scenarios around which the interaction will occur. The system interface is also modeled in terms of perceptions and actions the system can perform on the environment.

Design

The design phase aims at defining the system architecture accordingly to the functional and nonfunctional requirements analyzed in the previous phase. AOSE approaches design at two levels called the macro and the micro levels. The macro level concerns the specification of the system architecture in terms of components (e.g., agent types or multiagent systems) and of their dependencies. Here, available architectural styles (organizational patterns) can be used as a reference structure for the architecture. An example of system architecture model in *Tropos* is depicted in Fig. 6.

> The `Robots Team system` is defined in terms of `Cleaning Robot` agents with the following four individual goals: clean its environment by removing dirt whenever possible, that is pick-up any garbage and carry it to a near waste bin; keep itself operational by monitoring its internal state and in particular its battery charge state. Whenever the battery state is low, move to the charging station; be nice to other-people or objects that are close by, e.g. it should not collide with others. Moreover it should understand requests by an hotel customer like: "do not clean here now" or "do a quick cleaning now"; be collaborative with the other robot, that is answer to a request for help giving information about the percentage of assigned work done, the battery charge state and the location.

The corresponding agent model according to the *Prometheus* methodology is illustrated in Fig. 4.

The micro level concerns the design of the single agents. It specifies the agent's knowledge and reasoning capabilities, and the interaction protocols along with it will interact with the other agents. Interaction protocols are usually specified with diagrams as the one depicted in Fig. 5. Table 1 summarizes design model sets of current AOSE methodologies and supporting tools.

Implementation and Testing

Most currently available AOSE methodologies provide the developers a well-defined set of agent classes to implement and instantiate, according the specification that results from the design process. Guidelines or support for the implementation phase is usually considered out of the scope of the methodology.

The application of MDA principles to software development provides techniques to build automatic mappings from design specifications to code skeleton, in a chosen implementation platform. Research work on the application of these techniques to the case of AO systems is giving promising results (24).

Figure 6, depicts a fragment of agent code, in Jadex, which has been derived automatically from the agent's goal diagram of the *Architectural design* model in *Tropos*.

Agent programming environments, such as JADE and JACK, build on Java programming environments that provide their own supporting tools for programming and debugging (5). Current research addresses the need of debugging tools that can integrate the different programming paradigms and monitor the execution and communication of agents.

AO systems verification and testing is also mainly addressed in the research context.

Development Process and Tools

The development process of the AOSE methodologies involves a high degree of iteration within and or across the development phases. Process's features, from an overview on ten methodologies (18), are partially reported in Table 1.

Providing CASE tools at support of AOSE methodologies has been recognized a crucial step toward the adoption of *Agent-Oriented Software Engineering* methodologies by industry. Currently, specialized tools, which exploit model-checking or deductive reasoning techniques, are provided to support specific tasks such as the consistency verification of requirements (or design) specifications.

Visual modelers are provided by *Tropos* and *Prometheus*, whereas methodologies that adopt UML-based notation provide customization of UML modelers. The above-mentioned modelers provide also functions for automatic code generation toward specific Multi-Agent System platforms.

RESEARCH DIRECTIONS

Several challenges stimulate research in AOSE, as pointed out by Luck (2) and Zambonelli (25). Worth mentioning are efforts toward unification of AOSE methodologies and definitions of standards, as well as research on designing software with autonomic properties.

Given the great number of AOSE methodologies that can be found in literature, and the fact that each one defines its own concepts and system structure, interoperability becomes a main challenge. The Agentlink AOSE Technical Forum Group[8] addressed this issue by studying and comparing meta-models of existing methodologies to find commonalities and to give clear definitions of the core concepts used in AO systems development. The final objective was to propose a unified AO meta-model to become a reference for future agent-oriented modeling languages and development tools. This work is summarized by Bernon (26). The definition of standards for AOSE, including AO meta-models, is currently being investigated by other parallel initiative, such as IEEE/FIPA, OMG, and ISO.

Meta-models of the AO development process and of its products are at the core of *method engineering* approaches, which propose a project-specific methodology by composing coherent parts of existing methodologies, called method fragments. Method engineering has been successful applied in OO development (27). It requires a repository of method fragments specified accordingly to process and product meta-models. Construction guidelines support the use of the repository for deriving a personalized development methodology, which fits the needs of specific projects. Currently, a wide repository of method fragments coming from well-known AOSE methodologies, such as *Gaia*, and *Prometheus, Tropos*, has been included in the Open Process Framework (28). A similar approach is pursued by the FIPA Methodology Technical Committee. The method engineering approach allows, on one side, to overcome the need of a universally applicable methodology, and on the other side, it forces methods interoperability by means of meta-models.

The need of more solid tools to support agent systems developers is motivating studies on automating the generation of code from AO specifications and the verification of specifications and system testing. Adapting verification and testing techniques from concurrent and distributed systems may be not sufficient for the case of AO systems. Autonomous and deliberative behaviors of AO systems that operate in an open world may lead to unpredictable scenarios, and it may become difficult to say whether the AO systems are behaving "as wished." These problems become harder and harder as soon as the number of agents increases, the emergent behaviors are likely to be manifested. Studies on automating test cases generation and execution are promising toward managing scalability and evolvability issues. More generally, providing adequate development techniques and methods to support dependability characteristics, such as fault avoidance, fault tolerance, fault removal and fault forecasting, will make AO systems more robust, trustworthy, secure, and safe.

Research on the integration with other recently proposed computational paradigms, such as service-oriented architecture and autonomic computing, is also under way. According to the service-oriented architecture (29) model for distributed applications, new applications can be created at run-time by dynamically aggregating existing components, each one providing predefined computational services.

Autonomic computing (30) aims at creating computational systems, which can manage themselves. More specifically, these systems should automatically configure and reconfigure under varying (and unpredictable) conditions; they should self-optimize their operations by monitoring their components and fine tuning their workflow to achieve system goals; and they should automatically discover problems and recover from situations that might cause malfunctions. These properties are called in brief self-* properties. The autonomic computing vision takes inspiration from the autonomic function of the human central nervous system, which controls key functions without conscious awareness or involvement. This vision shares many goals with AO computing. AOSE seems to offer candidate solutions both at the design and the technology levels to manage the complexity of autonomic systems.

AGENT TECHNOLOGY

INTRODUCTION

Agent technology is a rapidly growing subdiscipline of computer science on the border of artificial intelligence and mainstream software engineering studying the construction of intelligent systems. It is centered around the concept of an (intelligent/rational/autonomous) *agent*. Generally, An agent is a software entity that displays some degree of autonomy; it performs actions in its environment on behalf of its user but in a relatively independent way. It takes initiatives to perform actions on its own by "deliberating" its options to achieve its goal(s).

Although there is no generally accepted precise definition of an agent, some consensus surrounds the (possible) properties of an agent (1,2): Agents are hardware or software-based computer systems that enjoy the properties of:

- Autonomy. The agent operates without the direct intervention of humans or other agents, and it has some control over its own actions and internal state.
- Situatedness. Agents are situated in an environment. They sense it and act in it.
- Reactivity. Agents perceive their environment and react to it in a timely fashion.
- Pro-activity. Agents take initiatives to perform actions and may set and pursue their own goals.
- Social ability. Agents interact with other agents (and humans) through communication; they may coordinate and cooperate while performing tasks.

Other properties that agents may have are *mobility* (the ability of an agent to move around in an electronic network and the Web in particular), *veracity* (the assumption that an agent will not knowingly communicate false information), *benevolence* (the assumption that an agent will always try to do what is asked of it), and *rationality* (the assumption that an agent will act to achieve its goals, and it will not act in such a way as to prevent its goals being achieved, its beliefs permitting), cf. Ref. 1.

Thus we observe that agents have both informational and motivational attitudes; they handle and act on certain types of information (such as knowledge, or rather beliefs) as well as motivations (such as goals). Many researchers adhere to a stronger notion of agency that is sometimes referred to as a "cognitive" agent, which is an agent that realizes the above properties by means of mentalistic attitudes that pertain some notion of a mental state. The mental state involves such notions as knowledge, beliefs, desires, intentions, goals, plans, commitments, and so on. The idea behind this notion is that through these mentalistic attitudes, the agent can achieve autonomous, situated, reactive, proactive, and social behavior in a way that is mimicking or at least inspired by the human way of thinking and acting. So, in a way we may regard agent technology as a modern incarnation of the old ideal of creating intelligent artifacts in artificial intelligence (AI). Indeed, some modern textbooks in AI (3,4) even identify AI with the study of agents!

However, we may also regard agent technology as a next step after the currently very popular *object* techno- logy in the form of object-oriented programming. Some researchers regard agents as a special kind of objects, and some use the term "active objects" for agents (cf. Ref. 2, p. 26,27). However, in principle, some fundamental differences exist between agents and objects. In object-oriented programming, objects are simply "used": For instance, a call to a method of an object, will provided everything works normally just be executed by that object. In some sense, objects are just passive entities that can be employed in a system. For agents, however, it is different. An agent cannot be controlled directly by some program outside that agent (such as another agent). The agent should be *requested* to perform a task or to provide a piece of information. This request may be denied for reasons that concern that agent: Perhaps it is too busy, the request is not in line with its own goals, or perhaps even the agent is not in the right "mood". (We will later see how far these "human-like" qualities of agents may go.) In short, one may say that the main difference between agents and objects is the lack of autonomy of the latter (no control over its internal state and actions), whereas for the concept of an agent, it is one of the defining properties.

It is also important to note that the property of situatedness that agents are supposed to possess puts them apart from the expert systems from the 1980s. Expert systems are not situated: They only get information (symptoms) as input (from a user) and yield information (a diagnosis) as output (to that user). They do not really sense an environment, and they do not act directly in such an environment.

Although the initial research on agents focused on models of individual agents, more recent developments in agent technology emphasize particularly models and architectures of multiagent systems, in which multiple agents share the same environment and interact with it and each other. Here, we see the emergence of an interesting amalgam of the areas of (distributed) artificial intelligence and distributed computing in mainstream computer science. As a consequence, one may discern a trend toward *distribution* (of resources, "intelligence", and reasoning) and *delegation* of tasks between agents. Below, we will sketch the main research issues. But first, we turn to the start of agent technology: Philosophical ideas about (human and artificial) agents that act autonomously in an environment. These agents act based on decisions involving their "mental states," in particular that pertain to knowledge and objectives.

PHILOSOPHICAL BACKGROUND

The field of agent technology emerged out of philosophical considerations on how to reason about courses of action and human action, in particular. An area of analytical

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

philosophy is occupied with what is called *practical reasoning*, in which one studies so-called practical syllogisms that constitute patterns of inference regarding actions. As an example, a practical syllogism may have the following form (5).

Would that I exercise.
Jogging is exercise.
Therefore, I shall go jogging.

Although this example has the form of a deductive syllogism in the familiar Aristotelian tradition of "theoretical reasoning", on closer inspection it seems that this syllogism does not express a purely logical deduction: The conclusion simply does not follow logically from the premises. It constitutes a representation of a *decision* of the agent (going to jog), where this decision is based on mental attitudes of the agent, which are his/her beliefs ("jogging is exercise") and his/her desires or goals ("would that I exercise"). So, practical reasoning is "reasoning directed toward action—the process of figuring out what to do", as Wooldridge (6) puts it. The process of reasoning about what to do next on the basis of mental states such as beliefs and desires is called *deliberation*. The philosopher Michael Bratman has argued that humans (and more generally, resource-bounded agents) also use the notion of an *intention* when deliberating their next action (7). An intention is a desire that the agent is committed to and will try to fulfill until it believes it has achieved it or has some other rational reason to abandon it. Thus, we could say that agents, given their beliefs and desires, choose some desire as their intention, and "go for it". As such, we can view Bratman's theory as an extension of the more general theory of *intentional stance* of Daniel Dennett (8). This stance views complex entities (including humans, animals, and computers) as if they were rational agents that deliberate their beliefs and desires for deciding their next actions. As an aside, we remark that Dennett's intentional stance is very much related to similar theories in psychology and biology, and as ethology, in particular, where humans, including children and animals, are supposedly endowed with a *theory of mind* about other such entities. Thus, humans can reason about the mental states of these entities (Ref. 9, p. 838–841). Bratman's philosophical theory has been formalized through several studies, in particular the work of Cohen and Levesque (10) Rao and Georgeff (11), and van der Hoek et al. (12), and it has led to the *Belief-Desire-Intention model (BDI)* of intelligent or rational agents 11. Since the beginning of the 1990s, researchers have turned to the problem of realizing artificial agents. We will discuss this development in some more detail below.

AGENT LOGICS

As mentioned above, to get a more precise grasp on the philosophical considerations of Bratman, AI researchers started to use formal tools in the form of especially devised logics for formalizing the main ideas. These approaches are based on *modal logics*, which are logics that concern modalities such as knowledge, belief, time, obligation, and action. Modal logics have been proposed in philosophy to analyze the properties of these modalities. Semantics of these logics are usually provided by "possible world semantics" or "Kripke-semantics" (13), in which modal operators are interpreted by means of an accessibility (or possibility) relation, relating possible worlds according to the modality at hand. So, for instance, for temporal logic, this accessibility relation expresses the flow of time, whereas for epistemic logic (the logic of knowledge) the accessibility relation points at possible alternative worlds that the agent deems possible on the basis of its (lack of) knowledge. For example, a knowledge operator then expresses truth in all epistemically alternative worlds designated by the accessibility relation (cf. Refs. 14 and 15).

Cohen and Levesque (10) used a (linear-time) temporal logic for the description of agent behavior. In their work, which has been very influential in subsequent agent research, they try to capture the notion of intention in terms of more primitive notions such as belief, goal, and action. So, the culmination of their paper is a definition of intention in terms of these notions. Actually they give two, because two natural notions of intention are suggested: intention to *do*/ *perform* an action and intention to *be* in a particular state or situation. So for instance, an example of the former is the intention to go on a journey, whereas an example of the latter is the intention to be in a particular city, for example, Paris. Of course, relations exist between these two kinds of intentions, but they are distinct concepts in principle.

Next, Rao and Georgeff came up with their famous BDI logic, which is sometimes also called BDI-CTL because it is based on the (branching–time) temporal logic CTL (computation tree logic). This logic is devised in mainstream computer science to reason about concurrent processes (16). Rao and Georgeff's approach to formalizing Bratman's philosophy is different from that of Cohen and Levesque. Apart from the fact that they use a branching–time logic (catering for possible choices of actions by the agent in a more direct fashion), they also do not build a definition of intention in terms of other notions. Rather they introduce in their logic three independent operators (*modalities*) for beliefs, desires (or goals), and intentions; then, they start to analyze possible relations between these three operators, which are captured by axioms. For instance, they propose to have an axiom $Intend(p) \rightarrow Desire(p)$, which indicates that an intention is a (special) kind of desire.

Finally, we mention that van der Hoek et al. (12) propose yet another approach to formalizing Bratman's theory of intentions. This approach, which is called KARO for Knowledge, Abilities, Results and Opportunities, comprising the core of the logic, is based not on temporal logic but on *dynamic logic*. Dynamic logic is a logic proposed in mainstream computer science to reason about programs (17). Here, it is used to reason about the actions of agents. Furthermore, several BDI-style operators are added such as knowledge, belief, desire, goal, and commitment to specify the behavior of agents.

AGENT ARCHITECTURES

Next, we turn to the issue of constructing agent-based systems. Since the philosophical and logical work on intelligent agents mentioned in the introduction was published, researchers have embarked on the enterprise of realizing agent-based systems. Actually, the first architecture for artificial agents was given by the philosopher Bratman himself together with two colleagues from artificial intelligence, David Israel and Martha Pollack. These authors devised their IRMA architecture (18). At around the same time, the influential BDI architecture (11) and its derivative Procedural Reasoning System (PRS) (19) were proposed, which in turn inspired the dMARS architecture (20). In brief, in the BDI architecture, the interpreter executes a *sense-reason-act* (or *deliberation*) cycle, repeating the following processes: getting (sense) input, leading to possible belief updates, in turn leading to generating new desires/goals, which are then filtered to intentions. These intentions cause the execution of actions usually by means of plans from a precompiled plan library. The BDI architecture and its derivatives are called *deliberative* agent architectures.

However, also other agent architectures exist. *Reactive* agent architectures perform no deliberation or any kind of reasoning; they simply react to an environment. A typical example of such a reactive agent architecture is the *subsumption architecture* proposed by Brooks, (21). In essence, this architecture consists of layered modules, that run in parallel when given input from the environment. However, the output of these layers may inhibit that of other layers, according to a hierarchy (called a subsumption hierarchy). In this way, a priority relation is given amongst several behaviors generated by the modules. For example, in robotic applications, collision avoidance takes priority over exploring and wandering around.

One may also combine reactive behavior and deliberation into one system, which generates *hybrid* agent architectures. Typically, these agents are also layered architectures in which the layers deal with reactive behaviors and deliberative behavior(s). *Horizontally* layered architectures resemble the subsumption architecture, where layers run in parallel after which possible conflicts in outcomes should be resolved in some way by means of a supervisory control framework. However, *vertically* layered architectures also exist, in which the input from the environment enters the top (or bottom) layer, and then input/output go through all layers successively, with final output from the bottom (or top, respectively) layer. The advantage of vertically layered architectures is that "conflicts" between layers are solved "on the fly", so to speak, whereas horizontally layered architectures typically will react faster (because of the layers running in parallel). An example of a horizontally layered architecture is the TouringMachines architecture, which was proposed by Ferguson (22). An example of a vertically layered architecture is Mller's InteRRaP (23). For more information about agent architectures, the reader is referred to Wooldridge (2).

AGENT-ORIENTED PROGRAMMING AND SOFTWARE ENGINEERING

Agent architectures are suitable for conveying the general ideas about the building blocks of agents. But of course, they are hard to use in building actual agents from scratch in some general-purpose programming language. To get a more systematic grip on the construction of agents, new developments came into existence. Some researchers took it onto themselves to provide methods and techniques (sometimes erroneously called a "methodology") for constructing agents in a principled way, similar to what has been done in the "traditional" ways of programming such as object-oriented programming. Typically, one discerns phases of the development of an agent system such as the (requirements) analysis phase, the design phase, and the actual implementation phase. This research area is generally referred to as *agent-oriented software engineering* (24,25). Several methods have been proposed in the literature so far. We mention here DESIRE (26), GAIA (27), AUML (28), TROPOS (29), OPERA (30). Most of these methods ultimately are meant to implement agent systems using generic, general-purpose programming languages such as JAVA or C++. However, some researchers feel that using agent concepts (such as those in the BDI model) in the analysis phase and design phase, but *not* in the implementation phase (since general-purpose languages do not contain agent notions), hampers a smooth and correct construction of these systems (e.g., Ref. 31).

These researchers devised dedicated *agent-oriented programming* languages to program agents directly in terms of mentalistic notions in the same spirit as the ones mentioned above. Thus, these languages typically contain beliefs, goals, commitments, and/or plans as built-in programming concepts (and nowadays mostly with a precise and formal semantics). The first researcher who proposed this approach was Yoav Shoham with the language AGENT0 (32). This language enables the programmer to program timed commitments of agents, based on their beliefs and messages (such as requests to perform actions) from other agents. Other languages include AgentSpeak(L) / Jason, (Concurrent) METATEM, CONGOLOG, JACK, JADEX, and 3APL/2APL (33–36). Although all these languages have in common that they employ several mentalistic notions as mentioned above, they still differ widely from each other. For instance, AgentSpeak(L) (and its JAVA-based interpreter JASON) can be viewed as a programming language based on (a simplified version of) the PRS architecture. It can deal with beliefs and goals, and it can generate plans on the basis of those by means of a plan library via an intricate mechanism using triggering events. METATEM is based on the idea of making logical specifications executable, which restricts, of course, the formulas one can use in the specification. These formulas are a certain subset of temporal logic mixed with other modalities such as knowledge. In a way, one can view this approach as "temporal logic programming". The (CON)GOLOG family of languages is based on the situation calculus, which is popular specification formalism to reason about action and change, proposed by AI pioneer John McCarthy (37). In essence, a CONGOLOG program, which is basically an imperative-style program, provides directions while doing planning to reach a goal ("sketchy planning"). JACK is an extension of JAVA with agent-oriented constructs, whereas JADEX is a BDI reasoning engine implemented in JAVA that provides an execution environment and an application platform interface. 3APL and its successor 2APL are rule-based languages proposed originally as simplifications of AgentSpeak(L), with rules for plan generation (given goals and beliefs) and plan revision (given beliefs, and—in the case of 2APL—to be applied only when current plans fail).

MULTIAGENT SYSTEMS AND AGENT SOCIETIES

Agent-based systems become truly interesting and useful if we have multiple agents at our disposal that share the same environment. Here, we have to deal with several of more or less autonomous agents interacting with each other. Such systems are called *multiagent systems* (MASs) (2) or sometimes also *agent societies*. The field of MASs as such can be viewed as generated from Distributed AI, but many computer scientists interested in distributed/parallel computing and concurrent programming, more in general, have been drawn to it. The advantages of a distributed way of solving problems and performing complex tasks are the following:

- Computations can be done in parallel (so, in principle, they can be done faster).
- Computations and reasoning can be done locally by the agents with limited information about the environment.
- The distributed nature of a MAS may improve robustness and reliability, because other agents may take over from failing agents.

However, a price must be paid: Performance may be lower (suboptimal) whereas centralized single-agent systems may perform optimally in the ideal case that all information and resources are available. On the other hand, these centralized systems typically are more brittle with respect to robustness and reliability, and they may take a very long time to come up with the optimal solution. Another possible price to be paid concerns the communication overhead in a MAS to let the agents cooperate and coordinate properly. (cf. Ref. 38).

AGENT INTERACTION: COORDINATION AND COMPETITION

When considering multiagent systems, especially when we want to design such systems, one needs to think about how the agents will mutually interact. Several kinds of interaction are possible. Generally, it is dependent on the *role* the agents play in the system. In fact, in most current agent-oriented software engineering methodologies, a multiagent system is designed by first considering the *organizational* or *social structure* of the system, in which roles of agents literally play a pivotal role. These roles determine all kinds of (social) properties of the agents that play a particular role, such as objectives, rights, and norms (30). Because of dependencies and power relations between roles, roles also ultimately determine how (role-playing) agents will/should interact and which *coordination type* they follow. In Ref. 39, three of these are distinguished: market, network, and hierarchy. In *markets*, agents are self-interested and competing with each other; in *networks*, there is mutual interest and cooperation, where *trust* in other agents is a crucial factor. In a *hierarchy*, there are dependency and power relations, and *delegation* of objectives and tasks takes place. Note that even in the case of cooperation, it is not a priori obvious how autonomous agents will react to requests from other agents: Because they ultimately have their own goals, it may be the case that they do not have the time to comply, or simply do not want to because they have incompatible objectives of their own.

Ultimately, when designing a MAS it should be specified how role-enacting agents should communicate with each other. This depends on the aims and characteristics of the application at hand, the way roles are related to each other, and how role objectives and norms are "passed" between related roles (30). To this end, communication protocols are employed, which specify who is to communicate with whom on what subject in what fashion. Communication protocols consist of communication actions that are taken mostly from standardized agent communication languages (see the next section). These protocols are application-dependent. For instance, agents in an auction scenario will use typical protocols for bidding. Several well-known protocols are defined in the auction theory literature, such as English, Dutch, and Vickrey auctions (40). Note that these protocols are not always fixed a priori: Depending on the setting (coordination type), these protocols may be subject to *negotiation* between agents ("*contract negotiation*" in Ref. 30).

In general, one can say that the designer of a multiagent system employs *mechanism design*, that is, the design of protocols that govern multiagent interactions such that desirable properties hold, such as guaranteed success (eventually agreement will be reached), certain efficiency and optimality criteria (such as *Pareto efficiency*), stability (agents that have an incentive to behave in a particular way, such as the *Nash equilibrium*, in which agents do not have any incentive to deviate from their behavior), and equity (are all agents treated fairly?) (cf. Ref. 40). Many of these criteria stem from the classic discipline of *game theory*, initiated by von Neumann and Morgenstern (42), which provides a rigorous, mathematical analysis of games.

In cooperative settings, one can consider coordination through *joint intentions*. As we have recognized the importance of the notion of intention (and BDI more generally) in the case of a single agent, we might also consider whether intentions (and other BDI notions) may be generalized to group notions. This method has resulted in notions such as *common knowledge*, *common/mutual belief*, and *joint intentions (*42). Work along these lines has yielded coordination models based on *teamwork*, in which teams are formed on the basis of joint intentions (goals) and recognized potential for cooperative action (43–45).

In more open forms of agent societies, such as networks and especially markets, room for *negotiation* between agents exists. Above, we have observed already that agents may negotiate their interaction contracts, including the protocols that will be used to interact with other agents in the system. However, other things may be negotiated as well, such as tasks and goods, depending on the application at hand (46). The area of agent negotiation has become a field of its own. A related area that is also getting more attention is that of agent *argumentation*. Argumentation is a classic field in philosophy and logic (47). It deals with trying to convince other agents of the truth or falsity of some state of affairs by putting forward reasons (arguments) for and against propositions, together with justifications for the acceptability of these arguments (2). It was already realized that argumentation can play a role in reasoning forms in AI, particularly the defeasible ones, where it is possible that preliminary conclusions have to be withdrawn when more information becomes available (48). Because traditional (game-theoretic) negotiation has severe limitations, especially in the setting of agents, namely that positions can neither be justified nor changed, researchers have turned to *argumentation-based negotiation*. Here we have negotiations in which argumentation is employed to reach an agreement (49,50). Argumentation takes place through a dialog, that is a series of arguments, communicated between agents. This topic brings us to the important subject of agent communication.

AGENT COMMUNICATION

As we have observed before, MASs will generally involve some kind of *communication* between agents. Agents may communicate by means of a communication primitive such as a *send* (agent, performative, content), which has as semantics to send to the agent specified the content specified with a certain illocutionary force, specified by the performative (e.g., inform or request). The area of agent communication (and agent communication languages) is a field of research in itself (51). It includes the languages that are used for communication [*agent communication languages* (ACLs)]. The most well-known ACLs are KQML (Knowledge Query and Manipulation Language) (52) and FIPA (53). These languages define performatives, such as inform, request, and confirm, without mandating any specific language for message content (cf. Refs. 2 and 38). These performatives stem from *speech act* theory in the philosophy of language, which was introduced by Austin (54) and further developed by Searle (55). Here it was observed that certain natural language utterances could be viewed as actions that change the state of the world by uttering them. These speech acts (performatives) are now used as building blocks for communication protocols for agents.

A related issue, particularly within heterogeneous agent societies, concerns the *(content) language* (*ontology*) agents use to reason about their beliefs and communicate with each other. Of course, if agents stem from different sources (designers) and have different tasks, generally they will employ different and distinct ontologies (concepts and their representations) for performing their tasks. When communicating, it generally is not efficacious to try to transmit their whole ontologies to each other or to translate everything into one giant "universal" ontology if it would exist anyway. Rather, it seems that a kind of "ontology negotiation" should take place to arrive at a kind of minimal solution (i.e., sharing of concepts) that will facilitate communication between those agents (56,57).

NORMS AND E-INSTITUTIONS

In general, one has to consider the issue of balancing the individual agent's autonomy with its behaviour in an agent society. Often this is regarded in a way similar to the way human societies operate: the behaviour of an agent in a society is constrained by *norms*. These are properties that agents should adhere to, either specified declaratively or procedurally by means of *protocols*. Typically the norms that an agent has to obey concern prohibitions and permissions to perform certain actions, which may be role-dependent. A MAS in which norms govern the behaviour of the agents is called a *normative system* (58,59, p. 276). The subsystem of a normative system that specifies (and enforces) the norms on agents in a MAS, is called an *electronic institution* (*e-institution*) (60).

APPLICATIONS

This brings us to an important question: What kind of applications are particularly suited for an agent-based solution? Although it is hard to say something about this topic in general, one may particularly think of applications in which (e.g., logistical or planning) tasks may be distributed in such as way that subtasks may be (or rather preferably so) performed by autonomous entities (agents). For instance, in situations where it is virtually impossible to perform the task centrally, either because of the complexity of this task or a large degree of dynamics (changes) in the environment in which the system has to operate. So, applications such as cooperative distributed problem solving agents, task and resource allocation in agent systems, distributed sensing agents, multiagent planning, and robotic cooperating teams, as well as workflow and business management and the management of industrial systems, fall into this category. These applications have become important subareas of agent research themselves. For instance, although planning is a classic subject within AI, particularly research in distributed planning has been taken up within the context of multiagent systems (61,62).

Also in the area of information retrieval and management, especially in case of large amounts of (complex) information, there are applications of agents of this kind: Information agents may, for example, function as brokering and matchmaking entities to connect providers and users of information and services. This method is essentially a distributed way of searching information. In these applications, one thus views agents more or less as a novel computing paradigm, related to grid, peer-to-peer and ubiquitous computing.

Of course, also applications also exist in which there is a natural notion of a "cognitive" agent, that is, an agent possessing mental attitudes. For instance, in virtual environments such as (entertaining or serious) gaming where virtual characters need to behave in a natural or '*believable*' way and have human-like features, agents seem to be the obvious choice for their realization. The cognitive attitudes of an agent may also be employed fruitfully in human–machine interaction applications, in interaction with advanced software systems, and in robotic applications.

Thus, this category includes synthetic, embodied, emotional, and believable agents; agent based simulation and modeling of cognitive and social behavior; human-machine interfaces; as well as humanoid and sociable robots.

We should not forget the common-sense meaning of agent, which is "someone representing you or who looks after your affairs on your behalf". So, this definition yields the application of personal software assistants, in which agents play the role of proactive assistants to users working with some application (2). Examples are personal information agents and web agents. In the same vein, we have applications in e-commerce/e-business (such as comparison shopping agents and auction bots in auctions and electronic markets) applications for the Web (where agents may act on behalf of a user), and *mobile* agents that travel to other platforms on behalf of their users.

ADDITIONAL DEVELOPMENTS

In this section, we will sketch a few more developments. First, as agent programming gets more mature, one realizes the need for the *formal verification* of agent programs. Because it is deemed imperative to check the correctness of complex agent-based systems for very costly and life-critical applications, one tries to develop formal verification techniques for agents such as model checkers (63). By no means is this a trivial matter. Having agent logics available as mentioned above does not mean that these logics can be used directly for verification. One of the problems known from the literature (e.g., Ref. 64) is that agent logics such as BDI-CTL are not grounded in computation. That is to say the notions used in those logics, such as beliefs, desires, and intentions, as well as semantical structures such as possible worlds and accessibility relations, are not related directly to computational notions. So, researchers are working to bridge the gap between agent programs and agent logics. The aim here is to obtain verification methods, preferably (semi-) automated ones, such as proof systems and model checkers.

On another front, research considers extensions to the deliberation process of agents, which includes notions that seem to be "irrational" at first sight, such as *emotions*. The idea here is that emotions may provide heuristics in choosing between (many) alternative options of goals and plans. Thus, they enhance the decision-making capabilities of agents. Also, it is to be expected that the agent will behave more "human-like", which is an aspect that is important in its own right in certain applications (such as believable virtual characters and advanced human–machine interfaces) (see e.g., Ref. 65). Another example of reconsidering agent deliberation is in the context of "hybrid" agent systems with "humans in the loop", where there is 'mixed initiative' (from both humans and artificial agents), which gives rise to the notion of *adjustable autonomy* of the agent. That is, in some cases the agent is more autonomous (has more initiative) than in other cases (66).

CONCLUSION

In this article, we have reviewed the area of agent technology. In particular, we have recognized how the idea of agent technology and agent-oriented programming evolved from philosophical considerations about human action to a way of programming intelligent artificial (computer-based) systems. We have also looked at the important and promising subfield of MAS, in particular the main issues of interest here and possible applications. Since (multi) agent programming is a way to construct complex intelligent systems in a structured and anthropomorphic way, it appears to be a technology that is widely applicable, and it may well become one of the main programming paradigms of the future.

AGILE SOFTWARE DEVELOPMENT

> *Plan-driven methods work best when developers can determine the requirements in advance ... and when the requirements remain relatively stable, with change rates on the order of one percent per month.*
>
> —Barry Boehm (1)

WHAT IS AGILITY IN SOFTWARE DEVELOPMENT?

In this section, we discuss the model underlying agile software development and typical characteristics of software development projects that might be prudently handled via an agile development methodology.

Agile Model

Agile methods (13–15) are a subset of iterative and evolutionary methods (10,11) and are based on iterative enhancement (8) and opportunistic development processes (16). Each iteration is a self-contained mini-project with activities that span requirements analysis, design, implementation, and testing (10). Each iteration leads to an iteration release (which may be only an internal release) that integrates all software across the team and is a growing and evolving subset of the final system. The purpose of having short iterations is so that feedback from iterations N and earlier, and any other new information, can lead to refinement and requirements adaptation for iteration $N + 1$. The customer adaptively specifies his or her requirements for the next release based on observation of the evolving product, rather than speculation at the start of the project (6). There is quantitative evidence that frequent deadlines reduce the variance of a software process and, thus, may increase its predictability and efficiency (17).

The pre-determined iteration length serves as a timebox for the team. Scope is chosen for each iteration to fill the iteration length. Rather than increase the iteration length to fit the chosen scope, the scope is reduced to fit the iteration length. A key difference between agile methods and past iterative methods is the length of each iteration. In the past, iterations might have been three-or six-months long. With agile methods, iteration lengths vary between one and four weeks, and intentionally do not exceed 30 days.

Research has shown that shorter iterations have lower complexity and risk, better feedback, and higher productivity and success rates (10).

An area of commonality among all agile methodologies is the importance of the people performing the roles and the recognition that, more so than any process or tool, people are the most influential factor in any software project. Brooks acknowledges the same in *The Mythical Man Month* (18),

> *The quality of the people on a project, and their organization and management, are more important factors in success than are the tools they use or the technical approaches they take.*

Unfortunately, there are commonalities among some agile methods that may be less than positive. One is that, unlike more classic iterative methods, explicit quantitative quality measurements and process modeling and metrics are de-emphasized. Possible justifications for this lack of modeling and metrics range from lack of time, to lack of skills, to intrusiveness, to social reasons. Additionally, only relatively small agile teams will be likely to be able to self-organize; self-organization is one of the agile principles) into something resembling a Software Engineering Institute (SEI) Capability Maturity Model (CMM) scale (19). Level 4 or 5 organization.

Agile Development and Principles

In February 2001, several software engineering consultants joined forces and began to classify a number of similar change-sensitive methodologies as *agile* [a term with a decade of use in flexible manufacturing practices (20,21) which began to be used for software development in the late 1990s (22)]. The term promoted the professed ability for rapid and flexible response to change of the methodologies. The consultants formed the Agile Alliance and wrote *The Manifesto for Agile Software Development* and the *Principles Behind the Agile Manifesto* (23,24). The methodologies originally embraced by the Agile Alliance were Adaptive Software Development (ASD) (25), Crystal (14,26), Dynamic Systems Development Method (DSDM) (27), Extreme Programming (XP) (28), Feature-Driven Development (FDD) (29,30) and Scrum (31,32).

Agile Software Development Values. The Agile Alliance documented its value statement (24) as follows:

We are uncovering better ways of developing software by doing it and helping others do it. Through this work we have come to value:

Individuals and interactions	*over*	*processes and tools*
Working software	*over*	*comprehensive documentation*
Customer collaboration	*over*	*contract negotiation*
Responding to change	*over*	*following a plan*

That is, while there is value in the items on the right, we value the items on the left more.

The implication is that formalization of the software process hinders the human and practical component of software development, and thus reduces the chance for success. Although this statement is true when formalization is misused and misunderstood, one has to be very careful not to overemphasize and under-measure the items on the left-hand side, which can lead to the same problem, poor quality software. The key is appropriate balance (33).

The Principles. The Agile Alliance also documented the principles they follow that underlie their manifesto (24). As such, the agile methods are principle-based rather than

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

rule-based (10). Rather than have pre-defined rules regarding the roles, relationships, and activities, the team and manager are guided by these principles:

1. *Our highest priority is to satisfy the customer through early and continuous delivery of valuable software.*
2. *Welcome changing requirements, even late in development. Agile processes harness change for the customer's competitive advantage.*
3. *Deliver working software frequently, from a couple of weeks to a couple of months, with a preference to the shorter time scale.*
4. *Business people and developers must work together daily through the project.*
5. *Build projects around motivated individuals. Give them the environment and support they need, and trust them to get the job done.*
6. *The most efficient and effective method of conveying information to and within a development team is face-to-face conversation.*
7. *Working software is the primary measure of progress.*
8. *Agile processes promote sustainable development.*
9. *The sponsors, developers, and users should be able to maintain a constant pace indefinitely.*
10. *Continuous attention to technical excellence and good design enhances agility.*
11. *Simplicity – the art of maximizing the amount of work not done – is essential.*
12. *The best architectures, requirements, and designs emerge from self-organizing teams.*
13. *At regular intervals, the team reflects on how to become more effective, then tunes and adjusts its behavior accordingly.*

Characteristics of Projects Suitable for Agile Methods

Agile software development methodologies are not necessarily suitable for all projects. Boehm and Turner (33) share their view of the characteristics of projects that operate in agile "home grounds," where home ground is defined as the situation for which the approach has the greatest potential for success. The agile home ground is summarized in Table 1. It is important to note that some agile methodologists feel that their methodologies are suitable for most any project. Empirical and theoretical studies are needed to both support and refute the characteristics described by this home ground and the scope, effectiveness, and cost of the agile approach.

The general characteristics of agile and plan-driven methods led Boehm and Turner (33) to define five critical factors that can be used to describe a project environment and can be used to help determine the appropriate balance between agile and plan-driven methods:

1. Size (number of people on team).
2. Criticality (the impact of a software defect in terms of comfort, money, or lives).
3. Dynamism (the degree of requirements and technology change).
4. Personnel[1] (ratio of high and low skill level of team-to-team size).
5. Culture (whether the individuals on the team prefer predictability/order or change).

Table 1. Agile and Plan-driven Home Grounds (Adapted from Ref. 34)

Project Characteristics	Agile Home Ground
Primary goals	Rapid value, responding to change
Size	Smaller teams and projects
Environment	Turbulent, high change, project focused
Customer relations	Dedicated on-site customer, focused on prioritized product releases (increments)
Planning and control	Team has an understanding of plans and monitors to this plan
Communications	Passed from person to person (tacit, interpersonal)
Requirements	Prioritized, informal stories and/or features and more formal use cases. Requirements are likely to change in unpredictable ways
Development	Simple design, short increments
Test	Automated, executable test cases are used to further define the specifics of the requirements
Customers	Dedicated, co-located CRACK* performers
Developers	At least 30% experts or very experienced team members; no unexperienced personnel
Culture	Team enjoys being empowered and having freedom (thriving on chaos)

*CRACK = Collaborative, Representative, Authorized, Committed, and Knowledgeable

Boehm and Turner have created a polar chart as a means for visually displaying a team's values for each of these criticality factors. An example of such a polar chart is in Fig. 1. Each of the five factors has an axis. Each axis is labeled with carefully chosen values based on Boehm and Turner's experience. For each axis, the further from the graph's center the project lies, the more appropriate are plan-driven methods. Conversely, the more a point lies toward the center of the chart, the more a project may benefit from agile methods.

Consider the black polygon joining the points of a sample project in Fig.1. Starting at the top of the chart (Personnel), this team is comprised of a large number of novices and a small number of experts. Additionally, the requirements (Dynamism) are not expected to change much throughout the project. The team members have a fairly strong preference for order and predictability (Culture). There are

[1] Boehm and Turner adapt levels of Software Method Understanding and Use as defined by Cockburn (14). 1B personnel are team members who can perform procedural steps with training. 1A personnel are able to perform discretionary method steps. Level 2 personnel are able to tailor a method to fit a new situation. Level 3 personnel are able to revise a method to fit an unprecedented situation.

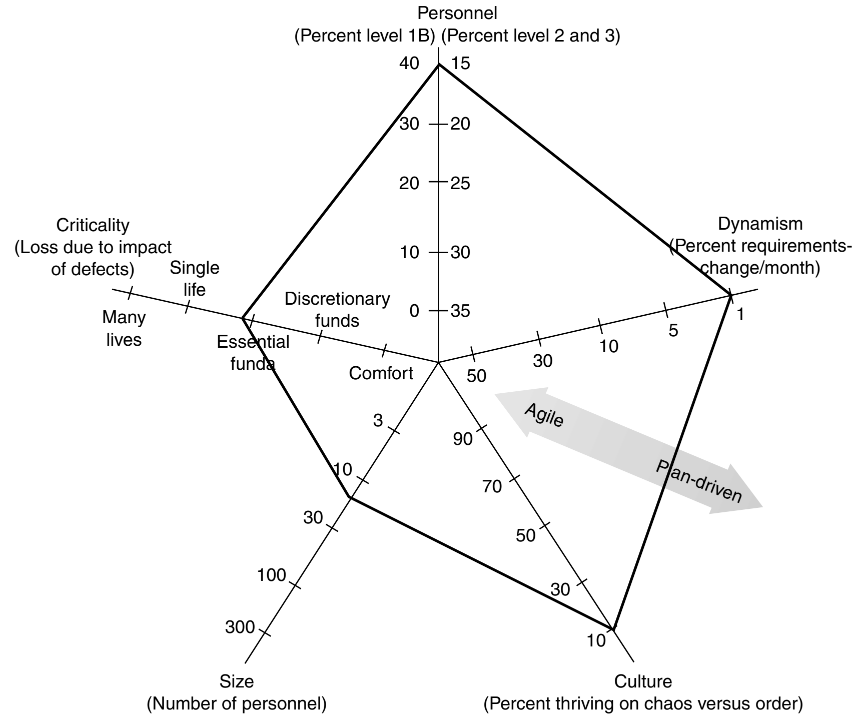

Figure 1. Example polar chart (adapted from Ref. 33).

about 15 people on the team (Size). The impact of a software defect could result in the loss of essential funds (Criticality) (i.e., the business could lose a large amount of money if the software fails). An example could be a retail point-of-sale application failure in which customers leave the store because the computers are not working. Based on the shape of the polar chart for this particular application, the project may not be suitable for an agile methodology. As a general rule, high-risk projects (34) may require more than agile methodologies may offer.

EXAMPLES OF AGILE SOFTWARE DEVELOPMENT METHODOLOGIES

This section provides a brief introduction to three agile methodologies. The three were chosen to demonstrate the range of applicability and specification of the agile methodologies. For each methodology, we provide an overview and discuss documents and artifacts produced by the development team, the roles the members of the development team assume, the process, and a discussion.

Extreme Programming (XP)

XP (28,35) originators aimed at developing a methodology suitable for "object-oriented projects using teams of a dozen or fewer programmers in one location" (36).

The methodology is based on five underlying values: communication, simplicity, feedback, courage, and respect.

1. **Communication.** XP has a culture of oral communication and its practices are designed to encourage interaction. The communication value is based on the observation that most project difficulties occur because someone *should have* spoken with someone else to clarify a question, collaborate, or obtain help. "Problems with projects can invariably be traced back to somebody not talking to somebody else about something important" (28).
2. **Simplicity.** Design the simplest product that meets the customer's needs. An important aspect of the value is to only design and code what is in the current requirements rather than to anticipate and plan for unstated requirements.
3. **Feedback.** The development team obtains feedback from the customers at the end of each iteration and external release. This feedback drives the next iteration. Additionally, there are very short design and implementation feedback loops built into the methodology via pair programming and test-driven development (37).
4. **Courage.** The other three values allow the team to have courage in its actions and decision making. For example, the development team might have the courage to resist pressure to make unrealistic commitments.
5. **Respect.** Team members need to care about each other and about the project.

Although one may be able to come up with reasonable quantitative metrics for the first three values, it is quite difficult to assess the other two, at least in advance, unless quantitative risk-based metrics and models are used (34,38).

Documents and Artifacts. In general, XP relies on "documentation" via oral communication, the code itself, and tacit knowledge transfer rather than written documents and artifacts. The following relatively informal artifacts are produced:

- **Story cards**, paper index cards that contain brief requirement descriptions. The user story cards are intentionally not a full requirement statement but are, instead, a commitment for further conversation between the developer and the customer. During this conversation, the two parties will come to an oral understanding of what is needed for the requirement to be fulfilled. Customer priority and developer resource estimate are added to the card. The resource estimate for a user story must not exceed the iteration duration.
- **Task list**, a listing of the tasks (typically one-half to three days in duration) for the user stories that are to be completed for an iteration. Tasks represent concrete aspects of a story. Programmers volunteer for tasks rather than being assigned to tasks.
- **CRC cards (39) (optional)**, paper index card on which one records the responsibilities and collaborators of classes that can serve as a basis for software design. The classes, responsibilities, and collaborators are identified during a design brainstorming/role-playing session involving multiple developers. CRC stands for **C**lass-**R**esponsibility-**C**ollaboration.
- **Customer acceptance tests**, textual descriptions and automated test cases that are developed by the customer. The development team demonstrates the completion of a user story and the validation of customer requirements by passing these test cases.
- **Visible wall graphs**, to foster communication and accountability, progress graphs are usually posted in a team work area. These progress graphs often involve how many stories are completed or how many acceptance test cases are passing.

Roles

- **Manager**, owns the team and its problems. He or she forms the team, obtains resources, manages people and problems, and interfaces with external groups.
- **Coach**, teaches team members about the XP process as necessary, intervenes in case of issues, and monitors whether the XP process is being followed. The coach is typically a programmer and not a manager.
- **Tracker**, regularly collects user story and acceptance test case progress from the developers to create the visible wall graphs. The tracker is a programmer, not a manager or customer.
- **Programmer**, writes, tests, and designs, code; refactors; and identifies and estimates tasks and stories (this person may also be a tester).
- **Tester**, helps customers write and develop tests (this person may also be a programmer).
- **Customer**, writes stories and acceptance tests; picks stories for a release and for an iteration. A common misconception is that the role of the customer must be played by one individual from the customer organization. Conversely, a group of customers can be involved or a customer representative can be chosen from within the development organization (but external to the development team).

Process. The initial version of the XP software methodology (28) published in 2000 had 12 programmer-centric, technical practices. These practices interact, counterbalance, and reinforce each other (13,28). However, in a survey (40) of project managers, chief executive officers, developers, and vice-presidents of engineering for 21 software projects, it was found that none of the companies adopted XP in a “pure” form wherein all 12 practices were used without adaptation. In 2005, XP was changed to include 13 primary practices and 11 corollary practices (35). The primary practices are intended to be (35) useful independent of each other and the other practices used, although the interactions between the practices may amplify their effect. The corollary practices are likely to be difficult without first mastering a core set of the primary practices.

Below, the 13 primary technical practices of XP are briefly described:

- **Sit together**, the whole team develops in one open space.
- **Whole team**, uses a cross-functional team of all those necessary for the product to succeed.
- **Informative workspace**, place visible wall graphs around the workspace so that team members (or other interested observers) can get a general idea of how the project is going.
- **Energized work**, XP teams do not work excessive overtime for long periods of time. The motivation behind this practice is to keep the code of high quality (tired programmers inject more defects) and the programmers happy (to reduce employee turnover). Tom DeMarco contends that, “extended overtime is a productivity-reducing technique” (41).
- **Pair programming (42)**, refers to the practice whereby two programmers work together at one computer, collaborating on the same design, algorithm, code, or test.
- **Stories**, the team members write short statements of customer-visible functionality desired in the product. The developers estimate the story; the customer prioritizes the story.
- **Weekly cycle**, at the beginning of each week, a meeting is held to review progress to date, have the customer pick a week’s worth of stories to implement that week (based on developer estimates and their own priority), and to break the stories into tasks to be completed that week. By the end of the week, acceptance test cases for the chosen stories should be running for demonstration to the customer to drive the next weekly cycle.

- **Quarterly cycle**, the whole team should pick a theme or themes of stories for a quarter's worth of stories. Themes help the team reflect on the bigger picture (i.e., at the end of the quarter, deliver this business value).
- **Slack**, in every iteration, plan some lower-priority tasks that can be dropped if the team gets behind such that the customer will still be delivered their most important functionality.
- **Ten-minute build**, structure the project and its associated tests such that the whole system can be built and all the tests can be run in ten minutes so that the system will be built and the tests will be run often.
- **Test-first programming**, all stories have at least one acceptance test, preferably automated. When the acceptance test(s) for a user story all pass, the story is considered to be fulfilled. Additionally, automated unit tests are incrementally written using the test-driven development (TDD) (43) practice in which code and automated unit tests are alternately and incrementally written on a minute-by-minute basis.
- **Continuous integration**, programmers check into the code base completed code and its associated tests several times a day. Code may only be checked in if all its associated unit tests and all unit tests of the entire code base pass.
- **Incremental design**, rather than develop an anticipatory detailed design before implementation, invest in the design of the system every day in light of the experience of the past. The viability and prudence of anticipatory design has changed dramatically in our volatile business environment (13). Refactoring (44) to improve the design of previously written code is essential. Teams with robust unit tests can safely experiment with refactorings because a safety net is in place.

Below, the 11 corollary technical practices of XP are briefly described:

- **Real customer involvement**, the customer is available to clarify requirements questions, is a subject matter expert, and is empowered to make decisions about the requirements and their priority. Additionally, the customer writes the acceptance tests.
- **Incremental deployment**, gradually deploy functionality in a live environment to reduce the risk of a big deployment.
- **Team continuity**, keep effective teams together.
- **Shrinking team**, as a team grows in capacity (because of experience), keep their workload constant but gradually reduce the size of the team.
- **Root cause analysis**, examine the cause of a discovered defect by writing acceptance test(s) and unit test(s) to reveal the defect. Subsequently, examine why the defects was created but not caught in the development process.
- **Shared code**, once code and its associated tests are checked into the code base, the code can be altered by any team member. This collective code ownership provides each team member with the feeling of owning the whole code base and prevents bottlenecks that might have been caused if the "owner" of a component was not available to make a necessary change.
- **Code and tests**, maintain only the code and tests as permanent artifacts. Rely on social mechanisms to keep alive the important history of the project.
- **Daily deployment**, put new code into production every night.
- **Negotiated scope contract**, fix the time, cost, and required quality of a project but call for an ongoing negotiation of the scope of the project.
- **Pay-per-use**, charge the user every time the system is used to obtain their feedback by their usage patterns.

Discussion. The main advantages of XP relative to small, co-located teams have been demonstrated by several industrial case studies, including (45–49):

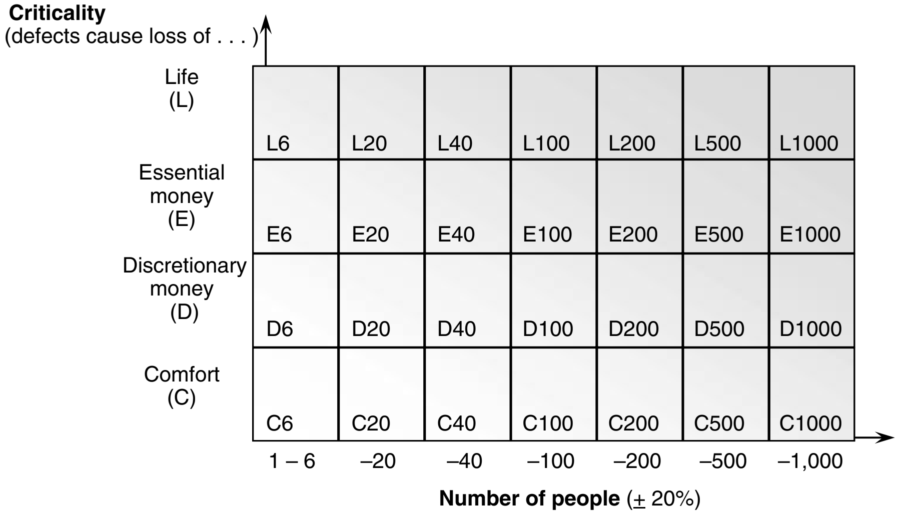
- Improved quality;
- Improved productivity (although the measures were relatively inexact);
- Improved team morale;
- Anecdotally, improved customer satisfaction.

The possible drawbacks of XP are as follows:

- XP may not be applicable for other than small, co-located teams developing noncritical software, although XP has been successfully used with mission-critical projects (50), distributed teams (51), and for scientific research (52).
- XP de-emphasizes documentation and relies on social mechanisms to keep alive the important history of the project. As a result, XP must be adapted for projects that require traceability and audit-ability.
- Some developers may not transition to pair programming easily; transitioning to the test-driven development practice may require technical training for some developers.
- The real customer involvement practice has shown to be very effective for communicating and clarifying requirements, but is a pressured, stressful, and time-consuming role (53).

Crystal

The RUP (4,5) is a customizable process framework. Depending on the project characteristics, such as team size and project size, the RUP can be tailored or extended to match the needs of an adopting organization. Similarly, the family of Crystal Methods (14) were developed to address the variability of the environment and the specific characteristics of the project. However, RUP generally starts with a plan-driven base methodology and tailors down for smaller, less-critical projects. Conversely, Crystal author Alistair Cockburn feels that the base methodology should be "barely sufficient." He contends, "You need one less notch of control than you expect, and less is better when it comes to delivering quickly," (13). Moreover, because the



Life (L)	L6	L20	L40	L100	L200	L500	L1000
Essential money (E)	E6	E20	E40	E100	E200	E500	E1000
Discretionary money (D)	D6	D20	D40	D100	D200	D500	D1000
Comfort (C)	C6	C20	C40	C100	C200	C500	C1000
	1 – 6	–20	–40	–100	–200	–500	–1,000

Figure 2. The family of Crystal Methods (adapted from Ref. 14).

project and the people evolve over time, the methodology so too must be tuned and evolved during the course of the project.

Crystal is a family of methods because Cockburn believes that there is no "one-size-fits-all" development process. As such, the different methods are assigned colors arranged in ascending opacity; the most agile version is Crystal Clear, followed by Crystal Yellow, Crystal Orange, and Crystal Red. The graph in Fig. 2 is used to aid the choice of a Crystal Method starting point (for later tailoring). Along the x-axis is the size of the team. As a team gets larger (moves to the right along the x-axis), the harder it is to manage the process via face-to-face communication and, thus, the greater the need for coordinating documentation, practices, and tools. The y-axis addresses the system's potential for causing damage. The lowest damage impact is loss of comfort, then loss of discretionary money, loss of essential money, and finally loss of life. Based on the team size and the criticality, the corresponding Crystal methodology is identified. Each methodology has a set of recommended practices, a core set of roles, work products, techniques, and notations.

All the Crystal Methods emphasize the importance of people in developing software. "[Crystal] focuses on people, interaction, community, skills, talents, and communication as first order effects on performance. Process remains important, but secondary" (13). There are only two absolute rules of the Crystal family of methodologies. First, incremental cycles must not exceed 4 months. Second, reflection workshops must be held after every delivery so that the methodology is self-adapting. Currently, only Crystal Clear and Crystal Orange have been defined. Summaries of these two methodologies are provided below.

Crystal Clear. Crystal Clear (14,26) is targeted at a D6 project and could be applied to a C6 or an E6 project and possibly to a D10 project (see Fig. 2). Crystal Clear is an optimization of Crystal that can be applied when the team consists of three to eight people sitting in the same room or adjoining offices. The property of close communication is strengthened to "osmotic" communication, meaning that people overhear each other discussing project priorities, status, requirements, and design on a daily basis. Crystal Clear's model elements are as follows:

- **Documents and artifacts**: release plan, schedule of reviews, informal/low-ceremony use cases, design sketches, running code, common object model, test cases, and user manual.
- **Roles**: project sponsor/customer, senior designer-programmer, designer-programmer, and user (part time at least).
- **Process**: incremental delivery, releases less than 2–3 months, some automated testing, direct user involvement, two user reviews per release, and methodology-tuning retrospectives. Progress is tracked by software delivered or major decisions reached, not by documents completed.

Crystal Orange. Crystal Orange is targeted at a D40 project. Crystal Orange is for 20–40 programmers working together in one building on a project in which defects could cause the loss of discretionary money (i.e., medium risk). The project duration is between 1 and 2 years and time-to-market is important. Crystal Orange's model elements are as follows:

- **Documents and artifacts**: requirements document, release plan, schedule, status reports, UI design document, inter-team specs, running code, common object model, test cases, migration code, and user manual.
- **Roles**: project sponsor, business expert, usage expert, technical facilitator, business analyst, project manager, architect, design mentor, lead designer-programmer, designer-programmer, UI designer, reuse point, writer, and tester.
- **Process**: incremental delivery, releases less than 3–4 months, some automated testing, direct user involvement, two user reviews per release, and methodology-tuning retrospectives.

Discussion. No empirical case studies of Crystal teams have been published. Anecdotally, the main advantages of Crystal methods are as follows:

- The family of methods accommodates teams of any size and criticality.
- The philosophy underlying the Crystal methods emphasizes simplicity, agility, and communication.

Possible drawbacks of Crystal are as follows:

- The flexibility of the methods may not provide enough prescriptive guidance to all teams on which software development practices to use.
- Not all of the Crystal methods have been defined.

Feature-driven Development (FDD)

FDD (29,30) authors Peter Coad and Jeff de Luca characterize the methodology as having "just enough process to ensure scalability and repeatability and encourage creativity and innovation all along the way" (13). Throughout, FDD emphasizes the importance of having good people and strong domain experts. FDD is build around eight best practices: domain object modeling; developing by feature; individual class ownership; feature teams; inspections; regular builds; configuration management; and reporting/visibility of results. UML models (54,55) are used extensively in FDD.

Documents and Artifacts

- **Feature lists**, consisting of a set of features whereby features are small, useful in the eyes of the client, a client-valued function that can be implemented in two weeks or less. If a feature would take more than two weeks to implement, it must be further decomposed.
- **Design packages**, which consist of sequence diagrams and class diagrams and method design information
- **Track by Feature**, a chart that enumerates the features that are to be built and the dates when each milestone has been completed.
- **"Burn Up" Chart**, a chart that has dates (time) on the x axis. On the y axis is an increasing number of features that have been completed. As features are completed, this chart indicates a positive slope over time.

Roles

- **Project manager**, the administrative lead of the project responsible for reporting progress, managing budgets, and fighting for and managing resources including people, equipment, and space.
- **Chief architect**, responsible for the overall design of the system including running workshop design sessions with the team.
- **Development manager**, responsible for leading the day-to-day development activities including the resolution of resource conflicts.
- **Chief programmer**, as outlined by Brooks' ideas on surgical teams (18), an experienced developer who acts as a team lead, mentor, and developer for a team of three to six developers. The chief programmer provides the breadth of knowledge about the skeletal model to a feature team, participates in high-level requirements analysis and design, and aids the team in low-level analysis, design, and development of new features.
- **Class owner**, responsible for designing, coding, testing, and documenting new features in the classes that he or she owns.
- **Domain experts**, users, clients, sponsors, business analysts, and so on who have deep knowledge of the business for which the product is being developed.
- **Feature teams**, temporary groups of developers formed around the classes with which the features will be implemented. A feature team dynamically forms to implement a feature and disbands when the feature has been implemented (two weeks or less).

Process. The FDD process has five incremental, iterative processes. Guidelines are given for the amount of time that should be spent in each of these steps, constraining the amount of time spent in overall planning and architecture and emphasizing the amount of time designing and building features. Processes 1 through 3 are done at the start of a project and then updated throughout the development cycle. Processes 4 and 5 are done incrementally on 2-week cycles. Each of these processes has specific entry and exit criteria, whereby the entry criterion of Process N is the exit criteria of Process N-1.

- **Process 1: Develop an overall model** (time: 10% initially, 4% ongoing).
  Domain and development team members work together to understand the scope of the system and its context. High-level object models/class diagrams are developed for each area of the problem domain. Model notes record information about the model's shape and why some alternatives were selected and others rejected.
- **Process 2: Build a features list** (time: 4% initially, 1% ongoing).
  Complete list of all the features in the project; functional decomposition that breaks down a "business activity" requested by the customer to the features that need to be implemented in the software.
- **Process 3: Plan by feature** (time: 2% initially, 2% ongoing).
  A planning team consisting of the project manager, development manager, and chief programmer plan the order in which features will be developed. Planning is based on dependencies, risk, complexity, workload balancing, client-required milestones, and checkpoints. Business activities are assigned month/year

completion dates. Every class is assigned to a specific developer. Features are bundled according to technical reasons rather than business reasons.

- **Process 4: Design by feature** (time: 34% ongoing in 2-week iterations).
  The chief programmer leads the development of design packages and refines object models with attributes. The sequence diagrams are often done as a group activity. The class diagrams and object models are done by the class owners. Domain experts interact with the team to refine the feature requirements. Designs are inspected.
- **Process 5: Build by feature** (time: 43% ongoing in 2-week iterations).
  The feature team implements the classes and methods outlined by the design. This code is inspected and unit tested. The code is promoted to the build.

Progress is tracked and made visible during the design-by-feature/build-by-feature phases. Each feature has six milestones, three from the design-by-feature phase (domain walkthrough, design, and design inspection) and three from the build-by-feature phase (code, code inspection, promote to build). When these milestones are complete, the date is placed on the track-by-feature chart, which is prominently displayed for the team. When a feature has completed all six milestones, this completion is reflected on the "Burn Up" chart. All features are scoped to be completed within a maximum of two weeks, including all six milestones.

Discussion. No empirical case studies of FDD teams have been published. Anecdotally, the main advantages of FDD are as follows:

- Teams that value and are accustomed to object-oriented analysis and design and associated documentation and inspections will transition to FDD more easily than some of the other agile methods.
- The documentation produced could lead to higher quality projects and enable traceability and auditability.

Possible drawbacks of FDD are as follows:

- The up-front design may not make FDD as agile as other methodologies.
- Teams must purchase and use UML design tools.

SUMMARY

In this article, we presented an overview of the agile software development model and the characteristics of the projects that may be suited for the use of this model. Additionally, we provided overviews of three representative methodologies: XP, Crystal, and FDD. A summary of the distinguishing factors of these three methodologies is presented in Table 2.

Table 2. Summary of XP, Crystal, and FDD Methodologiese

Agile Methodology	Distinguishing Factor
XP	• Intended for 10–12 co-located, object-oriented programmers • Five values • 13 primary and 11 corollary highly specified, disciplined development practices • Minimal archival documentation • Rapid customer and developer feedback loops
Crystal	• Customizable family of development methodologies for small to very large teams • Methodology dependent on size of team and criticality of project • Emphasis of face-to-face communication • Consider people, interaction, community, skills, talents, and communication as first-order effects • Start with minimal process and build up as absolutely necessary
FDD	• Scalable to larger teams • Highly specified development practices • Five subprocesses, each defined with entry and exit criteria • Development are architectural shape, object models, and sequence diagrams (UML models used throughout) • 2 week features

There are other defined agile software development methodologies as well, including ASD (25), Agile Modeling (56), DSDM (27), Lean Development (57), and Scrum (13,31). Additionally, teams can configure an agile RUP methodology. All agile methodologies consider software development to be an empirical process that necessitates short "inspect and adapt" feedback loops throughout the project. Furthermore, although we have not explicitly focused on such in this article, all of the agile methods do support either implied or explicit verification and validation processes. In some instances, it manifests as pair programming, in some as test-driven development, and in some as explicit unit, integration, system, and acceptance testing of the classic type. In general, there is also an underlying business model that often hinges on customer satisfaction, but in reality is very much driven by resource constraints and end-user expectations in terms of functionality and end-product quality. It is probably wise for a potential adopter of agile methodologies to first explicitly define the business model (including expected resource constraints and product quality), and then pick an appropriate process model (using a combination of scientific quantitative and qualitative methods) based on that information and the project characteristics (33).

ANALYTICAL CUSTOMER RELATIONSHIP MANAGEMENT

INTRODUCTION

As bandwidth continues to grow, and newer information appliances become available, marketing departments everywhere see this as an opportunity to get in closer touch with potential customers. In addition, with organizations constantly developing more cost-effective means of customer contact, the amount of customer solicitation has been on a steady rise. Today, with the internet as the ultimate low-latency, high-bandwidth, customer contact channel with practically zero cost, customer solicitation has reached unprecedented levels.

Armed with such tools, every organization has ramped up its marketing effort, and we are witnessing a barrage of solicitations targeted at the ever-shrinking attention span of the same set of customers. Once we consider the fact that potentially good customers, i.e., “those likely to buy a product,” are much more likely to get a solicitation than those who are not so good, the situation for the good customers is even more dire. This issue is really testing the patience of many customers, and thus, we have witnessed a spate of customers signing up to be on “no solicitation” lists, to avoid being bombarded with unwanted solicitations.

From the viewpoint of the organizations, the situation is no better. Even though the cost of unit customer communication has dropped dramatically, the impact of unit communication has dropped even faster. For example, after a lot of initial enthusiasm, it is now widely accepted that the impact of web page banner advertisements in affecting customer opinion is practically negligible. On the other hand, the impact of targeted e-mails, especially with financial offers, is quite high. In essence, each organization is spinning its wheels in trying to target the same set of good customers, while paying insufficient attention to understanding the needs of the “not so good customers” of today, and converting them into good customers of tomorrow. A clear example of this mutual cannibalism of customers is the cellular phone industry, where each service provider is constantly trying to outdo the others. “Customer churn” is a well-accepted problem in this industry.

A well-accepted wisdom in the industry is that it costs five to seven times as much to acquire a new customer than to retain an existing one. The reason is that the organization already has the loyalty of existing customers, and all that is required for retention is to meet the customer’s expectations. For customer acquisition, however, the customer must be weaned away from another organization, which is a much harder task. As a result, it is crucial that the selection of customers to target is done with care, and that the right message be sent to each one. Given these needs, it becomes important for an organization to understand its customers well. Thus, one can consider customer relationship management to consist of two parts as follows:

$$\text{CRM} = \text{customer understanding} + \text{relationship management}$$

This equation is not new, because in the classic “neighborhood store” model of doing business, the store had a highly localized audience, and the store owner knew practically everyone in the neighborhood—making it easy for him to meet the needs of his customers. It is the big corporations, serving a mass customer base, that have difficulty in understanding the needs of individual customers. The realization of this gap of knowledge has been one of the driving factors for the rapid adoption of CRM software by many corporations. However, the initial deployment of CRM software has been for the second part of the CRM equation, namely “relationship management.” As described, relationship management efforts without an understanding of the customer can be marginally effective at best, and sometimes even counterproductive.

The approach that resolves this dilemma is the use of data analytics in CRM, with the goal of obtaining a better understanding of the needs of individual customers. Improved customer understanding drives better customer relationship management efforts, which leads to better and more frequent customer responses and in turn leads to more data collection about the customer—from which a more refined customer understanding can be gained. This positive feedback cycle—or “virtuous loop” as it is often called—is shown in Fig. 1.

Although this picture is very desirable, unfortunately several technical and organizational challenges must be overcome to achieve it. First, much customer data are collected for operational purposes and are not organized for ease of analysis. With the advance of data analysis techniques, it is becoming feasible to exploit these data for business management, such as to find existing trends and discover new opportunities. Second, it is critical that this knowledge cover all channels and customer touch points, so that the information base is complete and delivers a holistic and integrated view of each customer. This knowledge includes customer transactions, interactions, customer denials, service history, characteristics and profiles, interactive survey data, click-stream/browsing behavior, references, demographics, psychographics, and all available and useful data surrounding that customer. This information may also include data from outside the business as well, for example, from third-party data providers such as Experian or Axciom. Third, organizational thinking must be changed from the current focus on products to include both customers and products, as illustrated in Fig. 2. Successful adoption of CRM requires a change in focus by marketing from “who I can sell this products to?” to “what does this customer need?” It transforms marketing from tactical considerations, i.e., “how do I get this campaign out of the door” to strategic focus, i.e., “what campaigns will maximize customer value?”

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

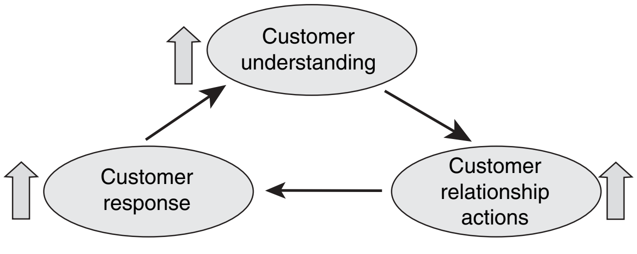

Figure 1. "Virtuous circle" of CRM.

The goal of this article is to introduce the data analytics opportunities that exist in customer relationship management, especially in the area of customer understanding. As the data collected about customers is becoming more complete, the time is ripe for the application of sophisticated data mining techniques towards better customer understanding. The rest of this paper is organized as follows: in Section 2 we introduce the concept of analytical customer relationship management. Section 3 briefly describes the underlying technologies and tools that are needed, namely data warehousing and data mining. Section 4 describes a number of organizational issues that are critical to successful deployment of CRM in an organization, and Section 5 concludes the paper.

ANALYTICAL CUSTOMER RELATIONSHIP MANAGEMENT

Significant resources have been spent on CRM, leading to the success of CRM software vendors such as Seibel, Oracle, and Epiphany. However, in the initial stages sufficient attention was not paid to analyzing customer data to target the CRM efforts. Simple heuristics and "gut-feel" approaches led to profitable customers being bombarded with offers (often turning them off), while there being little attempt to develop today's the "less valuable" customers into tomorrow's valuable ones. This lack of attention to customer needs is the cause of decreasing customer satisfaction across a wide variety of industries.[1]

Fortunately, however, the tremendous advancement in data management and analysis technologies is providing the opportunity to develop fine-grained customer understanding on a mass scale and to use it to better manage the relationship with each customer. It is this approach to developing customer understanding through data analysis, for the purpose of more effective relationship management, that we call *analytical customer relationship management (ACRM)*. ACRM can make the customer interaction functions of a company much more effective than they are currently.

Customer Segmentation

Customer segmentation is the division of the entire customer population into smaller groups, called *customer segments*. The key idea is that each segment is fairly homogeneous from a certain perspective, although not necessarily from other perspectives. Thus, the customer base is first segmented by the value they represent to an organization, and then by the needs they may have for specified products and services.

The purpose of segmentation is to identify groups of customers with similar needs and behavior patterns, so that they can be offered more tightly focused products, services, and communications. Segments should be identifiable, quantifiable, addressable, and of sufficient size to be worth addressing. For example, a vision products company may segment the customer population into those whose eyesight is perfect and those whose eyesight is not perfect. As far as the company is concerned, everyone whose eyesight is not perfect falls in the same segment, i.e., of potential customers, and hence, they are all the same. This segment is certainly not homogeneous from the perspective of a clothing manufacturer, who will perhaps segment on attributes like gender and age.

A company's customer data are organized into *customer profiles*. A customer's profile consists of three categories of data, namely (*1*) identity, (*2*) characteristics, and (*3*) behavior. These categories correspond to the following questions: *Who is the person? What attributes does he/she have? How does he/she behave?* Two types of segmentation can be performed based on the profile, namely

- Group customers based on common characteristics, and identify their common patterns of behavior.
- Group customers based on common patterns of behavior, and identify their common characteristics.

As shown in Fig. 3, each customer segment represents a different amount of profit per customer; the treatment of each segment can be different. The figure shows examples of the type of questions the company can ask about segments. Also included are some overall strategic questions about which segments to focus on, and how much.

Customer Communication

A key element of customer relationship management is communicating with the customer. This communication consists of two components, namely (*1*) deciding what message to send to each customer segment, and (*2*) selecting the channel through which the message must be sent. Message selection for each customer segment depends on the strategy being followed for that segment, as shown in Fig. 4. The selection of the communication channel depends on several characteristics of each channel, including cost, focus, attention, and impact.

Typical communication channels include television, radio, print media, direct mail, and e-mail. Television is a broadcast channel, which is very good at sending a common message to a very large population. Although it is very effective in building brand recognition, it is difficult to target a specific segment, as well as to measure response at the individual customer level. Radio, like television, is a broadcast medium, and hence, it is difficult to use for targeted communication to individual customers. Some television and radio stations, e.g., public radio and public television, develop a fairly accurate sample of their listener/

[1] Of course, customer expectation keeps rising over time, and the source of dissatisfaction today is very different than that of a few years ago. However, all organizations must constantly fight this battleindustries, as illustrated in Fig. .[2]

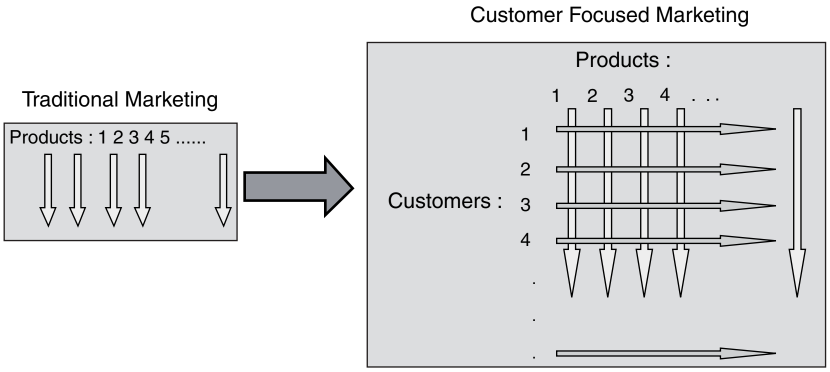

Figure 2. Change of focus from product only to customer + product.

viewer base through periodic fundraisers. Print media like newspapers and magazines can be used for much more focused communication, because the subscriber's profile is known. However, the readership of print media is usually much larger than the subscription base—a ratio of 1:3 in the United States—and hence, for a large part of the readership base, no profile is available. Direct mail is a communication channel that enables communicating with individual customers through personalized messages. In addition, it provides the ability of measuring response rates of customers at the individual level, because it enables the contacted customer to immediately respond to the message, if so desired. Finally, given its negligible cost, e-mail is becoming the medium of choice for customer contact for many organizations.

Figure 4, courtesy of Stevens and Hegarty (2), illustrates the problem of formulating the customer communication strategy. Each communication channel has its own characteristics in terms of cost, response rate, and attention. The goal of communication strategy optimization is to determine the (set of) communication channel(s) for each customer that minimizes cost or maximizes sale, profit, and so on. Although communication channel optimization has been a well-studied problem in the quantitative marketing literature, characteristics of new channels such as e-mail and the Web are not well understood. Thus, there is a need to revisit these problems.

Sending the message to each customer through the chosen communication channel is not enough. It is crucial to measure the impact of the communication. This measurement is done by using an approach called *response analysis*. As shown in Fig. 5, response analysis metrics, e.g., number of respondents, acquired customers, number of active customers, and number of profitable customers, can be calculated. These are analyzed to (*1*) determine how effective the overall customer communication campaign has been, (*2*) validate the goodness of customer segmentation, and (*3*) calibrate and refine the models of the various communication channels used. Although response analysis for traditional communication channels is fairly well understood, for new channels like e-mail and the Web, hardly anything is known. Understanding how customers relate to these new medium, which aspects they like and which they do not, and what are the right set of metrics to measure the usage of the medium, are all open questions and have attracted much research (3–5).

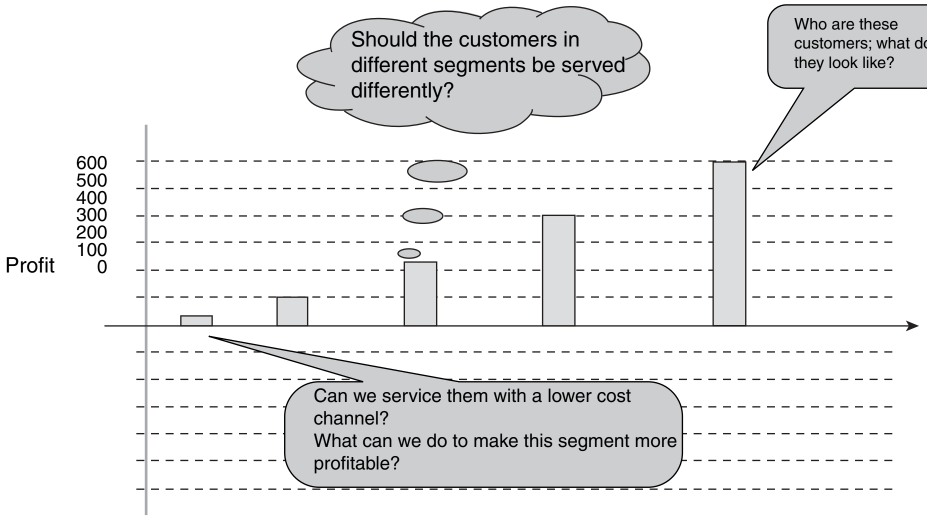

Figure 3. Segmentation of customers by profitability.

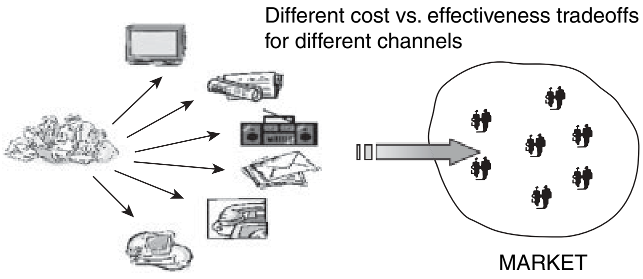

Figure 4. Formulating the optimal customer communication strategy.

Customer Retention

Customer retention is the effort carried out by a company to ensure that its customers do not switch over to the competition's products and services. A commonly accepted wisdom, which is acquired through substantial experience, is that it is five to seven times more expensive to acquire a new customer than to retain an existing one. Thus, it is of paramount importance to retain customers, especially highly profitable ones. A good loyal customer base that persists for a long time is one of the best advertisements for a business, creating an image of high quality. This image helps in attracting other customers who value long-term relationships and high-quality products and services.

Figure 6 shows how a company thinks of its various customer segments, from a current and future profitability perspective. Clearly, the quadrants on the right bottom and the right top should be targeted for retention. In addition, the right top customer quadrant must be targeted for strengthening the relationship, as there is significant unrealized potential.

A successful customer retention strategy for a company is to identify opportunities to meet the needs of the customer in a timely manner. A specific example is of a bank that used the event "ATM request for cash is rejected due to lack of funds" to offer unsecured personal loans to credit-worthy customers the next day. This offer was found to have a very high success rate, with the additional advantage of building customer loyalty. Classically, this analysis has been done at an aggregate level, namely for customer segments. Given current-day analytic tools, it should be possible to achieve it at the level of individual customers.

Customer Loyalty

From a company's perspective, a loyal customer is one who prefers the company's products and services to those of its competition. Loyalty can range from having a mild preference all the way to being a strong advocate for the company. It is well accepted in consumer marketing that an average customer who feels closer to a company (high loyalty) is significantly more profitable than one who feels less close (low loyalty). Thus, ideally a company would like all its customers to become loyal, and then to quickly advance up the loyalty chain.

Figure 7, courtesy of Heygate (1), illustrates the concept of tracking a customer to identify events in his/her life. Many of these events offer opportunities for strengthening the relationship the company has with this customer. For

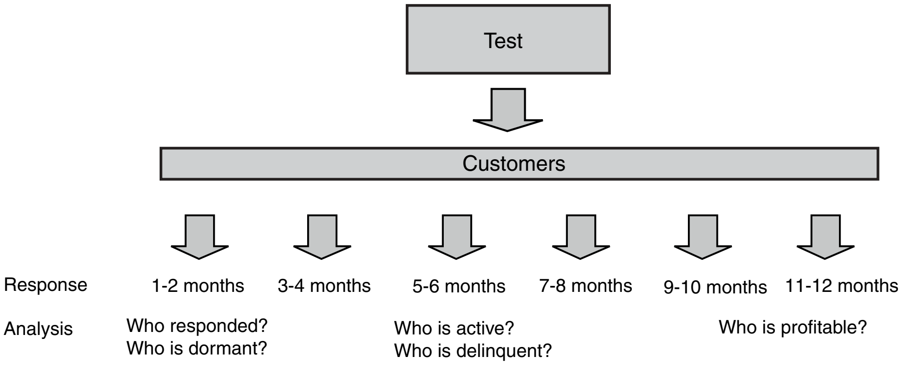

Figure 5. Analyzing the response to customer communications.

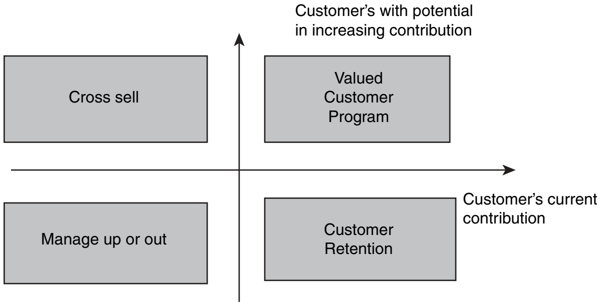

Figure 6. Treatment of various customer segments.

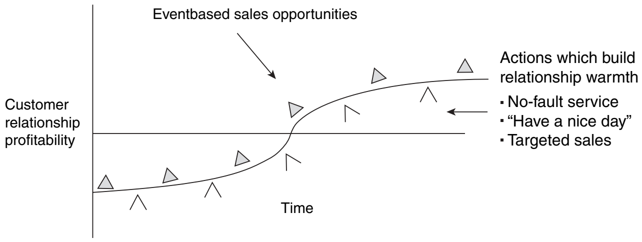

Figure 7. Lifetime impact of customer loyalty.

example, sending a greeting card on a customer's birthday is a valuable relationship-building action—with low cost and high effectiveness.

In marketing language, this strategy is called "event marketing," where the idea is to use the occurrence of events as marketing opportunities. Sometimes even negative events can be used to drive sales. For example, a bank adopted the policy of offering a personal loan to every customer whose check bounced or there were insufficient funds for ATM withdrawal. This program was very successful and enhanced the reputation of the bank as being really caring about its customers.

The data mining community has developed many techniques for event and episode identification from sequential data. There is a great opportunity for applying those techniques here, because recognizing a potential marketing event is the biggest problem here.

DATA ANALYTICS SUPPORT FOR ANALYTICAL CRM

In this section we describe the back-end support needed for analytical CRM. Specifically, we first outline a generic architecture and then focus on the two key components, namely data warehousing and data mining.

Data Analytics Architecture

Figure 8 shows an example architecture needed to support the data analytics needs of analytical CRM. The key components are the data warehouse and the data analysis tools and processes.

Data Warehouse

Building a data warehouse is a key stepping stone in getting started with analytical CRM. Data sources for the warehouse are often the operational systems, which provide the lowest level of data. Data sources are designed for operational use, not for decision support, and the data reflect this fact. Multiple data sources are often from different systems, running on a wide range of hardware, and much of this software is built in-house or highly customized. Data from multiple sources are mismatched. It is important to clean warehouse data because critical CRM decisions will be based on it. The three classes of data extraction tools commonly used are as follows: data migration that allows simple data transformation, data scrubbing that uses domain-specific knowledge to scrub data, and data auditing that discovers rules and relationships by scanning data and detects outliers.

Loading the warehouse includes some other processing tasks, such as checking integrity constraints, sorting, summarizing, and build indexes. Refreshing a warehouse requires propagating updates on source data to the data stored in the warehouse. The time and frequency to refresh a warehouse is determined by usage, types of data source, and so on. The ways to refresh the warehouse include data shipping, which uses triggers to update the snapshot log table and to propagate the updated data to the warehouse, and transaction shipping, which ships the updates in the transaction log. For technical details on transforming, refreshing, and maintaining data warehouses, see Refs. 6–13.

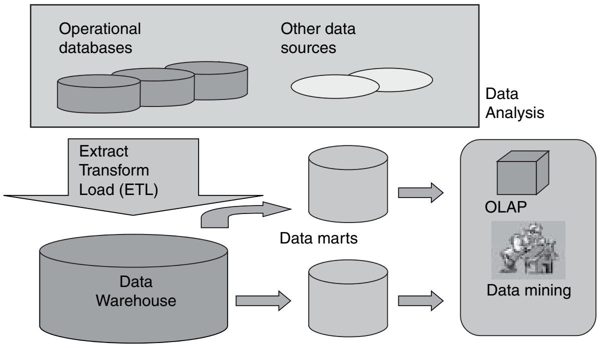

Figure 8. Data analytics architecture.

The key entities required for CRM include *Customer, Product, and Channel*. Usually information about each of these entities is scattered across multiple operational databases. In the warehouse these databases are consolidated into complete entities. For example, the Customer entity in the warehouse provides a full picture of who a customer is from the entire organization's perspective, including all possible interactions, as well as their histories. For smaller organizations the analysis may be done directly on the warehouse, whereas for larger organizations, separate data marts may be created for various CRM functions like customer segmentation, customer communication, and customer retention. A typical approach for designing entities in a data warehouse is called *dimensional modeling*, which organizes data into *fact tables* and *dimension tables*. Fact tables contain measurements or metrics of business processes and foreign keys of dimension tables. Dimension tables store the context of measurement, including the demographics of customers, time and place. A typical example is to store the content of each transaction such as transaction amount and products purchased in a fact table, while recording the characteristics of the associated customer, the channel, and the products in dimension tables. Interested readers are referred to Refs. 14 and 15, for modeling in data warehouse.

Data Mining

The next generation of analytic CRM requires companies to span the analytical spectrum and focus more effort on looking forward. The "what has happened" world of report writers and the "why has it happened" OLAP worlds are not sufficient. Time-to-market pressures, combined with data explosion, are forcing many organizations to struggle to stay competitive in the "less time, more data" scenario. Coupled with the need to be more proactive, organizations are focusing their analytical efforts to determine what will happen, what they can do to make it happen, and ultimately to automate the entire process. Data mining is now viewed today as an analytical necessity. The primary focus of data mining is to discover knowledge, previously unknown; predict future events; and automate the analysis of very large datasets.

The data mining process consists of several steps. First the data collected must be processed to make it mine-able. It requires several steps to clean the data and to handle mismatches in format, structure, semantics, and normalization and integration. A very good book on the subject is Ref. 16. Once the data have been cleaned, various data mining algorithms can be applied to extract models from it. Several data mining techniques have been developed, and the one to be applied depends on the specific purpose at hand. Reference 17 provides an excellent introduction to various data mining algorithms, whereas Ref. 18 shows how they can be applied in the context of marketing.

The most common data mining task is *classification*, which refers to assigning a new object one of the predefined classes by examining its features. The classification task is to learn a prediction model from a training set consisting of examples with features and preassigned classes. Such a model can be then used to predict the class of a new object. For example, one may classify customers as *good, okay*, and *bad* customers by using classification techniques based on their transaction records and provide incentives only to a handful of good customers for product/service promotion. Classification techniques can be extended to handle nondiscrete outcomes, e.g., estimating the lifetime value of a customer. Bayesian classifier (19,20), decision trees (21–24), decision rules (25,26), support vector machine (27,28), neural networks (29–31), and genetic algorithms (32,33) are among the most popular classification techniques.

Another common data mining task is *clustering*, which partitions a group of objects into a set of more homogeneous subgroups. Clustering is also called *unsupervised learning*, especially in the artificial intelligence community, as opposed to classification (also known as *supervised learning*) that requires domain experts assigning classes to examples in a training set. In clustering, objects are grouped based on pairwise similarities. It is up to the designer to determine the appropriate similarity metrics in a specific domain. Commonly used similarity metrics include reciprocal Euclidean distance, correlation coefficient, and cosine function. For example, customers can be segmented by their socioeconomical status, and different promotion packages can be tailor-made for different clusters of customers. Well-known clustering techniques include k-means, k-nearest neighbors (34,35), partitioning or hierarchical clustering (36–39), and expectation-maximization (EM) algorithm (40,41).

A common data mining task that was more recently proposed is *association mining*, which determines groups of closely related objects. A well-known example is the *market basket example* that identifies the set of products that often go together in customers' shopping carts; e.g., people who buy milk tend to also buy bread. Such association rules can be used to plan item placement on shelves and to design attractive packages. Association rule mining techniques can be extended to identify trends in time-variant data. For example, time series patterns derived from the transactions of former customers may help us better understand the ex-customer's behavior and subsequently retain (good) customers. Various techniques have been proposed to identify association rules (42–52) and sequential and time series patterns (53–65).

Once a model has been developed, it can be used for two kinds of purposes. The first purpose is to gain an understanding of the current behavior of the customers. A model used for this purpose is called a *descriptive model*. Both clustering and classification intend to find a descriptive model from existing data. The second purpose is to use the model to make predictions about the future behavior of the customers. A model used for this purpose is called a *predictive model*. The descriptive model, which is extracted from past behavior, is used as a starting point from which a predictive model can be built. Such an approach has been found to be quite successful, as it is based on the assumption that past behavior is a good predictor of future behavior, with appropriate adjustments. This assumption holds quite well in practice.

Finally, a data mining task that has been widely adopted by many online stores is *personalization*, which intends to provide information about products/services that fits a customer's personal need. A personalization system, often better known as a *recommendation system*, maintains an interest profile for each customer and recommends to a customer only those products/services that are highly related to his/her interest profile. Although traditional approaches require users to explicitly specify their interest profiles, modern recommendation systems adopt data mining techniques to build interest profiles from previous transactions. Two types of approaches have been proposed for building personal interest profiles: the *content-based approach* and the *collaborative approach*. The content-based approach derives the *content* features of a customer's past interaction data and builds a prediction model for each customer that, when given the content features of an item, indicates the probability that the customer likes the item. Various classification techniques have been applied in this context (66-70). The collaborative approach considers the *social* features of users' interests and recommends items to a customer by taking into account other customers' preferences. There are two broad categories of approaches for estimating the preference of an unseen item to a customer: *memory-based* and *model-based* approaches (71). The memory-based approach uses a rating matrix, with rows being customers and columns being items, to represent customers' ratings on items. It computes a weighted sum on rows or columns of the rating matrix for predicting the preference of a customer to an item (72–77). Possible weighting schemes include correlation, cosine and regression. The model-based approach builds a coherent prediction model for *all* customers based on customers' ratings. The prediction model takes as input a customer and an item and outputs the probability that the customer likes the item. Various techniques in classification (71,78–80), clustering (81–83), and association mining (84–88) have been proposed for building such a prediction model.

ORGANIZATIONAL ISSUES IN ANALYTICAL CRM ADOPTION

Although the promise of analytical CRM, both for cost reduction and revenue increase, is significant, this cannot be achieved unless there is successful adoption of it within an organization. Adaptation of an analytical CRM system within an organization is considered a business transformation project. In addition to deployment of new technology, it requires significant changes to existing processes that define how an enterprise should interface and treat all its customers and partners. In this section we describe some key organizational issues in CRM adoption.

Customer First Orientation

Companies that offer several products and services have traditionally organized their customer facing teams, e.g., sales, marketing, customer service, and so on, vertically along product lines, called "Lines of Business (LOBs)." The goal of any such product marketing team is to build the next product for its LOB; the goal of the sales team is to identify the customers who would be likely to buy this product, and customer service is trained to support the specifc product sets. Organizations adopting such a model, also known as functional-based organizations, causes customer needs and companies overall goals to be treated as secondary when compared with the LOB's priorities and needs. In such an organizational model, initiatives such as cross-selling become a big challenge because either the sales team does not have knowledge of other products that the company has to offer or does not have any financial incentive to offer products from other LOBs that customers may want to buy. The vertical organizational model also influences the enterprise architecture by having each LOB have its own customer database and associated business applications resulting in a complex enterprise architecture.

In addition to the architecture, a functional-based organizational model dictates what data about the customers should be collected. The collected data in such an organization are usually transactional in nature and less focused on customer's behavior and needs and make some analytical computations very difficult and less reliable, if not impossible. Additionally, it is possible for each LOB to have its own data about a given customer. The LOB-specific data about a customer can be inconsistent, resulting in a data inconsistency problem.

To overcome the above challenges and improve the chance of success in a CRM analytic project, the customer-focusing teams of an organization must be reoriented to make them focus on customers in addition to product lines while eliminating barriers caused by the vertical organizational model. These teams can be organized around well-defined customer segments, e.g., infants, children, teenagers, young professionals, and so on, and each given the charter of defining product design, marketing, sales, and service strategies that are geared to satisfying the needs of their customer segment. As part of this, some activities might be targeted to individual customers.

Attention to Data Aspects of Analytical CRM

The most sophisticated analytical tool can be rendered ineffective if the appropriate data are not available. To truly excel at CRM, an organization needs detailed information about the needs, values, and wants of its customers. Leading organizations gather data from many customer touch points and external sources, and bring these data together in a common, centralized repository, in a form that is available and ready to be analyzed when needed. This process helps ensure that the business has a consistent and accurate picture of every customer and can align its resources according to the highest priorities. Given this observation, it is critical that sufficient attention be paid to the data aspects of the CRM project, in addition to the software.

As discussed, most functional-based organizations lack that data required to make the analytical CRM project successful. The challenges are two-fold. The first challenge is when data (e.g., customer data) coming from each LOB need to be integrated into an enterprise-wide database to be used by ACRM applications. Differences in database schema and data content between LOBs may create data quality issues that can make the analytical CRM application less reliable. The second challenge is to adjust ongoing business processes to collect the necessary data and use the analytic CRM to focus on customer and companies priorities rather than an each LOB's priorities. In many cases, such adjustment requires changes in the way sales, marketing, and executive teams are compensated as well as how each LOB contribution to overall company is recognized.

Organizational "Buy In"

Although data mining and data warehousing are very powerful technologies, with a proven track record, there are also enough examples of failures when technology is deployed without sufficient organizational "buy in." As described, the parts of the organization that will benefit the most from analytical CRM are the business units, i.e., marketing and sales, and not the IT department. Thus, it is crucial to have "buy in" from the business units to ensure that the results will be used appropriately.

As described, deployment of analytical CRM is a company-wide business transformation project. It requires deployment of new technologies and transition from LOB-centric processes to company-centric processes. Example of such processes are how commissions are computed for sales, marketing, and executive teams as well as the way each LOB's contribution to the company is recognized. Transitioning from LOB-centric processes to company- centric processes requires some specific actions.

First, a CRM project needs to be owned and sponsored by a corporate executive from the business side who manages the business and technical development teams, and a cross-functional team who manages the scope of the project. The team is responsible to identify a road map for migration from the existing environment to the new one. As part of the road map, business and technology changes and impact to the different groups (i.e., business case) needs to be identified and communicated early in the project lifecycle to all affected units. It is important to make sure all impacted units have representation in the cross-functional team. The ideal (cross-functional) team should have enthusiastic members, who are committed, and are also viewed as leaders in their respective parts of the organization. This will make the dissemination of the successes much easier.

Second, all affected LOBs must support the road map and make commitments to adapt the new processes introduced by analytical CRM systems. Third, the new processes need to have an appropriate set of measurable metrics, to ensure that all steps for project success are being taken. Fourth, the project needs to be regularly reviewed by the executive team to ensure that any potential issue is addressed in a timely manner. Finally, incentives for performing well on the project should be included as part of the reward structure to ensure motivation.

Incremental Introduction of CRM

Introducing CRM into an organization must be managed carefully. Given its high initial cost, and significant change on the organization's processes, it is quite possible that insufficient care in its introduction leads to high expense, seemingly small early benefits, which can lead to low morale and excessive finger-pointing and possibility of failure.

As shown in Fig. 9, courtesy of Forsyth (89), it is better to have an incremental "pay-as-you-go" approach rather than a "field-of-dreams" approach. The benefits accrued from the first stage become evident and act as a catalyst for accelerating the subsequent stages. This makes the choice of the first project and its team very critical. Ideally, the project must be in a potentially high-impact area, where the current process is very ineffective. The process transformation and end-user training are two major success factors of a CRM project. The "pay-as-you-go" approach provides a way to transform the process and to train end users gradually. The gradual adaptation of a new system is an important factor in the success of any large project like CRM that impacts many aspects of a business.

Architectural Challenges

As discussed, in many companies, the enterprise architecture is a reflection of how LOBs operate. In a LOB-centric business model, each LOB has its own set of applications and databases and associate processes. To migrate to a single corporate-wide CRM system, a migration plan should be put in place to sunset LOB-centric systems and processes and move all existing data and interfaces to work in the new environment. This migration creates a set of special challenges, including scalability, support for company and LOB-specific functions, data integration, and performance. The architecture should also comply with any applicable corporate-wide standards.

Deployment Platform

In the recent decade, many companies have been dealing with the "buy" vs. "build" question for complex systems like CRM. Many companies decided to stop internal deployment of CRM systems and to license CRM applications from companies like Siebel, SAP, and PeopleSoft. However, deployment of these licensed applications has taken more time and cost more thanexpected. because their integration into the existing environment and process impacts have been greater than expected. Thus, it is important for the team to put a realistic plan together when starting a new CRM project.

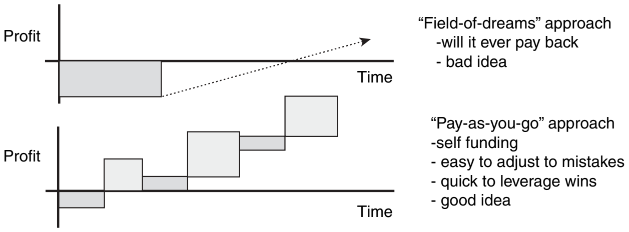

Figure 9. Incremental approach to CRM adoption.

Advancements in the application hosting and high cost of deployment and operation of CRM systems have created a market for hosting the CRM applications. In this business model, a company instead of having its CRM application will subscribe to a CRM application service. The application service provider is responsible for operation and maintenance of the environment, and the company pays a subscription fee. This new approach was pioneered by salesforce.com and has been followed by other CRM companies.

CONCLUSION

The Internet has emerged as a low-cost, low-latency, and high-bandwidth customer communication channel. In addition, its interactive nature provides an organization with the ability to enter into a close, personalized dialog with its individual customers. The simultaneous maturation of data management technologies like data warehousing, and analysis technologies like data mining, has created the ideal environment for making customer relationship management a much more systematic effort than it has been. Although there has been a significant growth of software vendors providing CRM software, and of using them, the focus so far has largely been on the "relationship management" part of CRM rather than on the "customer understanding" part. Thus, CRM functions such as e-mail-based campaigns management and online ads are being adopted quickly. However, ensuring that the right message is being delivered to the right person and that multiple messages being delivered at different times and through different channels are consistent is still in a nascent stage. As a result, companies are overcommunicating with their best customers, while insufficient attention is being paid to develop new ones into the best customers of the future.

In this article we have described how ACRM can fill the gap. Specifically, we described how data analytics can be used to make various CRM functions like customer segmentation, communication targeting, retention, and loyalty much more effective.

ASPECT-ORIENTED SOFTWARE DEVELOPMENT: AN INTRODUCTION

INTRODUCTION

Software development is a challenging task because of the complexity, heterogeneity, and distributed nature of modern software systems and the interactions and dependencies that need to be managed therein. An established approach to solving complex problems is by breaking them into smaller, more manageable, and easily understandable parts, for example, modules. After the subproblems are solved, all the solutions are combined to provide a solution to the initial complex problem. In software engineering, the same division and combination principles are applied: the division into subproblems is termed as *modularization*, and the combination of solutions is termed *composition*.

Modularity of software has long been the primary tool used in software development and a subject for computer science research. Fundamental software-structuring mechanisms such as procedures, functions, objects, and components are essential modularization mechanisms used in contemporary software-development paradigms. Each of these modules is intended to represent a clearly identified part of the software, and altogether they interact to provide the complete solution expected from the software application. This practice improves the individual module's understandability and facilitates its change, when needed. This practice is what has been referred to as the principle of *separation of concerns* by Dijkstra in his seminal book *A Discipline of Programming* (1).

A *concern* in software development is an interest, that pertains to the system's development, its operation, or any other matters that are critical or otherwise important to a stakeholder (2). The principle of separation of concerns thus states that each concern that is relevant to the software application is best treated separately. For instance, in *object-orientation* (one of today's most widely used development paradigms) separation of concerns is achieved by decomposing an application into individual real-life or conceptual objects and exploiting the object-oriented software-development principles (i.e., encapsulation, polymorphism, inheritance, and delegation) for application development. In an ideal situation, each object pertains to a single concern. Nevertheless, despite the wide support for separation of concerns in modern software-development paradigms (such as object-orientation), concerns still exist that are difficult or even impossible to modularize by means of the established mechanisms. For instance, such concerns as synchronization policies in multithreaded systems, logging, persistence, error handling, real-time constraints, and faulttolerance are often intermixed with (or, in other words, spread across) several other modules in the system. Such concerns are said to crosscut the other modules and, therefore, are called *crosscutting concerns*.

A practical example of the extent of crosscutting in a system is provided by Kiczales et al. in Ref. (3) and is reproduced in Fig. 1. This figure shows the modules (object-oriented classes) of the Apache Tomcat Web server represented as vertical bars, whereas the implementation of the *logging* concern is indicated by the horizontal lines (which represent lines of logging code). The logging concern clearly crosscuts many distinct modules.

Crosscutting concerns, such as logging in Fig. 1, complicate software development because they do not fit the primary decomposition of the development paradigm (the object boundaries in Fig. 1). As a result, the responsibilities of the individual modules are not clearly demarcated. Not only is an object responsible for its core state and behavior (pertaining to its business functionality, for instance) but also for that of the crosscutting concern (such as logging). This phenomenon is referred to as *tangling*. At the same time, we observe the *scattering* effect whereby a given crosscutting concern, for example, logging, is not modularized in a single element and hence hampers our ability to reason about its effect and behavior with respect to the other modules; such reasoning requires inspection of all the modules where logging is realized. In practice, this straightforwardly translates into an inability to reuse the implementation of a crosscutting concern, without resorting to code duplication. This practice goes against the established best practice of separation of concerns that we highlighted above because the crosscutting effect results in software that is difficult to understand and maintain. Addressing this problem of crosscutting is the main focus of *aspect-oriented software-development* (AOSD) techniques.

AOSD techniques provide systematic means for identification, modularization, and composition of concerns that normally would be crosscutting in other development paradigms (e.g., object-oriented or procedural paradigms) (4). With AOSD, such a concern will continue to exert a broad, crosscutting influence on other concerns, but its representation and realization can be localized in a single module.

AOSD CONCEPTS

AOSD techniques provide systematic means for identification, modularization, and composition of crosscutting concerns throughout software development lifecycle. Modules in other contemporary paradigms are all rooted in functional decomposition (e.g., subroutines, functions, objects, and components). To characterize these modules, Kiczales et al. (5) coined the term *generalized procedure* and argued that such generalized procedures are to be invoked explicitly via a direct call "by name" at the *syntactic location* in the software artifact where their execution is desired.

For instance, consider the code fragment in Fig. 2, taken from the implementation of a concurrent buffer. Two major concerns exist in this implementation: buffer functionality and concurrency locks. The concurrency-locking concern is

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

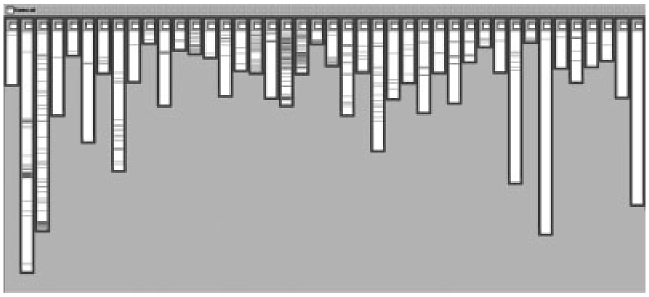

Figure 1. An example of a crosscutting concern (logging) in a software application [3].

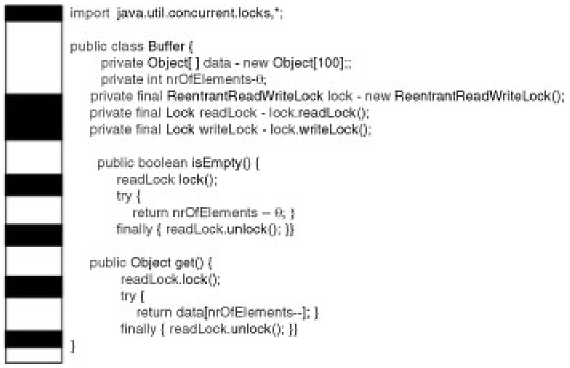


```
import java.util.concurrent.locks.*;

public class Buffer {
        private Object[ ] data - new Object[100];;
        private int nrOfElements-0;
      private final ReentrantReadWriteLock lock - new ReentrantReadWriteLock();
      private final Lock readLock - lock.readLock();
      private final Lock writeLock - lock.writeLock();

       public boolean isEmpty() {
          readLock lock();
          try {
             return nrOfElements – 0; }
          finally { readLock.unlock(); }}

      public Object get() {
           readLock.lock();
           try {
              return data[nrOfElements--]; }
           finally { readLock.unlock(); }}
}
```

Figure 2. A fragment of a concurrent buffer in Java.

a crosscutting concern because it crosscuts the implementation of each method of the buffer, as illustrated by the black lines on the left-hand side of the figure. To invoke the locking/unlocking functionality, the *lock()* and *unlock()* methods must be called by name at the syntactic locations where their functionality is required. Furthermore, the buffer object must hold the functional buffer state as well as the locking semaphores. Aspect-orientation proposes a fundamentally new kind of modularization and composition that goes beyond generalized procedures. The elements of AOSD supporting this new modularization and its composition techniques are presented next.

Aspect

A crosscutting concern is encapsulated within a dedicated module called an *aspect;* an *aspect* is a modularized crosscutting concern. The specification of an aspect's interaction with the other modules is its primary distinction with respect to modules based on the concept of generalized procedures. For aspects in the implementation of a software artifact, this means that, in contrast to the explicit invocation of a generalized procedure, an aspect's invocation is not bound to such an explicit, syntactically located invocation statement. Instead, an explicit specification about when an aspect will be applied can be either attached to an aspect (e.g., as in Ref. 6) or provided in separate dedicated *composition specifications* (e.g., Refs. 7 and 8). For aspects in requirements, architecture, and design, this, distinction means reasoning about the crosscutting concerns and about their dependencies and interactions with other concerns without having to inspect multiple modules.

The aspect's invocation mechanism has also been referred to as *implicit invocation* by Xu et al. (9) and was uniformly characterized with respect to generalized procedures by Kiczales and Mezini in Ref. (10): *"one useful way to uniformly characterize the different mechanisms is as establishing different kinds of bindings along a path from points in a program to the implementation of an operation that must execute at those points."* Whereas procedures are one way to introduce bindings from a point in a program (i.e., where the procedure call resides) to their implementation, pointcuts and advice are a means to introduce additional points and bindings. The points to which advices can be bound are termed joinpoints, and the bindings are specified by pointcuts. These concepts are described next.

Joinpoint and Joinpoint Model

In all aspect-oriented techniques, aspects can only be invoked, or composed with other modules, at some well-defined and principled points within the software artifacts. These points are referred to as *joinpoints*. All possible kinds of joinpoints for the given AOSD approach are described in a *joinpoint model*. As stated in Ref. 2: "A joinpoint is a point of interest in some artifact in the software lifecycle through which two or more concerns may be composed. A joinpoint model defines the kinds of joinpoints available and how they are accessed and used." For example, in most aspect-oriented programming languages, the possible kinds of joinpoints are method calls, field references and assignments, exception handler executions, method executions, and so forth. In requirements, joinpoints can be specific requirements or concerns encapsulating those requirements. In design, elements of a UML diagram, for instance, can serve as joinpoints.

Pointcut

The set of joinpoints at which a given aspect should interact with some other modules is specified via a *pointcut*. Pointcuts can be defined *by extension*, for example, enumerating each joinpoint relevant for the given aspect application, or *by intension*, for example, via some kind of more abstract joinpoint selection criteria. These criteria typically are properties of the joinpoints to be selected (e.g. name patterns, structural or dynamic relations with other joinpoints, etc.). Because aspects normally have a broad influence on the system, affecting a number of other concerns, defining their interactions by enumerating joinpoints is rather inefficient. Consequently, in AOSD, pointcuts are normally defined by intension. Thus, a pointcut is a predicate that matches joinpoints.

Advice

As discussed above, an aspect affects a set of other concerns at the joinpoints. In AOSD terminology, it is said that aspects *advise* other concerns. An *advice* represents the semantics of an aspect that will interact with some other concern at a joinpoint. Depending on the AO approach used and the lifecycle stage of aspect modeling, the advice can take a variety of forms. For instance, in Fig. 2, the *lock()* and *unlock()* operations of the synchronization concern will be contained in code-level advices that impose additional behavior on the buffer object (see the section titled "Concurrent Buffer Example in AOP").

Traditionally, an *advice* in AOSD implies a behavior-related interaction between aspectual and nonaspectual artifacts. Such an interaction is also defined in respect with some temporal, conditional, or unconditional order. For instance, the behavioral modification can be applied by an advice *before, after, instead of*, or *concurrently* with the original behavior of the advised artifact.

Intertype Declarations

Although an advice normally modifies behavior at the advised joinpoints, some AOSD approaches use an additional mechanism called *inter-type declarations* (or *introductions*) for directly modifying the structure of the original artifacts. For instance, an intertype declaration may insert a new requirement into a viewpoint or a new variable declaration into a class or even change subtype relations, and so forth.

Composition/Weaving

In AOSD, traditionally the *composition* or *weaving* is the integration of the separated crosscutting elements back into the modules crosscut by them. For instance, during composition the *lock()* advice of a concurrency aspect would be inserted into the *buffer* class and would produce the same result as shown in Fig. 2. In the case of implementation-level aspects, such weaving is often part of the compilation to executable code, but load-time and run-time weaving is also possible in many aspect languages and frameworks.

Recently, some AOSD works have pointed out that, especially in the case of nonimplementation artifacts, it is not always necessary to integrate the aspectual elements in other modules; often a *composition specification* is sufficient for reasoning about aspectual and nonaspectual module interactions (8, 11, 12). The *composition specification* defines which aspectual elements (advice, intertype declarations, and so forth.) affect which joinpoints (selected by pointcuts) of which nonaspectual modules and defines what are the temporal, conditional, or unconditional circumstances of aspect invocation.

ASPECT-ORIENTED SOFTWARE-DEVELOPMENT LIFECYCLE

Aspect-oriented software-engineering techniques have the same objectives as any other software-engineering techniques: to understand, represent, and realize software systems. The unique contribution of AOSD is in providing additional abstraction and reasoning capabilities via the constructs discussed above. These constructs assist in modularizing concerns that would otherwise be scattered (i.e., included piece by piece) in other concern modules. Such concern scattering also results in the entanglement of elements of independent concerns in the same module. By using aspects such scattering and tangling issues are removed, which in turn leads to simpler and more-cohesive modules for concern representation.

AOSD does not enforce any particular sequence or lifecycle activities; individuals choosing to use this technology may continue to use their own established activities along with the additional modularization and reasoning mechanisms of AOSD. Nevertheless, a number of AOSD approaches currently strive to provide a whole AO development process covering the set of activities that leads from requirements to implementation. For instance, the AOSD with Use-cases approach (13) provides support for requirement modeling via use cases, their refinement into design, and guidelines for mapping these designs onto an AO implementation language. Similarly the Theme (14, 15) approach consists of Theme\Doc part for requirements analysis and Theme\UML part for design representation of the aspects from Theme\Doc. Detailed guidelines then are provided (16) for realizing Theme designs in the AspectJ and Hyper/J AO programming languages.

However, being a relatively young area, AOSD has not yet consolidated its development activities into an established set, as has, for instance, object-oriented development. Thus, several analysis, architecture, design, and implementation approaches exist that are not necessarily linked into an end-to-end development process. In the rest of this article, we discuss a subset of current AOSD approaches, without focusing on one specific approach that covers the end-to-end software development process. This choice is motivated by the goal of outlining the diverse and varied approaches that constitute AOSD rather than detailing a specific approach. Readers interested in any particular approach are pointed to further sources via relevant references. At the same time, we detail a specific requirements, architecture, design, and implementation approach to outline how the AOSD concepts fit with the established lifecycle artifacts. Because it is not possible to cover all facades of AOSD in this introduction, we also provide additional references to related topics, where appropriate.

ASPECT-ORIENTED REQUIREMENTS ENGINEERING

Crosscutting concerns, such as logging, distribution, and fault tolerance, first manifest themselves in requirements, and this is where one must start treating them. Aspect-oriented requirements-engineering (AORE) approaches aim to facilitate identification and analysis of such crosscutting concerns during requirements engineering to understand their potential effects and tradeoffs with respect to other stakeholder requirements. Often AORE approaches extend existing requirements-engineering techniques with additional support for modularization and composition of crosscutting concerns. Such support is missing in most contemporary requirements-engineering techniques. For instance, in the classical use-cases approach (17), nonfunctional requirements (NFR) cannot be readily modeled. Although techniques such as goal-based approaches

(18, 19) support modularization and analysis of such NFRs, they lack effective composition mechanisms to explore the complex dependencies and interactions fully, as such an analysis entails. Thus, AORE focuses on providing systematic means for modularization and composition of crosscutting concerns in requirements.

Aspects in AORE

Presently, a number of AORE approaches are researched actively (4, 8, 11, 13, 20). Some provide an additional modularization unit to represent requirements-level aspects (e.g., Refs. 4, 13, and 20), whereas others strive to use uniform modules for both aspectual and nonaspectual requirements artifacts (e.g., Refs. 8 and 11). In both cases, a requirements-level aspect is an artifact that encapsulates a concern that has a broad influence on the requirements in several other requirements-level artifacts. A summary of key concepts and techniques for AORE is provided by Baniassad et al. in Ref. 21, whereas a detailed comparative analysis between AORE and other contemporary requirements-engineering techniques is provided in the survey by Chitchyan et al. (22).

One may note that some (although not many) established non-AO requirements approaches already provide systematic modularization support for crosscutting concerns. For instance, the goal-based approaches (18, 19) support modularization of both functional and nonfunctional goals. However, the main distinction between the AO and non-AO requirements approaches is in the support for composition in the former. Contemporary (non-aspect-oriented) RE approaches hardly provide any composition support, with compositions often entangled with the requirement artifact development process. For instance, the composition of goals and softgoals is an integral part of goal interdependency graph development; goal compositions cannot be represented or reasoned about in isolation from the whole set of goals in the graph. In AORE, the compositions are normally represented in separate dedicated composition modules to reason about the dependencies and interactions exerted by crosscutting requirements rather than attached to the aspectual artifacts.

In the rest of this section, we will use the AORE with Arcade approach (4) to illustrate the AORE concepts. AORE with Arcade builds on the viewpoints-based requirements-engineering approach (23, 24) and provides a dedicated module for aspect representation. An aspectual module here contains requirements that affect requirements of several viewpoints. For instance, an aspect may contain requirements about security, concurrency, and so forth. As common in all RE approaches, this viewpoint-based approach provides a unique identifier for each concern (via its name) and each of its distinct requirements (via number-based ids unique within the scope of each concern).

Compositions in AORE with Arcade are defined in dedicated composition modules. The joinpoint model exposes unique identifiers of requirements and viewpoint/aspect names. The pointcuts are defined by extension, which enumerates the module name and id pairs for each requirement that participates in a composition. A pointcut can also use a *wildcard*, for example, a universal quantifier, such as *all*. An example of a pointcut with use of a wildcard is, for instance, "*all* requirements with id = 1". Of course, pointcuts by extension are only one way of representing aspect compositions in requirements. Name-pattern-based (25, 26) and semantics-based (8) pointcut definitions are also used in several AORE approaches. An example of a name-pattern-based pointcut in the aspect-oriented V-graph-based approach (25) is "Register.*". This pointcut references all goals of "Register" type in a goal graph, independent of their topic names. A semantics-based pointcut definition, however, refers to the content (i.e., meaning) of the requirement that participates in a composition rather than its id or name patterns. One such approach is proposed in Ref. 8; it uses the grammatical semantics of the natural language as a basis for composition.

In AORE with Arcade the requirements in the aspects are the advices that are imposed upon viewpoints. This approach does not use intertype declarations and does not execute an actual composition to produce new requirements specification with advising requirements inserted into the viewpoints. Instead, the Arcade compositions are used as an analysis tool to detect requirement interactions and conflict points and to enable trade-off analysis. This same approach is taken in several other AORE works, (e.g., Refs. 8 and 27). The AO V-graph approach (25), however, does have a dedicated intertype declaration mechanism, whereby new goals are inserted into the goal graph at the identified points. AO V-graph also provides a tool-supported mechanism for transforming the original goals and aspects into an integrated-goalgraph. This integrated graph, however, is not used for analysis but only for validating the expected composition results.

In summary, AORE uses the joinpoint, pointcut, advice, and intertype declaration notions of AOSD to provide improved separation of concerns and composition at the requirements level. The composition definitions are often used as an analysis tool for conflict-point identification and interaction understanding. However, the actual transformational compositions are also realized in some approaches. It is also essential to note that not all aspectual artifacts identified at the requirements level will subsequently be represented as code-level aspects. On the contrary, some may well transform into other software artifacts (e.g., architectural topology) or business-related decisions (e.g., procedures for security policy used by the business) before an application is implemented. In addition, new aspects, often related to the selected development technology, will develop at the other stages of software development, but these will not be visible in requirements.

Concurrent Buffer Example in AORE

The Arcade example for the buffer and its related concurrency requirements is illustrated in Fig. 3. Note, that the XML notation of the Arcade approach is used, where viewpoints, aspects, and composition elements are defined, each of which contains a set of requirement elements. A set of composition actions and operators is also used (here touched upon briefly) where necessary to explain the general meaning of the composition. Details of the Arcade approach can be found in Ref. 4.

```
<Viewpoint name= "Buffer">
      <Requirement id ="1"> Check if the buffer is empty. </Requirement>
      <Requirement id ="2"> Get an element from the buffer</Requirement>
</Viewpoint>                                                          (a)
```

```
<Concern name ="Concurrency">
      <Requirement id ="1"> System locks the buffer. </Requirement>
      <Requirement id ="2"> System unlocks the buffer. </Requirement>
</Concern>                                                            (b)
```

```
Composition: ConcurrentBuffer
<Composition>
      <Requirement aspect="Concurrency" id="1">
         <Constraint action="enforce" operator="before">
            <Requirement viewpoint="Buffer" id="all"/>
         </Constraint>
         <Outcome action="fulfilled"/>
      </Requirement>
      <Requirement aspect="Concurrency" id="2">
         <Constraint action="enforce" operator="after">
            <Requirement viewpoint="Buffer" id="all"/>
         </Constraint>
         <Outcome action="fulfilled"/>
      </Requirement>
</Composition>                                                        (c)
```

Figure 3. AORE with Arcade representation of Buffer, Concurrency, and their composition.

Figure 3(a) shows the Buffer viewpoint, which has two requirements: first, stating the need to check if the buffer is empty, and second, instructing to get an element from the Buffer. The Concurrency aspect is demonstrated in Fig. 3(b), and contains two requirements: one for locking the Buffer and another for unlocking it. Finally, the interaction between the Buffer viewpoint and the Concurrency aspect is shown in the composition defined in Fig. 3(c). From this composition, we see that the requirements with id numbers 1 and 2 of the Concurrency aspect influence all the requirements of the Buffer viewpoint. Thus, Concurrency is a crosscutting concern with respect to Buffer. The requirement with id = 1 of the Concurrency aspect will be *enforced* (enforce action) *before* (before operator) all requirements of Buffer, whereas the requirement with id = 2 will be *enforced after* (after operator) all requirements of the Buffer. Thus, the Concurrency requirements with ids 1 and 2 advise the Buffer's requirements.

As shown in Fig. 3, the pointcuts for composition are quantified as viewpoint = "Buffer" and id = "all", and advice is defined by reference to concern and id pairs (e.g., aspect= "Concurrency", and id = "1"). The composition states that the advice must be imposed before/after the joinpoints selected via the pointcuts. The composition does not carry out any immediate transformation of the composed requirements. Instead, it is an analysis tool that explicitly shows the effect of the aspects on the viewpoints and the interactions between the two.

ASPECT-ORIENTED ARCHITECTURE

The architecture of a computing system is concerned with the description of its general structure. With the emergence of AOSD, several architectural-design approaches have focused on researching how aspects manifest in the architecture and how they should be represented (22, 28–30). A discussion of several aspect-oriented architecture (AOA) approaches is provided in Ref. 22. In this section, we discuss the work on aspect-oriented architecture description languages (ADLs) because these have been the main focus of development of aspect-oriented techniques at the architecture level.

Aspects in Aspect-Oriented Architecture (AOA)

In accordance with Medvidovic and Taylor (3), the necessary elements of an ADL are components, connectors, and architectural configurations. Components and connectors must have associated interfaces that detail the operations, messages, and variables the components use to interact with each other. These interactions and their rules are modeled via connectors. Most ADLs aiming to incorporate AOSD concepts have defined several extensions to this base set of ADL constructs. While discussing AO ADLs, we will use the work of Pinto and colleagues (32–34) as an example AO ADL, primarily because we believe that this work uses only the minimal set of extensions necessary to accommodate AOSD concepts in an ADL.

The majority of AO ADLs [such as Prisma (35), Fractal (36), and DAOP-ADL (37, 38)] have opted to add a new *aspect* construct into the ADL to represent a crosscutting concern at the architectural level. The AO ADL by Pinto and colleagues (32–34), however, suggests that no need exists to use a special type of component for an aspect. Component interface in this AO ADL is described as either provided by a given component or used (i.e., required) by it. The interface contains a set of operations and state variables. The operations are given role names.

AO ADL (32–34) encapsulates the broad crosscutting influence of aspectual concerns in the architectural connectors. Thus, instead of defining new *aspect* components, this approach refines the connectors by extending their semantics with *aspectual bindings*. Whereas regular bindings in the connectors represent the composition of architectural elements, the *aspectual bindings* represent the composition between components that have a broadly scoped interaction with the other components.

The *joinpoint model* of the AO ADL by Pinto and colleagues (32–34) comprises the role names and operation names exposed by the components. When defining an aspectual binding, a *pointcut* may be defined as, for instance, “any component playing a particular role” or “any component that has an operation with a given name in one of its provided interfaces”, and so forth.

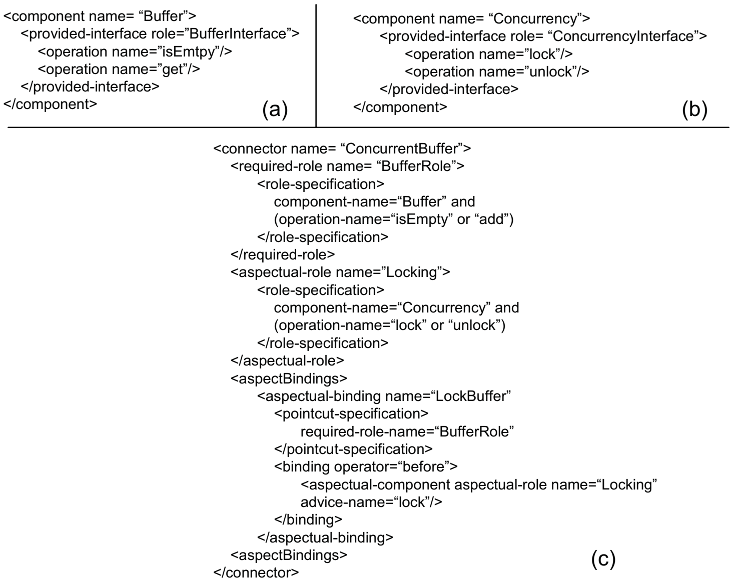
An *advice* in the AO ADL by Pinto and colleagues (32–34) is an operation, which is bound in the aspectual binding to a set of joinpoints selected by a pointcut. This advice operation can be imposed before, after, or concurrently with the advised operation. The AO ADL by Pinto and colleagues (32–34) does not use any constructs for *intertype declarations*. Instead, when it is necessary to introduce a new state variable or operation, the traditional notion of *composite component* is used. The modified component then is represented by a compound component with the original and additional interfaces. So far, the notion of intertype declaration has not been used much in AOA work (except for in Ref. 35), and the above discussed use of the traditional compound component for this purpose makes definition of such new construct unnecessary.

Thus, as shown by the above discussion, the accommodation of aspects within architecture design can be achieved without drastic changes to the traditional ADL constructs. For instance, Pinto and colleagues (32–34) do this by only extending the connector semantics. With such an approach, when no aspects are used in a system, the same component bindings as in non-AO systems can be used, which both minimizes changes to ADL constructs and enables component reuse.

It must be noted that in architecture, crosscutting concerns are not necessarily always related to individual components. For instance, work by Garcia et al. (39) illustrates that aspects are also useful in representing *architectural decisions* that affect multiple architectural views. In addition, not all identified crosscutting concerns can be modularized into components; some of them will continue to reside in multiple components (40) (e.g., beacuse of processing efficiency or other reasons). In such cases, it could still be useful to have a way of aspect documentation.

Concurrent Buffer Example in AOA

The AO ADL example for the buffer and its related concurrency elements is shown in Fig. 4 below. Here both Buffer and Concurrency concerns are represented as components, with their related operations. In this case, the Buffer provides two operations: *isEmpty* and *get* [Fig. 4(a)]. Similarly, the Concurrency component provides the *lock* and *unlock* operations [Fig. 4(b)]. The connector for these



```
<component name= “Buffer”>
   <provided-interface role=”BufferInterface”>
      <operation name=”isEmtpy”/>
      <operation name=”get”/>
   </provided-interface>
</component>
```

(a)

```
<component name= “Concurrency”>
     <provided-interface role= “ConcurrencyInterface”>
          <operation name=”lock”/>
          <operation name=”unlock”/>
     </provided-interface>
</component>
```

(b)

```
<connector name= “ConcurrentBuffer”>
   <required-role name= “BufferRole”>
        <role-specification>
           component-name=“Buffer” and
           (operation-name=“isEmpty” or “add”)
        </role-specification>
   </required-role>
   <aspectual-role name=”Locking”>
        <role-specification>
           component-name=“Concurrency” and
           (operation-name=“lock” or “unlock”)
        </role-specification>

(c)

Figure 4. AOA representation of Buffer and Concurrency concerns and their connector.

two concerns is shown in Fig. 4(c), in which an aspectual binding is defined to pre-advise (operator = before) all operations of the Buffer (pointcut specification: “Buffer-Role” where component name = “Buffer” with operation names “isEmtpy” or “get”) with the lock (advice name = “lock”) operation of the Concurrency component. If desired (although not shown here), a similar binding could have been defined to post-advise (if used with operator = after) all Buffer operations with the *unlock* operation of the Concurrency component.

ASPECT-ORIENTED DESIGN

In a vein similar to AORE and AOA, several approaches have been proposed for modeling and analysis of aspects during detailed design. Mostly, these approaches are based on the UML or its extensions; they provided support for modularization of crosscutting concerns and for specifying their compositions with other design elements [for a detailed analysis of aspect-oriented design techniques, see the survey by Chitchyan et al. (22)]. Most interesting approaches in this context are Theme/UML (15, 16) and the works by Klein et al. (41) and Cottenier et al. (42). We discuss Theme/UML in more detail below. The work by Klein et al. focuses on semantics of design composition and treats aspect composition as a model-composition problem. The approach proposed by Cottenier et al. exposes the state semantics of the design elements and bases the aspect compositions on these state chart specifications (exposed as part of the joinpoint model). This approach is rooted in the notion of model-driven engineering whereby weaving takes place at the design level, and code for the target platform is generated.

Aspects in Aspect-Oriented Design (AOD)

The vast majority of the work on AOD has opted to extend UML to accommodate aspect-oriented concepts. Some approaches have extended the UML meta-model (14, 15, 43), others have provided dedicated AOD profiles (44), and yet others have used a subset of UML’s built-in extension mechanisms, such as stereotypes (28, 29, 45). In the rest of this section, we will use the Theme/UML (15, 16) approach to demonstrate the AO concepts in design because this approach is one of most referenced and generic AOD approaches developed so far.

In the Theme/UML approach, the UML meta-model is extended to support modularization of designs into *themes. Themes* are UML packages that may encapsulate any feature, concern, or requirement that must be handled in the system (16). Here, the notion of a *crosscutting theme* is used for aspect representation. A crosscutting theme is a theme that provides some behavior that crosscuts other behavior in designs (16). In Theme/UML, the behavior is modeled via sequence diagrams, whereas structural crosscutting (i.e., nonbehavioral elements that could be included into a base theme via a crosscutting theme) can be modeled via class and package diagrams. Other approaches also use other UML modeling elements, such as activity diagrams (13), or focus on a subset of crosscutting, for example modeling only the structural elements as aspects via a dedicated ≪aspect≫ stereotype (43), or modeling only the various joinpoint selection queries (46, 47) and so forth.

The joinpoints in Theme/UML are represented as parameterized class and operation names that are defined and referenced in a theme’s template parameters section. These parameters define the Theme/UML pointcuts. During theme composition, these parameterized names are assigned to specific classes and operations via *binding* specifications. The binding specification also elaborates on the details of composition (e.g., merge or override the operation from the base theme with that of the crosscutting one). Thus, the binding in Theme/UML specifies the precedence of operations (e.g., which operation will be executed first), the type of advice (e.g., before/after or around), and, where necessary, conflict resolution between elements of themes to be merged. The work on joinpoint-designation diagrams (JPDD) (46, 47) provides a set of somewhat-modified (because of parameterization, addition of indirect relationships, etc.) UML-based modeling elements for capturing the intention of joinpoint selection queries, i.e., pointcuts. The JPDDs represent the conceptual models of queries: whether the joinpoints are selected on basis of object interaction (control flow-based queries realized via UML-based sequence diagrams), data interchange (data flow-based queries realized via UML-based activity diagrams), or state change (state-based queries realized via UML-based state charts). Each of these JPDD types can be used in combination with the others and the (modified) class/object diagrams.

Although Theme/UML does not explicitly define *introduction* as a construct, the theme merging requires inclusion of the nonparameterized elements of the contributing crosscutting themes into the final result. Thus, such nonparameterized crosscutting theme elements as classes, operations, attributes, and relationships (e.g., inheritance) can be perceived as introductions into the composed theme: They modify/crosscut the structure of the original base themes. With JPDDs, the introductions can be asserted via class/object diagrams. Moreover, here the powerful notion of *indirect relationships*(46, 47) is also used, whereby the existence of the relationship is stated without naming its precise location. For example, a new class in the class hierarchy can be introduced without stating its precise location. Instead, using the indirect inheritance relation, one may state that this class will be added somewhere in the given hierarchy.

Concurrent Buffer Example in AOD

The Theme/UML example for the buffer and its crosscutting concurrency concern is shown in Fig. 5 below.

Here both Concurrency and Buffer concerns are represented as themes. Concurrency [shown in Fig. 5(a)] is the crosscutting theme. Concurrency has *lockedOp()* and *unlockedOp()* template operations intended to replace respectively the original*_locked()* and *unlocked()* operations of some ConcurrenctClass by pre-advising these original operations with *lock()* operation of Concurrency and by post-advising them with its *unlock()* operation. The execution order of the operations (i.e., pre-advising, original operation, and post-advising) would normally be

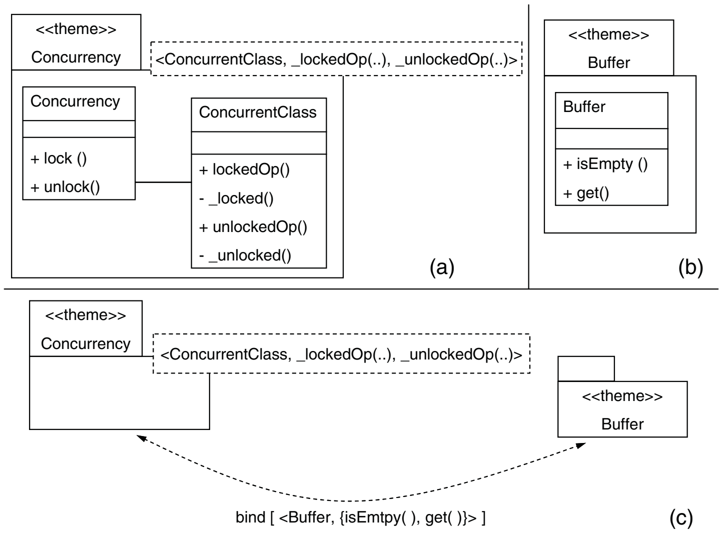

Figure 5. AOD with Theme representation of Concurrency and Buffer themes and their binding.

presented via an additional UML interaction diagram that is omitted in Fig. 5.

The base Buffer theme, which contains two public operations, *isEmpty()* and *get(),* is presented in Fig. 5(b). To specify that the Buffer theme is crosscut by the Concurrency theme, they are bound, as shown in Fig. 5(c). The binding specification [shown at the bottom of Fig. 5(c)] states, that

- the Buffer class of the Buffer theme instantiates the parameterized ConcurrentClass of the Concurrency theme, and
- both *isEmtpy()* and *get()* operations instantiate the *_lockedOp()* and *_unlockedOp()* operations. Each *isEmtpy()* and *get()* operation will be advised by both the *_lockedOp()* and *_unlockedOp()* operations, because the two former operations are grouped via curly brackets.

ASPECT-ORIENTED PROGRAMMING (AOP)

The aspect-oriented paradigm is endowed with a large and vibrant body of AOP languages (see http://www.aosd.net) and frameworks (e.g., Refs. 7, 48 and 49), that can be applied in the development stage of the software lifecycle. This situation can be explained by the fact that AOP first emerged as a programming-level technique but is perhaps more accurately motivated by the fact that almost every AOP language has its particular purpose and characteristics. A survey of the contemporary work on AOP languages and language execution models is available from Ref. 50.

Aspects in AOP

In this section, we discuss the instantiation of the aspectual elements for AOP by using as an example a particular programming language: AspectJ (6, 5). AspectJ can be considered as the flagship language of aspect orientation as it has made a transition from being a research topic to the state-of-the-practice.

AspectJ extends the Java language with aspect-oriented constructs for pointcuts, advice, and inter type declarations; it permits to encapsulate these into a class-like module: the *aspect*. Like an ordinary class, an aspect can also have methods, fields, and initializers of its own. Advices in AspectJ (and most other aspect languages) can be seen as anonymous methods, bound to a pointcut rather than to a method name and with bodies not essentially different from regular Java methods. The advice body contains regular statements and expressions that are executed when the advice is invoked at a joinpoint captured by its pointcut. Most often, specific keywords and pseudo-variables are available for use in advices only. AspectJ, for example, offers access to the currently executing joinpoint through the pseudo variable *thisJoinPoint*. Nevertheless, in some AOP languages, interesting exceptions from such an advice model occur. Most notably, *domain-specific aspect languages* (DSALs) permit the implementation of an aspect's advice in a dedicated domain-specific language. Interestingly, some earliest aspect languages are DSALs: D is a DSAL for synchronization concerns (51) and RG was designed specifically as an optimization aspect performing loop fusions. More recently, DSALs have emerged for aspects such as business rules (52) and advanced transaction management (53).

The invocation of any advice is determined by a pointcut, which is defined (traditionally, although not always) within the aspect itself by means of a set of predefined *pointcut predicates*. Such predicates permit to quantify over joinpoints (and their properties) to identify the joinpoints of interest to the aspect. In AspectJ, joinpoints are principled points in the execution of the program, such as field references or assignments, method executions, calls, and returns, to name but a few. These joinpoints can be qualified by the signatures and names of the fields, by methods and classes they apply to, and also with respect to the

```
1    public aspect Locking {
2      private final ReentrantReadWriteLock lock = new ReentrantReadWriteLock();
3      private final Lock readLock = lock.readLock();
4
5      pointcut lockedMethods(): execution(* SimpleBuffer.*(..));
6
7      before(): lockedMethods() {
8       readLock.lock();
9      }
10
11      after(): lockedMethods() {
12             readLock.unlock();
13      }
14  }
```

Figure 6. The Locking aspect in AspectJ.

dynamic scope in which the joinpoint is executed. Most aspect languages feature a similar pointcut specification language, with some notable exceptions using the language's reflective facilities (e.g., AspectS (59)) or computational logic (e.g., Carma (55, 56) and Alpha (57)) to define pointcuts.

As a result of composition, most AOP languages produce a merged executable code from the aspectual and nonaspectual modules. In AspectJ, a compiler is used to compose the aspects' implementation with the Java classes by "weaving" the aspect code into the classes that are crosscut by the aspect. The term "weaver" has historically been used for aspect-oriented compilers, because these had generally been implemented as a preprocessor to other compilers. The AspectJ compiler, for example, was using such an approach but now performs weaving on the bytecode of (compiled) classes. Currently, an entire body of research investigates efficient execution and compilation mechanisms for aspect languages (58, 59). Research is under way, for example, for efficient weaving of aspects with complex and dynamic pointcuts (60) or weaving of aspects that can be dynamically removed from the running software application. These weavings require sophisticated weaving techniques that are sound and that minimize the run-time performance overhead.

Concurrent Buffer Example in AOP

We can now change the implementation of our concurrent buffer example from Fig. 2 so that the crosscutting concern of concurrency locking is modularized as an aspect. From the code in Fig. 2, one can distill that the joinpoints of the concurrency locking aspect and the buffer functionality are the execution of the methods of the buffer (i.e., *isEmpty(), get(), . . .*). Indeed, whenever the method *isEmpty()* executes, we need to lock the *readLock* and unlock it when the execution has finished. Figures 6 and 7 show the implementations of the *Locking* aspect and the *SimpleBuffer* class using the AspectJ language. The code for both concerns is now cleanly separated. The *Buffer* class is merely dealing with the functionality of a buffer and the entire locking concern is modularized in the aspect.

For simplicity, the *lockedMethods()* pointcut of the aspect captures all method execution joinpoints of the *SimpleBuffer* class. Line 5 of Fig. 6 defines this pointcut by means of the *execution* pointcut-predicate. This predicate accepts a method signature as an argument and captures all joinpoints that are executions of methods characterized by that signature. The signature consists of the return type, class name, method name, and argument types of method. In the definition of such a signature, wildcards can be used to describe a pattern, rather than concrete signatures. In the example, we use the "*" wildcard to match any return type and method name. Similarly, the ".." wildcard is used to match any type pattern in the argument list. Therefore, the *lockedMethods()* pointcut will capture all executions of any method defined on the SimpleBuffer class.

The actual aspect behavior is expressed in a *before* advice that executes the locking and in an *after* advice that executes the unlocking. Each of these advices is defined such that they are executed when a joinpoint captured by the *lockedMethods()* pointcut occurs. The binding of the advice to the pointcut is specified in the header of each advice (lines 7 and 11). As such, when the *isEmpty()* method executes, the aspect is implicitly invoked and the before advice executes, followed by the *isEmpty()* method body. The after advice is executed when the *isEmpty()* method execution finishes.

```
public class SimpleBuffer {
 private Object[] data = new Object[100];
   private int nrOfElements=0;

   public boolean isEmpty() {
          return nrOfElements == 0;
   }

public Object get() {
    return data[nrOfElements--];
}
}
```

Figure 7. The SimpleBuffer class without synchronization code.

AOSD APPLICATIONS AND OPEN RESEARCH CHALLENGES

Several nontrivial applications of AOSD techniques have been reported in literature, both in terms of nontrivial studies in academic research labs and in real-world industrial settings. A significant number of these relate to middleware and distributed systems, both from the perspective of taming the complexity of the middleware itself (61, 62), and supporting modularization of crosscutting concerns in distributed applications (63–65). Other nontrivial application studies pertain to modularizing persistence-related functionality, (66, 67), and evolution of operating-system code, (68). Several industrial AOP frameworks, for example JBoss (48) and Spring (69), target enterprise component architectures, whereas the mysql database system (http://www.mysql.org) now uses AspectJ as the underlying logging mechanism. In terms of industrial adoption, AspectJ has made a transition from state-of-the-art to becoming state-of-the-practice, whereas frameworks such as JBoss and Spring are also seeing increasing use in Enterprise Java applications.

Seveal empirical studies of AOSD techniques have also been reported, (70–73). These studies quantify the comparative benefits and drawbacks of AOSD compared with other software-development paradigms, such as OO. Similarly, studies demonstrating the nontrivial nature of crosscutting concerns in industrial code (74) highlight the fundamental complexity of software systems that AOSD techniques aim to address.

Despite the promising applications and empirical studies, several open research challenges remain. The major challenge to industrial adoption is in the area of aspect testing. Although a few techniques have been proposed to date, (75–77), extensive research is needed to understand whether current software testing techniques can be applied in an AOSD context and, more importantly, what specific testing challenges need to be addressed for using AOSD in an industrial setting. Related to this is the issue of composition fragility. Most AOSD techniques employ syntactic references (or wildcards quantifying over such syntactic references) as a basis of composition specifications.[1] This use strongly couples aspects to other modules, which not only makes testing of aspects very challenging but also leads to composition fragility whereby changes in other modules invalidate pointcut specifications.[2] This problem has been highlighted by recent works, (8, 30), that advocate composition specifications based on high-level models and semantics. Finally, the deployment of aspects in heterogeneous environments is an area largely unexplored. Most current AOP techniques tend to focus on deploying aspects within the context of a single system or virtual machine. Aspect deployment in a heterogeneous distributed environment is a topic that requires close attention to make AOP techniques relevant to the emerging class of large-scale distributed systems such as those in ubiquitous and GRID-based systems.

ASSEMBLY LANGUAGE

INTRODUCTION

An assembly language is a symbolic representation of a corresponding machine language. Whereas a machine language program consists of bit patterns, an assembly language program consists of alphanumeric names (symbols), numbers, and other special characters. The names describe operations to be performed (mnemonics) as well as storage locations and registers from which data (operands) are to be fetched or stored. While the machine language instruction is the only instruction a computer can "understand," it is very difficult for humans to write a program using pure machine language directly. Assembly language was the first step taken some 60 years ago to facilitate programming and it led to the development of more powerful programming languages (higher level languages).

A program called the assembler is used to translate the assembly language code to its machine language equivalent. This translation process is known as assembling (*or assembly*). The *object code* produced is then loaded into the computer usually with the help of a *loader* (and a *linker*) before it is *run* (*or execute*) t here.

Today, with the availability of powerful high level languages, assembly language is not used for writing programs directly except in some special situations. Nevertheless, most compilers still translate programs written in high level language first to assembly language code and then use the assembler to generate the object code in machine language. Therefore, assembly language is still playing a key role in the operation of all computers. In situations when performance and/or resource limitations are essential and compiler-generated code may not be optimal, people often rely on assembly language programming to maximize program performance (e.g., the innermost loop of computationally very intensive program) or to preserve resources (e.g., memory space in embedded systems).

The idea of using symbolic code to write programs was developed soon after the first computers were built. Certainly, something was available on the EDSAC (done by David Wheeler) called "initial orders"(1). One punched three items into paper tape (a letter, a decimal address, and a final letter) and the Initial Orders (which were actually stored in a read only memory made from telephone uniselectors) would convert the letter to the binary machine language operation code (*op code*), convert the decimal address to binary, and then add 1 of 12 constants that had been preset by the programmer to that address depending on the final letter.

FORMAT OF ASSEMBLY STATEMENTS

An assembly language program consists of a collection of statements. An assembly statement is usually entered on one line and may consist of as many as four fields: the label, the operation, the operand, and the comment fields. The general format of a statement is:

```
Label Operation Operand Comment
```

For example:

`BEGIN ADD ALPHA,BETA,GAMMA` $\gamma = \alpha + \beta$

Some assemblers require that the fields start in particular columns. Such assemblers are said to require the statements to be in fixed format. Other assemblers allow a free format, wherein the field can be separated by one or more blanks or by special symbols.

1. Label field. A label is a user-defined symbol that is used as the name of a memory location. The name may then be used by other statements to refer to that memory location instead of the numerical machine address of the location. A label on a statement is needed only when the statement is referred to elsewhere in the program. It may be left blank.
2. Operation field. The operation field contains a symbolic name of an operation. The operation specifies an action to be performed by the computer either at assembly time or at run time, which depends on the type of operation. An operation may be one of three types.
   a. An executable instruction. This operation is to be carried out by the computer when running the program. It is represented here symbolically as a mnemonic of a machine language instruction (such as ADD, DIV, or BR). At assembly time, the mnemonic is translated by the assembler into a binary string, the *opcode*.
   b. A directive (pseudo operation). Directives are commands to the assembler to perform certain function during assembly time. For example, a directive may be called "DS" (Define Storage) which tells the assembler to reserve a block of memory space for the program.
   c. A macro call. A *macro* assigns a name to a sequence of assembly statements, called the body of the macro. When the name of the macro appears in the operation field of an assembly statement, the assembler will insert the body of the macro in that location of the program. Not every assembler provides such a facility.
3. Operand field. The operand field contains information needed by the operator in the operation field. It may consist of several subfields; each contains an operand, depending on the nature of the operation. An operand may be in the form of a symbolic name, such as ALPHA, which represents the memory location at which the operand resides. It may be a special reserved

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

name, such as R4, which specifies an internal register of the computer in which the operand resides. It may be a constant, such as 314, which defines the value of the operand directly. Or, it may even be a simple arithmetic expression made up of symbols, constants, and arithmetic operators, such as ALPHA + 4

4. Comment field. The comment field contains a description of the function of the statement. The comment field is strictly for the benefit of the programmer and is not part of the program itself. Most assemblers provide such a field but ignore it during assembly.

EXAMPLES OF ASSEMBLY LANGUAGE CODE

In his paper "Programming the EDSAC (2)," Campbell-Kelly showed an example of code using the first form of the initial order (Figure 1).

Location	Order	Notes
100	T L	Clear accumulator using location 0 as a rubbish bin
101	A 8L	Add location 8 into accumulator
102	E 105S	Transfer control to location 105 if accumulator ≥ 0
103	S 8L	Subtraction location 8 from accumulator
104	S 8L	Subtraction location 8 from accumulator
105	T 8L	Store accumulator in location 8, leave accumulator clear

Figure 1. An example of an early assembly language program to convert a number to its absolute value.

Only the symbols in the "Order" column are entered into the computer without any spacing. Basically, only the operation and the operand fields are used. Because absolute addresses are used, the program is not relocatable. The location field, like the comment field (Notes), is ignored. The S and L in the second field of each instruction specify the length of the operand. The first version of the initial order was soon replaced by an improved version. The program above can now be written in the subroutine form as below (Figure 2). Symbolic names are now used in the operand field and the program is more relocatable. The first line of the code is not an executable instruction, but rather is a directive (pseudo-operation) that instructs the initial order to save the location of θ which will be used in the subsequent code to calculate the address.

Location	Order	Notes
	G K	Control Combination
0	T D	Clear accumulator
1	A H	Add location h into accumulator
2	E 5θ	Transfer control to location 5θ if accumulator ≥ 0
3	S H	Subtraction location H from accumulator
4	S H	Subtraction location H from accumulator
5	T H	Store accumulator in location H, leave accumulator clear

Figure 2. Assembly language of program in Figure 1 written as a subroutine

The same example, using a popular computer architecture in the 1980s viz. the VAX-11, may have the following code (data input omitted):

```
NUM: .BLKW    1           ;reserve a 32 bit
                            memory space for
                            input
ABS: .BLKW    1           ;reserve a 32 bit
                            memory space for
                            result
     .ENTRY   ABSOLUTE,0 ;a directive indicat-
                            ing the entry point
     MOVW     NUM,R2      ;Is NUM ≥ 0?
     BGEQ     POSITIVE    ;yes
     MNEGW    R2,R2       ;No, negate num
POSITIVE:
     MOVW     R2,ABS      ;absolute value is
                            in R2
     $EXIT_S              ;System call to return
                            control
     .END     ABSOLUTE    ;directive
```

The convention used in this assembly language is:

- All labels end with a colon(:)
- All directives start with a period(.)
- Any character string after a semicolon(;) on a line belongs to the comment field
- In the operation field, a system macro begins with the dollar sign ($)

On an MIPS computer, an example of reduced instruction set computer (RISC) architecture, the same program may take the following form:

```
       .data                # data section
num:   .word    −35
abs:   .word    0
       .text                # code section
main:                       # starts execution
                              at main.
       la       $s1, num    # load address of
                              number1 into $s1.
       lw       $t1, 0($s1)
       bge      $t1, $0, store
       neg      $t2, $t1
store: sw      $t2, 4($s1)  #put absolute into
                              memory location
                              number2.
       li       $v0, 10     # syscall code 10 is
                              for exit.
       syscall              # make the syscall.
```

The convention used in this assembly language is similar to that of the VAX, except instead of a ";" the symbol "#" is used to mark the beginning of a comment field and a macro does not begin with a special symbol.

Table 1. Example of address modes used in the VAX-11

Addressing mode	Assembler symbol	Effect	Example
Register	Rx $x = 0{-}14$	Operand is in the register named	ADDL R1,R2
Register deferred (indirect)	(Rx) $x = 0{-}14$	The memory address of the operand is in Rx	ADDL (R1),R2
Immediate (literal)	#constant	Operand is specified directly as a constant following the symbol #	ADDL #14,R1
Autoincrement	(Rx)+ $x = 0{-}14$	Same as register deferred except that the contents of the register are incremented after it is accessed	ADDL (R1)+,R2
Autoincrement deferred	@(Rx)+ $x = 0{-}14$	Same as autoincrement except the contents of Rx are used as a memory address of the operand	ADDL @(R1)+,R2
Autodecrement	−(Rx) $x = 0{-}14$	Same as autoincrement except that the contents of the register are decremented BEFORE the value is used	ADDL −(R2),R5
Displacement	displ(Rx) $x = 0{-}14$	The value represented by displ is added to the contents of Rx to form the effective address	ADDL 200(R3),R9
Displacement deferred	@displ(Rx)	Same as displacement except that the address calculated is the location of the effective address of the operand	ADDL @20(R3),R9
Relative	displacement	Same as displacement except that instead of using a general register, the program counter (R15) is used	ADDL X,R1
Relative deferred	@displacement	Same as displacement deferred using the program counter instead of the general register	ADDL @X,R1
Index	baseaddress[Rx]	The contents of the index register Rx are added to the base address, which can be specified using any of the above-mentioned addressing modes	ADDL X[R2],R6
Absolute	@#absoluteaddr	The memory address specified is the physical memory address independent of the program location	ADDL @#1000,R5

ADDRESSING MODES

As mentioned above, the assembly language is basically a symbolic representation of the machine language. As machine languages become more complicated, additional symbols are introduced to represent the new features in the machine language. One of the first features introduced is indexing and the use of the index registers. For example, an assembly language instruction for the IBM 704 may be as follows:

```
ADD ARRAY(4)
```

The effective memory address is computed by adding the contents of index register to the memory address represented by the symbol ARRAY. In the 1970s, as more complex instruct sets were devised to match the higher level language constructs, new addressing modes were also introduced. A machine such as the VAX-11 has no less than 12 different addressing modes. Table 1 summarizes those addressing modes and how they are represented in the VAX-11 assembly language.

Although each assembler may choose to use different symbols to represent different addressing modes, what is used in the VAX-11 assembly language is typical. With the emphasis on simplifying the instruction set, modern computers usually also have fewer addressing modes than that of the VAX-11. The Itanium has, for example, only four addressing modes: immediate, register, register indirect, and autoincrement.

DIRECTIVES (PSEUDO-OPERATIONS) AND PSEUDO-INSTRUCTIONS

Directives, also known as pseudo-operations in the early days of assembly language programming, are statements in assembly language that direct the assembler to perform certain functions during the assembly process. They may reserve some memory locations needed by the program or assign a constant value to a particular memory location. Directives do not produce executable machine language code. Some may mark the beginning of a program and data segment. In the examples above, .ENTRY, .END, .BLKW, .word, .data etc. are typical examples of directives.

In an attempt to limit the size of the instruction set, modern computers tend not to include an instruction if its function can be carried out by other instructions in the set. Although the practice has the advantage of simplifying the design of the processor, it makes assembly language less intuitive. As a result, the assembly languages of these machines often include pseudo-instructions, which have no corresponding machine language instructions, to facilitate programming and place the burden of translating these instructions to real machine language instructions to the assembler (Fig. 3). For example, in the MIPS example above, the instructions la (load address), abs (absolute value), and li (load immediate) are pseudo- instructions. The assembler translates each of these instructions to one or more regular assembly language instructions and then generates the machine code. For example li is converted to

```
lui     $17, 4097 [num]    ; la     $s1, num      # load address of number1
                                                  # into $s1.
lw      $9, 0($17)          ; lw     $t1, 0($s1)
addu     $10, $0, $9       ; abs    $t2, $t1
bgez    $9, 8
sub     $10, $0, $9
sw      $10, 4($17)         ; sw     $t2, 4($s1)  # put absolute into memory
                                                  #  location number2.
ori     $2, $0, 10         ; li     $v0, 10       # syscall code 10 is for exit.
syscall                    ; syscall              # make the syscall.
```

Figure 3. Examples of pseudo-instruction conversion: The source program on the right (after the semicolon on each line) is translated to that on the left. Note that the pseudo-instruction abs generates three instructions.

ori (OR immediate) and abs is converted to a sequence of three instructions.

MACROS

Another powerful feature incorporated in many assemblers is macro (also referred to as open subroutine in early literature). Assembly language programmers frequently need to repeat similar segments of code at various sites in a program. In such cases, the segment of code can be defined as a macro; then, during the assembly time, wherever the name of the macro appears in the program, the assembler replaces the name by the statements within the macro. This replacement is termed *macro expansion*.

To add flexibility and generality to macros, most assemblers allow macros to have (dummy) parameters. When invoking a macro, the programmer specifies corresponding arguments to replace the parameters in the macro. This causes the assembler to generate different code for different invocations of the macro.

A macro is similar to a subroutine because it assigns a name to a sequence of statements. However, several important differences exist between a macro and a subroutine.

1. A macro is invoked at *assembly time*. A subprogram is invoked at *execution time*.
2. When a macro is invoked, the *assembler* substitutes the macro body for the macro call. When a subroutine is invoked, the computer *hardware* transfers control to the beginning of the subroutine; upon completion, the hardware transfers control back to the calling program.
3. As many copies of the macro body exist in the object code as calls to the macro. Only one copy of the subprogram exists in the object code, regardless of the number of calls to the subprogram.

In the examples above, $EXIT_S in the VAX-11 program and *syscall* in the MIPS program are macros that are part of the system library.

AUTONOMOUS DECENTRALIZED SYSTEMS

Autonomous decentralized systems (ADS) are distributed computing systems, each of which is composed of subsystems with autonomy to control itself and coordinate with other subsystems. The ADS are constructed on the basis of the ADS concept; that is, a system is treated as result of integration of autonomous subsystems with the objective of resolving online property of online expansion, fault tolerance, and online maintenance (1,2). The data field (DF) architecture for the ADS makes each subsystem autonomous (3,4). Each autonomous subsystem includes its own management system, an autonomous control processor (ACP), and application software modules. Subsystems are connected mutually only through the DF. The ACP broadcasts data together with a content code, which is defined uniquely based on content of data, and it independently selects to receive data based on the content code (content-code communication). The ACP executes an application software module upon receiving all necessary data for the module (data-driven mechanism). Under the DF architecture, subsystems need not know the direct relation with others for communication and execution and need not inform others upon its addition to or deletion from the system. Then the subsystem can be constructed, modified, added, and deleted during operation of the other subsystems (online expansion). The subsystem independently checks to select correct data from multiple data with the same content code sent from the replicated subsystems to the DF. This independent checking mechanism enables each subsystem to prevent the propagation of faults from occurring in other subsystems (fault tolerance). In the DF, data are broadcasted with a test flag as well as with the content code. The ACP selects to receive data by the content code and to change subsystem operation mode from online to test when received data attaches a test flag. It starts test execution using test data, but it does not output executed result data to devices. Online and test modes coexist in the system, but the test subsystem does not interrupt online subsystems (online maintenance). The ADS concept is applied to the various fields of technologies (5,6), such as networks, including Internet, communication, multicomputers, software, control, and robotics, and they have been realized in application systems such as transportation, factory automation, office automation, and telecommunication. In these applications, the ADS improve lifecycle cost, software productivity, flexibility, and adaptability.

ADS CONCEPT

The cost-reduction constraints on computing resources, including networks, has lessoned the requirement for efficient utilization but has raised the need for making them easy to use and easy to construct. Computing systems increasingly have been required to be adaptable to applications (7). For these reasons, the ADS has the objective of meeting the following requirements of online property:

1. Online expansion. As system size increases, its step-by-step construction and expansion should be possible without stopping whole system operation.
2. Fault tolerance. Even if part of the system fails, the system should be able to continue operation without fault propagation.
3. Online maintenance. Maintenance and test procedures should be possible without suspending the system operation.

Systems requiring the online property have the following attributes:

1. The system always has faulty parts.
2. It changes constantly alternating among operation, maintenance, and expansion.
3. It hopes to accomplish its objective and function almost completely.

That is, the system is defined under the following standpoints:

1. Being faulty is “normal.”
2. The system is result of integration of subsystems.

On this standpoint, the system is called the autonomous decentralized system if the following two properties are satisfied as such a living thing, which is composed of largely autonomous and decentralized subsystems.

1. Autonomous controllability. If any subsystem fails, is repaired, and/or is newly added, the other subsystems can continue to manage themselves and to perform their own responsible functions.
2. Autonomous coordinability. If any subsystem fails, is repaired, and/or is newly added, the other subsystems can coordinate their individual objectives among themselves and it can operate in a coordinated manner.

These two properties assure online property of the system. Each autonomous subsystem requires its own intelligence to manage itself without directing to or being directed by other subsystems and to coordinate with the other subsystems. To realize an autonomous decentralized system with two properties, each subsystem is required to satisfy the following conditions:

1. Equality. Each subsystem is equal in function. No master–slave relation exists among subsystems.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

2. Locality. Each subsystem manages itself and coordinates with others based only on local information.
3. Uniformity. Each subsystem is uniform in structure and self-contained so that it manages itself and coordinates with others.

DF

The ADS is realized under a DF architecture with no central operating or coordinating system. Each subsystem has its own management system, the ACP to manage itself and to coordinate with the others. The subsystem includes application software modules and an ACP called "Atom." All subsystems are connected only through the DF (Fig. 1); all data are broadcasted into the DF as messages. The DF in the Atom is called the Atom data field (ADF). Individual data include a content code uniquely defined based on the content of the data. A subsystem selects to receive a message on the basis of content code (content-code communication) (Fig. 2). The sender need not point out the receiver's address. Physically, the DF corresponds to a network or memory. In the network, the broadcast message physically is deleted by its originating subsystem or the terminator in the network after the message is transmitted over entire system. When the DF corresponds to the memory, the first-in–first-out (FIFO) memory is used and messages in memory are deleted after all subsystems check whether to accept it or not. This content-code communication enables each subsystem to be autonomous in sending and receiving data. That is, subsystems need not know the relationship among sources and the destinations. This feature of the content-code communication ensures the locality of information necessary for each subsystem.

DATA-DRIVEN MECHANISM

The application software module in the subsystem starts execution after all necessary data are received (data-driven mechanism). This mechanism loosely couples modules. Each subsystem independently judges and controls its own execution. Required content codes for application software modules are preregistered in the ACP, which can dynamically assigns content codes based on changes in application software modules. The subsystem need not inform other subsystems if content codes assigned to the ACP are changed.

Each ACP has functions of managing the data, checking the data, and supporting the test and diagnosis (Fig. 3). The function of the application software module is characterized by the relation between the content codes of the input data and the output data. The data-driven mechanism is realized by the following two management modules of the ACP.

DF Management

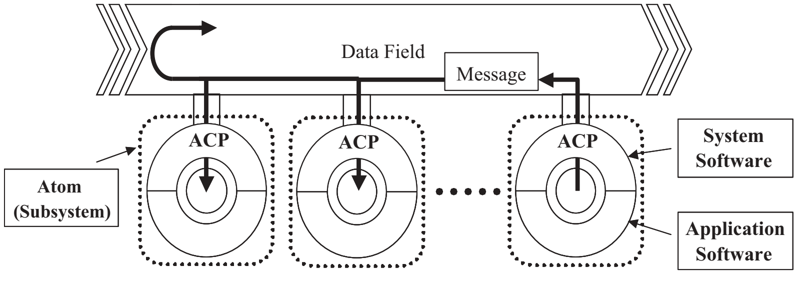
The DF management module acts as the interface between the DF and the ADF. The ADF includes the table of the relationship between application software modules in the Atom and content codes required to execute each application software module. According to registered content codes, the DF management module receives the data from the DF and stores it in the corresponding area in the ADF. The data that originates within the Atom is broadcasted into the DF by this management module.

Execution Management

The execution management module monitors the ADF. As soon as all the data necessary to the application software module is received in the ADF by the DF management module, the execution management module drives the application software module. With this execution management module, application software modules run asynchronously and freely. This autonomous execution property ensures that the application software module cannot be directed to execute by any other application software module so that it can continue its operation even in the event of fault occurrence, expansion, and maintenance of the other application software modules.

ADS TECHNIQUES

The online property of the system is resolved by following three techniques.



ACP: Autonomous Control Processor

Figure 1. DF architecture.

F	CC	SA	C	Data	CRC	F

F: Flag

CC: Content Code

SA: Sender Address

C: Control Code

CRC: Cyclic Redundancy Check

Figure 2. Message format.

Online Expansion

In the Atom-level expansion, application software modules are newly installed in or moved to others. They need only to register necessary content codes in their own ACPs and do not need to inform others. This local generation within the Atom requires no application software modules or subsystems to be revised and needs no interrupt operation. In the system-level expansion, different ADSs are integrated into one. Two types of systems integration are designed (Fig. 4). In the first type, different systems are combined into one system in which all data from systems are broadcasted to the combined DF (Fig. 4). In the second type, different systems are connected by a gateway, which selects the data to be passed through based on content codes (Fig. 4). The ACP of the gateway registers content codes necessary for the system on DF-A to pass through from DF-B, and data to be passed to DF-B from DF-A. During the registration of content codes in the gateway ACP, the subsystems need not stop operation.

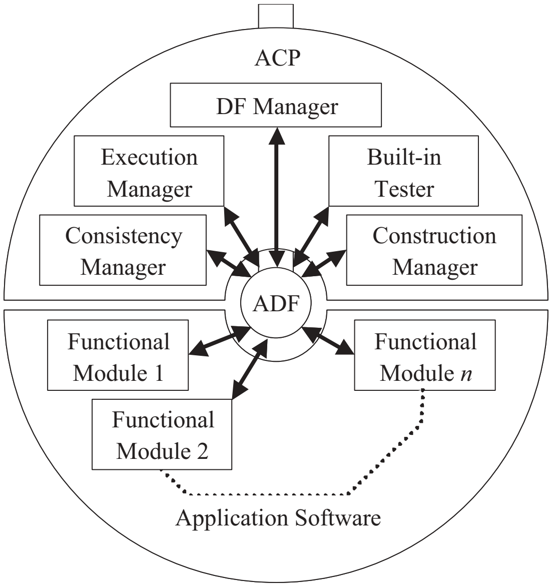


Figure 3. Modular software structure.

Fault Tolerance

DF architecture and its data-driven mechanism ensure that application software modules run freely and asynchronously. When fault tolerance of application software module is required, the module is replicated. Replicated application software modules run independently and send out processed results with the same content code to the DF. Faulty data are also sent out to the DF. The ACP in each subsystem receives all data with the same content code from replicated modules and selects the correct data from the “same” data (Fig. 5). Here, the data consistency management module in the ACP identifies the “same” data both by content code and by event number induced with the data. This event number is located in the message. The event number is set originally at the module receiving the information from an external source via input devices such as sensors and terminals. Although application software modules process data successively, the original event number is preserved in these processes. The “same” data with the same content code and event number is collected from the DF within a predetermined time interval or when it reaches a predetermined number. Correct data are selected from among the “same” data through majority voting logic flexibly adapted to correspond to the predetermined time interval or to the total number of received data. Under this logic, fault occurrence is detected and each application software module avoids being affected by fault propagation. After fault detection, faulty application software modules are recovered. In DF architecture, a subsystem with a replicated module can intercept any data broadcast from other replicated modules. Even if the subsystem includes a faulty application software module, it detects the internal faults via this interception. If an application software module is faulty, the subsystem continues operation by using correct data received from the other replicated application software module, not using its generating data. This recovery does not stop the entire system.

This data consistency mechanism ensures fault tolerance and easily can be adapted to system reconfiguration without stopping the operation.

Online Maintenance

DF architecture makes it easy for application software modules to be tested while the system is operating. An online test is supported by a BIT (built-in tester module) in

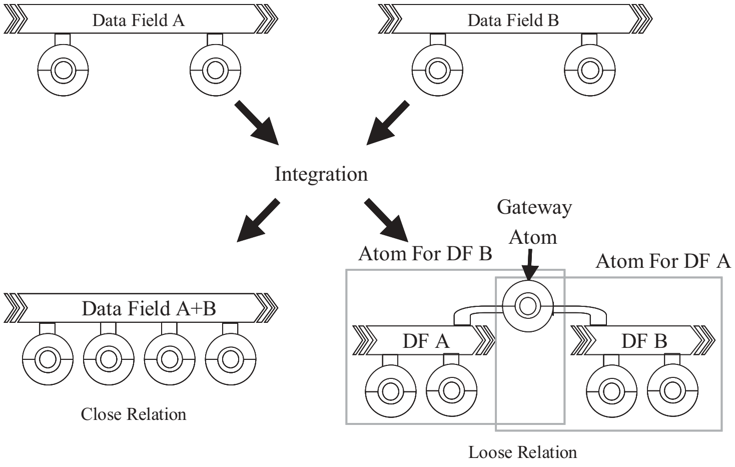

Figure 4. Online expansion.

each ACP and by an EXT (external tester module) as the application software module (Fig. 6). The BIT module in the subsystem sets its application software module in the test mode, generates test data, and checks test result. The application software module being in test mode receives data from the DF and processes it. It broadcasts test result data with a test flag to the DF. The BIT of the system in test mode prevents the signal from being sent to output devices such as controllers. Test result data are used successively to test other application software modules. The EXT monitors test data and test result data in the DF. By correlating test data with test result data, the EXT checks the fault occurrence in the application software module in the test mode and broadcasts the fault detection. The EXT also detects how a fault propagates among modules by monitoring these data. The BIT independently decides whether to change the test mode to online mode based on test results. This test mechanism makes it possible for both online and test modes to coexist in the system.

Software Productivity

In addition to evaluating online property, the ADS improves software productivity. Input and output data only via the DF encapsulated the application software module and has no direct relationship to other modules. The data-driven mechanism need not have the linkage among modules. Environment generation for the application software module only registers necessary content codes in its ACP. These software features make it possible to produce the application software module independently of other modules. The relationship between input data of module and output data of other modules generates data flow among the modules. In the design phase, incorrectness of data flow such as an infinite loop among the application software modules or incompleteness of modules for generating data is checked. Fault propagation is detected by using the data flow. Based on the analysis of data flow, modules on the critical path of the data flow are

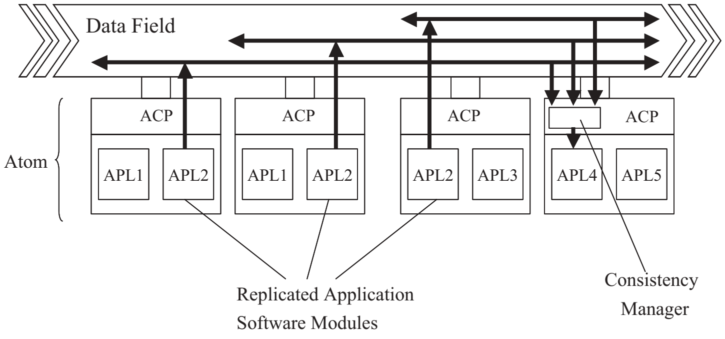

Figure 5. Fault tolerance.

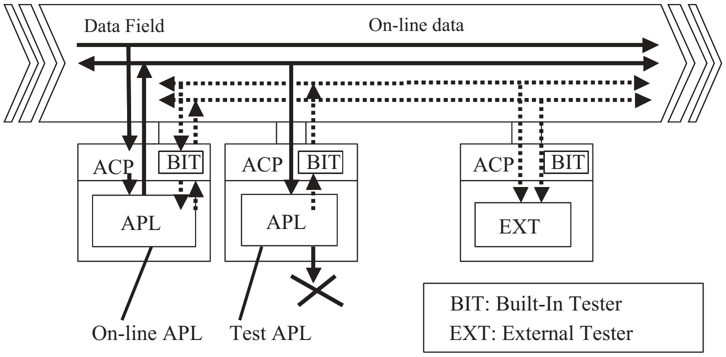

Figure 6. Online maintenance.

replicated to attain fault tolerance. This distributed software development helps to improve the productivity, especially for the software design and testing in a building-block manner.

APPLICATION

The ATOS of the Tokyo metropolitan-area railway system covers 23 train lines and 289 stations on these lines. The total line length is approximately 1100 km. This system serves around 14 million passengers per day. Train service runs about 22 hours a day and is running nonstop throughout the year. The minimum interval between trains at rush hour is 2 minutes. Recently the service types of train traffic have been increasing for the passengers. For example, there are the trains through the specially arranged routes across several different train lines, which is event-related train service not listed in the standard timetable (8).

One requirement for this system is that the construction takes place step by step without stopping the train service and without disrupting the operation of the current-installed parts of the system. This system has been developed over 10 years, and some of the current parts gradually will be replaced even before the entire system construction is completed. This system continuously is evolving and will continue to expand.

Figure 7 shows the structures of the overall system and the station subsystem. Each computer is equipped with the ACP to achieve the online property. The networks for

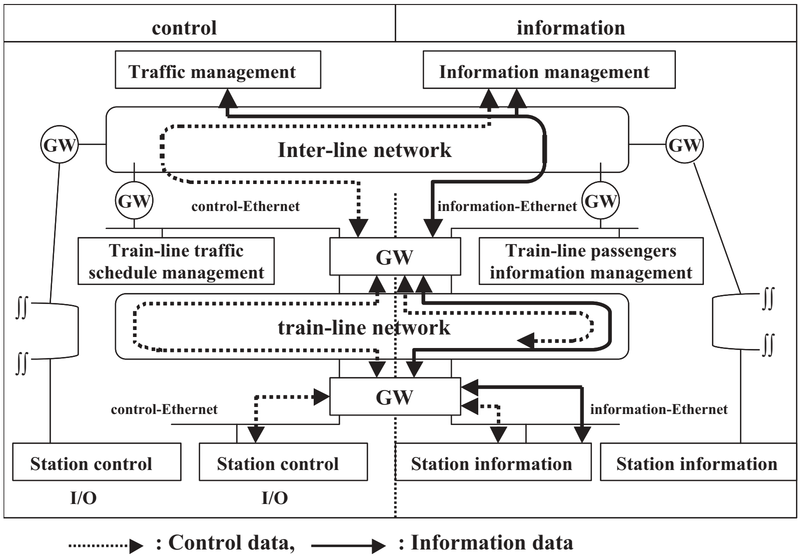

Figure 7. System structure of ATOS.

connecting among the station subsystems in the train line and among the train lines are used for both the control and the information missions. In the station subsystem, the computers for the control and the information are divided and connected by their own mission-oriented networks, the control Ethernet, and the information Ethernet, through the gateway.

The total system is composed of one interline network and 17 train-line networks. The system-wide traffic management subsystem produces the train-traffic schedules and monitors the traffic, and the system-wide information management subsystems supply the traffic information services, which are connected by an interline network. The system for one train line is composed of the station subsystems, a train line, traffic schedule management subsystem, and a train-line passenger's information service management subsystem. The train-line traffic schedules management subsystem distributes the train-line traffic schedules to the train station subsystems, monitors positions of the trains in the train-line, and makes the minor changes in the schedules. In the train-line traffic schedule management subsystem, the control Ethernet connects the train-line traffic reschedule management computer and the maintenance management computer. The train-line traffic reschedule management computer is replicated for fault tolerance. The train-line passengers' information service management subsystem connected to the interline network includes several computers connected by the information Ethernet. Each subsystem is composed of several computers connected by the Ethernet. In the system, the communication uses the ADS content-code communication protocol in the UDP mode. The bandwidth of the common network is divided into control and information missions.

FUTURE TREND OF ADS

The ADS concept and technologies have been applied in various fields of transportation, factory automation, utility management, satellite on-board control, newspaper printing factory, information services, e-commerce, community service, and so on. Most of them use the ACP as middleware run on standard operating systems, such as Windows and UNIX, and on a standard transmission protocol of TCP/IP. Some ADS technologies were approved to be the de facto standard of the ODVA (Open DeviceNet Vendor Association) in 1996, the Factory Automation System in Japan in 2000, the BAS (Building Automation System) in Japan in 2000, and the OMG (Object Management Group) in 2000.

CAPABILITY MATURITY MODELS (CMM)

INTRODUCTION

Today software is a major asset of many companies. Research and development investment primarily goes into software development for a majority of applications and products. To stay competitive with software development, many companies are putting in place improvement initiatives of their key processes that are generally engineering processes first. Often the improvement programs also include a broader reengineering perspective.

Strengthened process capability is key. If you do not know where you are and where you want to go, change will never lead to more added value for your business. Effective process improvement is achieved using the well-known capability maturity models (CMM and from now on CMMI as CMM has been sun set as of the end of 2005). This model provides a framework for process improvement and is used by many software-intensive development organizations; software could be the entire system or only one component, but the advantage of the newly promoted CMMI is that multiple disciplines can be addressed: software, systems, hardware, and services. The maturity model defines five levels of maturity plus an improvement framework for process maturity and, as a consequence, quality and predictability.

This model must be combined with a strong focus on business objectives and metrics for follow-up of change implementation. Otherwise, the main risk is to focus on processes exclusively and lose track of what is essential for customers and shareholders.

Model-based process improvement involves the use of a model to guide the improvement of an organization's processes. Process improvement grew out of the quality management work of Deming, Crosby, and Juran and is aimed at increasing the capability of work processes. Essentially, process capability is the inherent ability of a process to produce planned results. As the capability of a process increases, it becomes predictable and measurable, and the most significant causes of poor quality and productivity are controlled or eliminated.

Models provide a common set of process requirements that capture best practices and practical knowledge in a format that can be used to guide priorities. By using a model, organizations can modify or create processes using practices that have been proven to increase process capability.

THE ORIGIN

In 1986, Watts Humphrey, the SEI, and the Mitre Corporation responded to a request by the U.S. Federal Government to create a way of evaluating the software capability of its contractors. The group used IBM's concepts to create a software maturity framework, a questionnaire, and two appraisal methods. Over the next few years, this work was continued and refined.

In 1991, the SEI published the CMM for Software version 1.0, a model that describes the principles and practices underlying software process maturity. The CMM is organized to help software organizations improve along an evolutionary path, growing from an ad hoc, chaotic environment toward mature, disciplined software processes. The CMM was used and evaluated for two years and then revised and released as version 1.1 in 1993.

A similar revision was planned for 1997 as version 2.0; this version was developed but never released as an independent model. However, the proposed revision was used as the source for the CMMI integration effort.

The Software CMM (SW-CMM) focused primarily on process management. Among the "key process areas" in the model, only one, "Software Product Engineering," specifically targets the core engineering tasks, which range from the analysis of software requirements to software design, coding, integration, and testing at the concluding end. All other SW-CMM key process areas were written such that they could easily be applied to development work other than software. Along with the success of the SW-CMM in improving software development, this flexibility may explain the interest in applying the CMM concepts to disciplines beyond software; much of what was believed to be good with the SW-CMM had a utility that was not restricted to just the software area.

The five maturity levels of CMM and their respective impact on performance are described in Table 1.

To understand why and how the "CMMI project" has been started at the SEI, it is probably useful to have a quick look at the various sources that were available at the end of the 1990s. The various models in use were the following:

MODELS DESCRIPTION

SW-CMM: The original CMM developed at the Software Engineering Institute (SEI). In 1986, the SEI, with assistance from MITRE Corporation, began developing a process maturity framework intended to assist organizations in improving their software processes. In 1987, the SEI released a brief description of the process maturity framework and a maturity questionnaire (CMU/SEI-87-TR-23). The fully developed model (version 1.1) was released in 1993.

SE-CMM The Systems Engineering Capability Maturity Model (SE-CMM) describes the elements of an organization's systems engineering process that are essential to good systems engineering. This model was developed by the Enterprise Process Improvement Collaboration (EPIC), which included industry, government, and academic members. It was merged in 1998 with the INCOSE SECAM to form the Electronics Industry Alliance's EIA 731.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Table 1.

CMM Level	Title	Focus	Key Process Areas
5	Optimizing	Continuous process improvement on all levels	Process change management Technology change management Defect prevention
4	Managed	Predictable product and process quality	Quality management Quantitative process management
3	Defined	Standardized and tailored engineering and management process	Organization process focus Organization process definition Training program Integrated project management Software product engineering Inter-group coordination Peer reviews
2	Repeatable	Project management and commitment process but still highly people-driven	Requirement management Software project planning Software project tracking and oversight Software quality assurance Software configuration management Software subcontract management
1	Initial	Heroes and massive effort with chaotic results	

SA-CMM: A collaborative effort among the U.S. Department of Defense, the SEI, industry, and other U.S. government agencies, the Software Acquisition Capability Maturity Model (SA-CMM) supports benchmarking and improvements of the software acquisition process.

People CMM: This model addresses the ability of software organizations to attract, develop, motivate, organize, and retain competences and good skills.

IPD-CMM: The Integrated Product Development CMM (IPD-CMM) was published only in draft form.

FAA-iCMM: The first completed attempt at integration; this model developed at the U.S. Federal Aviation Administration (FAA) integrates material from many sources: the SE-CMM, the SA-CMM, the SW-CMM, EIA 731, Malcolm Baldrige, ISO/IEC 15504, ISO/IEC 15288, and ISO/IEC 12207. Now at Version 2, it is being used as a unified means of guiding process improvement across the entire FAA. It has also been adopted by Aviation Authorities in Europe.

ISO/IEC 12207: An international standard on software life-cycle processes; it was first issued in 1995 and amended in 2002. ISO is the International Organization for Standardization.

ISO/IEC 15504: A draft international standard that defines the requirements for performing process assessment as a basis for use in process improvement and capability determination. This initiative started in 1992 and changed several times the scope of the required part versus the informative part of the target standard. CMMI is fully compliant with ISO/IEC 15504 requirements.

Fundamentally, process improvement integration has a major impact in four areas: cost, focus, process integration, and flexibility.

By applying a single model, organizations that would otherwise use multiple models can reduce the cost of notably training, appraisals, and maintenance of redundant process assets.

An integrated process improvement program can clarify the goals and business objectives of the various initiatives. By integrating process improvement activities across a wider range of disciplines, it becomes easier to rally the troops to the process improvement banner.

A final benefit provided by integration is the ability to add disciplines as the business or engineering environment changes.

CMMI OVERVIEW

The CMMI Product Suite contains an enormous amount of information and guidance to help your organization improve its processes.

1. Materials to help you evaluate the content of your processes—information that is essential to your technical, support, and managerial activities.
2. Materials to help you improve process performance—information that is used to increase the capability of your organization's activities.

This integration was intended to reduce the cost of implementing multidiscipline model-based process improvement by

- Eliminating inconsistencies.
- Reducing duplication.
- Increasing clarity and understanding.
- Providing common terminology.
- Providing consistent style.
- Establishing uniform construction rules.
- Maintaining common components.
- Assuring consistency with ISO/IEC 15504.
- Being sensitive to the implications for legacy efforts.

The project milestones between 1997 and 2002 were as follows:

1997 CMMI initiated by U.S. Department of Defense and NDIA.

1998 First team meeting held.

1999 Concept of operations released; first pilot completed.

2000 Additional pilots completed.

CMMI-SE/SW version 1.0 released for initial use.

CMMI-SE/SW/IPPD version 1.0 released for initial use.

CMMI-SE/SW/IPPD/SS version 1.0 released for piloting.

2002 CMMI-SE/SW version 1.1 released.

CMMI-SE/SW/IPPD version 1.1 released.

CMMI-SE/SW/IPPD/SS version 1.1 released.

CMMI-SW version 1.1 released.

Since August 2006, a CMMI V1.2 has been available for use. The new version includes simplifications, reduction of the number of practices to implement, and restructuring, which were recommended by users (Table 2).

The fundamental organizational feature of all CMMI models is the "process area."

Any process improvement model must include a scale relating to the importance and role of the materials contained in the model. In the CMMI models, a distinction is drawn among the terms "required," "expected," and "informative."

The sole *required* component of the CMMI models is the "goal." A goal represents a desirable end state, the achievement of which indicates that a certain degree of project and process control has been achieved. Each process area has between one and four specific goals; the entire CMMI-SE/SW/IPPD/SS model (version 1.1) includes a total of 55 specific goals.

Examples include: Requirements Management REQM SG 1: Requirements are managed, and inconsistencies with project plans and work products are identified.

Project Monitoring and PMC SG 2: Corrective actions are control managed to closure when the project's performance or results deviate significantly from the plan.

In contrast to a specific goal, a generic goal has a scope that crosses all process areas. Generic goals are characteristics of the maturity. Consider, for example, GG 2: "The process is institutionalized as a managed process." In the CMMI glossary (CMMISE/ SW/IPPD/SS, version 1.1, Appendix C), a "managed process" is a performed process that is planned and executed in accordance with policy; employs skilled people having adequate resources to produce controlled outputs; involves relevant stakeholders; is monitored, controlled, and reviewed; and is evaluated for adherence to its process description.

The only *expected* component of the CMMI models is the statement of a "practice." A practice represents the "expected" means of achieving a goal. Every practice in the CMMI models is mapped to exactly one goal. Between two and seven specific practices are mapped to each specific goal; the entire CMMI-SE/SW/IPPD/SS version 1.1 model includes a total of 189 specific practices, which are mapped to the 55 specific goals.

In contrast to a specific practice, a generic practice has a scope that crosses all process areas. For example, one generic practice that is mapped to the generic goal to institutionalize a managed process (GG 2) addresses the training of people. Consider GP 2.5: "Train the people performing or supporting the process as needed."

Table 2. Description of maturity levels and process areas in V1.1

Level	Focus	Process Area
5: Optimizing	Continuous process improvement	Causal analysis and resolution Organizational innovation and deployment
4: Quantitatively Managed	Quantitative management	Quantitative project management Organizational process performance
3: Defined	Process Standardization	Organizational process focus Organizational process definition Organizational training Integrated project management Risk management Decision analysis and resolution Requirements development Technical solution Product integration Verification Validation
2: Managed	Basic project management	Requirements management Project planning Project monitoring and control Measurement and analysis Process and product quality assurance Configuration management Supplier agreement management
1: Initial		

CMMI models contain 10 types of *informative* components. The major ones are as follows:

Purpose. Each process area begins with a brief statement of purpose for the process area.

Reference. Explicit pointing from one process area to all or part of another process area is accomplished with a reference.

TypicalWorkProducts. When a practice is performed, there will often be outputs in the form of work products.

Subpractices. For many practices in the CMMI models, subpractices provide a decomposition of their meaning and the activities that they might entail as well as an elaboration of their use.

Discipline Amplifications. One of the most distinctive aspects of CMMI as compared with prior source models is the fact that the CMMI model components are discipline-independent. To maintain the usefulness of the discipline-specific material found in its source models, CMMI provides discipline amplifications that are introduced with phrases such as "For software engineering" or "For systems engineering."

Amplifications are informative material, so they are not required in an appraisal.

The move to V1.2 includes the following changes specified in Table 3.

A NEW REPRESENTATION: THE CONTINUOUS REPRESENTATION

One source model for CMMI, the SW-CMM, was a "staged" model. Another source model, the Systems Engineering Capability Model, was a "continuous" model.

A staged model provides a predefined road map for organizational improvement based on proven grouping and ordering of processes. The term "staged" comes from the way that the model describes this road map as a series of "stages" that are called "maturity levels." Each maturity level has a set of process areas that indicate where an organization should focus to improve its organizational process.

We have already emphasized that the key process areas at level 2 of the SW-CMM focus on the software project's concerns related to establishing basic project management controls. Level 3 addresses both project and organizational issues, as the organization establishes an infrastructure that institutionalizes effective software engineering and management processes across all projects.

Continuous models provide less specific guidance on the order in which improvement should be accomplished. They are called continuous because no discrete stages are associated with organizational maturity. EIA 731 and ISO/IEC 15504 are examples of continuous models.

In continuous models, the generic practices are grouped into capability levels (CLs), each of which has a definition that is roughly equivalent to the definition of the maturity levels in a staged model.

In a continuous appraisal, each process area is rated at its own capability level. An organization will most likely have different process areas rated at different CLs. The results can be reported as a capability profile.

Continuous models describe improvement through the capability of process areas, singly or collectively. A capability level includes a generic goal and its associated generic practices that are added to the specific goals and practices within the process area. When the organization

1: Initial		

meets the process area-specific goals and generic goals, it achieves the capability level for that process area.

Staged models describe the maturity of organizations through successful implementation of ordered groups of process areas. These groups, or stages, improve processes together, based on achievements in the previous stage.

We will not go into detail regarding the differences between these two representations; the discussion might become unclear at this stage, and this is a question to be debated with sponsors of process improvement initiatives: which representation fits the best with their target. Nevertheless, we can reinforce the concept of one model with two views or representations: CMMI provides a mapping to move from the continuous to the staged perspective. For maturity levels 2 and 3, the concept is straightforward and easy to understand. If an organization using the continuous representation has achieved capability level 2 in the seven process areas that make up maturity level 2 (in the staged representation), then it can be said to have achieved maturity level 2.

Similarly, if an organization using the continuous representation has achieved capability level 3 in the seven process areas that make up maturity level 2 and the 14 process areas that make up maturity level 3 (a total of 21 process areas in CMMI-SE/SW/IPPD/SS), then it can be said to have achieved maturity level 3.

USING CAPABILITY MODELS

Organizations generally have many different business objectives, such as produce quality products or services, create value for the stakeholders, be an employer of choice, enhance customer satisfaction, increase market share, or implement cost savings and best practices.

To meet any of these objectives, organizations must have a clear understanding of what it takes to produce products or services. To improve, they need to understand the variability in the processes that are followed, so that when adjusted, they will know whether the adjustment is advantageous.

As systems grow more complex, the processes used to develop them will follow suit. The complexity of processes inevitably increases to keep pace with the number of individuals who are involved in performance.

The CMMI Product Suite offers a growing number of multi- and single-discipline models, all developed with integrated process improvement in mind.

The best combination of disciplines for an organization will depend on its business, organization, environment, and process improvement objectives.

For Version 1.1 of the model, four combinations of disciplines are available from which to choose, with an increasing scope of coverage.

The CMMI-SW model covers software engineering (SW); the CMMI-SE/SW model covers both systems engineering (SE) and software engineering; the CMMI-SE/SW/IPPD model adds in integrated product and process development (IPPD); and finally, the CMMI-SE/SW/IPPD/SS model provides additional emphasis on supplier sourcing (SS) and managing suppliers.

In Version 1.2 and the constellation concept, three disciplines are covered: development (CMMI for development), acquisition (CMMI for Acquisition), and Services (CMMI for services). The two last disciplines are not yet officially released but announced for 2007 by the SEI. The three variants will share a core of 16 process areas. It is obvious that the more the CMMI is used, the more attempts are made to fit the needs in the field.

The relevant factors for the selection of CMMI model are as follows:

Core business of the organization: The organization's fundamental activities, business objectives, and organizational culture all influence the choice of the appropriate CMMI model. Ideally, the disciplines chosen are the ones that are most critical to the organization's success.

Organization: It might be helpful to align process improvement plans with any organizational changes that are concurrently under way. The IPPD extensions are particularly useful in change management.

Improvement scope and objectives: Reducing the number of disciplines in which improvement effort is deployed is not good in the long term. Organizations who started with SW-CMM and focused only on software discipline during a couple of years finally move to CMMI just because it will bring benefit to the whole if maturity models concepts are also applied in other disciplines.

Selecting the IPPD extension mentioned above with the CMMI-SE/SW model provides two additional process areas (integrated teaming and organizational environment for integration), plus one expanded process area (integrated project management). Selecting the SS extension of the CMMI-SE/SW/IPPD model provides one additional process area (integrated supplier management). There will be an interest in this model extension if the organization is part of an acquisition-oriented bigger organization or participates in a project where the acquisition of products and services from an external source is a central issue of concern.

APPRAISALS

One part of the CMMI Product Suite that deals with appraisals is the Appraisal Requirements for CMMI (ARC), version 1.1. This document comprises 42 "requirements" that provide a mixed set of requirements and design constraints on an appraisal method. For those who have been used to the CBA-IPI assessment method, there are several variances. The CBA IPI method was a mixture of document's checking and discovery of the reality of projects through interviews with a bigger focus on the discovery aspect when SCAMPI—the CMMI—based appraisal method, Standard CMMI Appraisal Method for Process Improvement, focuses more on verification.

One key principle is the process implementation indicator (PII), a proof that a practice is really implemented.

Table 4.

Characterstics	Class A	Class B	Class C
Amount of objective evidence gathered (relative)	High	Medium	Low
Ratings generated	Yes	No	No
Resource needs (relative)	High	Medium	Low
Team size (relative)	Large	Medium	Small
Appraisal team leader requirements	Lead appraiser	Lead appraiser or person trained and expeienced	Person trained and experienced

In CMMI, PIIs refer to the "footprints" that are the necessary or incidental consequence of practice implementation.

PIIs include artifacts as well as information gathered from interviews with managers and practitioners. There are three PIIs types:

Direct Artifacts: Tangible outputs resulting directly from implementation of a practice (e.g., Typical Work Products).

Indirect Artifacts: Artifacts that are a side effect or indicative of performing a practice (e.g., meeting minutes, reviews, logs, and reports).

Affirmations: Oral or written statements confirming or supporting implementation of the practice (e.g., interviews and questionnaires).
