PII-based process appraisal uses PIIs as the focus for verification of practice implementation. This process is in contrast to an observation-based approach (CBA IPI) that relies on the crafting of observations that pertain to model implementation strengths or weaknesses.

Essential SCAMPI method attributes are as follows:

1. *Accuracy*: Level of confidence that the appraisal results reflect the strengths and weaknesses of the assessed organization; i.e., no significant strengths and weaknesses are left undiscovered.
2. *Repeatability*: The degree to which the ratings and findings of an appraisal are likely to be consistent with those of another independent appraisal conducted under comparable conditions; i.e., another appraisal of identical scope will produce consistent results.
3. *Cost/Resource Effectiveness*: Person-hours spent planning, preparing, and executing an appraisal. A reflection of the organizational investment in obtaining the appraisal results.
4. *Meaningfulness of Results*: Usefulness of the results (findings) to the organization in establishing improvement initiatives.
5. Arc Compliance.

CMMI appraisal premises are as follows:

- Goal achievement is a function of the extent to which the corresponding practices are present in the planned and implemented processes of the organization.
- Practice implementation at the organizational unit level is a function of the degree of practice implementation at the instantiation level (e.g., projects).
- The aggregate of objective evidence available to the appraisal team is used as the basis for determination of practice implementation.
- Appraisal teams are obligated to seek and consider objective evidence of multiple types in determining the extent of practice implementation.

Three classes of appraisals have been defined by the SEI. They can be differentiated as in Table 4.

Most organizations use the three classes in combination in order to achieve a better result.

CMMI SCAMPI Class B/Class C Appraisals, as currently defined by the SEI Appraisal Requirements for CMMI, Version 1.1 (ARC), are used primarily to gauge the progress made toward meeting applicable capability or maturity level-specific or generic goals as determined by compliance with the guidance from specific and generic practices, identify remaining gaps, and deciding on plans for future process improvement actions. One way is to structure Class B appraisals to better understand an organization, their business goals, and more importantly, how the organization has interpreted the CMMI to meet specific business and quality goals.

Interpretation of the CMMI goals differs from one organization to the next, even when they are within the same company. A Class B appraisal gives the opportunity to appraise to what extent each of the process areas has been implemented, and how. It is important to gain this understanding and, more specifically, to recognize when and if alternative practices have been implemented. Alternative practices, for some organizations, are an acceptable approach and are usually tied to business goals, types of projects (new development, enhancements/maintenance, etc.), technology in use, and/or organizational cultures. However alternative practices must continue to meet the goals of the process areas.

One primary output of an appraisal is a characterization of practice implementation at the project level (instance of implementation). A practice may be as outlined in Table 5.

This output is based on data collection and aggregation. In performing such activities, two requirements of SCAMPI family have to be looked at:

- *Corroboration*: Must have direct artifacts, combined with either indirect artifact or affirmation.

Table 5.

Fully implemented (FI)	· Direct artifacts present and appropriate · Supported by indirect artifact and/or affirmation · No weaknesses noted
Largely implemented (LI)	· Direct artifacts present and appropriate · Supported by indirect artifact and/or affirmation · One or more weaknesses noted
Partially implemented (PI)	· Direct artifacts absent or judged inadequate · Artifacts or affirmations indicate some aspects of the practice are implemented · One or more weaknesses noted
Not implemented (NI)	· Any situation not covered by above, e.g., insufficient objective evidence to be characterized by one of the above

- *Coverage*: Must have sufficient objective evidence for implementation of each practice, for each instance. Must have face-to-face (F2F) affirmations (avoid "paper only appraisals"):
  - At least one instance for each practice.
  - At least one practice for each instance.
  - Fifty percent of practices for each PA goal, for each project, have at least one F2F affirmation data point.

A SCAMPI appraisal is divided into three phases: 1) initial planning and preparation, 2) on-site appraisal, and 3) reporting of results. Each phase includes multiple steps. The first phase involves analyzing requirements, developing a plan, selecting and preparing the team, obtaining and analyzing the initial objective evidence, and preparing for the collection on site of additional objective evidence.

The second phase focuses on collecting and examining objective evidence, verifying and validating that evidence, making sure that it is adequately documented, and developing the appraisal results (findings and ratings).

The third phase involves the presentation of the final findings to the sponsor, conducting any needed executive briefings, and appropriately packaging and archiving the appraisal assets, including submission of all information needed by the CMMI Steward (SEI).

Only a SCAMPI lead appraiser, who has been trained and authorized by the CMMI Steward, may lead a SCAMPI A appraisal.

To start an improvement program that leads to a full SCAMPI appraisal, an organization could use several Class C appraisals leading up to a Class B appraisal. Process improvements are made based on the findings of the quick looks at parts of the organization. The lessons learned in this way can be used to provide broader organizational improvements.

As improvements indicate that the part of the organization is ready for the next step, a Class B appraisal can be performed and its findings subsequently are used to prepare for the full SCAMPI A appraisal.

USING APPRAISAL RESULTS FOR PROCESS IMPROVEMENT

Software process improvement is a systematic, collaborative, and long-range method to evolve the way software work is organized and performed. Improvement methods include the IDEAL method, which is an integrated approach for PI defined by the SEI. IDEAL identifies five phases: initiating, diagnosing, establishing, acting, and leveraging. Each of these phases is centered on a particular activity:

- Specify business goals and objectives that will be realized or supported (**Initiating**).
- Identify the organization's current state with respect to a related standard or reference model **(Diagnosing)**.
- Develop plans to implement the chosen approach **(Establishing)**.
- Bring together everything available to create a "best guess" solution specific to organizational needs—for example, existing tools, processes, knowledge, and skills—and put the solution in place **(Acting)**.
- Summarize lessons learned regarding processes used to implement IDEAL **(Leveraging)**.

Software capability is a sophisticated mixture of these preceding statements, but some concepts must be considered as part of the software capability.

Capability implies that an organization can learn from the past, especially from mistakes, learn from others, and translate lessons learned into process evolutions. Improvement iteration cycles will only be complete if measurements are defined to quantify the improvement.

When maturity of the organization improves, the standard process changes. Getting from Level 2 to Level 3 implies that all good practices within projects are institutionalized and that an assessment process is in place that will help to identify the best practices across projects, which will be documented into the organization standard software process (OSSP).

The Steps to Implement Process and Tools in an Organization

The OSSP of the CMM and CMMI is a new process in the organization.

If an organization decides to develop an organization-wide environment, a project to develop the organization's development environment has to be initiated. Such a project will work very closely with the software development project teams.

The process implementation project is divided into several phases where all four IDEAL steps are performed in each phase until the project is ready and the process and tools are deployed and successfully used by the entire organization. A process implementation project can be divided into phases. The four phases address:

- *Phase 1*: Sell the process implementation project to the sponsors.
- *Phase 2*: Handle the major risks.
- *Phase 3*: Complete everything—templates, guidelines, and examples of Development Cases are ready, and a training curriculum is in place.
- *Phase 4*: Deploy it to the entire organization.

The recommendations for successfully implementing a process change are to:

- Identify change agents at various levels in the organizations.
- Plan the change in small, reasonable, and measurable steps.
- Communicate the changes using ground-level language appropriate to the level of the organization.

Measurement

Measurement is one common feature in the CMM. A common feature exists for each key process area from Level 2 to Level 5 and indicates when a practice is institutionalized. Metrics are so important that in the CMMI there is a measurement process area.

What is key in the CMM is to measure processes to determine their adequacy at Level 2 and their effectiveness

Table 6. Return-on-investment report: defect phase containment

Over 80% of defects found before Delivery

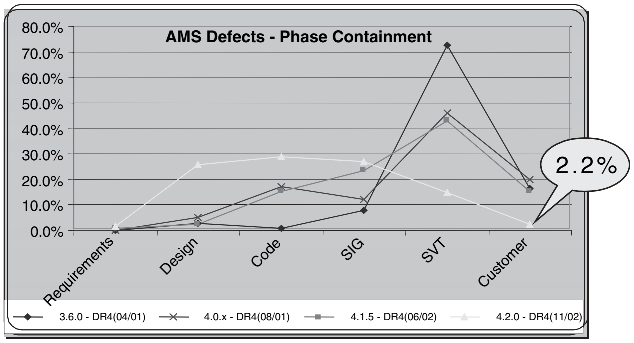
Caputo Impressed by Results
Code Reviews Play a Vital Role in Improvement

By the middle of 2002, the program was coming under more and more pressure to improve field quality and reduce the number of patches required to keep the product running.
The team decided to find ways to improve defect detection and removal during development.

What It Took To Get Defects Removed
Here is a listing of actions taken to improve detect detection and removal with focus on CMM Level 3:
Establishing phase containment programs.

- Increase code review coverage to 100%
- All requirements, design, coding, and test plans are inspected, results are recorded using tool & Compliance is reviewed via score card
- Established error tracking for document views

Defect Removal Results



AMS was able to substantially increase the number of defects found **prior** to SVT (System Verification Test)

- version 4.1.5: 41%
- version 4.2: 81%

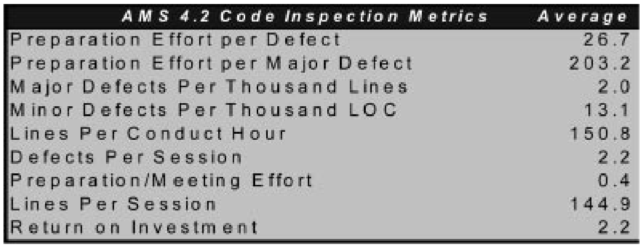
Cost Savings Apparent

Estimates show substantial ROI

Over $600K Saved in One Year
This estimate includes a reduction in the number of patches associated with version 4.2 as compared to version 4.1.5, and the labor associated with correcting bugs in the future.

Number of Patches Declines

As of December 2003, there have only been 3 patches since the release of Release 4.2 in June 2003, as compared to 18 patches for version 4.1.5, totaling over $600,000 cost savings, as a direct result in the ROI of the CMM Level 3 phase containment/ code reviews process improvement program.



AMS 4.2 Code Inspection Metrics	Average
Preparation Effort per Defect	26.7
Preparation Effort per Major Defect	203.2
Major Defects Per Thousand Lines	2.0
Minor Defects Per Thousand LOC	13.1
Lines Per Conduct Hour	150.8
Defects Per Session	2.2
Preparation/Meeting Effort	0.4
Lines Per Session	144.9
Return on Investment	2.2

The return in investment (ROI) is measured by estimating the cost to fix defects if they leak out testing to the customer, divided by the time invested in conducting the code inspections. The 2.2 ROI indicates that 2.2 bug fixing hours were saved for every 1 hour spent in code inspection. This ROI of 2.2 for version 4.2 was an improvement over the 0.9 ROI for version 4.1.5.

at Level 3. The shift from reporting to analyzing and acting on metrics is generally difficult, but a clear sign that the projects are more mature. Small and early successes managing a project quantitatively lead to accepting and understanding the benefits of measurement.

In addition to these general requirements, some key process areas have specific requirements for measures such as software project planning, software project tracking and oversight, and integrated software management. These requirements are related to project data that enable project estimates and project control.

The specific PA "measurement and analysis" of the CMMI integrates project control metrics and measurement made against business goals.

The project measurements artifact stores the project's metrics data. It is kept current as measurements are made or become available. It also contains the derived metrics calculated from the primitive data and should also store information, such as procedures and algorithms, about how the derived metrics were obtained. Reports on the status of the project—for example, progress toward goals (functionality, quality, and so on), expenditures, and other resource consumption—are produced using the project measurements.

PROCESS MANAGEMENT

Successful processes are not static. Processes must be managed. Having defined processes on any level of an organization also asks for process change management. To facilitate change, any process element should refer to a process owner who typically serves as a focal point for change proposals and change decisions. A process owner is an expert for a specific process and guides any type of evolution, improvement, or coaching. Any single instance of a process element should be placed under configuration control, which allows managing change in the context of several parallel projects.

Table 6 gives a good example of ROI calculation following process management.

CONCLUSION

The community of users of maturity models is rapidly growing all over the world. Several indicators can be looked at as follows:

- The variety of organizations adopting the maturity approach: from defense suppliers to the general industry players to banking and services.
- The various countries represented in the SEI training sessions: Europe and the Far East are now well represented.
- The wide audience of the annual SEPG conference and the sister events: European SEPG and Asian SEPG.
- The number of lead instructors and lead appraisers qualified by the SEI.

Process improvement based on maturity models is now reaching the mass market but will remain a competitive advantage for the organizations that adopt it and align process change management with their business strategy.

CLASS AND OBJECT

INTRODUCTION

Object-oriented technologies have become the main stream in software system development. To improve the quality of software systems, object-oriented methods help software developers produce reusable, extensible, robust, and portable systems. The object-oriented approach encompasses the entire software lifecycle from requirement and design to implementation and testing. Methods and languages, as well as supporting tools, are applied to different stages. Evolving from modular programming and abstract data type (ADT), object orientation separates the interface from its implementation so that the implementation is hidden. The software developer programs to the interface not to the implementation. Instead of designing and developing a software system based on processes and functions, objects become the first-class element. In this way, system decomposition is not based on functionalities in terms of main program and subroutines. It is based on the entities in a system. These entities with their data and operations are encapsulated into objects.

At the foundation of object-oriented technologies, class and object are important concepts. In the rest of this article, we provide a detailed description of these two concepts.

CLASS

With the increasing complexity and scale of software systems, extendibility, reusability, and reliability become important goals in software development. New software components should be easily added in the software systems. Existing components can be reused in different systems. Software systems should also be tolerant to faults. Traditional approaches use functions as a basis for the architecture of software systems. The designer structures the software systems around functions. This top-down functional decomposition is easy to obtain the system architecture initially. However, it is difficult to change the system architecture in the future. Most software systems undergo numerous changes after their first delivery. The model of software development should not only consider the period leading to that delivery but also consider the subsequent era of change and revision. Although functional decomposition can be useful for developing individual algorithms and close to computer architecture, it is not intuitive to model and analyze the requirement and design of real-world applications that are often organized into entities and their relationships.

The architecture of functional decomposition is main program/subroutine. In these top-down approaches, the main program is typically first identified. The subroutines are then developed. In contrast, object-oriented approaches decompose software systems around data from the bottom up. For example, the height, weight, and age of a person are identified first. They are then grouped into a class. The choice of main function is one of the very last steps to be taken in the software development process. The developer delays the description and implementation of the topmost function of the system as late as possible. Instead, the types of objects in a system are analyzed first. Software design progresses through the successive improvements of the understanding of these object types. This bottom-up process allows building robust and extensible solutions to parts of the problem and combining them into more and more powerful assemblies. These components, if assembled differently, may combine with other components and form other systems.

In the remainder of this section, we examine the basic building block of object-oriented systems: class.

Static Structure

Class is the basic notion from which everything in object technology derives. A class corresponds to an abstract concept and encapsulates a set of data together with the operations that apply to the data. The set of data is often called the attributes of the class. For example, “Person” is a concept and can be represented as a class. The class “Person” may contain the attributes like name, height, weight, and birth year. These attributes describe the information of the class, which is often hidden. Information hiding is an explicit mechanism for defining visibility/scope, which allows other classes to have limited rights to access these attributes. Information hiding is achieved via signatures, interfaces, and directives.

A class is a type that describes a set of possible data structures that may be represented in the memory of a computer and manipulated by a software system at the implementation level. A type is the static description of certain dynamic data elements that are processed during the execution of a software system. The notion of type is a semantic concept that directly influences the execution of a software system by defining the form of data structures that the system will create and manipulate at run time. The set of types often include primitive types such as integer, float, and character as well as user-defined types such as record types, pointer types, and array types. A class can be considered a user-defined type.

Intuitively, a class can be seen as a mold from which the instance of the class, called an object, can be built. Similar to a cake mold that can be used to make many cakes with the same shape, the instances of a class share common characteristics (attributes and operations). Any particular execution of a system may use the classes to create objects (data structures). Each such object is derived from a class. From another point of view, a class can be considered as a “frame” representing an abstract concept, whereas the instances, or objects, of the class are concrete individuals under the frame/concept. For example, “Person” is a frame/concept, whereas “John,” “Mary,” and “Bob” are instances/objects of “Person.” These objects share the common attributes such as name, height, weight, and birthyear.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

The software programs of a system are embedded in a set of classes in terms of operations. The program text is static and exists independently of any execution. In contrast, an object derived from a class is a dynamically created data structure, existing only in the memory of a computer during the execution of a system. Object-oriented programming languages include some module facility for organizing program text together with some type system for data structure. A module, in various forms such as operations, routines, and packages, is a unit of software decomposition. Software program texts are decomposed into module structures syntactically. The decomposition is typically around a set of data that is manipulated. All modules (operations) that control the same set of data are organized into the same class.

In non-object-oriented approaches, the type and module concepts remain distinct. In contrast, the notion of class merges the two concepts into a single construct in object-oriented approaches. A class is both a type and a module. This merger facilitates the encapsulation of the data that, for example, can be accessed only by the operation modules in the class. Information hiding is one of the important principles in object-oriented methods.

Attribute

Each class contains several attributes that characterize the properties of a set of objects. All objects of the same class have the same set of attributes. The values of these attributes distinguish different objects of the same class. For example, the class "Person" may contain the attributes such as name, height, weight, and birth year, which may be defined in object-oriented programming languages as follows:

```
class Person {
        string name;
        float height;
        float weight;
        int birthyear;
}
```

All instances of this class have these attributes but with potentially different values. One particular person may have the name of "John," height of 6 feet, weight 180 pounds, and born in 1980. Another person may have the name of "Mary," height of 5.5 feet, weight 120 pounds, and born in 1981. In addition to primitive types, class attributes may include other classes. For instance, each person has parents who are instances of the "Person" class as well. In this case, two additional attributes with user-defined type (the class "Person") can be added into the previous class definition as follows:

```
class Person {
        string name;
        float height;
        float weight;
        int birthyear;
        Person* father;
        Person* mother;
}
```

In object-oriented analysis and design, a system is decomposed around attributes. In a typical approach, classes and their attributes are identified by searching for the nouns (entities) in the requirements. These entities are the candidates of classes. Their properties are the candidates of the corresponding class attributes. In non-object-oriented approaches, conversely, system decomposition is around operations by searching for the verbs (processes) in the requirements.

Operation

The operation defines a certain computation (algorithm) applicable to all instances of a class. In general, the operations of a class manipulate the attributes in the class. In object-oriented analysis and design, the operations are identified in terms of the attributes in a class so that the computation and algorithm may apply to the attributes. For instance, the operation "age" can be defined to calculate the age of a person as follows:

```
int age() {
        return thisyear - birthyear;
}
```

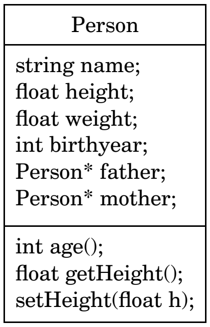
An operation consists of an interface (header) and a body. The interface of an operation may include the name, parameters, and return type. The body of an operation is a sequence of instructions describing the implementation of the computation and algorithm. The implementation of an operation is hidden from the user who only needs the interface information to invoke the operation (e.g., the user of a calculator does not need to know how the calculator performs its function). Some object-oriented programming languages separate the interface from its implementation and call the interface "operation" and the implementation "method." In this way, the same interface (operation) may have different implementations (methods) that can be dynamically selected at run time, called dynamic binding. This separation also facilitates the modification of the implementation as long as the interface stays unchanged. For the example of the Y2K problem, suppose the "birthyear" stores a two-digit format of data originally. The change from two-digit to four-digit for "birthyear" and "thisyear" only affects the implementation of the "age" operation. It does not affect the interface of the operation. Thus, the client who uses the operation need not be aware of this change.

In practice, it is common to have "getter" and "setter" operations to access the attributes of a class. For example, the operations "getHeight" and "setHeight" can be defined to access the "height" attribute as follows. These operations may be used to retrieve the height information of a person and change the height value when the person grows up:

```
float getHeight() {
        return height;
}
setHeight(float h) {
        height = h;
}
```

Class Diagram

In the previous sections, we introduced the basic concept of class and discussed attributes and operations using some examples at the implementation level. At the design level, graphical notations are often used for conveying concepts and information. For example, the Unified Modeling Language (UML) provides several diagrams, such as class, object, sequence, and collaboration diagrams, to model and represent object-oriented design. UML is a general-purpose language for specifying, constructing, visualizing, and documenting artifacts of software-intensive systems. It provides a collection of visual notations to capture different aspects of the system under development. In particular, a class diagram is one of the important diagrams provided by UML. In a class diagram, each class is represented as a rectangle typically with three compartments containing the name, attributes, and operations of the class. For example, the "Person" class can be represented as follows in the class diagram:



```
Person

string name;
float height;
float weight;
int birthyear;
Person* father;
Person* mother;

int age();
float getHeight();
setHeight(float h);
```

In class diagrams, only the important interface information of a class is represented so that the designers are able to concentrate on essential issues at the early stage of software development. They do not need to consider low-level implementation issues until necessary. Graphical notations, such as class diagrams, can also help the designers to communicate their design decisions.

Type

Similar to the record and array types, a class is a user-defined type from a programming language point of view. It combines a set of attributes as a single type. All instances of a class have the same set of attributes of the class. Unlike record type, a set of operations is also defined in the class type. Thus, all instances of a class may perform these operations on their own set of attributes. For instance, the "Person" class is a user-defined type. Its instance can be defined as follows:

```
Person p;
```

Like other variables in programming languages, the value of "p" can be assigned, changed, and accessed. Once "p" is assigned an instance/object of "Person," the operation defined in "Person" can be invoked to perform on "p," such as "p.age()" that calculates the age in terms of the attribute values of "p."

The type-checking facility is also available for the class type in object-oriented programming languages. Type mismatch can be checked by the compiler.

In general, the objective of a type system is to prevent illegal operations from being performed on inappropriate values. A strong typed language can guarantee that operations are only performed on values of the appropriate type. Strong typed languages, such as Java, can perform most their analysis and checks at the compile time.

Accessibility

Information hiding is one of the important principles in object-oriented approaches for the design of coherent and flexible architecture. The attributes of an object are encapsulated to restrict the accesses from outside the object. They usually can be manipulated only by the operations defined inside the class. That is, the class type defines the accessibility of attributes for all its objects. As well as the attributes, the operations can be hidden partially or completely. In this way, the class is more reusable and resilient to change.

Object-oriented programming languages often provide different levels of accessibility to the attributes and operations of objects. At one extreme, no attributes and operations can be accessed by the clients outside the object. At the other extreme, all attributes and operations can be accessed by the operations outside the object. Some object-oriented programming languages, such as C++ and Java, use "public" and "private" to represent unrestricted and no access, respectively. In the following declarations, for example, the "height" attribute cannot be accessed by any clients and the "getHeight" operation can be accessed by all clients:

```
private float height;
public float getHeight();
```

Most object-oriented programming languages also provide partial accessibility in between the two extremes. A certain kind of clients may be able to access the attributes and operations of an object. This set of clients can be defined in the class of the object. For example, "protected" is used, in C++ and Java, to refer to the corresponding attribute or operation that can only be accessed by the objects of the class and its subclasses. In addition, some programming languages separate different kinds of access rights, such as read, write, and execution. The clients may be further assigned by a class different access rights to the attributes of its objects.

Class Relationships

The primary tasks of object-oriented analysis and design include discovering classes and identifying relationships among classes. A class represents some useful concept and thus can be discovered by looking for nouns in the requirement specifications, whereas the behavior and operations of a class can be found by looking for verbs in the requirement specifications. Various relationships exist among different classes, which may be useful for the system designer to develop reusable and robust systems. We briefly introduce three important class relationships in this section, including inheritance, association/aggregation, and dependency.

Inheritance is an "is-a" relationship between classes. For example, a student is a person. A class "Student" can be identified as a kind of "Person" described in the previous sections. The class "Person" is called the superclass of the class "Student," whereas "Student" is a subclass of "Person." A subclass inherits the attributes and operations of its superclass. Moreover, a subclass may have its own specific attributes and operations. For example, the class "Student" may have specialized attributes such as GPA, in addition to all attributes of the class "Person." A subclass can overwrite some operations defined in the superclass, which may lead to polymorphism, where the different versions of the operation (defined in the class and subclasses) may be invoked through dynamic binding during the program execution.

Association or aggregation is a "has-a" relationship among classes. This relationship is usually implemented by using a class as the type of attributes. For example, a "Person" may have an attribute "address," and "address" can be identified as another class "Address" that has attributes "number," "street," "city," "state," "zip," etc. Generally, a class is associated with another class if its attributes refer to the other class. A class may also be associated with itself, by having itself as the type of attributes. For instance, a "Person" may have another "Person" as the type of its "father" or "mother," as described in the previous section.

Dependency is a "uses" relationship among classes. One class depends on another class if it comes into contact with the other class in some way. For example, the method age() of "Person" can be implemented by getting the system date that may be a type of the class "Date," extracting the current year from the system date, and subtracting the "birthyear" from the current year. In this way, the class "Person" depends on the class "Date" by using an object of "Date" to calculate the age. Association/aggregation is a stronger form of dependency.

OBJECT

An object is a run-time instance of some class. It is the concrete manifestation of a class. An object-oriented system creates a certain number of objects and lets these objects interact with each other at any time during its execution. The run-time structure is the organization of these objects and of their relationships. The dynamic and unpredictable nature is part of the reason for the flexibility of object-oriented approaches. Whereas class, discussed in the previous section, is concerned mostly with conceptual and structural issues, object includes behavioral aspects, in particular, the management of memory in the execution of object-oriented systems.

A simple class model may render complex instances, which reflects in part the power of object-oriented methods. Some interactions among the objects may be defined in the static structure in the classes. Many other object interactions may only be available at run time. It is often impossible to prevent the runtime object structures of systems from becoming large and complex. Such run-time complexity does not have to affect the static structure that should be kept as simple as possible. A small software text can describe a huge computation containing millions of objects from a simple class structure at execution time.

Dynamical Structure

The highly dynamic nature of the object-oriented model is described in terms of a run-time object structure. As opposed to traditional static approaches, the object-oriented environment lets systems create objects as needed at run time, based on a pattern that is often impossible to predict by a mere static examination of the static structure. Each object has to be created before it can be used in the software systems. At the initial state, only one object, the root object, is created. The systems repetitively create new objects on the object structure.

In object-oriented programming languages, the creation of a new object may involve the allocation of memory space for the attributes and the initialization of their values. Some special operation may be invoked to accomplish the initialization process when an object is created. The initial values of the attributes may be modified in the later stage at run time.

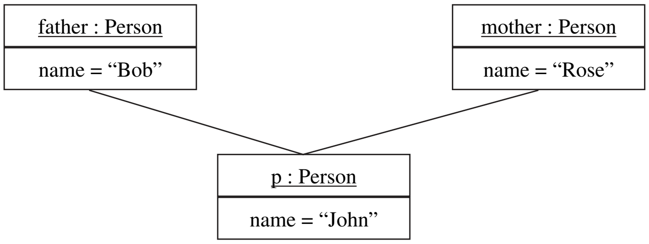
Similar to a record in traditional programming languages, an object, the instance of a class, is allocated memory space for its attributes defined in the class. The values of these attributes are stored in this memory space. For example, an object of the class "Person" may have the attribute values shown as follows:

Attributes	Values
name	"John"
height	6
weight	180
birthyear	1980

Unlike a record, an object has access not only to the attributes but also to the operations defined in its class. After an object is created, the client can use the reference to this object to refer to its attributes and invoke its operations.

Object Diagram

As well as a class diagram modeling classes and the static structure of object-oriented systems, UML provides an object diagram to model the dynamic structure of the systems. Object diagrams model the instances of things contained in class diagrams. They visually describe the objects and their interactions in the systems. An object diagram shows a set of objects and their relationships at a point in time. Graphically, it is a collection of vertices and arcs representing objects and links, respectively. For example, an object diagram of the objects of the "Person" class can be shown as follows:



In object diagrams, the “:” symbol is used to separate the object identifier from its class identifier. Both of them are underlined. An anonymous instance may be defined by omitting the object name as, for example, “: Person.” Each occurrence of an anonymous object is considered distinct from all other occurrences. It is also possible to omit the class name if it is unknown. In this case, the object name should be explicitly given. The attribute values can be shown to explicitly represent the state of the object at a given time. Objects may be connected by links to represent the relationships among them.

Object Identity

Each object created at the execution of an object-oriented system has a unique identity that is independent from the values of its attributes. Two objects of the same class have different identities. They may share the same values on their attributes, respectively. The values of the attributes may change at run time. However, object identity cannot change. Each object is assigned an identity ID (called OID) that is held during its lifetime in the system. For example, the object variables “p” and “q” of the class “Person” may be declared as follows:

Person p, q;

where “p” and “q” can refer to two distinct objects with different identities although they may share the same values of their attributes, for example, as follows:

Attributes	Values of p	Values of q
name	“John”	“John”
height	6	6
weight	180	180
birthyear	1980	1980

These two objects have exactly the same values of their attributes, but they are two distinct objects. Most object-oriented programming languages do not consider two objects with the same attributes and the attribute values as the same object. The concept of object identity compromises some operators, such as assignment and comparison, in traditional software systems. One object cannot simply assign its attribute values to the attributes of another object. Two objects cannot be compared by a comparison operator (< , >, ==) to render a definite result. For example, “ p == q” cannot be used to check whether “p” and “q” share the same values of their attributes, respectively. “ p = q” is incorrect if the user wants to assign all attribute values of “q” to the attributes of “p”, respectively. In these cases, the user has to compare or assign each field individually. At run time, the attribute values of “p” and “q” may be changed, e.g., as follows:

Attributes	Values of p	Values of q
name	“John”	“Mary”
height	6	5.5
weight	180	120
birthyear	1980	1981

In addition to attributes of basic types, objects may have attributes that represent other objects. For instance, each person having a father and a mother may have the following additional fields:

Attributes	Values
name	“John”
height	6
weight	180
birthyear	1980
father	f
mother	m

where “f” and “m” are the references to the objects of the “Person” class.

Member Access

In object-oriented programming, each attribute or operation belongs to some object. The user has to know the corresponding object before he/she can access an attribute or operation. Thus, not only the name of an attribute or operation and its parameters, but also the name of the targeting object needs to be available in order to access the member attribute or operation. The attributes and operations of an object can be accessed by other objects using the dot notation (with the “.” symbol), where the object name is before the dot and the attribute or operation name is after the dot. This kind of access is said to be qualified in that the targeting object of the call is explicitly identified. To get the height of John (object “p”), for example, we can use “p.getHeight()”.

To refer the member attributes or operations within the same object, one does not need the object name if no ambiguity. This is called the unqualified call because the targeting object is implicit. For example, the “getHeight” operation defined in the "previous Operation" section returns the value of "height" from the same object.

Current Instance

A class describes the properties and behavior of objects of a certain type. Sometimes, we may need to refer to the current instance of a class explicitly by using a reserved word ("this" in C++ and Java) in an object-oriented programming language. For instance, in the following method:

```
setHeight(float height) {
        this.height = height;
}
```

the assignment "this.height = height" avoids ambiguity because the two "height" variables refer to two different variables. The first "height" refers to an attribute defined in the current object. The second "height" refers to the argument of the operation "setHeight". Therefore, "this" is prefixed to the first "height" to explicitly identify the correct variable. Otherwise, "height = height" cannot accomplish the desired result.

Similarly, when an operation of the superclass is overwritten by a subclass, an object of the subclass has two definitions of the same operation: one defined in the superclass and the other defined in the subclass. The object may need to explicitly refer to the operation defined in the superclass by using a reserved word ("super" in C++ and Java) in object-oriented programming languages. For example, suppose a student has to be over five years old. Thus, the "age" operation in the "Person" class can be overwritten in the "Student" class:

```
int age() {
        int result = super.age();
        if (result < 6) // print out { \\ error processing }
        return result;
}
```

where "super.age()" is used to refer to the "age" operation defined in the superclass (the "Person" class in this case) to avoid confusion with the "age" operation defined in the subclass (the "Student" class in this case).

Memory Management

At run time, object-oriented systems dynamically create objects and let the objects interact with each other. Each object is allocated certain memory space at creation. The particular size of memory space for each object depends on the types of the attributes of the corresponding class. For example, the object of the "Person" class contains six attributes: one string type, two float types, one integer type, and two reference types. Thus, the size of memory space allocated to the object is the total size of all six types. It normally cannot be changed although the value of each attribute may be changed at run time.

When an object finishes its tasks and is no longer useful, it should be deleted from the system so that the memory space it occupies can be released. This task is important because these useless objects may eventually take huge memory space such that the system cannot create new objects anymore. This task is called garbage collection. Some object-oriented programming languages, such as Java, can manage automatic garbage collection. The developer does not need to worry about deleting useless objects. The run-time system of the language may search the memory and delete waste objects from time to time. Other object-oriented languages, like C++, do not provide the facility for automatic garbage collection. In this case, the developer has to explicitly delete an object when it is no longer useful.

SUMMARY

Class and object are the fundamental concepts of object-oriented technologies. They model the static and dynamic structures of object-oriented systems, respectively. A class declares several attributes and operations that can be accessed by the clients with limited right. An object is an instance of a class. Objects are created, used, and deleted at run time. Object-oriented systems manage objects and the memory space they occupy through their identities. Class and object are the basis for other object-oriented concepts, such as generalization, association, aggregation, and polymorphism.

COMPONENT-BASED SOFTWARE ENGINEERING

INTRODUCTION

Software systems are pushed continually to address increasing demands of scalability and correctness. To meet these requirements, software development has evolved into a process of reusing existing software assets rather than constructing a new software system completely from scratch (1). By reducing time-to-market, software reuse has improved the economic and productivity factors of software production (2).

The granularity of software reuse has evolved in tandem with the capabilities of existing programming languages—from functions/procedures found in imperative programming languages, to the object/class mechanisms available in object-oriented programming languages. The current context of software reuse also scales from stand-alone software development for a single machine to capabilities supporting distributed software systems. Component-based software engineering (CBSE) (3) is becoming an accepted engineering discipline for promoting software reuse throughout the software engineering lifecycle. Beyond software reuse, CBSE also offers a promising way to manage the complexity and evolution of the development process through a unique means of encapsulation and separation of concerns at different abstraction levels (4).

This article begins with a description of the key characteristics of a software component and then provides a survey of the major component models based on those key characteristics. The latter part of this article discusses the existing engineering issues in CBSE and examines the major research projects that are addressing the challenges. Finally, this article explores recent software engineering technology toward automation in CBSE, which promises to offer yet another channel for boosting the productivity of software development.

SOFTWARE COMPONENTS UNVEILED

Software Component and Component Interface

The definition of a software component has been addressed widely in the literature (5). A software component essentially represents a precompiled independent module, possibly from a third-party vendor, and can be composed to create an even larger software component or system. A precompiled module comes in binary form, thus third-party integration requires a software component to have a mechanism to describe itself before it can be used, just like a typical user's guide for a commercial product. This special role is played by the *component interface.*

How component interfaces are defined varies, but such definitions are mainly intended to expose just enough information for third-party applications to consume without having to disclose underlying implementation details. This type of information hiding is a common practice in industry for intellectual property protection. Most common interface constituents include some form of the following characteristics:

- *public methods* of the underlying components, which represent their functional offerings to third-party applications.
- *properties,* which are generally used for specifying component configuration and deployment requirements. A component is not only a functional unit for composition, but also exercises its role in the overall software product configuration and deployment. In addition to functional properties, distributed software components sometimes specify nonfunctional properties such as throughput, availability, and end-to-end delay (for a more detailed list, see Ref 6. In a distributed environment, a software product generated by component composition is evaluated on the overall functionality and satisfaction of nonfunctional properties.
- *events,* which are used for provisioning notification among components when something of interest happens. The notified components will trigger event handlers, which are registered beforehand as event listeners.

Although the component interface specification can be Unified Modeling Language (UML; see http://www.omg.org/uml/) -based (7), or formal methods-based (8), the most common approach in application development is to use an Interface Definition Language (IDL; see http://en.wikipedia.org/wiki/Interface_Definition_Language). To compose the components, third-party software applications need to make either (1) *static invocation* via interfaces that compile the component IDL into the whole application to generate the executable code, or (2) *dynamic invocation* to discover and invoke the component interface at run time without extra compilation. Although most IDLs dictate the programming language used for third-party applications (e.g., Java IDL can only be used in Java applications), certain IDLs are language neutral for third-party software applications (i.e., a language-specific IDL compiler can be used to compile the IDL into the designated language of the third-party software applications in order to compose the corresponding component). One such example is Common Object Request Broker Architecture (CORBA; see http://www.omg.org/corba) IDL, which permits interoperability of components written in different languages.

The remaining part of this section briefly surveys the most representative commercial component techno-

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

logy models in the market based on the afore-mentioned characteristics.

Major Component Technology Models

Microsoft COM and DCOM. Component Object Model (Com; see http://www.microsoft.com/com) is the binary standard set by Microsoft for all software components on the Windows platform. Every COM component can implement any number of interfaces, each representing a different view or behavior of the object. The Distributed COM(DCOM) extends COM with distribution based on the Remote Procedure Call (RPC) mechanism. Microsoft Transaction Server (MTS) further extends DCOM with a container adding transaction and other services, which constitutes the COM+ component model.

- **Environment:** Windows platform. DCOM further needs MTS as a container.
- **IDL:** Microsoft (MS) IDL. Each interface distinguishes itself by including a universally unique identifier (UUID) in the MS IDL interface definition. As COM represents a binary standard, the IDL can be used for various MS languages such as MS C++ and Visual Basic.
- **Property:** fields defined in IDL.
- **Event:** An event in a COM component is realized by implementing a miniature COM object called the *connection* point, which implements a standard event dispatch.
- **Invocation:** supports both static invocation and dynamic invocation. To enable dynamic invocation, a COM component needs to implement a specific interface rather than relying on any infrastructural support, which is in contrast to CORBA components described later.

Sun Enterprise Javabeans (EJB). EJB (see http://java.sun.com/products/ejb) is the server-side component model for developing enterprise business applications in Java. It is tailored to Java-based applications in which a "bean" is a component.

- **Environment:** An EJB is contained in an EJB container running on a J2EE Server. The container provides added services to EJB, such as transactions and security.
- **IDL:** There is no specific IDL to expose the EJB component as the EJB component implements standard interfaces. A client invokes the stub code of those interfaces to access the EJB component at the server side.
- **Property:** Properties of EJB components are represented as deployment attributes in an extended markup language (XML; see http://www.w3.org/xml) deployment descriptor file.
- **Event:** EJB provides event services by using a message-driven bean (MDB).
- **Invocation:** supports both static invocation and dynamic invocation. The latter actually leverages Java reflection, which is more of a Java feature rather than an EJB feature.

OMG CORBA Component Model (CCM). CORBA is the initiative of the Object Management Group (OMG; see http://www.omg.org) for enabling interconnections among distributed software components across heterogeneous platforms. CCM (see http://www.omg.org/technology/documents/formal/components.htm) was introduced with CORBA 3.0. In contrast to the prior CORBA object model, CCM is designed for loose coupling between CORBA objects, facilitating component reuse, deployment, configuration, extension, and management of CORBA services.

- **Environment:** Running inside a CCM container over a CORBA ORB.
- **IDL:** CORBA Component Implementation Definition Language (CIDL), which is implementation independent and can be compiled to different languages based on the requirement of the underlying ORB.
- **Property:** attributes defined in CIDL, which are used mainly for component configuration.
- **Event:** events are defined directly in CIDL. Events are transmitted via an *event channel*.
- **Invocation:** supports both static invocation and dynamic invocation. The latter is enabled only if the CORBA ORB implements the dynamic invocation interface (DII), which is in contrast to COM components, for which dynamic invocation relies on an individual component's implementation.

Microsoft .NET Component Model. This component model is listed last because it is a fairly new model compared with the preceding three component models. In the Microsoft .NET (see http://www.microsoft.com/net) framework, an *assembly* is a component that runs on the Microsoft Common Language Runtime (CLR) (9). Each .NET language (e.g., C#, VB.NET, C++.NET) can be compiled into assembly files in the form of intermediate code, which are further just-in-time compiled into native code that can be executed in the CLR. The interoperability for an assembly is at the logical, intermediate code level rather than strictly at the physical, binary level, which makes assembly components easier to use and integrate when compared with COM components. Additionally, the .NET component model provides a significant number of benefits including a more robust, evidence-based security model, automatic memory management, and native Web Services support.

- **Environment:** Windows platform, .NET framework, CLR.
- **IDL:** MS CIL, (Microsoft Common Intermediate Language).
- **Property:** represented as *metadata* in the MS CIL, which is readable and writable within the CLR.

- **Event:** events are defined as first-class language constructs in .NET programming languages.
- **Invocation:** supports both static invocation and dynamic invocation. The latter is realized by .NET reflection.

This section described major characteristics and representative samples of software component models. The next section discusses engineering principles for CBSE.

ENGINEERING COMPONENT-BASED SOFTWARE SYSTEMS

To achieve the benefits of CBSE mentioned earlier, there are many issues that need to be addressed. We describe a list of representative issues and supporting technologies.

Componentizing Large Software Projects. Componentization for a software application needs to identify reusable assets from the initial phase of the software engineering lifecycle. Domain analysis (10) can be applied to identify the similarities among software applications, and those similarities can be used as a basis for implementing software components. The most popular domain analysis technique is Feature-Oriented Domain Analysis (FODA) (11), for which the relationship between parent feature and child feature are specified. The result of FODA is a feature set, with each feature corresponding to a reusable component. Componentization via FODA can be either manual or automatic (12). Moreover, a product line (13) can be derived during the domain analysis phase to derive a family of software components that implement common features, but satisfy different specific needs (such as with different nonfunctional properties).

In CBSE, there are concerns that crosscut the modularization boundaries of individual components (e.g., Quality of Service (QoS), distribution, and synchronization). Consequently, there is a need for componentization to capture those concerns in a modular way as well. The idea of aspect-oriented programming (AOP) (14) can be applied to CBSE. AOP essentially provides a means to capture crosscutting aspects in a modular way with new language constructs and a new type of translator called a *weaver* to compose the aspects into the base components. AOP can provide benefits to CBSE in the sense that crosscutting assets can be identified during domain analysis (15) or software modeling (16). The crosscutting assets can be used to derive aspectual components (17) that are weaved into the main components to realize component composition.

Ensuring the Reusability of Software Components. Software component reusability requires comprehensive support ranging from language design and infrastructural enabling to application architecture.

- **Language Design:** The language in which the components are written needs to be flexible and descriptive with reduced run time overhead [an example of such a language is Cecil (18,19)]. The reusability of .NET components has also been greatly enhanced with the logical interoperability of CIL. In contrast, although COM is a binary standard for components, its reusability is restricted to the physical code level, which requires much more complicated effort from the component user.
- **Infrastructural Enabling:** Infrastructure support provides separation of concerns—security, transaction, persistence, and memory management can all be managed by the underlying infrastructure with the software component implementation remaining as lean as possible to achieve a finer granularity, thus making it more reusable. Examples of such infrastructure include J2EE servers and EJB containers for EJB components, ORB and CCM containers for CORBA components, and CLR for .NET components.
- **Application Architecture:** CBSE not only motivates the reusable components in the small, but also motivates the reusable design in the large. Design patterns (20) offer a reusable solution to recurring problems in software design, which can help in developing a library of components accommodating a relatively fixed set of concepts in a specific problem domain.

Predictable Assembly for Software Components. Although component composition largely targets syntactical composability, it is also desirable to provide behavioral predictability for an assembled software system at design time before component composition. Predictability is not possible for any arbitrary design; with constraints such as memory space and battery life omnipresent, real-time embedded systems have sufficient grounds to apply predictable assembly based on computation of constraints and design space pruning (21,22).

Publishing and Discovering Software Components. Software components can only be used by registering with a central repository that provides for both static discovery and dynamic discovery, which can take two forms: proprietary or public. Proprietary publishing can only be discovered and used by third-party software with the designated (matching) platform or component technology. One example is CORBA components, which are published via an interface repository and discovered via the CORBA naming service. Recent emergence of service-oriented architecture (SOA) (23) can be seen as a component-based software system with public publishing and discovery infrastructure based on the Universal Description, Discovery, and Integration (UDDI) standard, for which Web services can be consumed across a heterogeneous distributed environment (23).

TOWARD AUTOMATION IN CBSE

CBSE boosts productivity in terms of reusability and manageability of software components (5). Recent progress in software engineering has seen yet another dimension for enhancing productivity through automation, particularly automation in both component generation and component assembly.

Automation in Component Generation

There are two directions toward automatic component generation. One is a model-driven approach (e.g., model-driven architecture; MDA; see http://www.omg.org/mda) for code generation based on high-level implementation-independent models. The other is the concept of a software factory[1](24), which leverages domain-specific best practices and schematizes those best practices for automatic component generation.

MDA. MDA is an initiative from OMG for capturing the essence of a software system in a manner that is independent of the underlying implementation platform. Model-driven software development permits a software solution to be more easily targeted to different platforms while also protecting key software assets from obsolescence. Model-driven approaches, like MDA, can assist in re-engineering legacy software systems and commercial-off-the-shelf (COTS) software into platform-independent models (PIMs). A PIM can be mapped to software components on platform-specific models (PSMs), such as CORBA, J2EE, or .NET. In this way, legacy systems and COTS components can be reintegrated into new platforms efficiently and cost-effectively (25). The vision of MDA also includes standards that enable generative construction of interoperating bridges between different technologies leveraging application and platform knowledge. One of the MDA technologies is an Interworking Architecture (see http://www.omg.org/cgi-bin/doc?formal/02-06-21), which provides a bridge that allows COM and CORBA objects to interoperate from model-driven specifications.

Software Factory. With new component models and infrastructure emerging each year, CBSE is becoming more complicated from the viewpoints of design, implementation, and deployment. Nevertheless, the goal of CBSE is not only to promote software reuse but also to boost the industrialization of software components in a manner similar to the success of hardware components. Toward that end, a software factory is defined as a "software product line that configures extensible tools, process, and content using a software factory template based on a software factory schema to automate the development and maintenance of variants of an archetypical product by adapting, assembling, and configuring framework-based components" (24). Compared with MDA, the major difference is that a software factory focuses on domain-specific modeling to present the best practice, whereas MDA is more ambitious aiming at generating full component code for any PSM.

Automation in Component Assembly

Although the preceding section on automatic component generation can be seen as an effort toward creating a component factory, the concept of automatic component assembly is focused on creating a software system factory. Among related research projects, UniFrame (6,26) is a framework for assembling heterogeneous distributed components with nonfunctional property guarantees. It uses a unified meta-component model (UMM) (27) to encode the meta-information of a component, such as functional properties, implementation technologies, and cooperative attributes. In UniFrame, a generative domain model (GDM) (10) is also used to capture the domain knowledge and to elicit assembly rules for automatic generation of glue/wrapper code to bridge the heterogeneity. Upon violation of nonfunctional property constraints for the assembled system, a discovery service is triggered to identify alternative component candidates and the automatic component assembly process is repeated until nonfunctional requirements are satisfied. Complementary to the UniFrame approach, Cao et al. (28) propose a rule-inference-based approach for choosing alternative components, which simplifies the discovery process for alternative component candidates. Also, rather than using GDM for generating glue/wrapper code generation rules, Cao et al. (28) use dynamic binary code adaptation to instrument hook code for component assembly at run time.

CONCLUSION

CBSE has been recognized as an important approach for promoting reusability and manageability of software systems. This article identified the key characteristics of CBSE and introduced several mainstream component technology models. The article also examined the primary CBSE challenges and introduced related work. With the rapid evolution of the software engineering discipline, CBSE is also evolving accordingly. As such, pilot efforts on adopting automated software engineering in component-based software development, such as those described here, have much promise. Although still in their early stages, these approaches provide new opportunities for promoting productivity of component-based software development and are becoming active research topics for CBSE communities.

COMPUTER ANIMATION

INTRODUCTION

Computer animation is widely used in games, movies, and TV programs. Topics such as human animation, fluid dynamics, rigid bodies, cloth simulation, flocking, and deformable models are covered in this field. In this article, we introduce the key techniques used for such kind of animations by observing the life of a virtual character "Joe," who is living in cyberspace.

MOTION SYNTHESIS AND ANATOMICAL MODELS

Joe is a handsome, middle-age "virtual" office worker who is hardworking, rich, and an enthusiast of unusual hobbies. He wakes up every morning at 5 o'clock and goes to jog. He has three modes of jogging: keyframe animation,[1] physically based, and data driven (Fig. 1).

Joe hates his running motion generated by keyframe animation as it looks so unnatural; the animator was very lazy and used only four keyframes for this motion. All the dynamics are ignored and his body moves like a puppet controlled by a first grader. When he uses this mode, all the other pedestrians laugh at him.

The next mode is physically based.[2] In this mode, the motion of the body is simulated by forward dynamics (1–5).[3] At every frame, the torques are applied to the joints and the movements are computed. The problem is then how to compute the torque that results in a natural running motion. Joe uses a PD controller (6,7)[4] for that purpose. He thinks this mode is a bit better as his jogging motion satisfies the laws of dynamics. For example, while his body is moving in the air, his body is pulled down to the ground by the gravity, and he can feel the impact of the ground reaction force when the foot lands onto the ground. He saw the Hodgins family (Fig. 2) (8) jogging using this mode. He said "Hi" to them, but unfortunately it looked like they just ignored him and ran away. Actually, they tried to grin back but their necks were immediately pulled back to the original posture as the feedback gain was too strong. Joe liked to use this mode a few years ago, but he realized the PD controller did not work any more after he gained too much weight. PD control is very sensitive to the change of physical parameters such as mass and moment of inertia. One day, he went out to jog and fell to the ground immediately. He had to continue the locomotion miserably like a toy until a kind pedestrian helped him to switch off the PD controller.

[1] Keyframe animation is the most well known and fundamental technique to generate 3-D character animation. It can be used to generate scenes of rigid objects like boxes or balls rolling on the floor, airplanes flying in the air, or human characters moving around in the environment. The method is very simple and intuitive; several keyframe postures must be prepared, and then the system interpolates these postures by linear interpolation or polynomial curves such as B-splines (Fig. 1). The method is intuitive and simple, but whether the motion looks natural depends on the skills of the animator.

[2] Physically based animation is a common term for all sorts of animation techniques that are based on the laws of physics. Such techniques are used in almost all sorts of animation, which those of characters, trees, cloth, hair, and liquid.

[3] Forward dynamics is a term used commonly in robotics. When simulating the movements of a multibody system such as a robot or a human, the status of the system is represented by the generalized coordinates θ, which includes parameters such as the location \ orientation of the root and the joint angles of the rotational joints. Based on Newton's laws of dynamics, the motion equation of the system can be written as

$$\tau = M\ddot{\theta} + V + G \tag{1}$$

where τ is the externally added force \ torque to the body, M is the mass matrix, V is the Coriolis force, and G is the gravity force. By specifying the torque applied to the body, the acceleration of the generalized coordinates can be computed as follows:

$$\ddot{\theta} = M^{-1}(\tau - V - G) \tag{2}$$

By using $\ddot{\theta}$, the generalized coordinates and their velocities can be computed by integration. This computation, to calculate the movements of the system by giving the torque as the input, is called forward dynamics. Forward dynamics was considered as a heavy computation process in the old days (1), Only methods of $O(N^3)$ complexity existed, where N is the degrees of freedom of the system; however, nowadays, methods of $O(N)$ are available (2). The opposite procedure is called inverse dynamics, which is to compute the torque/force generated at the joints from the motion data. Inverse dynamics analysis is used in the sports and the manufacturing area to examine how much torque is required at each joint to achieve a given movement. It is also used in spacetime constraints when the objective function includes terms of joint torques (3–5).

[4] PD control was developed originally in robotics to control robot manipulators. It has been used in computer animation to control multibody systems such as humans. The equation of PD control can be written by

$$\tau = k(\theta_d - \theta) + d(\dot{\theta}_d - \dot{\theta}) \tag{3}$$

where τ is the torques to be made at the joints, $(\theta, \dot{\theta})$ are the generalized coordinates the body and their derivatives, $(\theta_d - \dot{\theta}_d)$ are their desired values at the keyframes, and k, d are constants each called elasticity and viscosity, respectively. It is possible to say that in this mode the body is pulled toward the keyframes by the elastic and the damping forces. The larger the deviation from the desired motion is, the larger the torques exerted to the joints will be. The acceleration $\ddot{\theta}$ will be computed based on Newton's laws of dynamics, and the velocity and the generalized coordinates of the body is finally updated.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

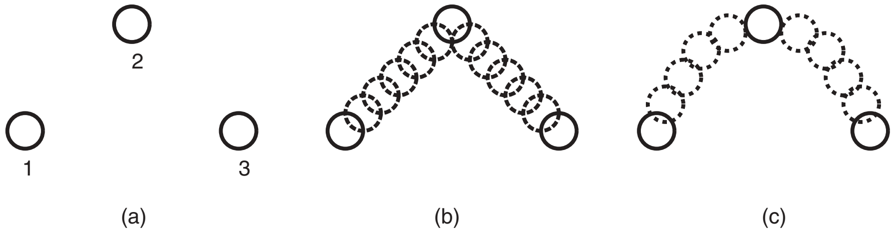

Figure 1. The trajectory of a ball flying generated from three keyframes shown in (a), by using (b) linear interpolation and (c) cubic interpolation.

Now, he simply uses the **motion capture**[5] data to control himself. The data are captured by an optical motion capture system that is mostly used today. As they are real human motion, they look realistic and natural. As several techniques to edit the motion have been developed, such as inverse kinematics[6] or spacetime constraints (9–13)[7], the same jogging motion can be used for different situations such as zigzag running or running up hills (Fig. 3).

Figure 2. The Hodgins family [Hodgins and Pollard (8)].

[5] Motion capture system is a device to digitize the 3-D trajectory of the human motion. Three different types of motion capture systems exist in the market: optical, magnetic, and mechanical. Currently, the optical system has the highest share for its high precision, robustness, and large capturing volume.

[6] Inverse Kinematics is a term originally used for a problem to compute the generalized coordinates of the system from the 3-D position of its segments/end effectors. In computer animation, it is a term for a technique to edit the posture of a virtual character by changing the location of the body segments by dragging it with a mouse. The animator can drag any position of the character in the scene, and then the generalized coordinates of the body are updated in a way that the body follows the movement of the mouse cursor naturally (Fig. 3). Inverse kinematics is a problem that makes use of the redundant degrees of freedom (DOF) of the system. The DOF of the human body is much larger than the DOF of instructions by the user, which is two/three in case the user controls the segment by a mouse. Several methods exist: cyclic coordinate descent method, pseudo inverse method, and analytical methods. The opposite word is forward kinematics, which means to calculate the 3-D position/orientation of the end effectors from the generalized coordinates.

[7] Spacetime constraints (9) is a method to calculate the trajectory of the body by optimizing an objective function while satisfying constraints specified by the user. The problem can be written in the following form:

$$\min_{\theta} J = \int f(\theta)dt - s.t. \tag{4}$$

$$C_1(\theta) = 0 \tag{5}$$

$$C_2(\theta) \leq 0 \tag{6}$$

where J is the objective function, θ are the trajectories of the generalized coordinates of the body, and C_1 and C_2 are the equality and inequality constraints, respectively. For example, it is possible to generate a natural-looking jumping motion by minimizing the following function during jumping (10,11)

$$\min_{\theta} J = \int_{t_0}^{t_f} (m(t) - M_0)^2 dt \tag{7}$$

where $m(t)$ is the linear and angular momentum of the body at the moment of jump, (t_o, t_f) are the time the jumping starts and ends, and M_o is the linear and angular momentum of the body at time t_o. Spacetime constraints have also been used for motion editing and for retargeting the captured motion to a character with different body size (12,13). This technique can be performed by solving the following optimization problem

$$\min_{\theta} J = \int_{t_0}^{t_f} (\theta(t) - \theta_0(t))^2 dt. \tag{8}$$

where $\theta_0(t)$ is the original motion data. In this case, the idea is to keep the whole motion as similar as possible to the original motion.

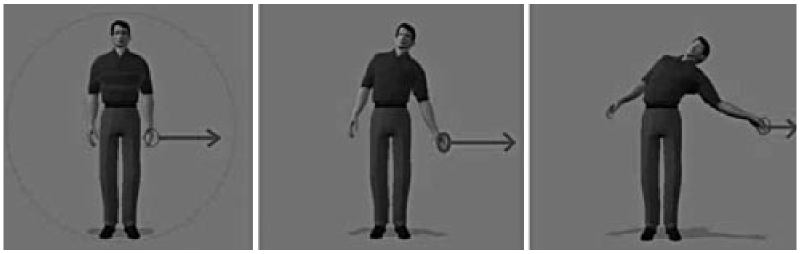

Figure 3. Changing the posture of a human figure by using inverse kinematics. The user specifies the motion of the hand, and the system calculates the joint angles of the body automatically.

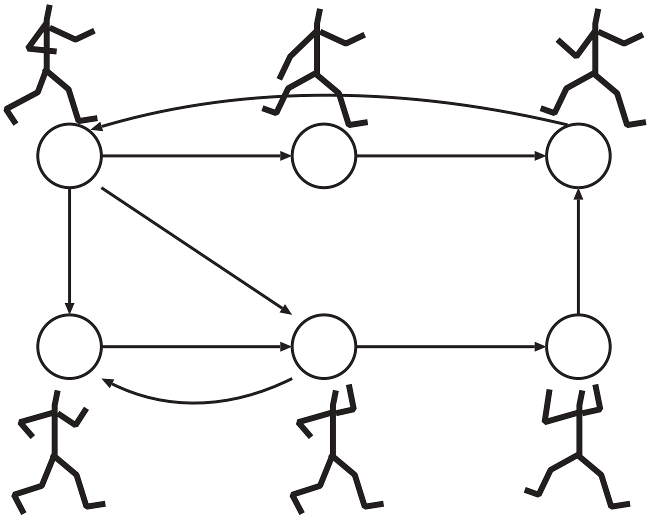

Figure 4. MotionGraph.

Recently, several real-time statistical approaches[8] have been proposed that can produce motions by interpolating various captured motions (14,15). These methods are more reliable than simple editing techniques, although they require many samples. Joe now uses such a statistical approach and feels much more comfortable because he does not face any problems as before. He can run up the stairs and change his stride smoothly to avoid stepping onto chewed gum or dog's stool. For switching from one motion to another, such as from running to walking, he uses the MotionGraph (16–18) (Fig. 4) [9]. Joe came back from jogging, took off his wet clothes, and stood in front of the mirror. He was satisfied to glare at his thick muscular body slightly sweating [Fig. 5(a)]. He bent his elbow and his bicep muscle pumped up under the skin (19) [Fig. 5(b)]. The muscle is modeled in a way that the volume is kept constant, and therefore, when it is shortened, the cross-sectional area increases (20). The body is composed of bones, muscles, the fat layer, and the skin. Collisions between the tissues are always monitored. When the muscles contract, they will deform in a way such that they do not penetrate the bones. The fat layer moves over the surface of the muscles, and finally the skin covers the whole body. His body is modeled by the musculoskeletal system generated from the Visible Human Dataset (21). Analytic models (21–28)[10] are effective

[8] Statistical approaches first search the motions in the motion database that are similar to the required motion and interpolate these motions to obtain the desired motion. For example in Refs. 14 and 15, reaching motion to arbitrary positions were generated by mixing several appropriate sample reaching motions.

[9] MotionGraph is a technique to control the avatar interactively using the captured motion data. In the MotionGraph, each posture is considered as the node of a graph, and in case the posture and the velocity of the body at the nodes are similar, they are connected by an edge (Fig. 4). As far as the avatar moves along the edges of the MotionGraph, smooth transition can be expected.

[10] Anatomic models are used to model realistic humans. Surface/volumetric data of the muscles, bones, fat, and skin from the visible human dataset (21) or from high resolution CT images are used to model the anatomic structure of the body. They have been used to model the facial expressions (19,22–24) and the surface of the body (19,20,25). The muscles deform according to the control signals. The muscles can also be used to simulate realistic kinematic movements (26–28).

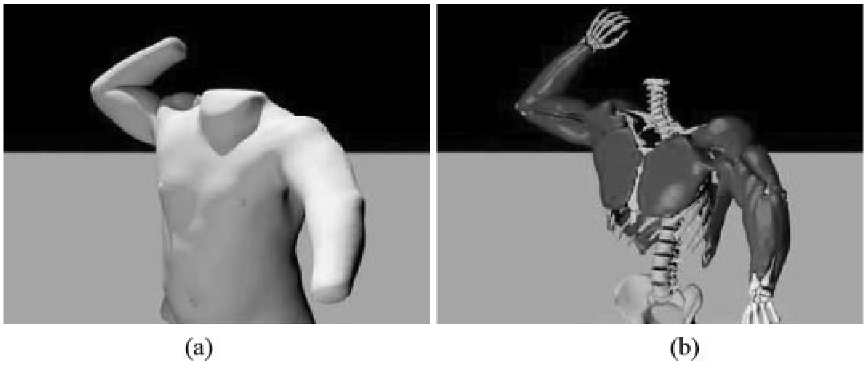

Figure 5. Joe's skin and his muscles modeled under his skin (19).

to model not only the body (19,20,25) but also the face (23,24) (Fig. 6). Using the analytic models, it is possible to generate wrinkles on the forehead and dimples at the cheeks.

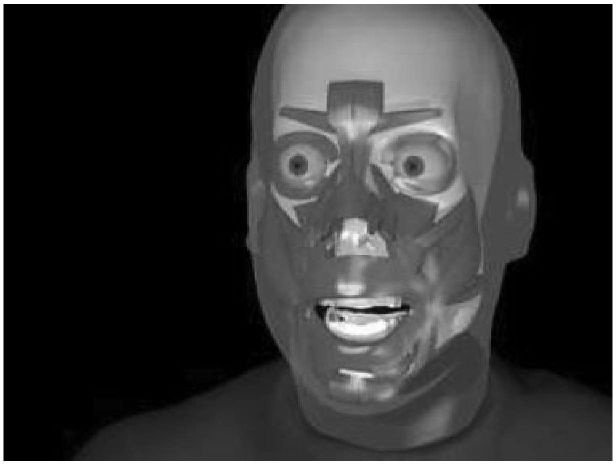

Figure 6. Joe's muscles under his face (24).

PHYSICALLY-BASED ANIMATION (RIGID BODIES, FLUIDS, HAIR, CLOTHES ETC.)

Before he took a shower, he went into the kitchen, poured a glass of water, and drank it (Fig. 7) (29). Thanks to the progress in fluid simulation(29,30),[11] he can enjoy drinking pure water instead of thick, high-viscosity drinks such as protein milk or porridge, or drinks like powder that are modeled by particles (Fig. 8).[12] He once sufferred from constipation and hemorrhoids as he was only drinking protein milk every day.

After drinking water, he went to take a shower. The splashing water coming out from the shower is modeled by the particle system. Of course, rendering a scene of taking a bath is not a difficult task anymore, but there is no point using the computer resources to calcualte the complex fluid dynamics for a bathing scene of a middle age man like Joe. After the shower, he shaved his face quickly and blowdried

[11] Fluid simulation is used to simulate flows of liquid and smoke. u, which is the velocity vector field of the flow, is updated by solving the Navier-Stokes equation:

$$\frac{\partial u}{\partial t} = -(u \cdot \nabla)u - \frac{1}{\rho}p + v\nabla^2 u + F \tag{9}$$

together with the equation of mass conservation:

$$\nabla \cdot u = 0 \tag{10}$$

where ρ is the fluid density, v is the kinematic viscosity, F is the external force, and p is the pressure of the liquid. By solving Equations (9) and (10) together, the velocity field u and pressure p is updated at each time step. Usually, the space is split into Cartesian grids, and the above equations are solved for all the grids at their centers. For simulation of smoke, particles are put into the grids, and their motions are computed using the velocity vector field by Euler integration. For simulation of liquid, it is necessary to track and to visualize the boundary between the liquid and the air. The level set method (30) is used to perform liquid simulation. An implicity function ϕ that returns a negative value inside the liquid and a positive outside of it is first defined. ϕ can be updated using the vector field by solving the following equation:

$$\frac{\partial \phi}{\partial t} + u \cdot \nabla\phi = 0 \tag{11}$$

The new boundary can be calculated by tracking $\phi = 0$. Because rendering of liquid requires the visualization of the boundary and the splashes, particles can be used together with the level set method to increase the visual reality (29).

[12] The particle system is very convenient as it can model various natural phenomenon such as smoke and splashing water. The motion of every particle is modeled by simple mass point dynamics:

$$ma(t) = F \tag{12}$$

$$v(t + \Delta t) = v(t) + a(t)\Delta t \tag{13}$$

$$x(t + \Delta t) = x(t) + v(t)\Delta t \tag{14}$$

where m is the mass of the particle, x, v, a are the position, velocity, and acceleration of the particle, respectively, Δt is the sample time, and F is the external force. The problem of particle systems is that the fluid gets split easily into smaller pieces and as a result, it looks like a collection of particles (as it actually is) instead of fluids.

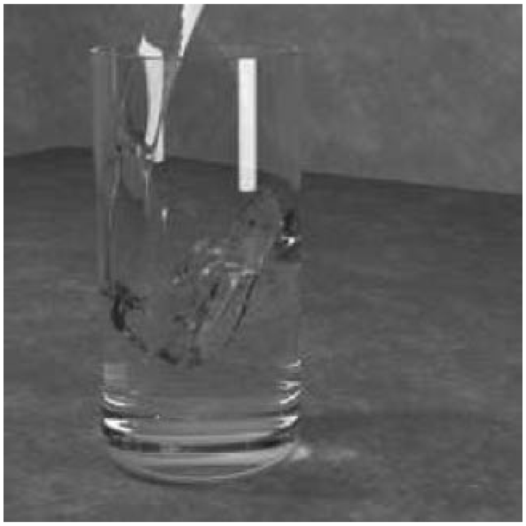

Figure 7. Pouring water in to the glass (29).

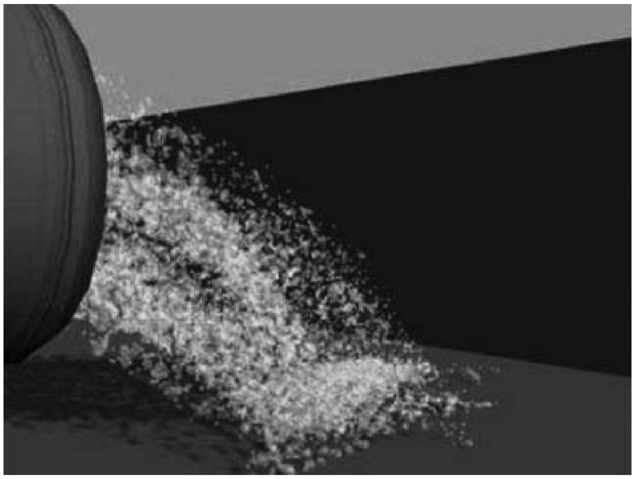

Figure 8. This is what he was drinking previously.

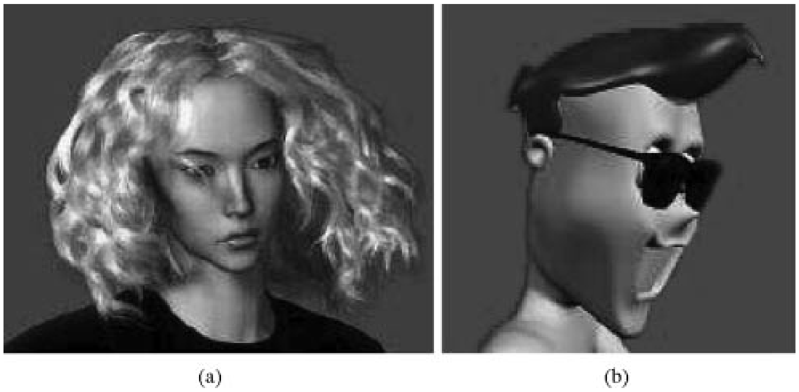

Figure 9. (a) Joe's hair blown in the wind (31). (b) His hair was like this until a few years ago.

his hair (31)[13] [Fig. 9(a)]. Watching his hair being blown dry naturally by the wind, he remembered the old days when he could only have either a skin head (so that no computation is needed for his hair) or a rigid body hair cap composed of polygons [Fig. 9(b)]. Now, he does not have to feel miserable anymore as computers are fast enough to simulate hair by physical animation.

Then, he went to the kitchen to eat breakfast. His breakfast is always cereal, and he pours the Cheelios from the box into his bowl (32) (Fig. 10). The movements of each Cheerio poured into the bowl as they collide[14] with each other was

[13] To simulate the motion of hair in a realistic manner, it is necessary to use physically based methods. The heavy computation cost is caused by the collision detection, and physical simulation of the great number of particles/rigid bodies composing the hair. Choe et al. (31) combined impulse-based simulations and the implicit integrators to compute the motion of hair efficiently.

[14] Collision detection is one of the main problems to solve when doing physical simulation. It is important not only for simulation of rigid bodies, but also for simulation of deformable objects such as cloth. It is necessary to detect when the bodies are colliding, and then add impulses/forces to the objects that are involved in the collision. Usually, rough estimation is done first by checking the collision of the bounding boxes of the objects first. The bounding box is a rectangular box that surrounds the object. Once the collisions between the bounding boxes are found, a precise collision detection based on the shapes of the objects is conducted.

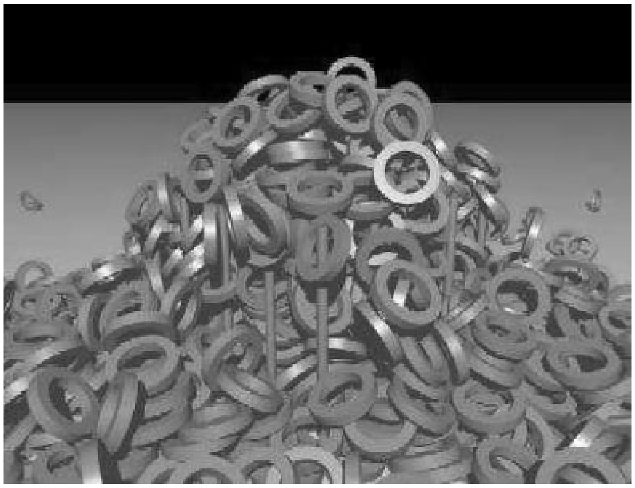

Figure 10. Joe eats Cherrios for breakfast (32).

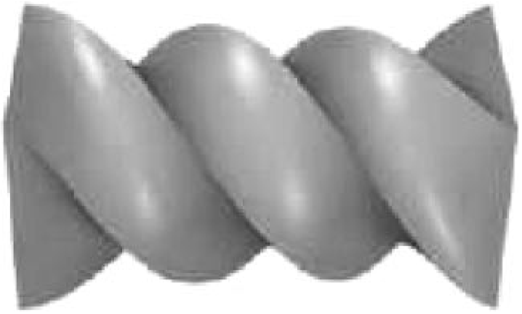

Figure 11. Using the Laplacian coordinates, a rectangular shape tube can be squeezed as shown above without any problem (35).

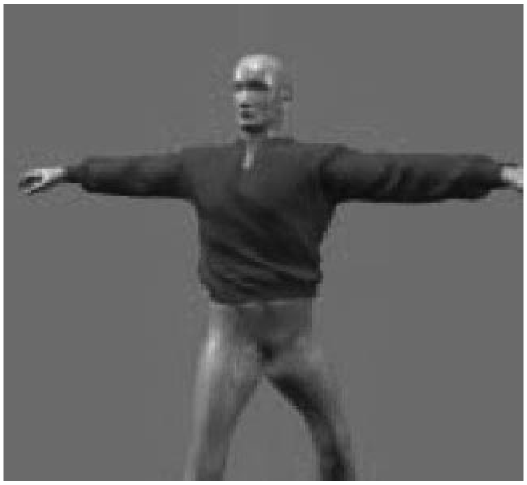

Figure 12. This is the shirt Joe loves most (38).

simulated by rigid body simulation (33,34)[15] After breakfast, Joe tried to brush his teeth. He squeezed the tube of toothpaste. But unfortunately, it was empty. Because Joe is a stingy guy, he tried to squeeze out the last bit of the toothpaste (Fig. 11) (35). The scene of the poor tube squeezed over and over (Fig. 11) was generated by using Laplacian coordinates (36,37)[16], which works robustly for drastic deformtion of 3-D three-dimensional objects.

Joe first wore his UNIQLO shirt, and spread out his hands to see whether it fit him well (38) (Fig. 12). After finding out it is OK, he wore his underwear, shirt, and suit. These clothes are all modeled by particles aligned in

[15] The main difficulty for simulating many rigid bodies in the scene is how to detect their collisions and to compute the impulses. Classic methods to simulate the collisions by Poisson's law, which is to apply elastic force proportional to the amount of penetration of objects, is unstable, and the decision of elastic parameters must be done carefully. An impulse-based simulation (33) is a popular method to simulate rigid bodies colliding. Instead of computing the forces between the objects, it computes the impulses added to the colliding bodies based on the velocity of the colliding points. Static contacts can also be simulated by a concept called micro-collisions.

Another popular method to simulate rigid bodies is developed by Jakobsen (34), which is based on particle systems. Rigid bodies are modeled by several particles that are connected by edges of fixed length. Collisions of objects are simulated simply by pushing the penetrating vertex back onto the nearest surface on the other object. In this method, the position of particles are updated by Verlet Integration, which makes the system work more stably.

[16] Laplacian coordinates enable large deformation of complex detailed meshes while keeping the shape of the details in their natural orientation. Let us define the position of the vertices in the original surface by v_i and the corresponding vertices in the deformed surface by v_i'. The Laplacian coordinate of vertex i is defined by the following equation:

$$\delta_i = v_i - \frac{1}{d_i}\sum_{j\in N_i} v_j \tag{15}$$

where N_i is the set of vertices that surrounds vertex i and d_i is the number of elements in N_i. Suppose we want to specify the location of some of the vertices in the deformed surface as

$$v_i' = u_i, i \in \{m, \ldots, n\}, m < n \tag{16}$$

and solve for the remaining vertices $\{v_i'\}, i \in \{1, \ldots, m-1\}$. In Ref. 36, this problem is solved by minimizing the difference of the Laplacian coordinates before and after the deformation:

$$\min_{\{v_i'\}, i\in\{1,\ldots,m-1\}} \sum_{i=1}^{n} \|\delta_i - \delta_i'\|^2 + \sum_{i=m}^{n} \|v_i' - u_i\|^2 \tag{17}$$

which can be solved by quadratic programming. Other additional constraints, such as keeping the volume constant (35), can be added when solving this problem.

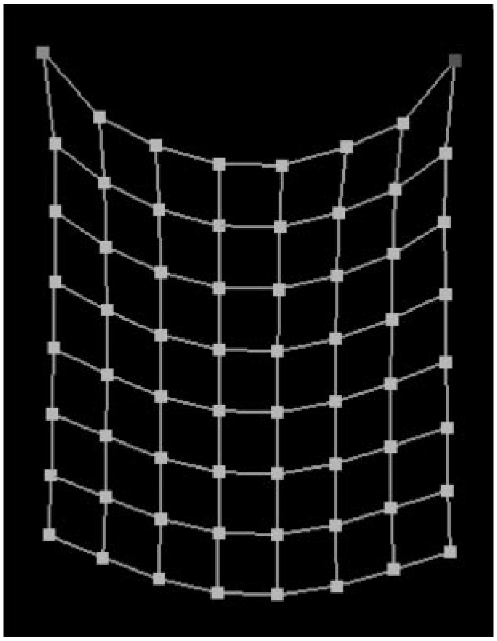

Figure 13. Cloth is modeled by particles and springs/dampers that connects them.

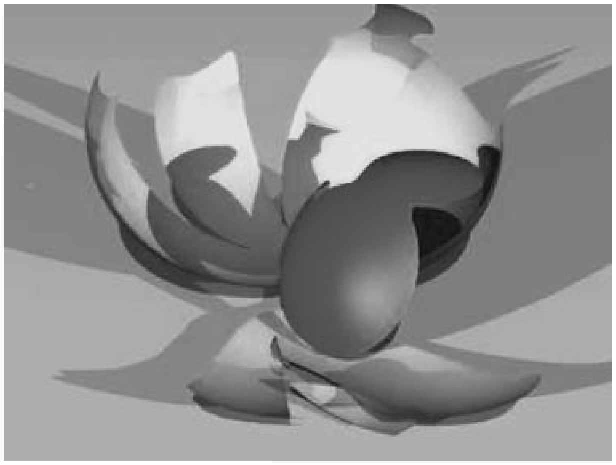

Figure 14. The ring cracked into pieces, which is definitely a bad sign (40).

grid that are connected to the adjacent particles with springs dampers (Fig. 13). The implicit integrator (38)[17] enables stable and quick simulation of clothes. Before going to work, he stood in front of the family altar, hit the ring by the stick, and prayed for his ancestors. He learned this custom when he traveled to Japan. When he hit the ring, the ring cracked (39)[18] into pieces and fell down onto the ground (Fig. 14) (40). It was a sign of bad luck.

[17] Implicit integraton enables simulation systems to take larger steps to update the position and the velocity of the particles. In the traditional explicit forward Euler method, the integration is done in the following way:

$$\begin{pmatrix}\Delta x\\ \Delta v\end{pmatrix} = h\begin{pmatrix} v_0 \\ M^{-1} f_0\end{pmatrix} \tag{18}$$

where x, v are the positions and velocities of the particles, the force f_0 is defined by $f(x_0, v_0)$, M^{-1} is the mass matrix, and h is the time step. The step size h must be selected small enough otherwise, the system could be blowed off. To avoid this error in the implicit integration method, instead of Equation (18), the following equation is solved:

$$\begin{pmatrix}\Delta x\\ \Delta v\end{pmatrix} = h\begin{pmatrix} v_0+\Delta v \\ M^{-1} f(x_0+\Delta x_0, v_0+\Delta v)\end{pmatrix} \tag{19}$$

In the forward method, we only have to calculate f_0 and integrate forward, but in the implicity backward method, we have to calculate Δx, Δv that satisfies Equation (19). This method can be performed by first expanding the Taylor series $f(x_0+\Delta x_0, v_0+\Delta v)$ at x_0,v_0 as

$$f(x_0+\Delta x_0, v_0+\Delta v) = f_0 + \frac{\partial f}{\partial x}\Delta x + \frac{\partial f}{\partial v}\Delta v \tag{20}$$

By substituting this equation into Equation (19), we get

$$\begin{pmatrix}\Delta x\\ \Delta v\end{pmatrix} = h\begin{pmatrix} v_0+\Delta v \\ M^{-1} f_0 + \frac{\partial f}{\partial x}\Delta x + \frac{\partial f}{\partial v}\Delta v\end{pmatrix} \tag{21}$$

By substituting $\Delta x = h(v_0 + \Delta v)$ into the bottom of Equation (21), we can get

$$\Delta v = hM^{-1}\left(f_0 + \frac{\partial f}{\partial x} h(v_0+\Delta v) + \frac{\partial f}{\partial v}\Delta v\right) \tag{22}$$

and solve for Δv. Then, Δx can be calculated by $h(v + v_0)$. The backward implicity method is more stable than the foward explicit method as the motion of the particles are calculated not only based on the status at $t = t_0$, but checking whether you can go back to the original position from the updated position using the derivative values at $t = t_0 + \Delta t$. As a result, the system can update the status with fixed large time steps.

[18] Simulation of objects being **cracked** and **broken** is required for many scenes in games and movies. O'Brien and Hodgins (39) simulated objects being broken by calculating where the destruction should start and how it should propagate all over the object.

Figure 15. Another bad sign in the morning.

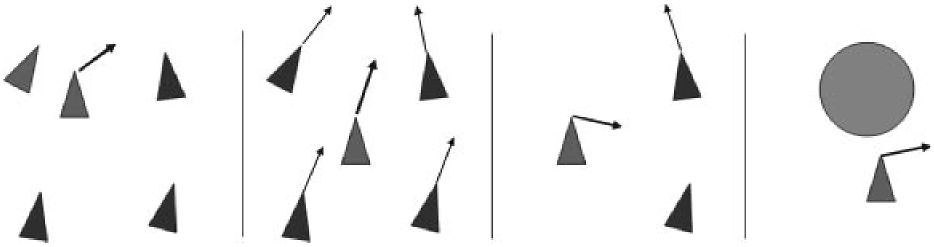

Figure 16. Forces applied to the individual flocking object: (from left to right) separation, alignment, cohesion and avoidance.

FLOCKING, CROWD, 2-D ANIMATION, REACTIVE MOTION

He went out his house and walked toward the subway station. He saw crows flocking (41)[19] in the sky while he was leaving his house (Figs. 15 and 16). At that time, the subway station was very crowded[20] and thousands of people were walking in and out (42) (Fig. 17). A long queue was at the platform waiting for the arrival of the train. Every morning, he witnesses the chaotic scene of the queue of people rushing into the train and getting pushed out by the passengers trying to get off. Joe was selecting the motion carefully to proceed most effectively without colliding with the other passengers (43) (Fig. 18). His strategy was based on reinforcement learning (43–46)[21] Joe rushed so harshly and something unexpected happened; accidentally he pushed the breast of a young lady with his arm (Fig. 19).

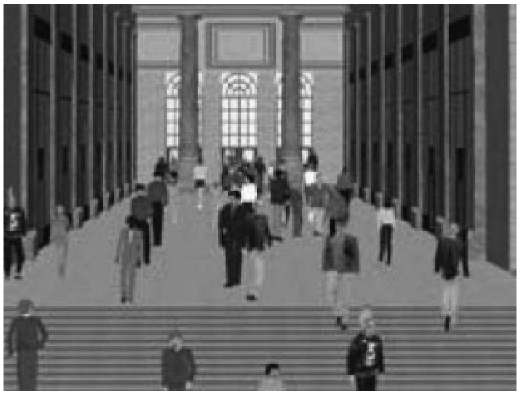

Figure 17. Here is where the battle starts in the morning .

[19] Flocking (41) is a physically based animation technique used to simulate scenes of birds flocking or fishes schooling. Each module that represents the individual is considered as a particle, and it is controlled not only by the self-driving force which is determined by the destination/direction it wants to proceed, but also by the following four external forces (Fig. 16):

1. Separation force works as potential fields that push away the individuals to avoid collision with the others.
2. Alignment force makes the individual proceed towards the same direction as the other flock-mates.
3. Cohesion force makes the individual move to the average position of local flock-mates. It spaces everyone out evenly, and applies a boundary to contain the members.
4. Avoidance keeps the flocks from running into buildings, rocks, or any other external objects in the environment.

[20] The topic to simulate thousands of characters moving around in the scene is called crowd simulation. Most crowd simulation techniques are agent based, which means that each character is self-motivated and decides his/her motion based on the objective, the destination, and the distance with the other characters. The agent-based method originates from flocking. Because humans are much more self-motivated than birds or fishes, various other techniques are combined with flocking to make the scene look realistic.

[21] Reinforcement learning is an approach to achieve real-time optimal control. It is related closely to dynamic programming in the sense that it determines the optimal motion using only the information at each state. More specifically, at each time step i, suppose the avatar selects an action and gets a reward defined by r_i. The optimal policyp π offers an action at every state that maximizes the following return value:

$$R = \sum_i \gamma^i r_i \tag{23}$$

where $0 \leq \gamma \leq 1$. The term γ^i is added because more uncertainty exists in the future. It has been used to help pedestrians avoid other obstacles/avatars walking in the streets (43,44), to control a boxer to approach and hit the target (45), and to train a computer-controlled fighter in computer games (46).

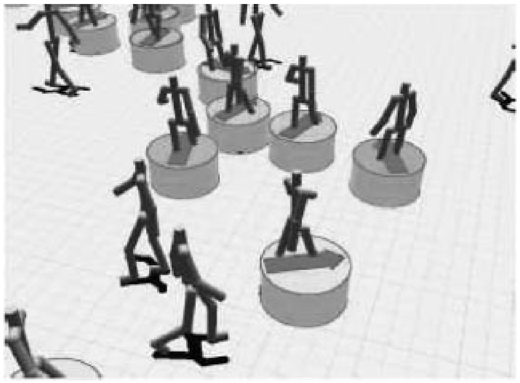

Figure 18. Joe can select the near-optimal movements that makes him proceed towards the train while avoiding the other passengers (43).

His elbow deformed[22] the soft breast of the lady. Joe was happy for awhile, but at the next moment, he was pulled out from the train by this lady, and they started to argue. Soon, the woman realized that Joe was actually a muscular man. This woman was also an enthusiast of unusual hobbies and surprisingly, started to get attracted to Joe! Joe felt so lucky that he forgot about all the bad signs in the morning. He started to talk about his hobbies, such as jogging, muscle training, and cartoon animations. Then the woman replied, “Cartoon animations!? Great, I am actually an Otaku![23] Hey, why don’t you come to my home and watch some Manga songs now?” “Absolutely!!” Joe agreed, and Joe called his boss to tell them that he was sick and he would not be coming into work that day. The woman’s name was Joie, which was the same name as the girl Joe liked in junior high. After arriving to Joie’s home, they sat on the sofa in front of the computer, and visited the YouTube website to watch the theme songs of the cartoon animations. The TV songs of the 2-D cell animations (47,48)[24] that he watched in the 1980s calms his mind, especially when he is feeling harassed like this morning (Fig. 20).

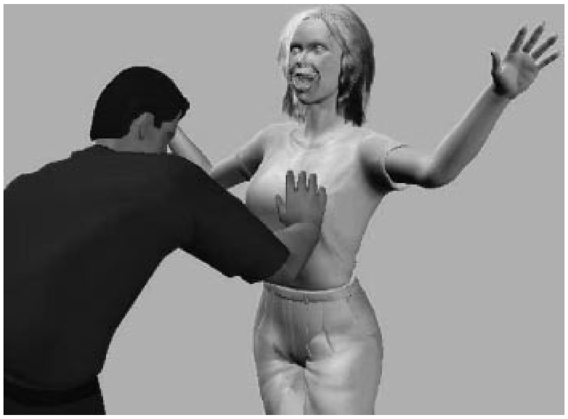

Figure 19. The breast is deformed by Laplacian coordinates with constraints of constant volume.

After watching “Maicching Machiko Sensei,” which is an animation that is not suitable for kids but acceptable for adults like Joe and Joei, they stared at each other in a good mood. Unfortunately, an even more muscular guy, who looks like the Hulk,[25] opened the door and came into the room. Joei had a lot of muscular boyfriends and unfortunately, one of her boyfriends stepped into her room at the worst time. Seeing Joe and Joei together made this boyfriend not only appear physically like the Hulk, but also act mentally like the Hulk.

The boyfriend started to destroy everything in the room and rushed to Joe. Joe was not confident to fight well, but as he was just watching some cartoon songs of the transforming robot “Daitarn 3,” he was brave enough to fight back. Joe could predict the attacks available by the boyfriend as his movements were so similar to the Hulk, and Joe was so fond of the Hulk that he had watched it many times. Joe expanded the game tree (49)[26] (Fig. 21), and he discovered that whatever motion he selects, he is going to be knocked to the ground in the end. Therefore, he selected the motion

[22] Objects such as soft tissues are called deformable objects. Techniques to handle deformable objects are required to generate animations not only for the surface of human skin but also for tissues inside the body for simulation of surgical operations and nonrigid objects like jelly or plastic objects.

[23] Otaku are people who are obsessed with cartoons, hero stories, animation figures, toys, and games. It is a Japanese term that had a negative meaning originally; it meant implicitly the people who are not good at communicating with other people, and watch cartoons and hero stories obsessively on TV. However, when the word spread internationally, thanks to the popular Japanese cartoon/hero story culture, it was taken as a positive word. It means the group of people who enjoy such hobbies. Many Otaku people are in the world now, who discuss the details and the side stories of animations and who wear the costumes of the heroes in the stories.

[24] 2-D cell animation is the traditional animation created by drawing pictures on transparent sheets called cell. Today, the costs of creating 2-D animation have been reduced significantly because of the use of computers. In the old days, all animations were drawn by the animators who required a huge amount of time and labor cost. Nowadays, computers reduce such manual labor not only through computer-based editing of 2-D cell pictures, but also by using 3-D computer animation to generate 2-D cell animation. Techniques for rendering 3-D models in 2-D cell animation style are called toon rendering (Fig. 20). In such case, nonphotorealistic rendering techniques are used to color the polygons. Techniques to render video captured movie data in 2-D cell animation style have also been developed (47). A poisson filter can be used to add cartoon taste to captured motion data (48). In TV animations such as “SD Gundam Force,” “The World of Golden Eggs,” and “Zoids” toon rendering is used for production. In games such as “Dragon Ball Z: Sagas”, “DragonQuest VIII”, and “Metal Gear AC!D2”, toon rendering is used for real-time rendering.

[25] The Hulk is a cartoon written by writer Stan Lee, penciller Jack Kirby, and inker Paul Reinman. It was first published in Marvel Comics in 1962. The hero, Dr. Robert Bruce Banner, tranforms into the Hulk when his tension reaches some threshold. The Hulk, who is enormously muscular and has green skin, is very destructive, attacks his enemies, and destroys the buildings and infrastructures of the town. It was remade recently into a Hollywood movie using new techniques of computer graphics in 2003.

[26] Game tree is used for strategy making of computer-based players of games such as tic-tac-toe, chess and go. Every node represents the ply of one of the players, and the out-going edge represents the available move at each ply. Recently, Shum et al. (49) proposed a method to apply it to simulate competitive interactions such as boxing and chasing.

that would minimize his damage, which was to receive an upper cut at the chin (50) (Fig. 22). Thanks to the momentum-based inverse kinematics, he could keep his balance by stepping backward (50,51).[27] But Joe was certainly not powerful enough to cope with the crazy boyfriend anymore. The second attack was a somersault kick; the sound of the kick passing through the air and smashing Joe's face was sound rendered (52,53)[28] by the method proposed by Dobashi et al. (53). The boyfriend's leg smashed Joe's nose and he fell to the ground like a ragdoll[29]. The motion to fall down onto the ground was simulated by Zordan's

[27] A great demand exists for scenes where people are pushed away or knocked to the ground in movies and games because recreating such dangerous scenes is difficult. Ragdoll physics are often used when the character falls to the ground. If the avatar is just supposed to take a few steps backward and start a new motion, then techniques that take advantage of motion capture data are also available (50,51).

[28] Sound rendering techinques are used to increase the sense of immersion by generating sound synchronized with the animation. In the original sound rendering paper (52), the sound was prerecorded; however, in Ref. 53, the sound was simulated fluid dynamics.

[29] Ragdoll physics is the simulation of a multibody system without actively torque or force applying at the joints. The body will just fall down like a doll in that case, but it is enough to simulate a dead body.

CONCURRENT PROGRAMMING

INTRODUCTION

Concurrent programming refers to the development of programs that address the parallel execution of several tasks. A *process* or *task* represents the execution of a sequential program or a sequential component in a concurrent program. Each task deals with one sequential thread of execution; thus, no concurrency is allowed within a task. However, overall system concurrency is obtained by having multiple tasks executing in parallel. The tasks often execute asynchronously (i.e., at different speeds) and are relatively independent of each other for significant periods of time. From time to time, the tasks need to communicate and synchronize their operations with each other. Concurrent programming has been applied extensively in the development of operating systems, database systems, real-time systems, interactive systems, and distributed systems.

HEAVYWEIGHT AND LIGHTWEIGHT PROCESSES

The term "process" is used in operating systems as a unit of resource allocation for the processor (CPU) and memory. The traditional operating system process has a single thread of control and thus has no internal concurrency. Some modern operating systems allow a process, referred to as a *heavyweight process*, to have multiple *threads* of control, thereby allowing internal concurrency within a process. The heavyweight process has its own memory. Each thread of control, also referred to as a *lightweight process,* shares the same memory with the heavyweight process. Thus, the multiple threads of a heavyweight process can access shared data in the process's memory, although this access must be synchronized.

The terms "heavyweight" and "lightweight" refer to the context switching overhead. When the operating system switches from one heavyweight process to another, the context switching overhead is relatively high, requiring CPU and memory allocation. With the lightweight process, context switching overhead is low, involving only CPU allocation.

The terminology varies considerably in different operating systems, although the most common is to refer to the heavyweight process as a process (or task) and the lightweight process as a thread. For example, the Java virtual machine usually executes as an operating system process supporting multiple threads of control (1). However, some operating systems do not recognize that a heavyweight process actually has internal threads and only schedule the heavyweight process to the CPU. The process then has to do its own internal thread scheduling.

A *process*, which is also known as a *task*, refers to a dynamic entity that executes on a processor and has its own thread of control, whether it is a single-threaded heavyweight process or a thread within a heavyweight process (2). The task corresponds to a thread within a heavyweight process (i.e., one that executes within a process) or to a single-threaded heavyweight process. Many issues concerning task interaction apply regardless of whether the threads are in the same heavyweight process or in different heavyweight processes.

COOPERATION BETWEEN CONCURRENT TASKS

In the design of concurrent systems, several problems need to be considered that do not arise when designing sequential systems. In most concurrent applications, it is necessary for concurrent tasks to cooperate with each other to perform the services required by the application. The following three problems commonly arise when tasks cooperate with each other:

1. **The mutual exclusion problem**. This problem occurs when tasks need to have exclusive access to a resource, such as shared data or a physical device. A variation on this problem, where the mutual exclusion constraint can be relaxed in certain situations, is the multiple readers and writers problem.
2. **Task synchronization problem**. Two tasks need to synchronize their operations with each other.
3. **The producer/consumer problem**. This problem occurs when tasks need to communicate with each other to pass data from one task to another. Communication between tasks is often referred to as interprocess communication (IPC).

These problems and their solutions are described next.

MUTUAL EXCLUSION PROBLEM

Mutual exclusion arises when it is necessary for a shared resource to be accessed by only one task at a time. With concurrent systems, more than one task might simultaneously wish to access the same resource. Consider the following situations:

- If two or more tasks are allowed to write to a printer simultaneously, output from the tasks will be randomly interleaved and a garbled report will be produced.
- If two or more tasks are allowed to write to a data repository simultaneously, inconsistent and/or incorrect data will be written to the data repository.

To solve this problem, it is necessary to provide a synchronization mechanism to ensure that access to a critical resource by concurrent tasks is mutually exclusive. A task must first acquire the resource, that is, get permission to access the resource, use the resource, and then release the

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

resource. When task A releases the resource, another task B may now acquire the resource. If the resource is in use by A when task B wishes to acquire it, B must wait until A releases the resource.

The classic solution to the mutual exclusion problem was first proposed by Dijkstra (3) using binary semaphores. A binary semaphore is a Boolean variable that is accessed only by means of two atomic (i.e., indivisible) operations, *acquire* (*semaphore)* and *release* (*semaphore*). Dijkstra originally called these the P (for acquire) and V (for release) operations.

The indivisible acquire (semaphore) operation is executed by a task when it wishes to acquire a resource. The semaphore is initially set to 1, meaning that the resource is free. As a result of executing the acquire operation, the semaphore is decremented by 1 to 0 and the task is allocated the resource. If the semaphore is already set to 0 when the acquire operation is executed by task A, this means that another task, say B, already has the resource. In this case, task A is suspended until task B releases the resource by executing a release (semaphore) operation. As a result, task A is allocated the resource. It should be noted that the task executing the acquire operation is suspended only if the resource has already been acquired by another task. The code executed by a task while it has access to the mutually exclusive resource is referred to as the *critical section* or *critical region*.

EXAMPLE OF MUTUAL EXCLUSION

An example of mutual exclusion is a shared sensor data repository, which contains the current values of several sensors. Some tasks read from the data repository to process or display the sensor values, and other tasks poll the external environment and update the data repository with the latest values of the sensors. To ensure mutual exclusion in the sensor data repository example, a `sensor Data Repository Semaphore` is used. Each task must execute an *acquire* operation before it starts accessing the data repository and execute a *release* operation after it has finished accessing the data repository. The pseudocode for acquiring the sensor Data Repository Semaphore to enter the critical section and releasing the semaphore is as follows:

```
acquire (sensorDataRepositorySemaphore)
Access sensor data repository[This is the critical
section.]
release (sensorDataRepositorySemaphore)
```

The solution assumes that, during initialization, the initial values of the sensors are stored before any reading takes place.

In some concurrent applications, it might be too restrictive to only allow mutually exclusive access to a shared resource. Thus, in the sensor data repository example just described, it is essential for a writer task to have mutually exclusive access to the data repository. However, it is permissible to have more than one reader task concurrently reading from the data repository, provided there is no writer task writing to the data repository at the same time. This is referred to as the multiple readers and writers problem (2,4,5) and may be solved by using semaphores.

TASK SYNCHRONIZATION PROBLEM

Event synchronization is used when two tasks need to synchronize their operations without communicating data between the tasks. The source task executes a *signal (event)* operation, which signals that an event has taken place. Event synchronization is asynchronous.

The destination task executes a *wait (event)* operation, which suspends the task until the source task has signaled the event. If the event has already been signaled, the destination task is not suspended.

EXAMPLE OF TASK SYNCHRONIZATION

Consider an example of event synchronization from concurrent robot systems. Each robot system is designed as a concurrent task and controls a moving robot arm. A pick-and-place robot brings a part to the work location so that a drilling robot can drill four holes in the part. On completion of the drilling operation, the pick-and-place robot moves the part away.

Several synchronization problems need to be solved. First, there is a collision zone where the pick-and-place and drilling robot arms could potentially collide. Second, the pick-and-place robot must deposit the part before the drilling robot can start drilling the holes. Third, the drilling robot must finish drilling before the pick-and-place robot can remove the part. The solution is to use event synchronization, as described next.

The pick-and-place robot moves the part to the work location, moves out of the collision zone, and then signals the event `part Ready`. This awakens the drilling robot, which moves to the work location and drills the holes. After completing the drilling operation, it moves out of the collision zone and then signals a second event, `part Completed`, which the pick-and-place robot is waiting to receive. After being awakened, the pick-and-place robot removes the part. Each robot task executes a loop, because the robots repetitively perform their operations. The solution is described below and depicted using the Unified Modeling Language notation (6,7) in Fig. 1. Each robot task is depicted by a box with a thick outline. The event signals are shown as arrows.

```
pick & Place Robot:
while workAvailable do
    Pick up part
    Move part to work location
```

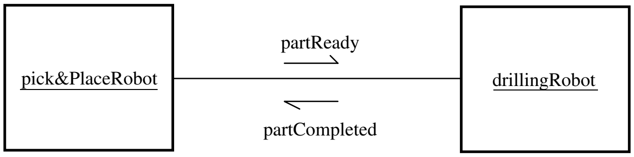

Figure 1. Example of task synchronization with two event signals.

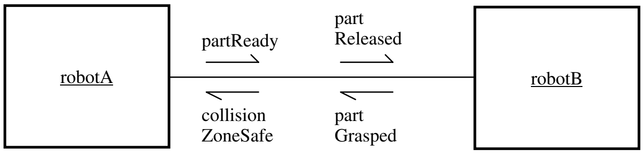

Figure 2. Example of task synchronization with four event signals.

```
    Release part
    Move to safe position
    signal (partReady)
    wait (partCompleted)
    Pick up part
    Remove from work location
    Place part
end while;
```

```
drilling Robot:
while workAvailable do
    wait (partReady)
    Move to work location
    Drill four holes
    Move to safe position
    signal (partCompleted)
end while;
```

Next, consider the case in which a giver robot hands over a part to a receiver robot. Once again, there is the potential problem of the two robot arms colliding with each other. However, this time we cannot prevent both robots from being in the collision zone at the same time because, during the hand-over, there is a time when both robots are holding the same part.

The solution we adopt is to allow only one robot to move within the collision zone at any given time. First, one robot moves into the collision zone. It then signals to the other robot that it has reached the exchange position. The second robot now moves into the collision zone. An event signal `collision Zone Safe` is used for this purpose. The giver robot signals a second event, `part Ready`, to notify the receiver robot that it is ready for the hand-over. Two more event signals are used during the hand-over, `part Grasped` and `part Released`. The part hand-over has to be as precise as a baton hand-over in a relay race. The solution is illustrated in Fig. 2 and described as follows:

```
Giver robot (robot A):
while workAvailable do
    Pick up Part
    Move to edge of collision zone
    wait (collisionZoneSafe)
    Move to exchange position
    signal (partReady)
    wait (partGrasped)
    Open Gripper to release part
    signal (partReleased)
    wait (collisionZoneSafe)
    Leave collision zone
end while;
```

```
Receiver robot (robot B):
while workAvailable do
    Move to exchange position
    signal (collisionZoneSafe)
    wait (partReady)
    Close Gripper to grasp part
    signal (partGrasped)
    wait (partReleased)
    Leave collision zone
    signal (collisionZoneSafe)
    Place part
end while;
```

Task synchronization may also be achieved by means of message communication as described next.

PRODUCER/CONSUMER PROBLEM

A common problem in concurrent systems is that of producer and consumer tasks. The producer task produces information, which is then consumed by the consumer task. For this to happen, data need to be passed from the producer to the consumer. In a sequential program, a calling operation (procedure) also passes data to a called operation. However, control passes from the calling operation to the called operation at the same time as the data.

In a concurrent system, each task has its own thread of control and the tasks execute asynchronously. It is therefore necessary for the tasks to synchronize their operations when they wish to exchange data. Thus, the producer must produce the data before the consumer can consume it. If the consumer is ready to receive the data but the producer has not yet produced it, then the consumer must wait for the producer. If the producer has produced the data before the consumer is ready to receive it, then either the producer has to be held up or the data need to be buffered for the consumer, thereby allowing the producer to continue.

A common solution to this problem is to use message communication between the producer and consumer tasks. Message communication between tasks serves two purposes:

1. Transfer of data from a producer (source) task to a consumer task (destination).
2. Synchronization between producer and consumer. If no message is available, the consumer has to wait for the message to arrive from the producer. In some cases, the producer waits for a reply from the consumer.

Message communication between tasks may be loosely coupled or tightly coupled. The tasks may reside on the same node or be distributed over several nodes in a distributed application.

With loosely coupled message communication, the producer sends a message to the consumer and continues without waiting for a response. Loosely coupled message

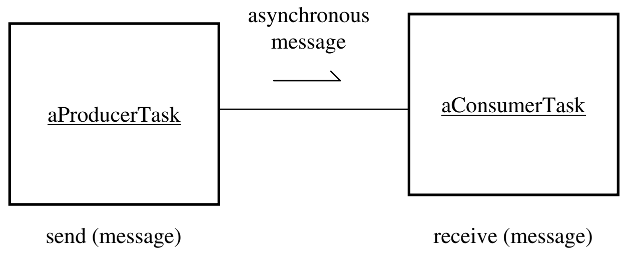

Figure 3. Loosely coupled (asynchronous) message communication.

communication is also referred to as asynchronous message communication.

With tightly coupled message communication, the producer sends a message to the consumer and then immediately waits for a response. Tightly coupled message communication is also referred to as synchronous message communication and in Ada as a rendezvous.

LOOSELY COUPLED MESSAGE COMMUNICATION

With *loosely coupled message communication*, also referred to as *asynchronous message communication*, the producer sends a message to the consumer and either does not need a response or has other functions to perform before receiving a response. Thus, the producer sends a message and continues without waiting for a response. The consumer receives the message. As the producer and consumer tasks proceed at different speeds, a first-in-first-out (FIFO) message queue can build up between producer and consumer. If there is no message available when the consumer requests one, the consumer is suspended.

An example of *loosely coupled message communication* is given in Fig. 3 using the UML notation. The producer task sends messages to the consumer task. A FIFO message queue can exist between the producer and the consumer. The message is labeled `asynchronous message`. Parameters of the message are depicted in parentheses, that is, `asynchronous message (parameter1, parameter2)`.

TIGHTLY COUPLED MESSAGE COMMUNICATION WITH REPLY

In the case of *tightly coupled message communication with reply*, also referred to as *synchronous message communication with reply,* the producer sends a message to the consumer and then waits for a reply. When the message arrives, the consumer accepts the message, processes it, generates a reply, and then sends the reply. The producer and consumer then both continue. The consumer is suspended if no message is available. For a given producer/consumer pair, no message queue develops between the producer and the consumer. In some situations, it is also possible to have *tightly coupled message communication without reply* (7).

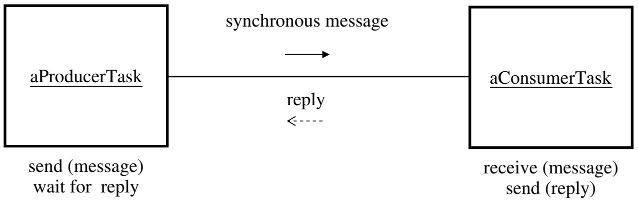

Figure 4. Tightly coupled (synchronous) message communication with reply.

An example of *tightly coupled message communication with reply* is given in Fig. 4 using the UML notation. The producer sends a message to the consumer. After receiving the message, the consumer sends a reply to the producer. The message is labeled `synchronous message`. Parameters of the message are depicted in parentheses, that is, `synchronous message (parameter1, parameter2)`. The reply is depicted in UML by a separate dashed message with the arrowhead pointing in the reverse direction of the original message.

EXAMPLE OF PRODUCER/CONSUMER MESSAGE COMMUNICATION

As an example of *tightly coupled message communication with reply*, consider the case where a vision system has to inform a robot system of the type of part coming down a conveyor, for example, whether the car body frame is a sedan or station wagon. The robot has a different welding program for each car body type. In addition, the vision system has to send the robot information about the location and orientation of a part on a conveyor. Usually this information is sent as an offset (i.e., relative position) from a point known to both systems. The vision system sends the robot a tightly coupled message, the `car ID Message`, which contains the `car Model ID` and `car Body Offset`, and then waits for a reply from the robot. The robot indicates that it has completed the welding operation by sending the `done Reply`.

In addition, the following event synchronization is needed. Initially, a sensor signals the external event `car Arrived` to notify the vision system. Finally, the vision system signals the actuator `move Car`, which results in the taking away of the car by the conveyor. The solution is illustrated in Fig. 5 and described next.

```
Vision System:
while workAvailable do
   wait (carArrived)
   Take image of car body
   Identify the model of car
   Determine location and orientation of car body
```

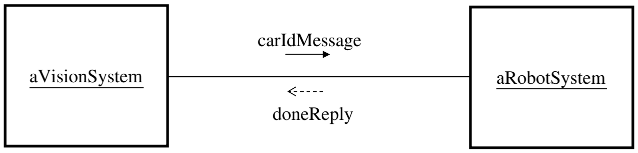

Figure 5. Example of message communication.

```
    send carIdMessage (carModelId, carBodyOffset) to Robot System
    wait for reply
    signal (moveCar)
end while;
Robot System:
while workAvailable do
    wait for message from Vision System
    receive carIdMessage (carModelId, carBodyOffset)
    Select welding program for carModelId
    Execute welding program using carBodyOffset for car position
    send (doneReply) to Vision System
end while;
```

INFORMATION HIDING APPLIED TO ACCESS SYNCHRONIZATION

The solution to the mutual exclusion described is error prone. It is possible for a coding error to be made in one of the tasks accessing the shared data, which would then lead to serious synchronization errors at execution time. Consider, for example, the mutual exclusion problem described. If the acquire and release operations were reversed by mistake, the pseudocode would be

```
release (sensorDataRepositorySemaphore)
Access sensor data repository[should be critical section]
acquire (sensorDataRepositorySemaphore)
```

As a result of this error, the task enters the critical section without first acquiring the semaphore. Hence, it is possible to have two tasks executing in the critical section, thereby violating the mutual exclusion principle. Instead, the following coding error might be made:

```
acquire (sensorDataRepositorySemaphore)
Access sensor data repository[should be critical section]
acquire (sensorDataRepositorySemaphore)
```

In this case, a task enters its critical section for the first time but then cannot leave because it is trying to acquire a semaphore it already possesses. Furthermore, it prevents any other task from entering its critical section, thus provoking a *deadlock*, where no task can proceed.

In these examples, synchronization is a global problem that every task has to be concerned about, which makes these solutions error prone. By using information hiding (8,9), the global synchronization problem can be reduced to a local synchronization problem, making the solution less error prone. With this approach, only the information hiding object need be concerned about synchronization. An information hiding object that hides details of synchronizing concurrent access to data is also referred to as a *monitor* (10), as described next.

MONITORS

A *monitor* combines the concepts of information hiding and synchronization. A monitor is a data object that encapsulates data and has operations that are executed mutually exclusively. The critical section of each task is replaced by a call to a monitor operation. An implicit semaphore is associated with each monitor, referred to as the *monitor lock*. Thus, only one task is active in a monitor at any one time. A call to a monitor operation results in the calling task acquiring the associated semaphore. However, if the lock is already taken, the task blocks until the monitor lock is acquired. An exit from the monitor operation results in a release of the semaphore; i.e., the monitor lock is released so that it can be acquired by a different task. The mutually exclusive operations of a monitor are also referred to as *guarded* operations or *synchronized* methods in Java.

Example of Monitor

An example of a monitor is given next. Consider the sensor data repository described above. The monitor solution is to encapsulate the data repository in an `Analog Sensor Repository` data abstraction object, which supports read and update operations. These operations are called by any task wishing to access the data repository. The details of how to synchronize access to the data repository are hidden from the calling tasks.

The monitor provides for mutually exclusive access to an analog sensor repository. There are two mutually exclusive operations to read from and to update the contents of the analog repository, as shown in Fig. 6. The two operations are as follows:

```
readAnalogSensor (in sensorID, out sensorValue, out upperLimit, out lowerLimit,
    out alarmCondition)
```

This operation is called by reader tasks that wish to read from the sensor data repository. Given the sensor ID, this operation returns the current sensor value, upper limit, lower limit, and alarm condition to users who might wish to manipulate or display the data. The range between the lower limit and the upper limit is the normal range within which the sensor value can vary without causing an alarm. If the value of the sensor is

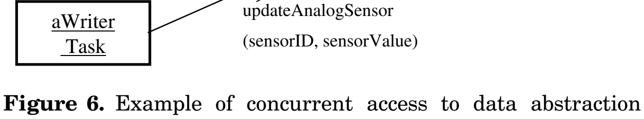

Figure 6. Example of concurrent access to data abstraction object.

below the lower limit or above the upper limit, the alarm condition is equal to low or high, respectively.

`updateAnalogSensor (in sensorID, in sensorValue)`

This operation is called by writer tasks that wish to write to the sensor data repository. It is used to update the value of the sensor in the data repository with the latest reading obtained by monitoring the external environment. It checks whether the value of the sensor is below the lower limit or above the upper limit and, if so, sets the value of the alarm to low or high, respectively. If the sensor value is within the normal range, the alarm is set to normal.

The pseudocode for the mutually exclusive operations is as follows:

```
monitor AnalogSensorRepository

readAnalogSensor (in sensorID, out sensorValue,
out upperLimit, out lowerLimit, out alarmCondition)
   sensorValue := sensorDataRepository (sensorID, value);
   upperLimit := sensorDataRepository (sensorID, upLim);
   lowerLimit := sensorDataRepository (sensorID, loLim);
   alarmCondition := sensorDataRepository
     (sensorID, alarm);
end readAnalogSensor;

updateAnalogSensor (in sensorID, in sensorValue)
sensorDataRepository (sensorID, value) := sensorValue;
if sensorValue >= sensorDataRepository (sensorID, upLim)
      then sensorDataRepository (sensorID,
        alarm) := high;
else if sensorValue <= sensorDataRepository
  (sensorID, loLim)
   then sensorDataRepository (sensorID, alarm)
     := low;
   else sensorDataRepository (sensorID, alarm)
     := normal;
end if;
end updateAnalogSensor;
end AnalogSensorRepository;
```

CONDITION SYNCHRONIZATION

In addition to providing synchronized operations, monitors support *condition synchronization*. This allows a task executing the monitor's mutually exclusive operation to block, by executing a *wait* operation until a particular condition is true, for example, waiting for a buffer to become full or empty. When a task in a monitor blocks, it releases the monitor lock, allowing a different task to acquire the monitor lock. A task that blocks in a monitor is awakened by some other task executing a *signal* operation (referred to as *notify* in Java). For example, if a reader task needs to read an item from a buffer and the buffer is empty, it executes a wait operation. The reader remains blocked until a writer task places an item in the buffer and executes a signal operation.

If semaphore support is unavailable, mutually exclusive access to a resource may be provided by means of a monitor with condition synchronization, as described next. The Boolean variable busy is encapsulated by the monitor to represent the state of the resource. A task that wishes to acquire the resource calls the `acquire` operation. The task is suspended on the `wait` operation if the resource is busy. On exiting from the wait, the task will set `busy` equal to true, thereby taking possession of the resource. When the task finishes with the resource, it calls the `release` operation, which sets `busy` to false and calls the `signal` operation to awaken a waiting task.

Below is the monitor design for mutually exclusive access to a resource. Additional examples of monitors and condition synchronization are given in Ref. (7).

```
monitor Semaphore
  -- Declare Boolean variable called busy,
     initialized to false.
private busy : Boolean = false;
  -- acquire is called to take possession of the
     resource
  -- the calling task is suspended if the resource
     is busy
public acquire ()
    while busy = true do wait;
    busy := true;
    end acquire;

-- release is called to relinquish possession of
   the resource
-- if a task is waiting for the resource, it will be
   awakened
public release ()
    busy := false;
    signal;
end release;
end Semaphore;
```

RUN-TIME SUPPORT FOR CONCURRENT PROGRAMMING

Run-time support for concurrent programming may be provided by

1. A kernel of an operating system. This has the functionality to provide services for concurrent programming. In some modern operating systems, a microkernel provides minimal functionality to support concurrent processing with most services provided by system-level tasks.
2. The run-time support system for a concurrent language.
3. A threads package, which provides services for managing threads (lightweight processes) within heavyweight processes.

With sequential programming languages, such as C, C++, Pascal, and Fortran, there is no support for concurrent tasks. To develop a concurrent multitasked application using a sequential programming language, it is therefore necessary to use a kernel or threads package.

With concurrent programming languages, such as Ada and Java, the programming language provides constructs for concurrent tasks, including task creation and deletion, as well as task communication and synchronization. In this case, the language's run-time system handles task scheduling and provides the services and underlying mechanisms to support inter-task communication and synchronization.

FURTHER READING

The body of knowledge on concurrent programming has grown substantially since Dijkstra's seminal work (3). Among the significant early contributions were Brinch Hansen (11), who developed an operating system based on concurrent tasks that incorporated semaphores and message communication, and Hoare (10), who developed the monitor concept that applies information hiding to task synchronization. Several concurrent programming algorithms were developed, such as the multiple readers and writers algorithm (12), the sleeping barber algorithm (3), the dining philosophers algorithm (13), and the banker's algorithm for deadlock prevention (3). Many of the original papers on concurrent programming are out of print. Because concurrent processing is such a fundamental concept, it has been described in textbooks for over three decades. The best modern sources of information on concurrent programming are books on operating systems, such as Silberschatz et. al. (5) and Tanenbaum (4), or books on concurrent programming languages, such as Java (14) or Ada (15). Two recommended references for further reading on concurrent programming are Bacon (2), which describes concurrent systems, both centralized and distributed, and Magee and Kramer (1), which describes concurrent programming with Java. The application of concurrent programming to the design of concurrent, distributed, and real-time applications is described in Gomaa (8).

DISTRIBUTED AND COLLABORATIVE DEVELOPMENT

Rapid advancements in computer, communications, and network technologies over the years have revolutionized how computers are used. One of the emerging application areas that has gained increasing usage and visibility is computer-supported cooperative work (CSCW). The main goal of CSCW systems is to facilitate effective collaboration among users who may be distributed across geographical distance and time, using computer-based means, which may range from e-mail to instant messaging to video conferencing to chance meetings in online virtual environments.

Meanwhile, due in large part to the widespread emergence of virtual organizations and the growing trend of outsourcing, software development is fast becoming a group activity that is performed by geographically and temporally distributed team members. It is no longer unusual to have a large-scale software development project that has members located in different time zones around the world; in many cases, the members have not even-met each other. Thus, it is no coincidence that supporting distributed software development teams is area of increasing focus in CSCW system design (1–4).

The key to successful software development in distributed environments is awareness of task status and activities of team members to enable coordination and conflict detection/avoidance, to whose end online file sharing and version control systems and general-purpose communications systems (e.g., e-mail and instant messaging applications) have often been used to provide awareness information in distributed software development. However, in general, such general-purpose systems are not considered ideal as source of awareness information, largely because these systems require collaborators to perform a significant amount of extra work (e.g., diligently documenting one's actions and activities in e-mail messages or online forums and carefully following e-mail discussion threads and file check-in and check-out history) to keep track of project progress and activities. In addition, unmediated generation and unfiltered reception of awareness-related messages can lead to information overload. Therefore, in CSCW, a desired goal is to automatically provide selective awareness information to distributed team members.

Nonetheless, general-purpose file sharing and communications systems have successfully been used to support many large-scale, open-source development efforts (5–7). Success of these tools in open-source development efforts forms a sharp contrast with ongoing efforts in the CSCW community to build specialized tools and technologies for providing awareness in distributed environments, which is especially notable considering that specialized awareness tools and technologies, with the possible exception of "buddy lists" in instant messaging applications, have not yet been widely adopted by software developers in their everyday work activities.

OVERVIEW OF COMPUTER-SUPPORTED COLLABORATIVE WORK SYSTEMS

The main goal of CSCW systems is to facilitate effective collaboration among users who may be distributed across geographical distance or time using computer-based means. With factors of geographical distance and time, collaborative work can be distinguished into four types of interactions, as shown in Fig. 1 (adopted from Ref. 8). For an in-depth overview of CSCW and issues, see Ref. 8. Face-to-face interaction occurs when all the collaborators are available in the same place at the same time. Common examples of this type of interaction include face-to-face group meetings and presentations. In synchronous distributed interaction, collaborators work together at the same time but are not located in the same place. Video conferencing and distance learning are good examples of such an interaction.

Asynchronous interaction occurs when collaborators are collocated but do not work with each other directly at the same time. This kind of interaction can often be found in workplaces with different work hours or shifts (e.g., hospitals) where communication is still required to pass along information and knowledge to coordinate tasks and activities. Asynchronous and distributed interaction occurs when collaborators are not collocated and unavailable for working together at the same time. Open-source development, in which collaborating software developers are often distributed around the world and have never met each other, is an example of this type of interaction.

In practice, software development typically involves multiple types of interactions. The main mode of interaction may also change as team requirements and needs change over time. For example, in the beginning of a given project, project members may frequently hold face-to-face meetings to raise and discuss issues in depth, to generate project plans and requirements, and to get familiar with each other. Once the project is well under way, the frequency of face-to-face interaction often decreases whereas that of distributed interaction increases, with project members communicating with each other via e-mail, instant messaging, and other electronic means. Whether software development occurs in a collocated or distributed environment, online file repository and version control system [e.g., CVS (9)] is almost always employed to store, control access to, and detect conflicts in source code files, project documents, and bug reports.

CONCEPTS, TERMINOLOGY, AND ISSUES

Fundamental to enabling collaborative work over geographical and temporal distance are the concepts of awareness and shared artifacts. *Awareness* refers to the ability of

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

	Same Time	Different Time
Same Place	face-to-face interaction	asynchronous interaction
Different Place	synchronous distributed interaction	asynchronous distributed interaction

Figure 1. Taxonomy of computer-supported collaborative work.

distributed collaborators to keep track of each other's activities and coordinate their work; see the next section for a detailed description and discussion of awareness. *Shared artifacts* (or shared data) collectively refer to software entities on which collaborators perform their work. For example, in group editing (10,11), where multiple authors can work on the same document at the same time, the documents being edited would constitute the shared artifacts. In an online chat or instant messaging (IM) session, the exchanged messages would collectively form the shared artifacts. For collaborative software development, the shared artifacts may include requirements and design documents, source code files, bug reports, and code libraries/packages. As such, shared artifacts always reflect the current state of collaborative work.

An important issue in providing shared artifacts in distributed collaborative work is the system architecture (i.e., the exact manner in which shared artifacts are shared and accessed by collaborators). In a centralized architecture, shared artifacts are stored and maintained at a single location, and collaborators access and make updates on them (12,13). In a replicated architecture, collaborators work on their own copies of shared artifacts (14) and the state is synchronized among the copies synchronously or asynchronously. In general, it is easier to maintain the same state of shared artifacts under concurrent updates for all the collaborators in a central architecture than doing so in a replicated architecture. However, there are two drivers for use of replicated architectures. First is supporting disconnected use of shared artifacts. If a user is disconnected from the network or has poor connectivity, working on a local copy of a shared artifact is the only option, with merging of updates into other copies occurring later. Second, elapsed time between making an update and observing its effect on shared artifacts can be slow and unpredictable in a centralized architecture, especially over a wide area network, which can make it difficult to get interactive response times. With a replicated architecture, updates can be made locally and then immediately distributed to other participants. Conflicting updates can, of course, occur, and a number of solutions have been developed by the CSCW community, ranging from use of locks to operation transforms that result in the same state at all sites, even if participants issue operations in parallel on the same object (10,11).

Distributed software development typically has a hybrid architecture, where the shared artifacts (e.g., source code files and other documents) are stored and maintained at a central (and often remote) location, but separate local copies are created per user at check-out time, and any conflicts between multiple versions of the same artifact are detected and (manually) resolved at check-in time by means of a version control system [e.g., CVS (9)]. This architecture is feasible, in part, because once separate copies of, say, source code files, are created, programmers tend to work on them in isolation, and thus, the issues of providing a high level of interactivity among collaborators and having to always synchronize the state of shared artifact replicas do not occur. Later in this article, we describe an emerging programming practice, called Pair Programming (15), in which a pair of programmers works on the same code at the same time, and how they coordinate their activities.

In addition to awareness and shared artifacts, another concept is that of a *shared workspace*. A shared workspace provides a sense of place where collaboration takes place. It is generally associated with some part of the screen real estate of the user's computer where the user "goes" to work on shared artifacts, discovers work status, and interacts with his/her collaborators. It is often supported by the graphical user interfaces (GUIs) (i.e., "windows") of application tools used for working on shared artifacts. CSCW systems exist that are specifically designed to provide a shared workspace [e.g., XTV (16) and TeamRooms (17)]. Regardless of how it is provided, the main function of a shared workspace is to provide awareness of work status and activities of individual collaborators on shared artifacts, which, in turn, are essential for coordinating and controlling collaboration and achieving group goals.

One key issue in providing a shared workspace is the degree to which users' activities in the workspace are "public" or known to their collaborators. To illustrate, consider XTV (16), which is a predecessor to Microsoft NetMeeting in terms of its ability to support application sharing. Specifically, XTV allows any X Windows applications to be shared between multiple, distributed hosts by capturing X Windows screen update events at the server host in real time, where the shared application is running, and distributing the captured events to a client host, which draws the windows of the shared application by replaying the received events. Therefore, in XTV, all the user actions with the shared application and resulting updates to the application windows are shown to everyone. That is, the shared workspace provided by the windows of the shared application is totally public.

On the other hand, other systems allow collaborators to perform both private and public activities in the shared workspace. For example, DistView (18) allows the windows of a shared application to be selectively shared (i.e., users have control over which application windows are shared and when). Specifically, DistView allows users to export windows at any time during application execution, which then become available for others to import. When a window is thus shared, it always shows a synchronized view of application data being displayed even when collaborators update the data and maintains the same physical attributes (e.g., window size). In DistView, a shared window also shows a telepointer that indicates the mouse movements of the current owner of the window, where the ownership of the window can be passed among collaborators. Therefore, in the same shared application, DistView provides both a public workspace through shared windows and a private workspace through unshared windows of the application.

Different approaches are appropriate for different applications. For example, XTV and other application sharing systems (e.g., Microsoft NetMeeting) are well suited for distributed meeting or presentation applications, where a well-defined, formal role of a coordinator or presenter exists whose shared artifacts (e.g., viewgraphs) and actions on them, such as transitioning to a new viewgraph, should be visible to everyone in their entirety. However, they may not be appropriate for other applications, including large-scale collaborative science (19) and distributed software development, where collaborators largely work in private, and collaboration often occurs on an as-needed basis. For such applications, the ability to provide private and public shared workspace and to allow users to make transitions between the two types of shared workspaces on demand is critical.

AWARENESS

Software development is inherently a collaborative activity, which typically involves a team of programmers, testers, managers, and customers working together over a period of time. Team members collectively produce a number of artifacts, including requirements documents, design documents, progress reports, and software modules/components. Team members may be collocated and can work together at the same time (e.g., as in a single-site corporate environment) or may be distributed over geographical distance and time (e.g., as in an outsourcing situation). In either case, critical to the success of a software development team is the ability to coordinate activities of team members, which is largely facilitated by the means of what CSCW researchers refer to as *awareness*(20,21).

In general, a group of people working together requires some “sense” of who is working on what and when, and “feel” for where the group work stands with respect to what the team is ultimately trying to achieve. Such awareness information plays a critical role in the effectiveness and success of team work. As explained in Ref. 22, it “provides a context for your own activity. This context is used to ensure that individual contributions are relevant to the group’s activity as a whole, and to evaluate individual actions with respect to group goals and progress. The information, then, allows groups to manage the process of collaborative working.”

Therefore, many software engineering practices and methodologies include rigorous provisions for providing adequate and timely awareness of work status and progress. For example, Extreme Programming is a recent software development methodology that emphasizes informal and frequent requirements gathering, communication, testing, and (customer) feedback (23). Part of the Extreme Programming practice includes daily, stand-up meetings, in which each of development team members report on: “the prior day’s accomplishments; any obstacles, difficulties, or stumbling blocks faced; and what he or she plans to accomplish during the current day on the basis of the selected stories and tasks” (23). It also includes use of a new programming paradigm, called Pair Programming, in which, to quote Ref. 15, “two programmers working side-by-side, collaborating on the same design, algorithm, code, or test. One programmer, the driver, has control of the keyboard/mouse and actively implements the program. The other programmer, the observer, continuously observes the work of the driver to identify tactical (syntactic, spelling, etc.) defects and also thinks strategically about the direction of the work. On demand, the two programmers can brainstorm any challenging problem. Because the two programmers periodically switch roles, they work together as equals to develop software.” In Pair Programming, the membership of a team may change as needed over the project lifecycle, which has a side effect of spreading in-depth knowledge about the design and status of individual software modules and components under development throughout the entire project team.

Although studies exist that apply the Extreme Programming practices in a distributed environment [e.g., (24,25)], its primary methods of providing awareness are built on the assumption that team members are collocated (to the extent that they can get together at a common place without difficulty) and are mostly available for collaboration at the same time. The issue of providing awareness becomes significantly difficult when team members are distributed across geographical distance and time. In distributed environments, collaborators are forced to interact with each other via electronic/computer-based media (e.g., audio/video conferencing and messaging systems), which significantly limits the availability of sensory, physiological, and environment cues (e.g., eye contacts, hand gestures, and audience attention on individuals) which are readily and seamlessly communicated in face-to-face meetings, shared offices, or collocated cubicle environments and are found to play a critical role in coordination and control of collaborative activities (6). Furthermore, information and knowledge sharing may be significantly reduced in distributed environments as opportunities do not exist for informal interactions among team members (e.g., water-cooler conversations, chance meetings in hallways, and “dropping by” colleagues’ offices for small talks). Without any provision, collaborators would have to diligently document coding, decision making, design, and other activities; collect support materials; and communicate them (say via e-mail) with their colleagues, who, in turn, would have to carefully review and understand the received materials to keep up-to-date with the current status of their work. Most of these tasks are usually “add-ons” to already heavy workloads, which can lead to significant loss of productivity. Using “off-the-shelf” audio/video conference bridges and project management tools is helpful but cannot replace rich awareness information that is readily available in collocated environments.

Therefore, much research in CSCW has focused on providing awareness for distributed teams of collaborators as seamlessly and effortlessly as possible. For example, DistEdit-based group editors (10,11) allow multiple, geographically distributed users to edit the same document at the same time and include a locking mechanism for allowing concurrent updates, in which the "locked regions" of the document are color-coded per individual author. These serve as an awareness mechanism, by which concurrent authors can easily tell who is working on which part of the document and thus avoid conflicting edits. TeamRooms (17) provides a desktop window that functions as a room-based virtual environment, where distributed users can place tools (e.g., for leaving notes for each other, text-based chatting, and brainstorming) and resources (e.g., URLs to online documents or websites) for group use. In addition to a "buddy list" of users currently in the room, TeamRooms provides a "radar view," a miniaturized version of the shared window that shows both the part of the room each user is currently viewing and the tools each user may be using. The radar view conveys some awareness of what each user is doing in the shared space. Application (or screen) sharing systems (e.g., XTV (16) and Microsoft NetMeeting) turn the desktop screen of a collaborator, in part or in their entirety, into a shared workspace on demand and allow distribute collaborators to closely keep track of each other's activities in highly interactive and synchronous sessions.

Distributed software development is a special form of collaborative work that requires a high level of awareness among team members at all times to seamlessly integrate, maintain, and keep track of progress of various software modules and related artifacts (e.g., specification of functional and operational requirements, design documents, change requests, and bug fixes). Awareness is also required to avoid conflicts and duplicate work among distributed members of development and administrative teams. Examples of awareness information specific to distributed software development include the following: who is working on what software modules, causal and temporal dependency relationships between different software modules, change history of a software module (including who has made changes and why), history of bug reports and fixes, and constituent components of a software release and their version information. In distributed software development, awareness should not only be provided in a timely and unobtrusive manner so as not to disrupt ongoing work but also persist over a long period of time (possibly beyond the lifetime of a software project) to facilitate knowledge building and information sharing among geographically and temporally distributed team members. In the remainder of this article, we describe and discuss various approaches to providing awareness for collaborative software development by distributed teams.

APPROACHES TO COLLABORATIVE SOFTWARE DEVELOPMENT IN DISTRIBUTED ENVIRONMENTS

In this section, we describe a few exemplary approaches to supporting collaborative software development for distributed teams. We note that although each of the described approaches is different in terms of specific mechanisms, the fundamental objective is the same, which is to provide adequate awareness to collaborating teams of software developers and managers to help them achieve a high level of activity coordination and efficiency in a distributed environment.

Virtual Environments as Shared Workspace

Providing shared workspace for distributed software developers and managers has been one of the main topics for CSCW researchers. One of the earlier examples in the area is ConversationBuilder (26), in which each software development activity (e.g., bug tracking) is modeled as a conversation. A conversation is essentially a software development process for a specific task and may specify a set of artifacts relevant to the task (e.g., code files and documentation), an (ordered) list of actions to be performed on the artifacts, user roles under which actions are to be performed, and per-artifact capability objects for specifying what actions can be performed on the artifact and by whom. Associated with a conversation is the concept of a conversation space, a virtual space where participants in a conversation can keep track of the current state of a conversation. To support real-life work patterns of software developers and managers, ConversationBuilder allows users to participate in multiple conversations at the same time. To accommodate new tasks, ConversationBuilder also allows users to create and enact new conversations. ConversationBuilder stores shared artifacts in a conversation in a hypertext database and provides a suite of client applications for providing configuration and versioning information of shared artifacts and graphically visualizing "relations between nodes in the hypertext, and relations among a user's conversations" (26).

Although conversation space objects in the ConversationBuilder function as the shared workspace among distributed conversation participants, they do not provide the sense of real space in the physical world; they are not intended to reflect real-life entities in a virtual world. In contrast, much research has been conducted in providing an online shared workspace built on real-life concepts or entities in the physical world. One of the main goals of such works is to minimize the "learning curve" of distributed users in adapting to and making effective use of virtual workspaces by building them with metaphors for familiar concepts, organizations, and objects that are commonly encountered in everyday life. And many such reality-based virtual workspaces have been built on the facilities provided by a pioneering virtual environment system, called Multi-User Dungeons (MUDs) (27).

Initially developed for online, multi-user gaming, a typical MUD environment includes a number of rooms that are connected with each other (via doors and hallways), objects that are contained in rooms, tools for working on or changing some state of objects, and players who represent human users. Players navigate a MUD environment by visiting connected rooms and (try to) achieve their goals by finding and performing operations on appropriate objects with provided tools. A key element in any MUD environment is that online players can meet each other, either by chance or by appointment in some room(s), and interact with each other (i.e., to collaborate or compete with each other). MUDs are generally implemented in a client-server system. That is, distributed users connect to MUD servers by using MUD client applications, which also provide a user interface (UI) for displaying a map of rooms, navigating rooms, and issuing commands. The earlier (and still predominant) means of providing UI is text-based, in which users specify their behaviors (e.g., "look east") or issue commands (e.g., "pick up") at the command line.

At the core of a MUD system is a MUD engine, a software entity that functions much like an operating system (OS) in that it allows a variety of custom systems to be built. These systems still retain the basic MUD concepts, such as rooms, objects, commands, and players, but apply them to different application domains other than online gaming and entertainment. Over the years, the number and variety of MUD-based systems have rapidly grown to the extent that a new phrase, Multi-User Dimensions, has been invented to refer to those systems in new application areas, which include online communities, distance learning, and collaborative network administration.

Given the built-in concepts of rooms, objects, and players, it is no surprise that MUDs have also been used to provide shared virtual workspaces and access to shared artifacts in collaborative, distributed software development (28,29). In a typical use scenario, distributed developers would enter a MUD environment by connecting to a MUD server specifically set up for their work and start navigating rooms. In a given room, a developer may find objects that represent project artifacts (e.g., source code files) and issue commands on the objects (e.g., "build"). A command issued in the virtual environment usually causes some preconfigured tools (e.g., a complier and linker in an IDE) to start executing out in the "physical world" (e.g., on the developer's local host). Online developers may encounter others who are connected to the MUD server at the same time and may decide to "chat" with each other via available communication tools in the environment. They may also create special-purpose rooms for, say, conducting scheduled meetings, and senior members of a project may provide "guided tours" of the project to newcomers by navigating rooms while conducting chat sessions with them at the same time (29). The presentation of a virtual environment may range from a text-based UI to a 3-D rendering of rooms, hallways, objects, and developers (via avatars).

When developing MUD-based virtual environments for distributed software development, one major issue to consider is how to map concepts, abstractions, and entities of software engineering to MUD's room-based metaphors. Depending on what a room represents, the semantics of a developer visiting a room can dramatically change. For example, if a room represents a specific activity to be performed as part of a software process, the objects contained in the room could be tools and artifacts needed for performing the activity (28). Developers can be assigned to specific activities (with appropriate access rights) in the process and work on them by visiting corresponding rooms. Constraints can be set for exiting a room to ensure that, for example, the corresponding activity has been completed to the extent that the downstream activities in the process can be performed. In another approach, rooms can represent software artifacts themselves (29), in which, for example, a room represents a software module, and objects contained in the room represent individual class files that make up the module. In this approach, visiting a room would mean that the visitor intends to work on the corresponding artifact. A comprehensive discussion of different mapping approaches to model software processes in MUD-based virtual environments can be found in Ref. 28.

Different mapping approaches have their own advantages and disadvantages. For example, when rooms represent software process activities, it is convenient to model the entire software process by way of connecting rooms and establishing appropriate exit constraints. However, modeling a software developer who works on multiple tasks at the same time is more difficult (28). When rooms represent software or project artifacts, dependency relationships among them can easily be made explicit by connecting appropriate rooms together. However, it would be not only difficult to support the multithreading work practices of individual project members but also inconvenient to represent the overall context in which modeled artifacts are used. Determining which approach to use in a given project is not trivial and depends on many factors, including the project size and required level of realism.

Awareness and Visualization Widgets

Providing awareness in virtual environments generally requires that some extra work be performed to first set up an appropriate environment (e.g., create rooms, objects, and commands in a MUD-based system). Furthermore, virtual environments are typically separated from the tools and systems that software developers and managers use to perform their work, which often means that users have to stop their work, context-switch, and go to a virtual environment to receive and generate awareness information. All of these factors can incur extra administrative and usage overheads and reduce the effectiveness of virtual environments. Ideally, users should be able to keep track of project status and others' activities without much effort and without intervening with their own work.

To this end, researchers have been working to bring awareness into users' "regular" workspaces. For example, Jazz (2,3) is an Eclipse-based integrated development environment (IDE) that includes a suite of embedded tools and mechanisms for providing awareness and enabling communication for a team of distributed developers. The basic idea is that "from the individual developer's perspective, the IDE is where coding takes place and is the home of many different development tools. If coding is a team effort, then why not add collaborative capabilities to the IDE toolset alongside the editor, compiler, and debugger?" (2). Specifically, Jazz provides a "buddy list" of developer team members as part of the IDE workspace. From this list, called the Jazz Band, team members can see the online status of each other, initiate multimedia communications sessions, and infer who is currently engaged in what activities and with whom. It also allows team members to initiate chat sessions from selected sections of code, save the exchanged messages as an annotation to the selected code, and review them at a later time. In addition, the folder and file list in the Jazz IDE provides version control information (e.g., who has checked out what items and when, update status on local copies of checked-out items, and commit status). These features allow developers to seamlessly keep track of the current status of their work as a whole and spontaneously initiate discussion and share knowledge without having to leave the IDE workspace, thus helping reduce "costs" associated with acquiring, generating, and using awareness to coordinate and collaborate in distributed software development.

CSCW tools, such as Jazz, have, as yet, not been widely used as a collaboration mechanism for distributed software developers. This use may only be a question of time, because it takes time for a new technology to be widely used, but another reason may be that, although while software development is a collaborative activity in terms of planning, designing, coordination, testing, and integration, writing code has mostly been considered as an isolated, individual activity. This perception of code-writing has recently been challenged by the advent of Pair Programming as part of the Extreme Programming (15). Pair Programming has been shown to enable (collocated) programmers to be more productive (in terms of lines of code produced per day per programmer) and to produce a higher quality of code (23). This has, in turn, provided a strong motivation for adapting Pair Programming in distributed team environments. For example, Baheti et al. (25) have created a Distributed Pair Programming (DPP) environment using Microsoft NetMeeting and have evaluated the performance of distributed student teams on a large class project. Their study has found that "software development involving Distributed Pair Programming is comparable to that developed using collocated pair programming or virtual teams without distributed pair programming." Ho et al. (24) has created a Eclipse plug-in module, called Sangam, to allow DPP in an Eclipse-based Java development environment. Sangam uses replicated state model for shared artifacts, allowing distributed partners to participate in Pair Programming without having to first synchronize their screen resolutions or refresh rates and without requiring a high network bandwidth, as is often the case with using screen sharing across a wide area network. However, it remains to be seen how well DPP would apply to large-scale projects, where team members are distributed not only geographically but also temporally across different time zones.

Another, and perhaps surprising, source of awareness for distributed software development teams is configuration management and version control systems [e.g., (CVS) (7,9)]. Dix (30) observes that when an artifact is shared in collaborative work, it is "not only the subject of communication, it can also become a medium of communication. As one participant acts upon the artifact, the other observes the effects of the action. We call this observation by the other participant feedthrough." Configuration management and version control systems work as a feedthrough mechanism by enabling users to keep track of who has worked on what modules, avoid concurrent and conflicting updates, and know whom to work with to integrate separately developed versions of the same module by examining the check-in and check-out state (or history) of individual modules. By maintaining interdependencies among software modules and their connections to other artifacts (e.g., design and requirements documents), these systems also allow users to help establish and maintain the context of their work. In addition, the logs of problem reports and fixes, along with developer descriptions and comments on the nature of a given bug and the rationale for its fix, function as a group memory mechanism, which helps newcomers to the project get up to speed, even when original members no longer work on the project or work in the same place (7).

However, configuration management and version control systems do not provide a comprehensive overview of the complete product under development and require a considerable amount of time and effort on the part of users to produce meaningful comments and descriptions of their development activities (7). Furthermore, the UI for discovering and gaining access to appropriate information in these systems is usually primitive and difficult to use.

To address these issues, research has been performed to provide the graphical means of visualizing and accessing the version history, current check-out (or owner) state, and known issues and fix status of all software modules and project artifacts. Also often represented in such visualizations are the release history of a given product and version information and dependency relationships among software modules and project artifacts that constitute a given release. The visualization techniques widely vary from a color-coded line representation of source code lines for representing age and authorship of corresponding code to a hypertext-based, interactive 3D view of source code files and interdependencies. See Ref. 4 for a comprehensive survey of exemplary works in this area. Most of these systems perform a syntactic analysis of source code files and collect change history data from a version control system to generate information to be visualized.

Open-Source Software Development

Open-source software development involves a largely dispersed group of software developers who do not necessarily know each other but have voluntarily come together to work on software problems and issues to achieve common goals. Over the years, a large number of large-scale open-source software projects have been undertaken that have not only been successful in terms of producing high-quality, high-performance software systems and tools but also have had a significant impact on the entire Information Technology (IT) and software industry. A few notable examples include: Linux operating system, Apache Web server, Mozilla Web browser, and Xerces XML parser from the Apache XML Project.

Open-source software development represents "an extreme case of geographically distributed development, where developers work in arbitrary locations, rarely or never meet face to face" (5). In addition, the process of open-source software development is not well-defined and lacks "many of the traditional mechanisms used to coordinate software development, such as plans, system-level design, schedules, and defined processes," which are "generally considered to be even more important for geographically distributed development than for collocated development" (5). There is no explicit or formal division of work (i.e., who is responsible for what) and "developers can contribute to any part of the code" (1). Furthermore, "no formal quality control programs exist and no authoritative leaders monitor the development" (6).

Given this seemingly chaotic environment, what is perhaps more surprising is that open-source developers do not employ sophisticated awareness and coordination mechanisms, other than e-mail (developer mailing lists) and version control systems [e.g., CVS (9)]. In general, e-mail (or any text-based chat tools) would not be considered as an effective or user-friendly means of providing awareness in distributed environments as e-mail is not directly used in producing/manipulating artifacts of software development. Thus, to use e-mail as the means of providing awareness implies that it is the responsibility of users (i.e., software developers and project managers) to manually compose and distribute necessary awareness information, which, in turn, would (significantly) increase the overall workload of individual users. Although a version control system is often part of a software development process, its main use is to allow users to detect and resolve conflicting code changes to the same source files according to some pre-defined policies. As discussed earlier in the section, without further provision, it is not easy to use a typical version control system as a useful awareness tool in distributed software development environment.

Despite the lack of formal processes and integrated, automated means of generating and distributing awareness, open-source developers are able to keep track of current project status by fostering an online culture of "keeping it public" (1). They create and subscribe to developer, bug-tracking, and other project-related mailing lists and take it upon themselves to carefully answer questions and closely follow discussion threads and status reports, even if they may not be directly relevant to their current tasks or interests. In addition, many subscribe to (CVS) commit logs so that they would be notified whenever code updates are made. Mailing list messages and commit log entries are also archived, and publicly accessible "how-to" and other project-related documents are provided so that newcomers to the project can be brought up-to-date without having to ask too many "newbie" questions. Open communications and public discussions are strongly encouraged to the extent that "if it doesn't happen on list, it doesn't happen" (1), and those members who do not follow the established protocol and commit code changes without first acquiring consensus from other members via public discussion may be publicly discredited. All of these factors combine to create the effect of "overhearing conversations" in open, collocated work environments and allow open-source developers to keep informed of who the "gurus" are in what subject areas, who are working on what, and who are responsible for ensuring integrity and functionality of what parts of the system/application under development.

In addition, an organizational hierarchy often emerges in which a relatively small group of contributors form a core development group that defines, designs, and implements the main functionality and architecture of the system under development, while the others become users, testers, and implementers of add-on features (1). There is no formal process for determining who should be assigned to which group. Rather, "leaders" emerge based on the level and quality of participation and (perceived) expertise in subject areas. In addition to implementing the core functionalities and maintaining the integrity of modules they are responsible for, core developers may also define and then refine (via public discussions) application programming interfaces (APIs) for add-on feature development by other contributors. On the other hand, the user group of an open-source project, which is typically much bigger in size than the core developer group (for example, see Ref. 6), provides "enough eyeballs" to catch and report bugs, which prompt core developers to create and distribute patches.

CONCLUSION

Critical to successful software development in distributed environments is awareness of current work status and activities of distributed team members (i.e., who is doing what, when, and why), which, in turn, enables seamless coordination and conflict avoidance and detection. Providing the right awareness at the right time and to the right people has been an active area of research in the field of CSCW. In this article, we have introduced and discussed key CSCW concepts (i.e., shared artifacts and shared workspace) and design issues related to providing awareness in distributed software development. In addition, we have described and discussed common collaboration practices in open-source development efforts. In sharp contrast with ongoing awareness research in CSCW, open-source developers successfully employ general-purpose communication and coordination tools (e.g., e-mail mailing lists, version control systems, and bug tracking systems) to provide awareness to a large number of widely distributed teams of volunteer software developers.

At first glance, the findings from open-source development communities seem to suggest that specialized awareness facilities are not really required in practice. However, a deeper analysis shows that open-source developers can effectively use general-purpose tools for generating and gathering awareness mainly because they work very hard at it. As described earlier, open-source developers carefully and rigorously document their actions and activities and share with others by posting them on online, public forums (e.g., e-mail mailing lists). They also diligently follow others' postings and dutifully answer questions. All of these activities take much time and effort on the part of individual contributors.

Thus, it would appear that open-source development can greatly benefit from use of specialized awareness utilities (1). However, employing such a tool would require a homogenous run-time environment for the tool, fresh download and installation of the tool by everyone, and, more importantly, commitment by everyone that they would regularly use the tool as they do with e-mail or CVS. All of these aspects may be very difficult to achieve among distributed developers who do not know each other and are not under control of any formal authority. As such, use of e-mail and CVS as sources of awareness information may have resulted, not from the superior utilities of these tools as an awareness mechanism, but from necessity and convenience of not having to deploy, learn, and use new software. This observation is in line with the current trend of online discussions and bug reporting and tracking operations migrating to the World Wide Web (WWW), which allows developers to access the same awareness information as before by using the single most widely deployed and used software application today, the Web browser.

The above observations do not account for the fact that specialized awareness facilities have not been widely adapted in software development, which we believe is largely because we do not yet have a good understanding of both complexities and subtleties of software development work and interaction patterns and requirements and work habits of software developers and managers. Most of the existing awareness facilities for distributed software development have been adapted from those developed for general workspace environments and thus may not be able to meet awareness requirements specific to distributed software development activities. Much research is still required to better understand distributed software development as a unique form of collaborative work.

EMBEDDED OPERATING SYSTEMS

INTRODUCTION

Many of the systems and devices used in our modern society must provide a response that is both correct and timely. More and more computer systems are built as integral parts of many of these systems to monitor and control their functions and operations. These embedded systems often operate in environments where safety is a major concern. Examples range from simple systems, such as climate-control systems, toasters, and rice cookers, to highly complex systems such as airplanes and space shuttles. Other examples include hospital patient-monitoring devices and braking controllers in automobiles.

We use operating systems (1) as interfaces between computer applications and computer hardware. Most noticeably, operating systems are used to access and control operations in desktop and notebook (laptop) personal computers (PCs). You are probably familiar with one or more of the following operating systems: Linux, Microsoft Windows (XP, NT, 2000, 98, 95), Apple Mac OS X, and UNIX.

In order to conveniently use a PC, we must first install and run an operating system. Operating systems are not only used to operate PCs, but also other types of microprocessor-driven devices, such as personal digital assistants (PDAs), which use smaller versions of PC operating systems such as Palm OS, Windows Pocket PC, and Embedded Linux (Embedix). These PDAs do not have a secondary memory and their main memory can vary in size from 8 MB to 64 MB. Processor speed may vary from several MHz to 400 MHz (Intel Xscale 400 MHz processor).

You will find operating systems even in devices whose main functions are not computation, such as DVD (digital video disk) players and VCRs (video cassette recorders). Microprocessors together with scaled-down versions of larger operating systems are embedded in these systems to control their operations. Time-critical or real-time systems use real-time operating systems, such as Wind River's VxWorks, which are more deterministic.

We can define an operating system (OS) as a program that provides a convenient environment for embedded applications consisting of multiple tasks. System calls are used for process/task management, memory management, input/output (I/O) drivers, and time delay. Error handling and recovery are also provided. An OS allows efficient sharing of resources among tasks in a single-user system or among users (each with one or more tasks) in a multiple-user system.

The goal of conventional, non-real-time operating systems is to provide a convenient interface between the computer applications and the computer hardware while attempting to maximize average throughput, to minimize average waiting time for tasks, and to ensure the fair and correct sharing of resources. However, meeting task deadlines is not an essential objective in non-real-time operating systems because its scheduler usually does not consider the deadlines of individual tasks when making scheduling decisions.

For real-time applications in which task deadlines must be satisfied, a real-time operating system (RTOS) with an appropriate scheduler for scheduling tasks with timing constraints must be used. Since the late 1980s, several experimental as well as commercial RTOSs have been developed, most of which are extensions and modifications of existing OSs such as UNIX. Most current RTOSs conform to the IEEE POSIX standard and its real-time extensions (2–4). Commercial RTOSs include LynxOS, RTMX O/S, QNX, VxWorks, and pSOSystem.

LynxOS is LynuxWorks' hard RTOS based on the Linux operating system. It is scalable, Linux-compatible, and highly deterministic. LynuxWorks also offers BlueCat Linux, an open-source Linux for fast embedded system development and deployment. RTMX O/S has support for X11 and Motif on M68K, MIPS, SPARC, and PowerPC processors. VxWorks and pSOSystem are Wind River's RTOSs with a flexible, scalable, and reliable architecture, and it is available for most CPU platforms. Here, we use VxWorks (5) to illustrate several RTOS features. This article is organized as follows: the next section describes process synchronization, followed by an introduction of real-time scheduling, a discussion on memory management, a focus on input/output issues, and finally, a conclusion.

INTERPROCESS COMMUNICATIONS

A process (or task) is the basic unit of work in a computer system. Here, we use the terms "process" and "task" interchangeably. A third concept is the "thread," which is usually defined as a lightweight process but with less overhead for its maintenance. Unless the system is very simple, there is usually more than one process in a real-time system. In a uniprocessor system, processes interleave their executions, giving the appearance of concurrent processing.

Processes can communicate with one another in a number of ways: (1) accessing (reading and/or writing) shared memory containing data structures; (2) via pipes or message queues; (3) using sockets (for interprocessor communication in a network) or socket-implemented remote procedure calls (RPC); and (4) signals.

As more than one process may attempt to access the same shared data structure at the same time, approach (1) requires mutual exclusion, which can be achieved by one of the following methods: (a) disabling of interrupts, (b) disallowing preemption, or (c) using semaphores.

In solution (a), interrupts are disabled before an access to the shared resource, thus the running process can access this resource while being the only process running in the CPU without the possibility of being interrupted by another ready process. After accessing this shared resource, interrupts are enabled again. This approach is the most

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

inefficient because time-critical processes or interrupt service routines (ISRs) responding to external events may not run even if they do not access the same shared resource while interrupts are disabled. Even in non-real-time systems, this solution is not appropriate for user applications.

In solution (b), the running process accessing the shared resource cannot be preempted by any other process (even with a higher priority than the running process) except ISRs. This solution can still lead to unacceptable real-time response and suffers the same problem as solution (a); that is, processes with higher priorities may not run even if they do not access the same shared resource while preemption is locked. The best mechanism for mutual exclusion and other synchronization problems in real-time and non-real-time systems is the semaphore described next.

Semaphores

A semaphore is like an arbiter for controlling access to a shared data structure, much like a traffic light used to control the flow of traffic (vehicles) passing through a shared intersection. Obviously, two vehicles cannot be simultaneously at the same spot; an attempt to do so would result in a collision. A semaphore can also be used to synchronize tasks and to guard multiple instances of a resource.

Conceptually, a semaphore is denned as follows:

Operations: wait and signal (P and V);

State of semaphore: (count, queue);

count ≥ 0 implies ‘count’ tokens (or privileges) are available;

count < 0 implies absolute value of ‘count’ $=$ number of processes waiting in this semaphore’s queue; and queue $=$ queue of processes waiting on this semaphore.

The wait and signal operations are defined as follows:

```
Wait(semaphore):
disable interrupts;
count = count - 1;
if count < 0 then
begin
    add calling process to semaphore queue;
    change this process’ state from running to
    waiting
    /* note that the calling process is now wait-
    ing in the queue */
end
enable interrupts;
return
Signal(semaphore):
disable interrupts;
count = count + 1;
if count <= 0 then
begin
    remove process from semaphore queue;
    change this process’ state from waiting to
    ready
    /* note that the removed process is not the
    calling process */
end
enable interrupts;
return
```

Note that we need to make the “wait” and “signal” operations atomic because they access and modify shared data (count and queue of waiting processes). This mutual exclusive access to shared data is ensured by disabling the interrupts before each operation and enabling the interrupts after each operation. Note that using a Test and Set Lock hardware instruction or having the real-time OS enforce the mutual exclusion are other ways to support the wait and signal operations, instead of disabling and enabling the interrupts.

In many OSs, especially embedded/real-time OSs, there are three types of semaphores optimized to handle different types of problems: (1) binary, (2) mutual exclusion, and (3) counting. All three types of semaphores are, in fact, defined the same way as given above; the initial value of the variable “count” determines the semaphore type.

UNIX, a general OS, provides the semaphore operations such as: semget() creates an array of one or more semaphores, semop() provides operations such as wait and signal on semaphores, and semctl() destroys a semaphore and deallocates associated memory. VxWorks, an RTOS, has the following semaphore operations: semBCreate() allocates and initializes a binary semaphore, semMCreate() allocates and initializes a mutual exclusion semaphore, semCCreate() allocates and initializes a counting semaphore, semTake() perfoms the wait operation on a semaphore, semGive() perfoms the signal operation on a semaphore, semFlush() unblocks all tasks waiting for a semaphore, and semDelete() destroys a semaphore and deallocates associated memory.

Now we solve several common problems with semaphores. Each example also illustrates the specific type of semaphore appropriate for the problem being solved.

Example 1: Sorting - A Synchronization/Ordering Problem. The problem is to sort an array of numbers by creating two tasks to sort each half of the array, and then merging the sorted halves into one sorted array. Before the merge can start, we have to ensure that the two sorting tasks must finish first. We use a binary semaphore “done” to solve this problem.

```
cobegin
    sort(l, n div 2)
    sort(n div 2 + 1, n)
coend
merged, n div 2, n)
Main process:
 :
done = create_semaphore(0);
create_process(first process);
create_process(second Process);
wait(done);
wait(done);
```

```
 :
Sort process:
 :
sorting steps;
signal(done);
terminate
```

Example 2: Mutual Exclusion. This standard mutual exclusion problem is to ensure that access to a shared resource or variable by more than one task results in a consistent value for this resource. Suppose that the access is to add one to the value of the shared variable. We solve this problem by first creating a mutual exclusion semaphore "mutex."

```
mutex = create_semaphore (1)
```

Then, we insert a wait operation before this mutually exclusive access (to the shared variable x) and a signal operation afterward.

```
Process a:
wait(mutex)
x = x + 1
signal(mutex)
Process b:
wait(mutex)
x = x + 1
signal(mutex)
```

Example 3: Buffer Pool - A Counting Problem. There are 10 temporary memory buffers, each can be allocated to one process only. The pseudocode for creating the counting semaphore "available_buffers," allocating a buffer, and releasing a buffer are shown below. Once the counter has been reduced to zero, the next process will be suspended waiting for a buffer to become available.

```
available_buffers = create_semaphore(10);
wait(available_buffers);
``allocate buffer'';
``return buffer to pool'';
signal(available_buffers);
```

The VxWorks RTOS provides the semCCreate() function to create a counting semaphore. For this example, we rewrite the above pseudocode using a VxWorks Wind counting semaphore, resulting in the following code:

```
available_buffers = semCCreate (10);
semTake(available_buffers, WAIT_FOREVER);
``allocate buffer'';
``return buffer to pool'';
semGive(available_buffers);
```

There are several simple programming rules that should be observed when using semaphores in concurrent programming. First, it is important that each task waits or signals the correct semaphore, so double-checking this process is critical in coding and debugging. Second, the value of variable "count" should conserve, that is, for each wait operation, there should be a corresponding signal operation that will be executed within a bounded period of time (or number of steps). We need to ensure that the execution of the tasks does not lead to deadlocks. Third, the initial value of variable count must be chosen carefully depending on the type of problem we are going to solve.

Real-Time Extensions

RTOSs often offer additional features to semaphores optimized for running real-time applications. We describe several such features in this section.

One feature employs priority inheritance algorithms to solve the priority inversion problem, which can occur when mutual exclusion is enforced. Priority inversion is a situation in which a higher-priority task is forced to wait for an indefinite period of time (which is not acceptable in a real-time system) in order for a lower-priority task to complete its execution.

The following example illustrates this situation. Suppose we have a preemptive system with a number of tasks including tasks A, B, and C. Task A has higher priority than task B, and task B has higher priority than task C. Task A and C may access the same resource controlled by a semaphore. At some point during their executions, task C (the lowest-priority task) has gained access to the resource. Now task A (the highest-priority task) waits on the mutual exclusion semaphore guarding this resource and is blocked (and must wait in this semaphore's queue), even though task A's priority is higher than task C's. This scenario is acceptable in a real-time system if task A does not need to wait longer than the time period (the critical section) for task C to use the resource. However, because this system is a preemptive system, task C may be preempted by task B (which has a higher priority) when it becomes ready and does not want to access the resource held by task C. Other tasks having higher priorities than task C's may continually preempt task C indefinitely, resulting in a indefinite waiting period for task A, which remains in the semaphore's queue.

A common solution to this problem is the priority inheritance algorithm or protocol. It ensures that a task holding a mutually exclusive resource executes at the priority of the highest-priority task waiting for this resource until it and all its previous instances, if any, signal the semaphore guarding this resource (that is, it has released all mutual exclusion semaphores for this resource). Then this task returns to its normal priority to continue execution. This protocol prevents this low-priority task accessing a mutually exclusive resource from being preempted for an indefinite period of time by tasks with lower priorities than that of the waiting task.

In the VxWorks RTOS, the SEM_INVERSION_SAFE option is provided and can be enabled as follows:

```
semMUTEX = semMCreate(SEM_Q_PRIORITY | SEM_
INVERSION_SAFE);
```

Another feature is a user-specified queuing discipline for the semaphore's queue, which, in general, follows a first-in-first-out (FIFO) order.

In the VxWorks RTOS, there are two possible queuing disciplines: priority (SEM_Q_PRIORITY) and FIFO

(SEM_Q_FIFO). We choose a queuing discipline when we create a semaphore as follows:

```
semA = semBCreate(SEM_Q_PRIORITY | SEM_EMPTY);
semB = semBCreate(SEM_Q_FIFO I SEM_EMPTY);
```

This queuing discipline selection is not available for POSIX-compatible semaphores.

Another feature is wait-timeout, which specifies how long a task will wait in a semaphore's queue. A timeout value of 0 indicates that the task does not wait at all. A bounded positive timeout value X indicates that the task will wait X time units before the wait operation fails. An infinite time value means that the task will wait indefinitely if needed; this value is the default value in the general definition of the wait operation.

In the VxWorks RTOS, these three timeout values are represented, respectively, by NO_WAIT (0), a positive value, and WAIT_FOREVER (-1):

```
semTake (newSem, NO_WAIT);
semTake (newSem, 100);
semTake (newSem, WAIT_FOREVER);
```

This timeout option is not available for POSIX-compatible semaphores. Other real-time extensions to semaphores include task-deletion safety and ownership of mutual exclusion semaphores.

PROCESS/TASK SCHEDULING

Scheduling a set of computer processes or tasks is to determine when to execute which task, thus determining the execution order of these tasks, and, in the case of a multiprocessor or distributed system (6), to also determine an assignment of these tasks to specific processors. This task assignment is analogous to assigning tasks to a specific person in a team of people. Scheduling is a central activity of a computer system, usually performed by the OS. Scheduling is also necessary is many non-computer systems such as assembly lines.

In non-real-time systems, the typical goal of scheduling is to maximize average throughput (number of tasks completed per unit time) and/or to minimize average waiting time of the tasks. In the case of real-time scheduling, the goal is to meet the deadline of every task by ensuring that each task can complete execution by its specified deadline. This deadline is derived from environmental constraints imposed by the application.

Schedulability analysis is to determine whether a specific set of tasks or a set of tasks satisfying certain constraints can be successfully scheduled (completing execution of every task by its specified deadline) using a specific scheduler.

Schedulability Test. A *schedulability test* is used to validate that a given application can satisfy its specified deadlines when scheduled according to a specific scheduling algorithm.

This schedulability test is often done before the tasks' runtime, that is, before the computer system and its tasks start their execution. If the test can be performed efficiently, then it can be done at run-time as an online test.

Schedulable Utilization. A *schedulable utilization* is the maximum utilization allowed for a set of tasks that will guarantee a feasible scheduling of this task set.

A hard real-time system requires that every task completes its execution by its specified deadline, and that failure to do so, even for a single task, may lead to catastrophic consequences. A soft real-time system allows some tasks or task instances to miss their deadlines, but a task that misses a deadline may be less useful or valuable to the system.

There are basically two types of schedulers: static and run-time (online or dynamic).

Optimal Scheduler. An *optimal scheduler* is one that may fail to meet a deadline of a task only if no other scheduler can.

Note that "optimal" in real-time scheduling does not necessarily mean "fastest average response time" or "shortest average waiting time." A task T_i is characterized by the following parameters:

S: start, release, ready, or arrival time
c: (maximum) computation time
d: relative deadline (deadline relative to the task's start time)
D: absolute deadline (wall clock time deadline)

Non-Real-Time Schedulers

First-in-First-Out. Processes in the ready queue are scheduled in the order they arrive. This scheduler is simple and fair, but the average waiting time may be long.

Shortest-Process-First. The shortest process in terms of computation time (CPU burst) is scheduled first. There are two variations: preemptive and non-preemptive. Starvation is a possibility in this scheduling strategy.

Round-Robin. Each process in the ready queue is scheduled FCFS for a time slice called the quantum. This scheduler is fair and reduces the average waiting time, but we have to ensure that the context-switch time is much less than the quantum.

Priority. Processes in the ready queue are scheduled according to their priorities (which may be fixed or dynamic).

Real-Time Scheduling and Schedulability Analysis

Scheduling of real-time tasks depends on the type(s) of tasks in the applications. Although non-realtime tasks are usually single-instance, there are two other common types of real-time tasks. A single-instance task executes only once. A periodic task has many iterations, and there is a fixed period between two consecutive executions of the same task. For example, a periodic task may perform signal processing of a radar scan once every 2 seconds, so the period of this task is 2 seconds. A sporadic task has zero or more instances, and there is a minimum separation between two consecutive releases of the same task. For example, a sporadic task may perform emergency maneuver of an airplane when the emergency button is pressed, but there is a minimum separation of 20 seconds between two emergency requests. An aperiodic task is a sporadic task with either a soft deadline or no deadline. Therefore, if the task has more than one instance (sometimes called a job), we also have the parameters p period (for periodic tasks) and minimum separation (for sporadic tasks)

The following are additional constraints that may complicate scheduling of tasks with deadlines:

(1) Resources shared by tasks.

(2) Precedence relations among tasks and subtasks.

(3) Frequency of tasks requesting service periodically.

(4) Whether task preemption is allowed.

If tasks are preemptable, we assume that a task can be interrupted only at discrete (integer) time instants unless we indicate otherwise. VxWorks uses preemptive priority scheduling of tasks, allowing the preemption of a running task if a higher-priority task arrives. The priority of a task can be based on its specified deadline or other attributes. For tasks having the same priority, VxWorks uses the round-robin scheduling algorithm to allow the CPU to be shared fairly. Preemption locks are offered to prevent task preemption, but they do not lock out interrupt handling.

Determining Computation Time

The application and the environment in which the application is embedded are main factors determining the start time, deadline, and period of a task. The computation (or execution) times of a task is dependent on its source code, object code, execution architecture, memory management policies, and actual number of I/Os.

For real-time scheduling purposes, we use the worst-case execution (or computation) time (WCET) as c. This time is not simply an upper bound on the execution of the task code without interruption. This computation time has to include the time the CPU is executing nontask code caused by this task as well as the time an I/O request spends in the disk queue.

Determining the computation time of a process is crucial to successfully scheduling it in a realtime system. An overly pessimistic estimate of the computation time would result in wasted CPU cycles, whereas an under-approximation would result in missed deadlines.

Uniprocessor Scheduling

We introduce scheduling in real-time systems by studying the problem of scheduling tasks on a uniprocessor system. Here, we describe schedulers for preemptable and independent tasks with no precedence or resource-sharing constraints. More details on real-time scheduling with resource and synchronization constraints can be found in Ref. 7.

To simplify our discussion of the basic schedulers, we assume that the tasks to be scheduled are preemptable and independent. A preemptable task can be interrupted at any time during its execution and resumed later. We also assume that there is no context-switching time. In practice, we can include an upper bound on the context-switching time (8) in the computation time of the task. An independent task can be scheduled for execution as soon as it becomes ready or released. It does need to wait for other tasks to finish first or to wait for shared resources. We also assume here that the execution of the scheduler does not require the processor, that is, the scheduler runs on another specialized processor. If there is no specialized scheduling processor, then the execution time of the scheduler must also be included in the total execution time of the task set. Later, after understanding the basic scheduling strategies, we will extend these techniques to handle tasks with more realistic constraints.

Fixed-Priority Schedulers: Rate-Monotonic and Deadline-Monotonic Algorithms. A popular real-time scheduling algorithm is the rate-monotonic (RMS or RM) scheduler, which is a fixed(static)-priority scheduler using the task's (fixed) period as the task's priority. RMS executes at any time instant the instance of the ready task with the shortest period first. If two or more tasks have the same period, then RMS randomly selects one for execution next.

Example. Consider three periodic tasks with the following arrival times (S), computation times (c), and periods (p, which are equal to their respective relative deadlines, d):

$$J_1 : S_1 = 0, \quad c_1 = 2, \quad p_1 = d_1 = 5.$$

$$J_2 : S_2 = 1, \quad c_2 = 1, \quad p_2 = d_2 = 4.$$

$$J_3 : S_3 = 2, \quad c_3 = 2, \quad p_3 = d_3 = 20.$$

The RM scheduler produces a feasible schedule as follows. At time 0, J_1 is the only ready task, so it is scheduled to run. At time 1, J_2 arrives. As $p_2 < p_1$, J_2 has a higher priority, so J_1 is preempted and J_2 starts to execute. At time 2, J_2 finishes execution and J_3 arrives. As $p_3 > p_1$, J_1 now has a higher priority, so it resumes execution. At time 3, J_1 finishes execution. At this time, J_3 is the only ready task, so it starts to run. At time 4, J_1 is still the only task, so it continues to run and finishes execution at time 5. At this time, the second iterations of J_1 and J_2 are ready. As $p_2 < p_1$, J_2 has a higher priority, so J_2 starts to execute. At time 6, the second iterations of J_2 finishes execution. At this time, the second iterations of J_1 is the only ready task, so it starts execution, finishing at time 8. The timing diagram of the RM schedule for this task set is shown in Fig. 1.

The RM scheduling algorithm is not optimal in general because there exist schedulable task sets that are not RM-schedulable. For a set of tasks with arbitrary periods, there is a simple schedulability test with a sufficient, but not necessary, condition for scheduling with the RM scheduler (9).

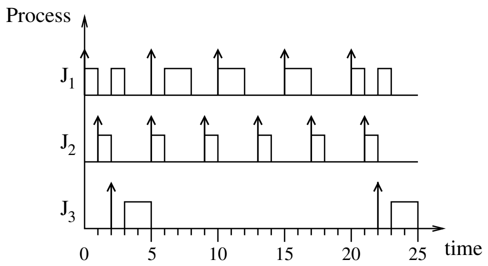

Figure 1. RM schedule.

Schedulability Test 1. Given a set of n independent, preemptable, and periodic tasks on a uniprocessor, let U be the total utilization of this task set. A sufficient condition for feasible scheduling of this task set is $U \leq n(2^{1/n} - 1)$.

However, using this simple schedulability test may underutilize a computer system because a task set whose utilization exceeds the above bound may still be RM-schedulable. There is a sufficient and necessary condition for scheduling using the RM algorithm. Its derivation is omitted here but can be found in Ref. 7.

Schedulability Test 2. Let

$$w_i(t) = \sum_{k=1}^{i} c_k \left\lceil \frac{t}{p_k} \right\rceil, \quad 0 < t \leq p_i$$

where c_k and p_k are, respectively, the computation time and the period of task J_k. The following inequality

$$w_i(t) \leq t$$

holds for any time instant t chosen as follows:

$$t = kp_j,\ j = 1, \ldots, i,\ k = 1, \ldots, \left\lfloor \frac{p_i}{p_j} \right\rfloor$$

if and only if task J_i is RM-schedulable. If $d_i not = p_i$, we replace p_i by $min(d_i, p_i)$ in the above expression.

Another fixed-priority scheduler is the *deadline-monotonic* (DM) scheduling algorithm, which assigns higher priorities to tasks with shorter *relative* deadlines. It is intuitive to see that if every task's period is the same as its deadline, then the RM and DM scheduling algorithms are equivalent. In general, these two algorithms are equivalent if every task's deadline is the product of a constant k and this task's period, that is, $d_i = kp_i$.

Dynamic-Priority Schedulers. An optimal run-time scheduler is the *earliest-deadline-first* (also known as EDF or ED) algorithm, which executes at every instant the ready task with the earliest (closest or nearest) *absolute* deadline first. The absolute deadline of a task is its relative deadline plus its arrival time. If more than one task have the same deadline, EDF randomly selects one for execution next. EDF is a dynamic-priority scheduler because task priorities may change at run-time depending on the nearness of their absolute deadlines. We now describe an example.

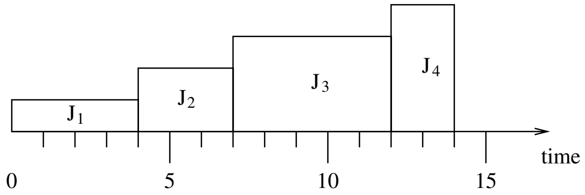

Figure 2. FIFO schedule.

Example. There are four single-instance tasks with the following arrival times, computation times, and absolute deadlines:

$$J_1 : S_1 = 0, \quad c_1 = 4, \quad D_1 = 15$$
$$J_2 : S_2 = 0, \quad c_2 = 3, \quad D_2 = 12$$
$$J_3 : S_3 = 2, \quad c_3 = 5, \quad D_3 = 9$$
$$J_4 : S_4 = 5, \quad c_4 = 2, \quad D_4 = 8$$

A first-in-first-out (FIFO or FCFS) scheduler (often used in non-real-time OSs) gives an infeasible schedule shown in Fig. 2. Tasks are executed in the order they arrive and deadlines are not considered. As a result, task J_3 misses its deadline after time 9, and task J_4 misses its deadline after time 8, before it is even scheduled to run.

However, the EDF scheduler produces a feasible schedule, shown in Fig. 3. At time 0, tasks J_1 and J_2 arrive. As $D_1 > D_2$ (J_2's absolute deadline is earlier than J_1's absolute deadline), J_2 has higher priority and begins to run. At time 2, task J_3 arrives. As $D_3 < D_2$, J_2 is preempted and J_3 begins execution. At time 5, task J_4 arrives. As $D_4 < D_3$, J_3 is preempted and J_4 begins execution.

At time 7, J_4 completes its execution one time unit before its deadline of 8. At this time, $D_3 < D_2 < D_1$, so J_3 has the highest priority and resumes execution. At time 9, J_3 completes its execution, meeting its deadline of 9. At this time, J_2 has the highest priority and resumes execution. At time 10, J_2 completes its execution 2 time units before its deadline of 12. At this time, J_1 is the only remaining task and begins its execution, finishing at time 14, meeting its deadline of 15.

Using the notion of optimality that we have defined in the introduction, the EDF algorithm is optimal for scheduling a set of independent and preemptable tasks on a uniprocessor system.

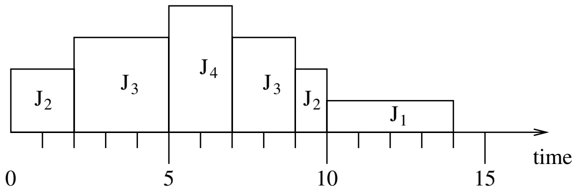

Figure 3. EDF schedule.

Theorem. Given a set S of independent (no resource contention or precedence constraints) and preemptable tasks with arbitrary start times and deadlines on a uniprocessor, the EDF algorithm yields a feasible schedule for S if and only if S has feasible schedules.

Therefore, the EDF algorithm fails to meet a deadline of a task set satisfying the above constraints only if no other scheduler can produce a feasible schedule for this task set. The proof of EDF's optimality is based on the fact that any non-EDF schedule can be transformed into an EDF schedule.

Another optimal run-time scheduler is the *least-laxity-first* (LL or LLF) algorithm (also known as the *minimum-laxity-first* (MLF) algorithm or *least-slack-time-first* (LST) algorithm). Let $c(i)$ denote the remaining computation time of a task at time i. At the arrival time of a task, $c(i)$ is the computation time of this task. Let $d(i)$ denote the deadline of a task relative to the current time i. Then the laxity (or slack) of a task at time i is $d(i) - c(i)$. Thus, the laxity of a task is the maximum time the task can delay execution without missing its deadline in the future. The LL scheduler executes at every instant the ready task with the smallest laxity. If more than one task has the same laxity, LL randomly selects one for execution next.

For a uniprocessor, both earliest-deadline-first (ED) and least-laxity-first (LL) schedulers are optimal for preemptable tasks with no precedence, resource, or mutual exclusion constraints. There is a simple necessary and sufficient condition for scheduling a set of independent, preemptable periodic tasks (9).

Schedulability Test 3. Let C_i denote the computation time of task J_i. For a set of n periodic tasks such that the relative deadline d_i of each task is equal to or greater than its respective period $p_i (d_i \geq p_i)$, a necessary and sufficient condition for feasible scheduling of this task set on a uniprocessor is that the utilization of the tasks is less than or equal to 1:

$$U = \sum_{i=1}^{n} \frac{c_i}{p_i} \leq 1$$

For a task set containing some tasks whose relative deadlines d_i are less than their respective periods, there is no easy schedulability test with a necessary and sufficient condition. However, there is a simple sufficient condition for EDF-scheduling of a set of tasks whose deadlines are equal or shorter than their respective periods.

We next consider the scheduling of sporadic tasks together with periodic tasks.

Sporadic Tasks. Sporadic tasks may be released at any time instant, but there is a *minimum separation* between releases of consecutive instances of the same sporadic task. To schedule preemptable sporadic tasks, we may attempt to develop a new strategy or reuse a strategy we have presented. In the spirit of software reusability, we describe a technique to transform the sporadic tasks into equivalent periodic tasks, which makes it possible to apply the scheduling strategies for periodic tasks introduced earlier.

A simple approach to schedule sporadic tasks is to treat them as periodic tasks with the minimum separation times as their periods. Then we schedule the periodic equivalents of these sporadic tasks using the scheduling algorithm described earlier. Unlike periodic tasks, sporadic tasks are released irregularly or may not be released at all. Therefore, although the scheduler (say the RM algorithm) allocates a time slice to the periodic equivalent of a sporadic task, this sporadic task may not be actually released. The processor remains idle during this time slice if this sporadic task does not request service. When this sporadic task does request service, it immediately runs if its release time is within its corresponding scheduled time slice. Otherwise, it waits for the next scheduled time-slice for running its periodic equivalent.

MEMORY MANAGEMENT

Data and programs are stored in the memory components of a computer system. Most RTOSs do not use virtual memory to ensure that processing time is more deterministic and overhead is substantially reduced. Therefore, the memory address space is not part of a task's context. We review several memory models below, from simple to complex. The simple memory models date back to the early days of computer design. Because of their low management overhead and access time predictability, they are often used in small embedded systems.

Bare Machine

This earliest memory model is simple and flexible. It has no operating systems and provides no services. It is used in small microprocessor and, thus, in many small embedded systems.

Resident Monitor

A resident monitor uses a static fence (an address) to divide (or separate) the memory space into two sections, one used exclusively by the OS (called the resident monitor in the early days of computing) and another assigned to the user's programs and data. The RM resides from memory location 0 up to 1, the address indicated by fence. The user's space is from the address indicated by the fence to maximum address. Note that the actual memory space allocated to the user may be smaller than fence, the maximum address. The first address assigned begins with the address indicated by the fence.

In this memory model, the logical address of a user's program or data space is different from the actual or physical address. To determine the physical address given a logical address, we need to add the logical address to the fence address. Thus, physical address = fence + logical address, or in assembly code, fence(logical address).

```
For user′ s program:
    if physical address < fence
then addressing error
    may cause an interrupt
```

Relocation

Relocation, or dynamic fence, allows more memory allocation flexibility by using a transient area separating the resident monitor and the user's space. This transient area can be used by either the monitor or the user. In this model, the first address of the monitor starts from 0 (as in the above model), but the first address of the user starts from the maximum address. Hence the user's space grows backward.

As above, to determine the physical address given a logical address, we need to add the logical address to the fence address.

Swapping

With the development of lower-cost and larger-size memory components such as disks, OS designers introduce swapping, which allows user's programs and data to be stored in the larger memory component. These programs and data can be swapped into or out of the main memory as needed. For the first time, the entire user's space needs not reside in the main memory during the lifetime of the user's job. To ensure good performance, that is, the processor is working on the user's application programs, we require that the time slice allocated to a user to be much larger than the swap time. In embedded RT systems, swapping can only be used in situations where a task will not be used for some significant period of time.

Paging

Paging is a modern approach (used today) that performs memory management using noncontiguous memory allocations.

Virtual Memory Management

The main idea is that the entire address space for a process needs not reside in the main memory for the process to execute. The early solution is overlaying, which is manual memory management by the user. Overlaying is done by the user's program. For virtual memory management to be successful, there must be program locality, which means that, during any period of time, a program usually references only a small subset of its data and instructions. Another motivation for virtual memory management is the presence of a memory hierarchy, that is, there are at least two memory levels such that the main memory has a high cost and a fast access time and a secondary memory has a low cost and a slow access time. This extra layer of memory mapping/processing and frequent disk I/O requests make the virtual memory model inappropriate for many real-time applications, where response time of the tasks must be bounded. In fact, tasks with hard deadlines are locked in memory so that there are no page faults.

INPUT/OUTPUT

Embedded and real-time systems applications interact with the computer hardware and the external environment much more closely and in a variety of formats, whereas non-real-time applications' I/O are via a standard keyboard/mouse and screen display/printer. For example, in an automobile, inputs to the embedded hardware/software are through the steering wheel, pedals, gear shifter, and an increasing array of electronic switches and buttons. Outputs are sent to the display dials and screens, and result in the activation of antiskid braking mechanisms, steering-ratio changes, and muting of the radio while the phone rings (to name a few of the many output effects).

To ensure portability of the code, most RTOSs provide I/O functions that are source-compatible with I/O in non-real-time OSs such as UNIX and Windows. However, because of the dynamic nature and domain-specificity of real-time applications, RTOSs also offer additional features tailored for embedded systems. For example, VxWorks allows the dynamic installation and removal of device drivers. VxWorks also allows the preemption of device drivers because they execute in the context of the task invoking them, whereas UNIX device drivers cannot be preempted because they execute in system mode. File descriptors or IDs (fds) are unique and specific to each process in UNIX and Windows, but they are globals (except for the standard input (0), output (1), and error (2)) accessible by any task in VxWorks.

As a result of the variety of input and output devices in an embedded real-time system, RTOSs provide far more flexibility for the device driver to handle I/O and to use customized I/O protocol. In non-real-time OSs, user I/O requests are processed first and heavily in the device-independent component of the I/O system before passing them to the device drivers (for the display and keyboard). However, RTOSs allow real-time I/O requests to bypass this standard I/O processing and delegate the control to the device drivers, which makes it possible to use specialized I/O protocols and to ensure satisfaction of requests' deadlines or throughput. In VxWorks, the I/O system in this case would act like a switch routing the I/O requests directly to the specified I/O device drivers.

CONCLUSION

This article has given a brief introduction to real-time/embedded systems, task synchronization, real-time scheduling, memory management, and I/O. The requirement to satisfy hard deadlines in embedded systems means that attention must be given to every task with a hard deadline, which makes it more challenging to develop embedded applications, which necessitate a realtime/embedded OS to ensure that real-time tasks complete by their specified deadlines.

EMBEDDED SOFTWARE

INTRODUCTION

Electronic devices are commonplace in our lives today. Many products we buy and use contain one or more miniature integrated circuits powered by electricity. Often these integrated circuits contain one or more central processing units (CPUs), with the CPU being the core computational hardware component of a programmable computer.

We usually describe a CPU found in these everyday products as an "embedded processor" and call the computer program that this CPU executes "embedded software." A good starting definition of embedded software is:

Embedded software is software that is ultimately integrated with other electrical and mechanical components and sold to the end-user as a complete product.

This definition is not precise, and there is much room for interpretation. However, by using the term "embedded" usually we are trying to denote something unique or different to distinguish the CPUs and the software found inside our everyday products from the CPUs and software found on our desktop, in the accounting back office, or in the server room. This article explores some issues faced by the developers of embedded software, emphasizing how these issues differ from or are more challenging than the issue faced by developers of desktop or back office software.

EMBEDDED SOFTWARE EXAMPLES

Table 1 lists some common products containing embedded software. The table provides a rough estimate of the software complexity incorporated in these products, expressed as total source-lines-of-code (SLOCs). Even by today's standards of software development, the software complexity of these products is enormous. In today's products, the dominant aspects of a product's functionality are expressed through software.

Economics drives the complexity explosion of embedded software. The microprocessors, microcontrollers, and digital signal processors in today's products permit the baroque expression of product features and functions. This expression is limited physically only by the cost of the memory to store and to execute the code and by the imagination of the product designer. The per-bit cost of memory—in the form of disk drives, flash memories, random-access memories, and read-only memories—drops roughly by a factor of two every two years (1). Today even a $100 product can hold upward of 50M SLOCs. Product creators say: "I can afford to put 50 Mbytes of memory and 200 Mbytes of ROM in my handheld product. I want to fill it up with quality software features that sell!"

Table 2 lists some characteristics often associated with embedded software. No single product will have all of these, but most embedded software will have at least some of these characteristics. Each characteristic can present special challenges to the software developer.

The following sections discuss several of the most difficult issues faced by embedded software developers:

- Software cost and development productivity
- Rapid time-to-market and hardware/software codesign
- Reliability and testing
- Heterogeneous multiprocessor software development
- Real-time systems
- Energy usage and energy management
- Human computer interfaces and human factors
- Security against attack and theft

These issues are not exclusive to embedded software nor do they cover all aspects of computer science that can be applied to the development process. The issues are chosen to illustrate many critical elements of embedded software that are different or more challenging for embedded software than for desktop or for back office applications.

SOFTWARE COST AND DEVELOPMENT PRODUCTIVITY

Software development cost and schedule are critical issues with virtually all software-intensive products. The explosion in the complexity of embedded software makes this especially true for products containing embedded software. Software development is a nonrecurring cost as it is a one-time expense. The cost of manufacturing the product is a recurring cost as it is incurred each time an individual product is made. Many products containing embedded software sell at very low prices, and thus, their recurring costs must be very small. However, the nonrecurring costs of software development must be amortized across the total sales to recover its cost.

A product containing a million lines of code could cost $20–40M to develop from scratch using even the best software engineering practices (2)[1]. The amortized cost of the software across even a million units would be $20–40, with a likely unsupportable percentage of the selling price in a competitive, low-cost market. The nonrecurring cost of software has become a critical cost issue even in very expensive products such as luxury automobiles or commercial airplanes, depending on the total quantity of software involved, the very strict quality requirements placed on the software development process, and the lesser sales volumes compared with less expensive products.

In a competitive environment, software reuse is the most effective tool we have to lower the cost of software development. Reuse effectively amortizes costs across a higher sales volume, lowering the per-unit cost. Producers of

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Table 1. Some Products Containing Embedded Software

Product	SLOC (M)	Comments
Next-generation jumbo jet airliner	1,000	critically reliable, active real-time control, high potential for product liability
2006 luxury sedan	30–50	highly reliable, up to 75 distributed CPUs, cost sensitive, active real-time control
Residential gateway	10–20	very low cost, quick to market
CT medical imager	4–6	highly reliable, potential for product liability
High-end cellular telephone handset	3–10	energy efficient, very low cost, reliable, 3–6 different CPUs, quick to market
Programmable digital hearing aid	.005–.02	10–30M multiply/accumulates per second at 0.001 watt power, extremely low cost, programmable post-manufacture

Table 2. Some Characteristics of Embedded Software

- Low cost
- Small "footprint"
- Short time to market
- High reliability
- "Close" to the hardware
- Codesigned with a system on a chip
- Software/firmware in ROM/PROM
- Low power and power management
- Very high performance on a specialized task
- Heterogeneous, multiple processors
- Software on a special-purpose processor
- Observing and controlling real-world signals
- Real time
- "Nontraditional" or safety-critical user interface
- Security against attack and theft

products containing embedded software use several methods of software reuse:

- Software product line concepts
- Commercial embedded operating systems
- Software/hardware platforms
- Software standards
- Open source software
- Value chains of third-party developers

The software product line (3)[2]—often called a software product family in Europe—attempts to achieve efficiencies similar to those attained with an assembly line in modern manufacturing methods. A product line approach recognizes that most products in a market segment are very similar, varying only in certain well-defined and predictable ways. For example, many different automobile models from a manufacture share several common functions, but they differ in parameters or in options in a specific configuration. The same is true for cellular telephone handsets and television sets. Software reuse becomes easier when the commonality and differences in the software design are exploited.

The software product line approach focuses first on software architecture:

> The software architecture of a program or computing system is the structure or structures of the system, which comprise software elements, the externally visible properties of those elements, and the relationship among them (4).

Developers find it easier to create reusable components when the architecture takes into account similarities as well as points of variation across the different products in the product family. Within the constraints of the architecture, developers can create reusable software components and other software assets for the initial products, and then they can refactor continuously those components to maintain the product line as new products are created. Companies adopting software product lines have reported case studies showing factors-of-two or better improvements in software development productivity over their previous "serendipitous" reuse strategies. Also, defects were decreased significantly and time-to-market was shortened considerably (5).

The software product line approach also recognizes that domain expertise[3] is an important aspect of embedded software design. Embedded software often interacts with real-world signals or mechanical systems. Domain knowledge and special mathematical skills—digital signal processing, digital communications, real-time control, image processing, or computer graphics, for example—facilitate effective software implementation. A focused development team with the correct mixture of software engineering skills and domain expertise can make the difference between a successful and an unsuccessful product.

Commercial embedded operating systems are a tremendous source of software reuse. In many embedded applications, most lines-of-code are provided by the operating system. Windows CE^{TM}, Symbian OS^{TM}, and Embedded Linux^{TM} are examples of commonly used operating systems. Usually, the embedded operating system provides components and skeletal architectures for the run-time environment, the user interface framework, the peripheral drivers, the media encoders/decoders, and the communication protocols needed by the product. The generality and extended functionality of the operating system allows the operating systems to be used across many of embedded products.

The generality of a commercial embedded operating system also can be a curse. The embedded operating

[1] See entry on SOFTWARE ENGINEERING.

[2] See entry on SOFTWARE ENGINEERING.

[3] See entry on DOMAIN EXPERTISE.

systems must be tailored and configured to eliminate features that are not used, requiring a significant effort. Even then, the resulting executable code size may be too large for low "footprint" applications or too complex for adequate testing. These factors are critical in highly distributed systems like those found in an automobile.

A software/hardware platform is a development environment and framework of software and hardware components designed to provide common features and functions that can be reused across an application domain. Often a platform is an outcome of a software product line, but it also can evolve from legacy products. Usually the platform provides a programmer interface layer above the operating system on which many similar applications can be built. Platforms can be proprietary, commercial, or a mixture of the two.

A cellular handset manufacturer or a television set manufacturer, for example, will develop a proprietary platforms that is then customized specifically for each of the different products in the product line. Commercial embedded application platforms are becoming more common in the industry. Qualcomm's Brew$^{\mathrm{TM}}$ and Nokia's Series 60$^{\mathrm{TM}}$ on Symbian OS are two examples of commercial platforms for development of mobile wireless applications. Platforms provide independent developers with a post-manufacture development opportunity, and they offer similar productivity advantages to those of a software product line.

Software standards are an effective concept used to increase embedded software reuse. Usually, standards specify interfaces between software modules or between hardware and software. However, standards can cover software architecture, run-time environments, security, testing, and software methodology. Standards do not specify the implementation, allowing competition among vendors for creative solutions. Standards can be industry-specific or application-specific, developed through cooperation directly between otherwise competing companies. Once the standard is worked out, it may be held and maintained by a vendor-neutral standards body (6) or by a consortium of companies. The Institute of Electrical and Electronics Engineers, International Organization for Standardization, International Telecommunications Union, and the World Wide Web Consortium are a few examples of standards bodies with significant impact on embedded software reuse. Sometimes standards are established informally as "de facto" standards when everyone merely follows the industry leader's interface practices.

Open source software (7) is another form of software reuse used in embedded systems. Under the open source license, software is made available in source form, allowing the product developer to benefit from features and bug fixes added by other developers. Sometimes the developers may be creating similar products, and sometimes not. Embedded Linux is a very successful example of software reuse via an open source license. Open source software is not necessarily free for commercial use nor is it public domain software. Usually, licensing fees and legal restrictions apply for use of the intellectual property contained in the software.

Third-party developers contribute to software reuse. Software development for complex products rarely is performed completely by the product developer alone. For example, semiconductor vendors will license significant software content, software tools, and example code to the purchaser of their programmable components as a way of winning business. For the most competitive programmable semiconductor products, semiconductor vendors may license production quality software components that can be dropped directly into an embedded software product. Similarly other companies—usually called "third-party developers"—spring up to provide specialized domain expertise, software integration skills, and licensed software for specialized processors. Third-party developers often provide complete hardware/software subassemblies containing significant embedded software. A diesel engine for an automobile or a jet engine for an aircraft would be examples of these subassemblies. Because third-party developers sell their software to multiple customers for multiple products, effectively they are promoting software reuse.

Embedded operating systems, third-party software, and open source software are all examples of a "value chain (1)" (sometimes called "value web") that fosters software reuse and allows embedded software products with millions (or even billions) of lines of code to be created so that the very high nonrecurring cost of its development is amortized effectively across a very large number of products.

RAPID TIME-TO-MARKET AND HARDWARE/SOFTWARE CODESIGN

The old cliché "time is money" is certainly true when it comes to product introduction. Time-to-market is a critical aspect of embedded software development for many products. Sales of a new consumer product—a digital still camera or a music player, for example—peak just before Christmas. The difference of a few weeks in the critical development schedule can make the difference between financial success and failure in the marketplace.

Embedded software development can be challenging especially in this environment. Software development costs go up when development schedules are shortened artificially. The developer may need a software process that consciously trades short development time for programmer efficiency to maintain a tight schedule[4].

Hardware/software codesign methodology often is employed to gain rapid time-to-market for products containing embedded software that is "close to the hardware" and when one or more integrated circuits are yet-to-be-developed. The software developer cannot wait for the hardware to start development of the software. Hardware/software codesign methods[5] must be used so that the software and hardware developments can proceed in parallel. Hardware/software codesign is a methodology for simultaneous development of new hardware, new software,

[4] See entry on SOFTWARE DEVELOPMENT METHODOLOGIES AND PROCESSES.

[5] See entry on HARDWARE/SOFTWARE CODESIGN.

and new development tools. The complex interactions among the application domain, the various hardware and software components, and the development tools must be simulated or modeled at varying levels of abstraction early in and throughout the design process. Embedded software allows the inevitable changes in requirements or minor hardware fixes to be implemented quickly and late in the development cycle. Consequently, software is frequently a preferred design choice for quick time-to-market products even when a more hardware-centric approach would have lower recurring costs.

RELIABILITY AND TESTING

Many products containing embedded software have high reliability requirements. We expect our telephones to be more reliable than our desktop computers. We expect our automobiles to be more reliable than our telephones, and we expect our airplanes to be more reliable than our automobiles. Reliability is a very key component of product liability costs (8), warranty costs, software maintenance costs, and ultimately product success.

We can achieve adequate reliability through application of good software engineering practices: software architecture, design for reliability, a quality software development process[6] and extensive test coverage[7]. However, no system is 100% reliable. Several aspects of embedded systems make achieving the desired level of reliability very difficult.

Adequate test coverage is difficult to achieve for software that senses and controls real-world signals and devices. We would like to test such software against all combinations and permutations of its environment, but this is difficult because of the real-world temporal variation in inputs and external state. If the software is very complex, it is even worse because the huge combinitorics of internal state compounds the problem. The product test cycle for telecommunications products can be 9–12 months over thousands of sample products in various configurations and environments. For a commercial aircraft, the software testing process can take years.

For higher reliability systems, reliability techniques such as redundancy and voting, error-checking and recovery, formal reliability models, formal software validation tools, temporal logic models of system behavior, requirement-driven margins of safety, and executable assertions must be used to augment rigorous testing (9).

Real-time embedded software executing on complex integrated circuits is more difficult to test and debug than software with relaxed time constraints. Real-time systems often follow the uncertainty principle: “When you test them, their reliability and performance change.” To achieve adequate testing, inputs must be provided to internal components, and internal state and outputs must be collected as nonintrusively as possible. Historically, this task was assigned to a logic analyzer or to a real-time test harness. However, today’s complex integrated circuits are pin-limited and bandwidth-limited relative to their internal computation rates. It is difficult to achieve high data transfer rates on and off the chip nonintrusively. Modern programmable integrated circuits may employ special test and debug ports—IEEE 1149.1 (Joint Test Action Group) standard, for example—and add special internal nonintrusive trace circuitry, similar to a built-in logic analyzer, to capture internal data. Combined with software design-for-test concepts, this internal circuitry increases real-time test coverage.

No product is without latent defects. Latent defects are a product liability—a future cost for financial compensation for injured parties. Manufacturers warrant their product against latent defects—a future cost for recalling, repairing, or replacing defective products. Product litigation and product recalls are expensive. These future costs depend on the number and the severity of defects in the current product and on the speed and the efficacy in which defects are fixed before they cause a problem. Embedded software defects have become a major cost factor. To predict and manage these costs, the developer can create a latent defect model to help drive pricing and maintenance decisions. Usually such models are based on metrics captured over the lifecycle of the software development process. For embedded software, frequently this means adding extra software and hardware to products to capture operational/test data in the field. Extra software and hardware also may be added to enable or to lower the cost of field upgrades. Latent defect models are statistical in nature and usually are based on historical metrics associated with the software developer’s software process as well as on the specific development and test metrics captured during the specific product’s development cycle[8].

When developers use a latent defect models for pricing and product improvement decisions, they need similar models and data from their third-parties and other sources of reusable software. The lack of models and data can be a barrier to using third-party or open-source software.

HETEROGENEOUS MULTIPROCESSOR DEVELOPMENT

Products with complex embedded software content are often heterogeneous multiprocessor systems. These systems can bring big advantages. Different CPUs or computational accelerators can be specialized and optimized for the specific task demanded of them. Real-time activities can be isolated physically from nonreal-time functions to simplify the analysis and design. Whole devices can be powered down when not used to save power. Mission-critical operations can be isolated physically from less reliable code so as to eliminate the unpredictable side effects of unreliable code. Multiple processors can lower or eliminate data transmission costs, which can be more expensive and time consuming than the computation itself.

However, multiple heterogeneous processor systems come with a development penalty. Programming different CPUs usually requires different programmer training and new design skills. Specialized processors or computational

[6] See entry on RELIABILITY TEST.

[7] See entry on SOFTWARE ENGINEERING PRACTICES.

[8] See entry on DEFECT MODELS IN SOFTWARE PROCESS.

accelerators may have development tool limitations that make them harder to program.

Tool stability and versioning is very important for efficient software development but especially so for embedded software for heterogeneous processors. For example, a subassembly manufacturer in the automotive industry will have developed and tested millions of lines of code that are then reused in hundreds of different vehicles manufactured by many manufacturers. A new version of a compiler may provide improved code performance or may fix compiler defects. But changing to the new compiler would require recompilation, revalidation, and testing of all the existing code used in each of the various products and product environments. This task is daunting and time consuming. Using the old compiler version for lifecycle maintenance on older products is preferred. However, keeping track of all versions of tools for all variations of software is hard. Embedded software developers usually keep all their software tools in the same configuration management system that contains the code they are developing to avoid unnecessary or unanticipated costs and delays caused by new tool versions.

REAL-TIME SYSTEMS

Many products contain real-time (10)[9] embedded software. Real-time software, like any other software, accepts inputs, updates the internal state, and produces outputs. However, the time relationship of the outputs relative to the inputs and the implicit or explicit representation of time in the software are what make software real time. Often real-time software is part of a feedback loop controlling real-world signals and mechanical devices—an aircraft "fly-by-wire" flight control system, for example. But real-time software also is important in products such as portable music or digital video players dealing with audio and video perception. Human perception is sensitive to temporal aspects of sound and vision.

Real time is more about predictable or deterministic computational performance than about fast or high throughput. A unit of computation can have a time deadline relative to some event. When failing to complete the computation before the deadline causes a failure, we call the deadline a "hard" deadline and the system is called a hard real-time system. If the system can miss the deadline occasionally and still meet requirements, we call the deadline a "soft" deadline and the system is called a soft real-time system. A flight control system usually is a hard real-time system, whereas an audio decoder is more likely a soft real-time system. In reality, real time is a continuum between hard and soft based on the allowable statistics and the severity of missed deadlines and the developer must make a corresponding tradeoff between determinism and speed. A flight controller almost always will use deterministic software techniques over faster but less predictable ones, whereas an audio decoder may meet requirements by using high throughput but occasionally using approximate computations or even sometimes allowing noticeable artifacts in the sound.

Designing complex embedded real-time systems is a tough task. It usually helps to consider time explicitly in the design and to develop a model of computation as part of the software architecture. A model of computation (11)—or "framework"—is a set of rules or design patterns that determine the interaction of all the time-critical components of the software. The choice of computational model depends on the domain and on the specifics of the real-time requirements. A good model of computation can lead to lower development cost and higher reliability.

A real-time operating system (RTOS) can provide reusable components and a framework for the chosen model of computation. Some embedded operating systems, such as Windows CE or Symbian OS, provide significant real-time features. Additionally, commercial RTOS vendors (12)—Wind River, Green Hills Software, or LynuxWorks, for example—provide robust frameworks for highly reliable, hard real-time embedded systems.

ENERGY USAGE AND ENERGY MANAGEMENT

Many products containing embedded software are battery powered. Customers prefer infrequent battery charging or replacement, which in turn means efficient use of energy (13). Usually, embedded software is involved in the energy management of energy-efficient products. Energy usage and energy management are key elements to the software design.

System designers use many different techniques for energy management. Some examples are as follows:

- Special CPUs or other processors
- Clock and power control of circuits
- Parallel computation
- Voltage scaling

Special processors—programmable digital signal processors or programmable digital filter banks, for example—can improve greatly the energy efficiency over a conventional CPU. Often these devices require custom programming and can exacerbate the issues with the heterogeneous multiprocessor nature of the software. However, the benefits of more energy efficiency make the challenges worthwhile (14).

The programmable, in-ear digital hearing aid is an excellent example of the marriage of embedded software and a programmable special-purpose signal processor. Although current-day digital hearing aids may contain some embedded software for control, they do most of the signal processing with hard-wired digital filters implemented directly in logic. They do not employ the superior software signal processing techniques demonstrated in the research laboratories because the power consumption would use up the battery in hours or even in minutes. An embedded digital signal processor, augmented with programmable digital filters or other specialized programmable processors, can provide superior sound quality and can adapt better to the hearing impairment. Because it is programmable, the same basic design can be adapted to a

[9] See entry on REAL-TIME SOFTWARE.

wider range of hearing disabilities and may even be reprogrammed in the audiologist's office. Ultimately this energy-efficient embedded software product will benefit over 600M hearing-impaired people worldwide.

Digital integrated circuits use one or more clock signals to synchronize digital logic operations. Every time the clock toggles, it consumes energy as it charges or discharges the electrical capacitance of the on-chip interconnect wires it drives. Usually the clock toggles at twice the frequency of the rest of the logic and consequently is one of the largest consumers of energy in an integrated circuit. When the clock toggles at its full rate, it is consuming energy even when the digital logic circuits it is synchronizing are not performing any useful work. Thus energy efficient integrated circuits control the clock rates for the various internal circuits and subsystems in an on-demand manner. This clock management function usually is performed by the embedded software.

Today's fastest and most dense integrated circuits contain exceedingly small transistors with minimal geometries under 65 nm. The very low voltages and very high clock rates enabled through these small transistors have a detrimental side effect on energy usage. When powered, these small transistors leak current in a manner analogous to a leaky faucet. The current lost to a single transistor is small, but the current lost in a large circuit of 500M transistors can be huge. When circuits are not performing useful work, power must be switched off to conserve the energy that would otherwise be lost. This power switching may also be part of the embedded software function, adding yet another layer of complexity. But more importantly, most of the circuits that are powered down contain registers or memory to hold internal state information. These data must be made available again to the software and other logic functions when they are reactivated. Critical state information that could be lost must be preserved in special memories or with special memory power-down configurations, or they must be recreated again and reinitialized when the circuit is powered up. This function also can be assigned to the embedded software. Power management is now a complex feature of energy-efficient integrated circuits requiring embedded software for correct operation.

Parallel computation can be used to lower energy consumption. The rate at which energy is consumed in a CMOS digital integrated circuit is directly proportional to the clock rate, whereas the time it takes the software to perform its task is inversely proportional to the clock rate. Total energy consumed for a fixed unit of software functionality remains constant over a wide range of clock rates. However, if you can lower the integrated circuit voltage, the rate of energy consumption drops as the square of the voltage, whereas the maximum achievable clock rate drops only roughly proportionally to the voltage. Operating the integrated circuit at its lowest operating voltage saves energy, albeit at a reduced clock rate. Two CPUs operating in parallel at a slow clock rate are roughly twice as energy efficient as a single CPU operating at twice the clock rate, assuming that the parallel computation still can achieve the same computational efficiency. Parallel computation is not always easy or achievable, but it can conserve energy when used effectively in an embedded system. Programming parallel processes is a difficult aspect of energy-efficient, embedded software design.

Voltage scaling is a similar concept. Voltage scaling recognizes that in many embedded systems the computational load is not uniform over time and may not even be predictable. Voltage scaling allows the software to select its own clock rate and select the required operating voltage, computational speed, and resultant energy consumption rate. When properly scheduled, the software can complete the current computational load "just in time," and, thus, achieve the best energy efficiency. For soft and hard real-time systems, voltage scaling can save energy, but it adds yet an additional layer of complexity to the software design. In dynamic applications, effective use of voltage scaling requires extra software components to predict future computational loads in advance.

HUMAN–COMPUTER INTERFACES AND HUMAN FACTORS

Frequently, the software embedded in a product interacts directly with a user. Thus, the product is an extension of the user in performing his task. The design of the software behind this interface is critical in the success or failure of the product.

Products with physically limited input and output capabilities can be difficult to use, and superior usability is a major factor of product success. For example, sales of a digital video recorder can improve when a more user-friendly interface is implemented to capture unattended broadcasts. Some products are meant to be used in eyes-free or hands-free environments or to be accessible by persons with a visual or physical impairment. Cellular telephones and automotive navigation systems, for example, may employ voice recognition and response to augment the traditional user interface. In complex and exacting tasks, such as piloting and aircraft, the user can be overwhelmed with information. A good interface will prioritize automatically and present only the most critical information, while avoiding information overload by suppressing the less important information. In any safety-critical system, such as in aircraft or in automobile electronics, human errors are a real safety concern. The user interface software must avoid confusing protocols, repetitive monotony, and user mental fatigue that can lead to human errors or lapses in judgment. The user interface must check and confirm potentially disastrous commands while maintaining the responsiveness the user needs to perform in an emergency under stress.

Attention to human factors is a key element of the design and testing process for embedded software that interacts directly with humans. User-centered design (15), sometimes called human-centered design, is one design process that attempts to inject the user's wants, needs, and variability into the software development and maintenance lifecycle. User-centered design recognizes that the user's behavior must be viewed in the context of the full range of the product's use scenarios. Users and potential users are involved continuously throughout the design cycle via user focus groups, assessments of usage scenarios task analyses and interface mock-ups or sketches, and testing with working prototypes and preproduction software. User-centered design ensures that the user is well represented in the design process, but it does not diminish the other aspects of good software design and software reuse processes.

User-centered design is not a panacea for interacting with the user. User interfaces for safety-critical embedded software are particularly demanding. Catastrophic errors usually are rare and occur as a result of the simultaneous occurrence of two or more even rarer events. The statistical margins of variations of human characteristics, user tasks, environmental conditions, and software defects are all difficult to predict, to observe, and to characterize through direct interaction with users. User-centered design must be combined with a strong safety methodology, such as the International Electrotechnical Commission's "Functional Safety of Electrical/Electronic/Programmable Electronic Safety-Related Systems" (IEC 61508) or the joint Radio Technical Commission for Aeronautics and European Organization for Civil Aviation Equipment DO-178B Level A software development standard.

SECURITY AGAINST ATTACK AND THEFT

We are all familiar with the issues of computer viruses and electronic theft in today's desktop and World Wide Web environments (16). Although not yet commonplace, embedded software products also are susceptible to these security issues. Because so much of our society depends on embedded software, terrorism is another threat. The threats are evolving. In the past, embedded software was constrained to ROM, was not connected electronically to a network, and was never upgraded. Tampering was difficult and ineffectual, so the threat was minimal. This situation is no longer true. Cellular handset developers, automotive companies, aircraft producers, media player developers, as well as most other industry segments are now taking digital security seriously. Cellular handset manufacturers are working with semiconductor vendors to put security features in hardware to thwart cellular handset cloning and viruses.

Content providers are concerned with theft of their products. In the near future, digital rights management (17) will be included in the embedded software of virtually all audio and video players and recorders. Digital rights management is a set of security features that allow a rightful owner or licenser of digital content to use it, but it keeps anyone from copying and distributing the content. Digital rights management usually involves some sort of encryption of the digital media combined with a mechanism to bind the use of the encrypted media to a specific hardware device or player. It also can include information unobtrusively embedded in the media—often called a "watermark"—to identify uniquely the source and distribution path of the media in such a way that an illegal copy and the illegal copier can be identified and prosecuted.

Security and protection against theft are becoming every bit as important in products with embedded software are they are in desktop software products. Security and digital rights management are primarily implemented with software and are becoming yet another critical software development issue with embedded software.

SUMMARY

Embedded software is commonplace. It is a defining constituent of the many products we use daily. More and more, products depend on electronics and software to implement the many new functions we demand. As a result, the complexity of embedded software is exploding.

Development of complex embedded software is a nonrecurring cost that must be amortized across sales of all products that use the software. Because of the high cost of developing software containing millions of lines of code, software reuse, in all its forms, is the only practical way to minimize this cost to the consumer.

The embedded software developer faces many special challenges. Among these challenges are quick time-to-market with hardware/software codesign, high-quality designs with high reliability, special design-for-test features enabling high test coverage, scalable modular designs incorporating many different CPUs and instruction sets, software architectures and computational models that address real-time applications, designs that support energy-efficient use of the underlying electronics, user-centric interfaces, and protection from the risks of computer hacking, terrorism, theft, and litigation.

FAULT-TOLERANT SOFTWARE

INTRODUCTION

Fault tolerance is the survival attribute of a system or component to continue operating as required despite the manifestation of hardware or software faults (1). Fault-tolerant software is concerned with all the techniques necessary to enable a software system to tolerate software design faults remaining in the system after its development (2). When a fault occurs, fault-tolerant software provides mechanisms to prevent the system failure from occurring (3).

Fault-tolerant software delivers continuous service complying with the relevant specification in the presence of faults typically by employing either single-version software techniques or multiple-version software techniques. We will address four key perspectives for fault-tolerant software: *historical background*, *techniques*, *modeling schemes*, and *applications*.

HISTORICAL BACKGROUND

Most of the fault-tolerant software techniques were introduced and proposed in 1970s. For example, as one of single-version fault-tolerant software techniques, the exception handling approach began to appear in the 1970s, and a wide range of investigations in this approach led to more mature definitions, terminology, and exception mechanisms later on (4). Another technique, checkpointing and recovery, was also commonly employed to enhance software reliability with efficient strategies (5).

In the early 1970s, a research project was conducted at the University of Newcastle (6). The idea of the recovery block (RB) evolved from this project and became one of the methods currently used for safety-critical software. RB is one of three main approaches in so-called *design diversity*, which is also known as multi-version fault-tolerant software techniques. N-version programming was introduced in 1977 (7), which involved redundancy of three basic elements in the approach: process, product, and environment (8). N self-checking programming approach was introduced most recently, yet it was based on the concept of self-checking programming that had long been introduced (9).

Since then, many other approaches and techniques have been proposed for fault-tolerant software, and various models and experiments have been employed to investigate various features of these approaches. We will address them in the following part of this article.

Definitions

As fault-tolerant software is capable of providing the expected service despite the presence of software faults (7,10), we first introduce the concepts related to this technique (11).

Failures. A failure occurs when the user perceives that a software program is unable to deliver the expected service (9). The expected service is described by a system specification or a set of user requirements.

Errors. An error is part of the system state, which is liable to lead to a failure. It is an intermediate stage in between faults and failures. An error may propagate (i.e., produce other errors).

Faults. A fault, sometimes called a *bug*, is the identified or hypothesized cause of a software failure. Software faults can be classified as design faults and operational faults according to the phases of creation. Although the same classification can be used in hardware faults, we only interpret them in the sense of software here.

Design Faults. A design fault is a fault occurring in software design and development process. Design faults can be recovered with fault removal approaches by revising the design documentation and the source code.

Operational Faults. An operational fault is a fault occurring in software operation due to timing, race conditions, workload-related stress, and other environmental conditions. Such a fault can be removed by recovery (i.e., rollback to a previously saved state and executed again).

Fault-tolerant software thus attempts to prevent failures by tolerating software errors caused by software faults, particularly design faults. The progression "fault-error-failure" shows their causal relationship in a software lifecycle, as illustrated in Fig. 1. Consequently, there are two major groups of approaches to deal with design faults: (1) fault avoidance (prevention) and fault removal during the software development process, and (2) fault tolerance and fault/failure forecasting after the development process. These terms can be defined as follows:

Fault Avoidance (Prevention). To avoid or prevent the introduction of faults by engaging various design methodologies, techniques, and technologies, including structured programming, object-oriented programming, software reuse, design patterns, and formal methods.

Fault Removal. To detect and eliminate software faults by techniques such as reviews, inspection, testing, verification, and validation.

Fault Tolerance. To provide a service complying with the specification in spite of faults, typically by means of single-version software techniques or multi-version software techniques. Note that, although fault tolerance is a design technique, it handles manifested software faults during software operations. Although software fault-tolerance techniques are proposed to tolerant software errors, they can help to tolerate hardware faults as well.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

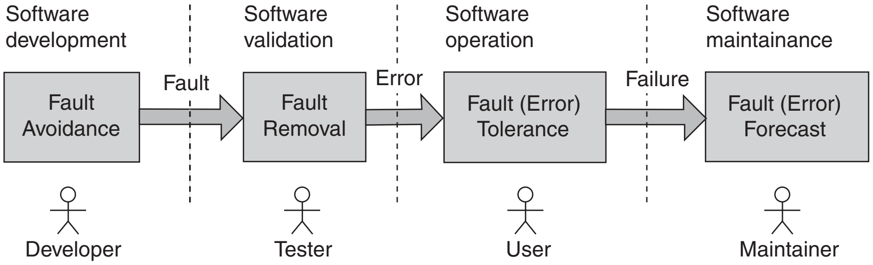

Figure 1. The transition of fault, error, and failure in a software lifecycle.

Fault/failure Forecasting. To estimate the existence of faults and the occurrences and consequences of failures by dependability-enhancing techniques consisting of reliability estimation and reliability prediction.

Rationale

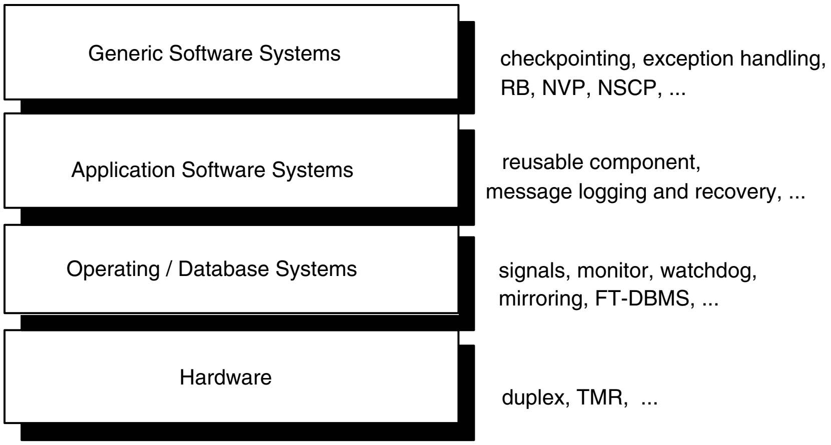
The principle of fault-tolerant software is to deal with residual design faults. For software systems, the major cause of residual design faults can be complexity, difficulty, and incompleteness involved in software design, implementation, and testing phases. The aim of fault-tolerant software, thus, is to prevent software faults from resulting in incorrect operations, including severe situations such as hanging or, at worst, crashing the system. To achieve this purpose, appropriate structuring techniques should be applied for proper error detection and recovery. Nevertheless, fault-tolerance strategies should be simple, coherent, and general in their application to all software systems. Moreover, they should be capable of coping with multiple errors, including the ones detected during the error recovery process itself, which is usually deemed fault-prone due to its complexity and lack of thorough testing.

To satisfy these principles, strategies like checkpointing, exception handling, and data diversity are designed for single-version software, whereas RB, N-version programming (NVP), and N self-checking programming (NSCP) have been proposed for multi-version software. The details of these techniques and their strategies are discussed in the next section.

Practice

From a user's point of view, fault tolerance represents two dimensions: availability and data consistency of the application (12). Generally, there are four layers of fault tolerance. The top layer is composed of general fault-tolerance techniques that are applicable to all applications, including checkpointing, exception handling, RB, NVP, NSCP, and other approaches. Some of the top-level techniques will be addressed in the following section. The second layer consists of application-specific software fault-tolerance techniques and approaches such as reusable component, fault-tolerant library, message logging and recovery, and so on. The next layer involves the techniques deployed on the level of operating and database systems, for example, signal, watchdog, mirroring, fault-tolerant database (FT-DBMS), transaction, and group communications. Finally, the underlying hardware also provides fault-tolerant computing and network communication services for all the upper layers. These are traditional hardware fault-tolerant techniques including duplex, triple modular redundancy (TMR), symmetric multiprocessing (SMP), shared memory, and so on. Summary of these different layers for fault-tolerance techniques and approaches are shown in Fig. 2.

Technologies and architectures have been proposed to provide fault tolerance for some mission-critical applications. These applications include airplane control systems (e.g., Boeing 777 airplane and AIRBUS A320/A330/A340/A380 aircraft) (13–15), aerospace applications (16), nuclear reactors, telecommunications systems and products (12), network systems (17), and other critical software systems.



Generic Software Systems

FAULT-TOLERANT SOFTWARE TECHNIQUES

We examine two different groups of techniques for fault-tolerant software: single-version and multi-version software techniques (2). *Single-version techniques* involve improving the fault detection and recovery features of a single piece of software on top of fault avoidance and removal techniques. The basic fault-tolerant features include *program modularity*, *system closure*, *atomicity of actions*, *error detection*, *exception handling*, *checkpoint and restart*, *process pairs*, and *data diversity* (2,18).

In more advanced architectures, *design diversity* is employed where *multiple software versions* are developed independently by different program teams using different design methods, yet they provide the equivalent service according to the same requirement specifications. The main techniques of this multiple-version software approach are RB, NVP, NSCP, and other variants based on these three fundamental techniques.

All the fault-tolerant software techniques can be engaged in any artifact of a software system: procedure, process, software program, or the whole system including the operating system. The techniques can also be selectively applied to those components especially prone to faults because of the design complexity.

Single-Version Software Techniques

Single-version fault tolerance is based on temporal and spacial redundancies applied to a single version of software to detect and recover from faults. Single-version fault-tolerant software techniques include a number of approaches. We focus our discussions on two main methods: checkpointing and exception handling.

Checkpointing and Recovery. For single-version software, the technique most often mentioned is the checkpoint and recovery mechanism (19). *Checkpointing* is used in (typically backward) error recovery, by saving the state of a system periodically. When an error is detected, the previous state is recalled and the whole system is restored to that particular state. A *recovery point* is established when the system state is saved and discarded if the process result is acceptable. The basic idea of checkpointing is shown in Fig. 3. It has the advantages of being independent of the damage caused by a fault.

The information saved for each state includes the values of variables in the process, its environment, control information, register values, and so on. Checkpoints are snapshots of the state at various points during the execution.

There are two kinds of checkpointing and recovery schemes: single process systems with a single node and multiple communicating processes on multiple nodes (3). For *single process recovery*, a variety of different strategies is deployed to set the checkpoints. Some strategies use randomly selected points, some maintain a specified time interval between checkpoints, and others set a checkpoint after a certain number of successful transactions have been completed.

For *multiprocess recovery*, there are two approaches: asynchronous and synchronous checkpointing. The difference between the two is that the checkpointing by the various nodes in the system is coordinated in synchronous checkpointing but not coordinated in asynchronous checkpointing. Different protocols for state saving and restoration have been proposed for the two approaches (3).

Exception Handling. Ideal fault-tolerant software systems should recognize interactions of a component with its environment and provide a means of system structuring, making it easy to identify the part of the system needed to cope with each kind of error. They should produce normal and abnormal (i.e., exception) responses within a component and among components' interfaces (20). The structure of exception handling is shown in Fig. 4.

Exception handling, proposed in the 1970s (21), is often considered as a limited approach to fault-tolerant software (22). As departure from specification is likely to occur, exception handling aims at handling abnormal responses by interrupting normal operations during program execution. In fault-tolerant software, exceptions are signaled by the error detection mechanisms as a request for initiation of an appropriate recovery procedure. The design of exception handlers requires consideration of possible events that can trigger the exceptions, prediction of the effects of those events on the system, and selection of appropriate mitigating actions.

A component generally needs to cope with three kinds of exceptional situations: interface exceptions, local exceptions, and failure exceptions. *Interface exceptions* are

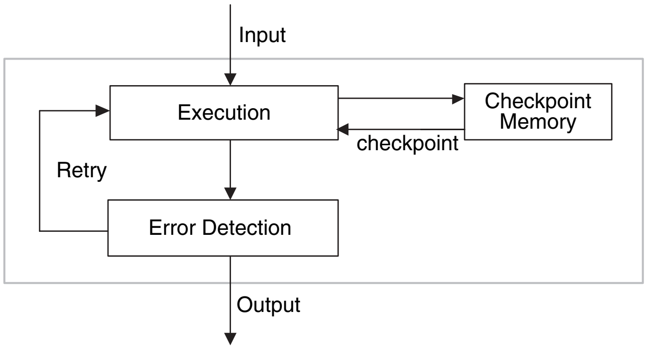

Figure 3. Logic of checkpoint and recovery.

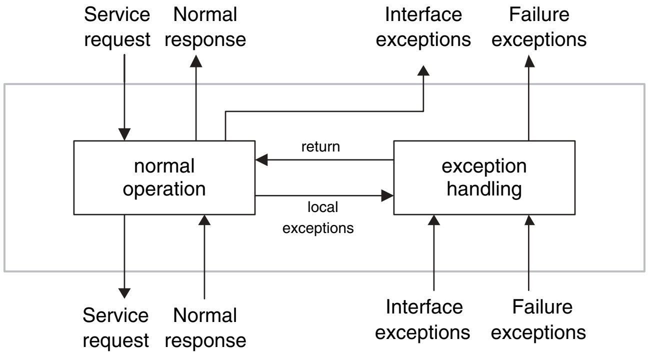

Figure 4. Logic of exception handling.

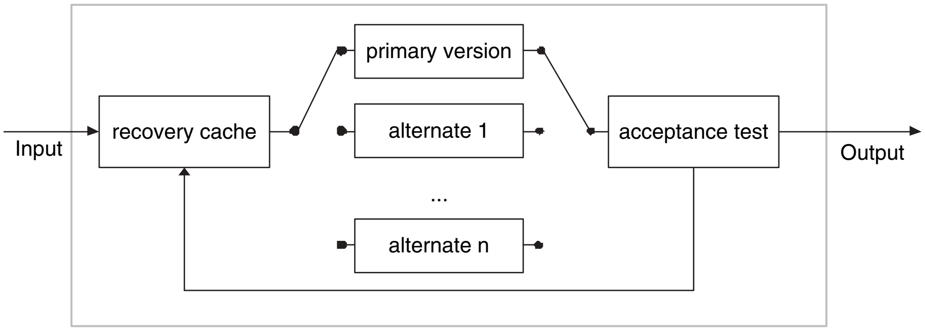

Figure 5. The recovery block (RB) model.

signaled when a component detects an invalid service request. This type of exception is triggered by the self-protection mechanisms of the component and is treated by the component that made the invalid request. *Local exceptions* occur when a component's error detection mechanisms find an error in its own internal operations. The component returns to normal operations after exception handling. *Failure exceptions* are identified by a component after it has detected an error that its fault-processing mechanisms were unable to handle successfully. In effect, failure exceptions notify the component making the service request that it has been unable to provide the requested service.

Multi-Version Software Techniques

The multi-version fault-tolerant software technique is the so-called *design diversity* approach, which involves developing two or more versions of a piece of software according to the same requirement specifications. The rationale for the use of multiple versions is the expectation that components built differently (i.e., different designers, different algorithms, different design tools, and so on) should fail differently (7). Therefore, in the case that one version fails in a particular situation, there is a good chance that at least one of the alternate versions is able to provide an appropriate output.

These multiple versions are executed either in sequence or in parallel, and can be used as alternatives (with separate means of error detection), in pairs (to implement detection by replication checks) or in larger groups (to enable masking through voting). Three fundamental techniques are known as RB, NVP, and NSCP.

Recovery Block. The RB technique involves multiple software versions implemented differently such that an alternative version is engaged after an error is detected in the primary version (6,10). The question of whether there is an error in the software result is determined by an acceptance test (AT). Thus, the RB uses an AT and backward recovery to achieve fault tolerance. As the primary version will be executed successfully most of the time, the most efficient version is often chosen as the primary alternate and the less efficient versions are placed as secondary alternates. Consequently, the resulting rank of the versions reflects, in a way, their diminishing performance.

The usual syntax of the RB is as follows. First of all, the primary alternate is executed; if the output of the primary alternate fails the AT, a backward error recovery is invoked to restore the previous state of the system, then the second alternate will be activated to produce the output; similarly, every time an alternate fails the AT, the previous system state will be restored and a new alternate will be activated. Therefore, the system will report failure only when all the alternates fail the AT, which may happen with a much lower probability than in the single-version situation. The RB model is shown in Fig. 5, while the operation of RB is shown in Fig. 6.

The execution of the multiple versions is usually sequential. If all the alternate versions fail in the AT, the module must raise an exception to inform the rest of the system about its failure.

N-Version Programming. The concept of NVP was first introduced in 1977 (7). It is a multi-version technique in which all the versions are typically executed in parallel and the consensus output is based on the comparison of the outputs of all the versions (2). In the event that the program

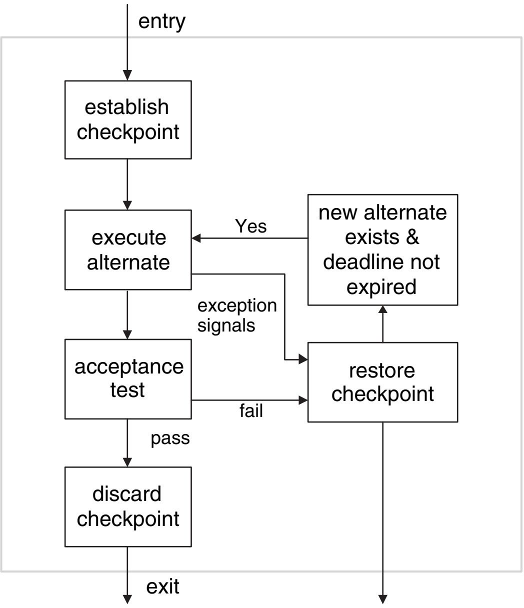

Figure 6. Operation of recovery block.

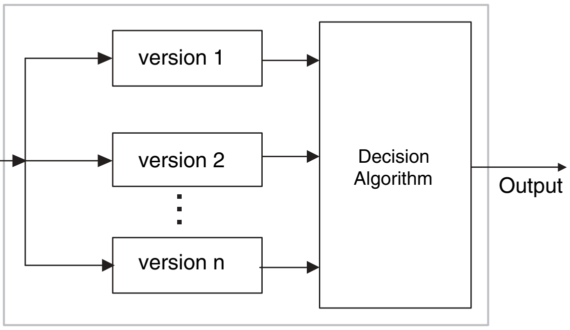

Figure 7. The N-version programming (NVP) model.

versions are executed sequentially due to lack of resources, it may require the use of checkpoints to reload the state before a subsequent version is executed. NVP model is shown in Fig. 7.

The NVP technique uses a decision algorithm (DA) and forward recovery to achieve fault tolerance. The use of a generic decision algorithm (usually a voter) is the fundamental difference of NVP from the RB approach, which requires an application-dependent AT. The complexity of the DA is generally lower than that of the AT. In NVP, because all the versions are built to satisfy the same specification, it requires considerable development effort but the complexity (i.e., development difficulty) is not necessarily much greater than that of building a single version. Much research has been devoted to the development of methodologies that increase the likelihood of achieving effective diversity in the final product (8,23–25).

N-Self Checking Programming. NSCP was developed in 1987 by Laprie et al. (9,26). It involves the use of multiple software versions combined with structural variations of the RB and NVP approaches. Both ATs and DAs can be employed in NSCP to validate the outputs of multiple versions.

The NSCP method employing ATs is shown in Fig. 8. Same as RB and NVP, the versions and the ATs are developed independently but each designed to fulfill the requirements. The main difference of NSCP from the RB approach is in its use of different ATs for different versions. The execution of the versions and tests can be done sequentially or in parallel, but the output is taken from the highest-ranking version that passes its AT. Sequential execution requires a set of checkpoints, and parallel execution requires input and state consistency algorithms.

NSCP engaging DAs for error detection is shown in Fig. 9. Similar to NVP, this model has the advantage of using an application-independent DA to select a correct output. This variation of self-checking programming has the theoretical vulnerability of encountering situations where multiple pairs pass their comparisons but the outputs differ between pairs. That case must be considered and an appropriate decision policy should be selected during the design phase.

Comparison Among RB, NVP, and NSCP. Each design diversity technique, RB, NVP, and NSCP, has its own advantages and disadvantages compared with the others. We compare the features of the three and list them in Table 1.

The differences between AT and DA are: (1) AT is more complex and difficult in implementation, but it can still produce correct output when multiple distinct solutions exist in multiple versions, and (2) DA is more simple, efficient, and liable to produce correct output because it is just a voting mechanism; but it is less able to deal with multiple solutions.

Other Techniques. Besides the three fundamental design diversity approaches listed above, there are some other techniques available, essentially variants of RB, NVP, and NSCP. They include consensus RB, distributed RB, hierarchical NVP, t/(n-1)-variant programming, and others. Here, we introduce some of these techniques briefly.

Distributed Recovery Block. The distributed recovery block (DRB) technique, developed by Kim in 1984 (27), is adopted in distributed or parallel computer systems to realize fault tolerance in both hardware and software. DRB combines RBs and a forward recovery scheme to achieve fault tolerance in real-time applications. The DRB uses a pair of self-checking processing nodes (PSP) together with both the software-implemented internal audit function and the watchdog timer to facilitate real-time hardware fault tolerance. The basic DRB technique consists of a primary node and a shadow node, each cooperating with a RB, and the RBs execute on both nodes concurrently.

Consensus Recovery Block. The consensus RB approach combines NVP and the RB technique to improve software reliability (28). The rationale of consensus RBs is that RB and NVP each may suffer from its specific faults. For example, the RB ATs may be fault-prone, and the DA in

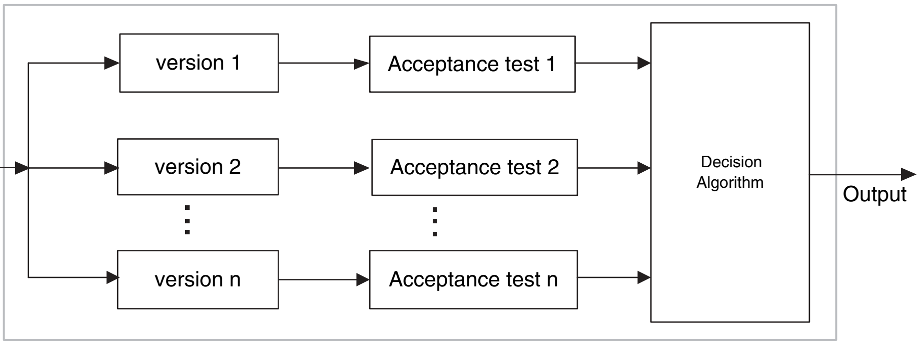

Figure 8. N self-checking programming using acceptance test.

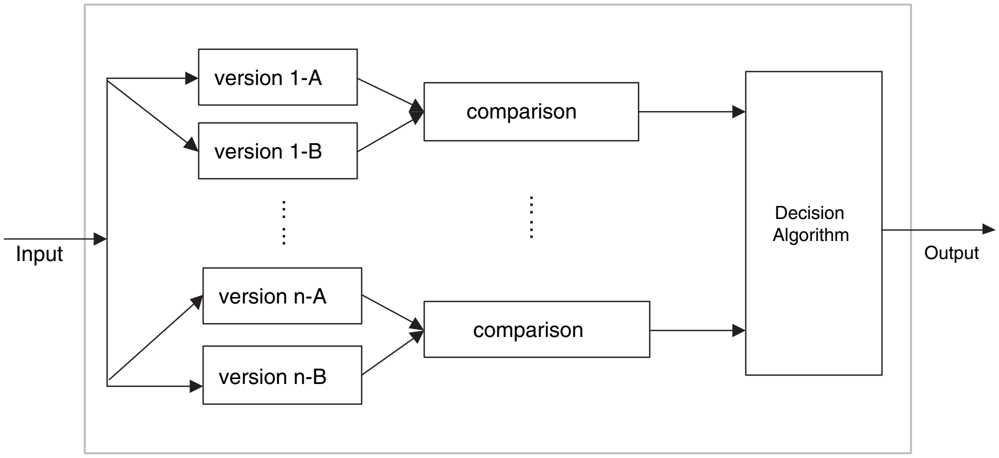

Figure 9. N self-checking programming using decision algorithm.

NVP may not be appropriate in all situations, especially when multiple correct outputs are possible. The consensus RB approach employs a DA as the first-layer decision. If a failure is detected in the first layer, a second layer using ATs is invoked. Obviously, having more levels of checking than either RB or NVP, consensus RB is expected to have an improved reliability.

t/(n-1)-Variant Programming. t/(n-1)-variant programming (VP) was proposed by Xu and Randell in 1997 (29). The main feature of this approach lies in the mechanism engaged in selecting the output among the multiple versions. The design of the selection logic is based on the theory of system-level fault diagnosis. The selection mechanism of t/(n-1)-VP has a complexity of O(n)—less than some other techniques—and it can tolerate correlated faults in multiple versions.

MODELING SCHEMES ON DESIGN DIVERSITY

There have been numerous investigations, analyses, and evaluations of the performance of fault-tolerant software techniques in general and of the reliability of some specific techniques (3). Here we list only the main modeling and analysis schemes that assess the general effectiveness of design diversity.

To evaluate and analyze both the reliability and the safety of various design diversity techniques, different modeling schemes have been proposed to capture design diversity features, describe the characteristics of fault correlation between diverse versions, and predict the reliability of the resulting systems. The following modeling schemes are discussed in chronological order.

Table 1. Comparison of Design Diversity Techniques

Features	Recovery block	N-version programming	N self-checking programming
Minimum no. of versions	2	3	4
Output mechanism	Acceptance Test	Decision Algorithm	Decision Algorithm and Acceptance Test
Execution time	primary version	slowest version	slowest pair
Recovery scheme	backward recovery	forward recovery	forward and backward recovery

Eckhardt and Lee's Model

Eckhardt and Lee (EL Model) (30) proposed the first probability model that attempts to capture the nature of failure dependency in NVP. The EL model is based on the notion of "variation of difficulty" over the user demand space. Different parts of the demand space present different degrees of difficulty, making the program versions built independently more likely to fail with the same "difficult" parts of the target problem. Therefore, failure independency between program versions may not be the necessary result of "independent" development when failure probability is averaged over all demands. For most situations, in fact, positive correlation between version failures may be exhibited for a randomly chosen pair of program versions.

Littlewood and Miller's Model

Littlewood and Miller (31) (LM model) showed that the variation of difficulty could be turned from a disadvantage into a benefit with forced design diversity (32). "Forced" diversity may insist that different teams apply different development methods, different testing schemes, and different tools and languages. With forced diversity, a problem that is more difficult for one team may be easier for another team (and vice versa). The possibility of negative correlation between two versions means that the reliability of a 1-out-of-2 system could be greater than it would be under the assumption of independence. Both EL and LM models are "conceptual" models because they do not support predictions for specific systems and they depend greatly on the notion of *difficulty* defined over the possible demand space.

Dugan and Lyu's Dependability Model

The dependability model proposed by Dugan and Lyu in Ref. 33 provides a reliability and safety model for fault-tolerant hardware and software systems using a combination of fault tree analysis and the Markov modeling process. The reliability/safety model is constructed by three parts: A Markov model details the system structure and two fault trees represent the causes of unacceptable results in the initial configuration and in the reconfigured state. Based on this three-level model, the probability of unrelated and related faults can be estimated according to experimental data.

In a reliability analysis study (33), the experimental data showed that DRB and NVP performed better than NSCP. In the safety analysis, NSCP performed better than DRB and NVP. In general, their comparison depends on the classification of the experimental data.

Tomek and Trivedi's Stochastic Reward Nets Model

Stochastic reward nets (SRNs) are a variant of stochastic Petri nets. SRNs are employed in Ref. 34 to model three types of fault-tolerant software systems: RB, NVP, and NSCP. Each SRN model is incorporated with the complex dependencies associated with the system, such as correlation failures and separate failures, detected faults and undetected faults. A Markov reward model underlies the SRN model. Each SRN is automatically converted into a Markov reward model to obtain the relevant measures. The model has been parameterized by experimental data in order to describe the possibility of correlation faults.

Popov and Strigini's Reliability Bounds Model

Popov and Strigini attempted to bridge the gap between the *conceptual* models and the *structural* models by studying how the conceptual model of failure generation can be applied to a specific set of versions (32). This model estimates the probability of failure on demand given the knowledge of subdomains in a 1-out-of-2 diverse system. Various alternative estimates are investigated for the probability of coincident failures on the whole demand space as well as in subdomains. Upper bounds and likely lower bounds for reliability are obtained by using data from individual diverse versions. The results show the effectiveness of the model in different situations having either positive or negative correlations between version failures.

Experiments and Evaluations

Experiments and evaluations are necessary to determine the effectiveness and performance of different fault-tolerant software techniques and the corresponding modeling schemes. Various projects have been conducted to investigate and evaluate the effectiveness of design diversity, including UCLA Six-Language project (2,35), NASA 4-University project (23,32,36), Knight and Leveson's experiment (24), Lyu–He study (33,37), and so on.

These projects and experiments can be classified into three main categories: (1) evaluations on the effectiveness and cost issues of the final product of diverse systems (7,24,38–42); (2) experiments evaluating the design process of diverse systems (8); and (3) adoption of design diversity into different aspects of software engineering practice (37,43).

To investigate the effectiveness of design diversity, an early experiment (7), consisting of running sets of student programs as 3-version fault-tolerant programs, demonstrated that the NVP scheme worked well with some sets of programs tested, but not others. The negative results were natural because inexperienced programmers cannot be expected to produce highly reliable programs. Another student-based experiment (24) involved 27 program versions developed differently. Test cases were conducted on these program versions in single-and multiple-version configurations. The results showed that NVP could improve reliability; yet correlated faults existed in various versions, adversely affecting design diversity. In another study, Kelly et al. (38) conducted a specification diversity project, using two different specifications with the same requirements. Anderson et al. (39) studied a medium-scale naval command and control computer system developed by professional programmers through the use of the RB. The results showed that 74% of the potential failures could be successfully masked. Another experiment evaluating the effectiveness of design diversity is the Project on Diverse Software (PODS) (40), which consisted of three diverse teams implementing a simple nuclear reactor protection system application. There were two diverse specifications and two programming languages adopted in this project. With good quality control and experienced programmers, high-quality programs and fault-tolerant software systems were achieved.

For the evaluation of the cost of design diversity, Hatton (41) collected evidence to indicate that diverse fault-tolerant software techniques are more reliable than producing one good version, and more cost effective in the long run. Kanoun (42) analyzed work hours spent on variant design in a real-world study. The results showed that costs were not doubled by developing a second variant.

In a follow-up to the work of Avizienis and Chen (7), a six-language NVP project was conducted using a proposed *N-version Software Design Paradigm*(44). The NVP paradigm was composed of two categories of activities: standard software development procedures and concurrent implementation of fault-tolerance techniques. The results verified the effectiveness of the design paradigm in improving the reliability of the final fault-tolerant software system.

To model the fault correlation and measure the reliability of fault-tolerant software systems, experiments have been employed to validate different modeling schemes. The NASA 4-University project (36) involved 20 two-person programming teams. The final 20 programs went through a three-phase testing process, namely, a set of 75 test cases for AT, 1100 designed and random test cases for certification test, and over 900,000 test cases for operational test. The same testing data have been widely employed (23,31,32) to validate the effectiveness of different modeling schemes.

The Lyu–He study (37) was derived from an experimental implementation involving 15 student teams guided by the evolving NVP design paradigm in Ref. 8. Moreover, a comparison was made between the NASA 4-University project, the Knight–Leveson experiment, the Six-Language project, and the Lyu–He experiment in order to further investigate and discuss the effectiveness of design diversity in improving software reliability. The results were further used in Ref. 33 to evaluate the prediction accuracy of Dugan and Lyu's Model. Lyu et al. (43) reported a multi-version project on The Redundant Strapped-Down Inertial Measurement Unit (RSDIMU), the same specification employed in the NASA 4-University project. The experiment developed 34 program versions, from which 21 versions were selected to create mutants. Following a systematic rule for the mutant creation process, 426 mutants, each containing a real program fault identified during the testing phase, were generated for testing and evaluation. The testing results were subsequently engaged to investigate the probability of related and unrelated faults using the PS and DL models.

Current results indicate that, for design diversity techniques, NSCP is the best candidate to produce a safe result, whereas DRB and NVP tend to achieve better reliability than NSCP, although the difference is not significant.

APPLICATIONS

There are many application-level methodologies for fault-tolerant software techniques. As we have indicated, the applications include airplane control systems (e.g., Boeing 777 airplane (14) and AIRBUS A320/A330/A340/A380 aircraft (15,45)), aerospace applications (16), nuclear reactors, telecommunications products (12), network systems (17), and other critical software systems such as wireless network, grid-computing, and so on. Most of the applications adopt single-version software techniques for fault tolerance (i.e., reusable component, checkpointing and recovery, and so on). The design diversity approach has only been applied in some mission-critical applications, for example, airplane control systems, aerospace, and nuclear reactor applications. There are also emerging experimental investigations into the adoption of design diversity in practical software systems, such as SQL database servers (46).

We may summarize the fault-tolerant software applications into four categories: (1) reusable component library (e.g., Ref. 12); (2) checkpointing and recovery schemes (e.g., Refs. 19 and 47); (3) entity replication and redundancy (e.g., Refs. 48 and 49); (4) early applications and projects on design diversity (e.g., Refs. 14,45,46). An overview of some of these applications is given below.

Huang and Kintala (12) developed three cost-effective reusable software components (i.e., watchd, libft, and REPL) to achieve fault tolerance in the application level based on availability and data consistency. These components have been applied to a number of telecommunication products.

According to Ref. 19, the new mobile wireless environment poses many challenges for fault-tolerant software due to the dynamics of node mobility and the limited bandwidth. Particular recovery schemes are adopted for the mobile environment. The recovery schemes combine a state saving strategy and a handoff strategy, including two approaches (*No Logging* and *Logging*) for state saving, and three approaches (*Pessimistic, Lazy, and Trickle*) for handoff. Chen and Lyu (47) have proposed a message logging and recovery protocol on top of the CORBA architecture, which employs the storage available at the access bridge to log messages and checkpoints of a mobile host in order to tolerate mobile host disconnection, mobile host crash, and access bridge crash.

Entity replication and modular redundancy are also widely used in application software and middleware. Townend and Xu (48) proposed a fault-tolerant approach based on job replication for Grid computing. This approach combines a replication-based fault-tolerance approach with both dynamic prioritization and dynamic scheduling. Kalbarczyk et al. (49) proposed an adaptive fault-tolerant infrastructure, named Chameleon, which allows different levels of availability requirements in a networked environment, and enables multiple fault-tolerance strategies including dual and TMR application execution modes.

The approach of design diversity, on the other hand, has mostly been applied in safety critical applications. The most famous applications of design diversity are the Boeing 777 airplane (14) and AIRBUS A320/A330/A340/A380 aircraft (15,45). The Boeing 777 primary flight control computer is a triple-triple configuration of three identical channels, each composed of three redundant computation lanes. Software diversity was achieved by using different programming languages targeting different lane processors. In the AIRBUS A320 series flight control computer (45), software systems are designed by independent design teams to reduce common design errors. Forced diversity rules are adopted in software development to ensure software reliability. In an experimental exploration of adopting design diversity in practical software systems, Popov and Strigini (46) implemented diverse off-the-shelf versions of relational database servers including Oracle, Microsoft SQL, and Interbase databases in various ways. The servers are distributed over multiple computers on a local network, on similar or diverse operating systems. The early results support the conjecture that reliability increases with the investment of design diversity.

SUMMARY

Fault-tolerant software enables a system to tolerate software faults remaining in the system after its development. When a fault occurs, fault-tolerant software techniques provide mechanisms within the software system to prevent system failure from occurring.

Fault-tolerant software techniques include single-version software techniques and multiple-version software techniques. There are two main techniques for single-version software fault tolerance: checkpointing and exception handling. Three fundamental techniques are available for multi-version fault-tolerant software: RB, NVP, and NSCP. These approaches are also called design diversity.

Various modeling schemes have been proposed to evaluate the effectiveness of fault-tolerant software. Furthermore, different applications and middleware components have been developed to satisfy performance and reliability demands in various domains employing fault-tolerant software. Fault-tolerant software is generally accepted as a key technique in achieving highly reliable software.

FORMAL PROGRAM VERIFICATION

The objective of formal verification is to produce a mathematical proof that a given implementation (or code) is correct; i.e., it behaves as specified. The specifications of behavior must be formal to achieve formal verification (see the article Formal Specification). Formal verification offers the highest level of software quality assurance, and it is critical for ensuring correctness of systems where life, mission, or security might be at stake.

Testing is currently the primary technique used for quality assurance. Most commercial software endures extensive testing until no more serious errors are revealed by testing and the customers choose to accept the reliability of the resulting code. The quality of assurance when based on testing depends on the quality of the test cases. The difficulty lies in the process of choosing "good" test cases. A test case is one element of the domain of possible inputs for the software. In most cases, it is impractical and impossible to apply testing for all elements of the input domain because the domain is vast and, often, infinite. Therefore, the chosen test cases must include a reasonable coverage of all possible inputs. However, even with a wide variety of well-chosen test cases, testing can only reveal errors; it cannot guarantee a lack of errors: On the other hand, verification can provide a guarantee of correct, error-free code; i.e., the code will produce specified outputs for *all* valid inputs, which is the topic of this article.

Formal verification is only concerned with one aspect of software quality assurances–code correctness with respect to specifications. Validation is a complementary aspect of quality assurance that establishes whether the mapping from the customer's requirements to the program specification is appropriate. Validation is a challenging problem because of the difficulty in interpreting the needs of the client and in developing suitable specifications (see the article Verification and Validation). Assuming the behavior of the software has been properly and adequately specified, this article will explain how to verify that code meets that specification.

MOTIVATION FOR VERIFICATION

In 1969, James C. King proposed a program verifier to prove the correctness of a program (1). At about the same time, Tony Hoare presented formal proof rules for program verification in his landmark paper on the topic (2). In the absence of mechanical verification, use of informal "proof arguments" can result in seemingly correct software with hidden errors. To understand how this is possible and why formal proofs are important, it is useful to discuss a recent example from the literature. In 2006, Joshua Bloch reported an error in using a binary search algorithm that develops when searching large arrays and observed that this problem is typical of such algorithms (3). His example is reproduced on the next page.

The pseudocode for this algorithm, which has been in use for decades, fails in line 6 if the sum of the low value and the high value is greater than die maximum positive integer value. In cases with a large number of elements, the value of "low + high" may overflow, which causes the algorithem not to perform as expected. Amazingly, this simple error has remained hidden in a common piece of code for many years. If this fairly simple and widely used code has an error, it is possible that nearly all current-day software, including safety-critical software, has similar errors, unless it has been verified formally.

```
1: public static int binarySearch(int[] a,
     int key) {
2:   int low = 0;
3:   int high = a.length -1;
4:
5:   while (low <= high) {
6:     int mid = (low + high) / 2;
7:     int midVal = a[ mid] ;
8:
9:     if (midVal < key)
10:         low = mid + 1;
11:     else if(midVal > key)
12:         high = mid - 1;
13:     else
14:         return mid; // key found
15:  }
16: return -(low + 1); // key not found.
17: }
```

Bloch also noted in Ref. 3 that the binary search code had been "proved" to be correct, although in actuality only a typical, informal argument had been given and not a formal proof. If integer bounds are specified and the code undergoes verification through a mechanical verification system (such as the one detailed later), the error would have been caught in a straightforward manner. A key goal is to replace informal proofs with automated ones. The example shows that a verification system must consider all aspects of correctness—including checking that variables stay within their specified bounds. Of course, this means that the verification system must include language support for writing mathematical specifications for the code.

Verification of modern object-oriented software systems involves several challenges:

- It must be scalable and enable independent proofs of correctness for each component implementation using only the specifications of reused components, not their code.
- It must enable full verification to guarantee that the implementation fulfills the completely specified behavior.
- It must be mechanical, requiring programmers to supply assertions, where necessary, but not be concerned with constructing the actual formal proofs.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Verification must be usable not only in relatively simple software, but also in large software systems. To provide scalable verification, the verification process must provide a method to reason about and to verify individual components. For example, suppose that there is a specification S and that I is one of its many implementations. Suppose also that I relies on other components with specifications S1 and S2. To verify the correctness of I with respect to S, the verification system must only require the specifications of reused components (S1 and S2) but not the corresponding implementations. A consequence of this requirement is that a specification should capture all the information needed to reason about and use a component, without divulging implementation details. If the verification system is component-based, allowing for specification and verification of each component in the system, then it might be scaled up for verification of larger systems, which also allows for reasoning about any level of a system even before all implementations are written, resulting in relative correctness proofs, meaning that the entire system is correct, if each subsystem is correct.

We distinguish full verification from “lightweight verification” that is based on lightweight specifications (see the article Formal Specification) with the intent of checking only certain characteristics of the code. Lightweight verification can be used to check for common, specification-independent programming errors such as dereferencing null pointers (4) or unexpected cycles in pointer-based data structure (5). Lightweight verification does not require specification or internal assertions to prove the absence of these simple errors. But other errors may remain. So, to prove the correctness of software (that the realization implements a complete specification of the behavior of the component), full specification and verification are necessary.

For verification to be practical and reliable, it must be mechanical. As observed in the example of the binary search algorithm, nonmechanical verification (because of the many details it relies on) is prone to human error. Given an implementation annotated with suitable assertions, corresponding specifications, and appropriate theorems from mathematics, an automated verification system will postulate a correctness assertion, mechanically. The implementation will be deemed correct if and only if the correctness assertion can be proved, also mechanically.

EXAMPLE CODE AND SPECIFICATIONS FOR VERIFICATION

To illustrate the principles of formal verification involving specification of components, we consider a simple example along with its full verification. To ensure that the results are general and applicable to modem object-based languages, we consider a data abstraction example that encapsulates objects. However, the same principles discussed here can be applied to detect (and correct) the errors in the binary search code. The code given below is intended to reverse a Stack object or variable, and it is typical of the kind of code written in modern imperative languages.

```
Procedure Flip(updates S: Stack);
        Var S_Reversed: Stack;
        Var Next_Entry: Entry;

        While (Depth(S) /= 0) do
                Pop(Next_Entry, S);
                Push(Next_Entry, S_Reversed);
        end;
        S :=: S_Reversed;
end Flip;
```

To complete formal verification of this code, we must have a precise snecification of Stack behavior and the Flip operation in a formal specification language. Figure 1, contains the specification of a Stack component in RESOLVE specification notation; see the Formal Specification article, where the specification of a queue component (similar to this) is described in detail.

The specification of a concept (such as Stack_Template) presents a mathematical model for the type provided by the concept and explains formally the behavior of operations to manipulate variables of that type. In this example, the Stack type is modeled by a mathematical string of entries. The exemplar clause introduces a Stack, S, which is used to describe a generic stack variable in this specification. The concept provides initialization details, constraints for the variables of the type, and specifications for each operation. As implied by the name, the initialization clause describes the initial state of a variable of the type. In this example, initially a Stack is empty. Since the mathematical model for a Stack is a string, the initial value of a Stack is the empty string. The constraint clause formally expresses that every Stack object is always constrained to be within bounds; i.e., the length of the string must be less than Max_Depth, which must be provided when Stack_Template is instantiated for a particular use.

```
Concept Stack_Template(type Entry; evaluates Max_Depth: Integer);
  uses Std_Integer_Fac, String_Theory;
  requires Max_Depth > 0;

  Type Family Stack is modeled by Str(Entry);
    exemplar S;
    constraint |S| <= Max_Depth;
    initialization ensures S = empty_string;

  Operation Push(alters E: Entry; updates S: Stack);
    requires |S| < Max_Depth;
    ensures  S = <#E> o #S;

  Operation Pop(replaces R: Entry; updates S: Stack);
    requires |S| > 0;
    ensures #S = <R> o S;

  Operation Depth(restores S: Stack): Integer;
    ensures Depth = (|S|);

  Operation Rem_Capacity(restores S: Stack): Integer;
    ensures Rem_Capacity = (Max_Depth - |S|);

  Operation Clear(clears S: Stack);

end Stack_Template;
```

Figure 1. A specification of a stack concept.

```
Operation Flip(updates S: Stack);
        ensures S = Rev(#S);
```

Figure 2. A specification of an operation to flip a stack.

The specification for an operation can be viewed as a contract between the client and the implementer. Before a call of any operation, the precondition (or requires clause) must be true. In this example, the Push operation requires that there is room in the Stack for another element. Similarly, to guarantee correct functionality, the Pop operation requires that there is at least one element in the Stack. The implementation of an operation must guarantee that the postcondition (or ensures clause) is satisfied at the end of the procedure if the precondition holds. The ensures clause for Push provides the guarantee that S is updated so that it becomes the original value of E (a parameter of Push) concatenated with the original value of S. RESOLVE denotes the incoming values with a # symbol to differentiate between the incoming and the outgoing values of a parameter in the specification. Pop removes the top entry from the parameter Stack S and replaces the parameter R with the top entry.

Given the specification of the Stack component and the mathematical modeling of Stacks as strings of entries, the Flip operation can be specified formally as in Fig. 2 using the mathematical string reversal operator (Rev). This specification can be written without knowledge (or even existence) of any implementation or Stack_Template.

To facilitate mechanical verification of the Flip code, programmers must annotate loops with suitable assertions as shown in Fig. 3.

To verify code involving a loop, the programmer must include a loop invariant (using the **maintaining** clause), a progress metric expression that decreases with each iteration of the loop (using the **decreasing** clause), and a list of all variables that the loop may change (using the **changing clause**). To prove termination, the decreasing metric must be an ordinal (i.e., it must have a least element). The metric cannot be an integer expression, for example, because it can be decreased f‘orever. Providing the list of changing variables in a loop makes it unnecessary to assert in the invariant that variables not affected by loops remain unchanged. The loop annotations are necessary, in general, to prove the correctness and termination of the loop. If a weak or wrong annotation were supplied, the ability to prove correctness of the operation would be compromised. The literature makes a distinction between partial and total correctness proofs. If code is only partially correct, there is a guarantee of correctness only if the code terminates. Total correctness additionally requires a proof that the code will terminate. In this article, we consider proofs of total correctness.

```
Procedure Flip(updates S: Stack);
        Var S_Reversed: Stack;
        Var Next_Entry: Entry;

        While (Depth(S) /= 0)
                changing S, S_Reversed, Next_Entry;
                maintaining #S = Rev(S_Reversed) o S;
                decreasing |S|;
        do
                Pop(Next_Entry, S);
                Push(Next_Entry, S_Reversed);
        end;
        S :=: S_Reversed;
end Flip;
```

Figure 3. An implementation of an operation to flip a stack.

The programmer-supplied invariant must be true at the beginning and at the end of each iteration, including the first and last iterations. When forming an invariant, the goal of the loop (and the entire operation) must be considered. For example, if Flip had a "**maintaining** |S| + |S_Reversed| = |#S|" clause, it would be a true invariant, but it would not fully describe the behavior of the loop and would not give the verifier the ability to prove the code to be correct with respect to the given specification. Alternatively if the assertion, "**maintaining** #S = S_Revetsed o S," were provided as the invariant, at the time the while loop is processed, the verifier will flag it because the assertion cannot be established to be an invariant. Similarly, if the decreasing clause is incorrect, no proof of the total correctness of the operation can be provided, because the verification systetm cannot guarantee the termination of the loop. Invariants and other annotations should be valid and should be goal-directed, i.e., sufficient to establish code correctness with respect to given specifications.

FORMAL VERIFICATION BASICS

Formal verification must be based on a *sound* and *complete* proof system. Soundness guarantees that if the code is incorrect, the verifier will not say that the code is correct. Completeness, on the other hand, assures that if the code is correct, the verifier will never say that the code is incorrect. Completeness can be only relative because of the inherent incompleteness in any nontrivial mathematical theory, on such as number theory on which proofs of programs are based. The more practical problems for completeness because of inadequate assertions, inexpressive languages for writing necessary assertions, or inadequate proof rules.

A proof system consists of proof rules for each statement or construct in a language. Given the goal and code of an implementation, the verifier applies proof rules (which replace code with mathematical assertions) and then simplifies the assertions with the objective of reducing the final assertion to "true."

For example, consider the following piece of assertive code (a combination of code, facts, and goals), also called a Hoare triple. In the example, S and T are two Stack variables. The swap statement (also the last statement in the Flip code in the previous section) exchanges the values of the participating variables, without introducing aliasing. All code is written and verified within a context, and the *Context* here includes mathematical String_Theory, the Stack_Template specification, as well as declarations of Stack variables. It is not listed explicitly in this article.

```
Context \
        Assume S = empty_string;
                T :=: S;
        Confirm T = empty_string;
```

To simplify the assertive code, a proof rule for the swap statement needs to be applied. In the rule shown below, it is necessary and sufficient to prove what is above the line to prove what follows below the line. This is the typical format of a formal proof rule. In the rule, *C* stands for Context. The notation, RP[x ⇝ y, y ⇝ x], means that concurrently, every x is replaced with y and every y is replaced with x. Intuitively, this rule means that to confirm what follows after the swap statement the same assertion needs to be confirmed before the swap statement but with x and y in exchanged in the assertion.

Proof Rule for the Swap Statement:

C \ code; **Confirm** RP[x ⇝ y, y ⇝ x];

C \ code; x :=: y; **Confirm** RP;

After the application of the swap rule, the following assertive code remains:

```
Assume S = empty_string;
Confirm S = empty_string;
```

The next statements to be processed by the verifier are Assume and Confirm clauses. The rule for removing the Assume clause has the effect of making the resulting assertion an implication. The rule for handling the Confirm clause is simply syntactic: Eliminate the keyword **Confirm**.

Assume Rule:

C \ code; **Confirm** IP **implies** RP;

C \ code; **Assume** IP; **Confirm** RP;

Confirm Rule:

C \ RP;

C \ **Confirm** RP;

In our example, after the application of the Assume Rule, we have the following assertion:

```
Confirm S = empty_string implies
    S = empty_string.
```

Subsequently following the application of the Confirm Rule produces the final assertion:

```
S = empty_string implies
    S = empty_string.
```

Since this implication is provable mechanically using mathematical logic, the assertion simplifies to:

true.

Thus, we can see that our final assertion is true; therefore, assuming the soundness of the proof rules we have employed, we can conclude that the original assertive code is correct. However, if we started out with an incorrect assertive code, as shown below, the verifier would produce a false assertion, assuming completeness of our rules.

Initial (incorrect) assertive code	Generated (unprovable) assertion

Assume S = empty_string; T: = :S;
Confirm S = empty_string;
	S = empty_string
	implies T = empty_string;

EXAMPLE VERIFICATION OF THE STACK FLIP CODE

To illustrate aspects of verifying more typical code, in this section, we consider verification of the Stack Flip code in Fig. 3 with respect to its specification in Fig. 2.

Given a specification and an implementation, the first step in verification is to generate the corresponding assertive code, in which assertions from specifications and programming statements are combined. The rule for generating the assertive code is not shown, but it is straightforward for this example. The requires clause of the operation becomes an assumption at the beginning. Because flip has no requires clause, the assumption is true trivially. Also, it is necessary that constraints on parameters to the operation become an assumption at the start of the assertive code. The ensures clause of the operation needs to be confirmed after the code.

```
Remember;
Assume |S| <= Max_Depth; // Constraints on parameter Stack S
Assume true; // Assumes the requires clause of Flip
        Var S_Reversed: Stack;
        Var Next_Entry: Entry;

        While (Depth(S) /= 0)
            changing S, S_Reversed, Next_Entry;
            maintaining #S = Rev(S_Reversed) o S;
            decreasing |S|;
        do
            Pop(Next_Entry, S);
            Push(Next_Entry, S_Reversed);
        end;
        S :=: S_Reversed;

Confirm S = Rev(#S); // Confirm the ensures clause of Flip
```

Also, the verifier generates the **Remember** statement at the beginning that allows the mechanical assertion generator to maintain the difference between values of the incoming and the outgoing variables until all the statements have been processed and the beginning of the code has been reached. At that time, the Remember Rule allows all “” signs to be removed.

Once assertive code is formed, we apply proof rules for statements in a goal-oriented manner starting with the last statement. If the proof rules are sound, then each application leads to a shorter assertive code (with one less statement) that if proved guarantees that the original assertive code is correct. In this example, the last statement is a swap statement. So the rule for the swap statement (discussed in the last subsection) is applied first, and this leads to the assertive code shown below.

```
Assertive code after processing swap statement:

Remember;
Assume |S| <= Max_Depth;
Assume true;
        Var S_Reversed:Stack;
        Var Next_Entry:Entry;
        While (Depth(S) /= 0)
        ...
        end;
Confirm S_Reversed = Rev(#S);
```

The next statement is a while loop statement. Before we discuss a rule for that statement and apply it, it is instructive to study a rule for the simpler if–then–else statement that is given below.

```
    If-then-else Rule:

C\ code; Confirm Invk_Cond(BE);
  Assume Math(BE); code; Confirm RP;
  C\ code; Assume not(Math(BE));
  code_2; Confirm RP;
---------------------------------------------------
C\ code; If BE then code; else code_2;
   end if; Confirm RP;
```

The if–then–else rule creates two assertions. One assertion assumes that the condition is true and alters the confirm statement based on the code in the “then” section. The other assumes that the condition is false and alters the confirm statement based on the code in the “else” section. These assertions are based on the mathematical form of the conditional statements, denoted by **Math** (BE) in the rule. For example, the condition Depth(S)/ = 0 is transformed to the mathematical statement | S | / = 0 based on the specification of Depth.

The proof rule must also check that any requirements for the use of the condition in the if statement are satisfied. For example, if the if statement has the condition, “Depth(S) + X / = 0,” then the verification system must be able to check the common problem of computational integer overflow also observed in the binary search code example. This is the purpose of the clause **“Confirm** Invk_Cond(BE)” in the rule, where Invk_Cond simply is a conjunction of constraints and preconditions emanating from die evaluation of the condition BE.

We have a while loop to be verified as the next statement in our example assertive code, and it has the following general format with suitable annotations:

```
C \ code; While BE changing VLst; maintaining
   Inv; decreasing P_Exp; do body; end;
   Confirm RP;
```

The rule has three parts (2), two of which are concerned with proving the invariance of the invariant through induction:

Base Case: It must be confirmed that the invariant is true before the while loop.

```
code; Confirm Inv;
```

Inductive Case: If the invariant is assumed true at the start of an iteration of the loop, it can be proved true at the end of the iteration. (For total correctness, it must also be shown that with each iteration of the while loop, the decreasing expression does decrease.)

```
Assume Inv and Math(BE); body; Confirm Inv;
```

The invariant must be strong enough to prove the assertion following the loop statement:

```
(Inv and not Math(BE)) implies RP;
```

A formal version of the while loop proof rule using the if–then–else rule is shown below, where the “then” part corresponds to the inductive proof of the invariant and the “else” part corresponds to the proof of the assertion after the loop statement. After applying this rule, and the rule for an if–then–else statement, the assertions simplify to what is discussed above.

```
          While Loop Rule:

C \ code; Confirm Inv; Change VLst; Assume Inv
    and ?P_Val = P_Exp; If BE then body; Confirm
    Inv and P_Exp < ?P_Val; else Confirm
    RP; end;
---------------------------------------------------
C \ code; While BE changing VLst; maintaining
    maintaining Inv; decreasing P_Exp; do
    body; end; Confirm RP;
```

As a result of the formation of the rule as one unit (instead of the three previously discussed) and to simplify invariants, the verifier-introduced **Change** statement is necessary. The Change statement differentiates between variables that are altered in the loop and variables that the loop leaves unaltered. Without it, the verifier would assume that in the inductive case, when the “**Assume** inv **and** BE” clause is processed, that these are unaltered variables that are modifiable by the application of rules on the code before the while loop. Thus, the statement has the effect of introducing new names for each variable listed in the changing clause by aging them with a “?” and by replacing each variable X witn ?X in subsequent assertions. In the case when a variable has been aged already and ?X is found in subsequent assertions, the verifier will introduce ??X and so on, as necessary. So, all verification-introduced variables will be preceded by one or more question marks, and they are all quantified universally.

The while loop rule yields two pieces of assertive code, one for each path in the if–then–else construct. In part one (when the loop condition is true), we confirm the invariant before the loop and also show that if true at the beginning of an iteration, it will be true at the end of the iteration. In our example, the invariant is the assertion, #S = (Rev(S_Reversed) o S), where #S refers to the value of S at the beginning of the operation and S refers to the current value of S at the start or end of the loop. Therefore, this invariant states that the concatenation of the reversal of the Stack, S_Reversed, and of the current Stack S, will equal the value of S at the start of the operation. Part one also forms an assertion that checks that the decreasing expression does decrease with each iteration by setting the value of the verification variable ?**P_Val** to the ordinal expression, in this example |S|, and then checking that the value of that variable has decreased after the loop body. Type checking will guarantee that the decreasing expression is an ordinal, so no verification obligation is raised by the decreasing clause.

The while rule yields a second piece of assertive code, "part two," associated with exiting the loop. Based on the invariant and the negation of the conditional statement, it checks that the original Confirm statement after the loop can be proven. However, it does not include the first confirm statement (the one confirming the invariant, Inv) because that is already an obligation in part one.

The two pieces of assertive code that result from applying the loop rule (and subsequently the if–then–else statement rule) on the example code are shown below.

Assertive code after processing while statement—Part One:

```
Remember;
Assume |S| <= Max_Depth;
Assume true;
        Var S_Reversed:Stack;
        Var Next_Entry:Entry;
Confirm #S = (Rev(S_Reversed) o  S);
Change S, S_Reversed, Next_Entry;
Assume (#S = (Rev(S_Reversed) o  S) and  ?P_Val = |S|);
Confirm true;           // Pre-Condition of Depth(S)
Assume |S| /= 0;
        Pop(Next_Entry, S);
        Push(Next_Entry, S_Reversed);
Confirm (#S = (Rev(S_Reversed) o  S) and  (|S| <  ?P_Val));
```

Assertive code after processing while statement—Part Two:

```
Remember;
Assume  |S| <= Max_Depth;
Assume true;
        Var S_Reversed:Stack;
        Var Next_Entry:Entry;
Change S, S_Reversed, N ext_Entry;
Assume #S = (Rev(S_Reversed) o  S);
Assume |S| = 0;
Confirm S_Reversed = Rev(#S);
```

First we discuss the proof of the second assertive code because it is easier to discharge. Application of the rules for the Change statement (that renames changing variables in assertions after the change statement with ? marks), the Remember statement (that strips the "#" signs off the values of the incoming variables), and handling of Assume and Confirm clauses lead to the implication shown below. (The verifier also applies the variable declaration rules although they have no impact because neither S_Reversed nor Next_Entry are in the assertion to be confirmed.)

```
Confirm (S = (Rev(?S_Reversed) o  ?S)
                implies  (|?S| = 0
                        implies  ?S_Reversed = Rev(S)));
```

The final clause "?S_Reversed = Rev(S)" must be shown. A mechanical proof system can complete the proof relying on mathematical units for definitions as shown below.

```
Proof:

Goal ?S_Reversed = Rev(S)
≡?S_Reversed = Rev(Rev(?S_Reversed) o  ?S)
  by replacement using implication fact
  S = (Rev(?S_Reversed) o  ?S)
≡?S_Reversed = Rev(Rev(?S_Reversed))
  by simplification using implication fact |?S| = 0
≡?S_Reversed = ?S_Reversed
  by double reverse theorem in String_Theory
≡ true
```

The first part of the while loop rule requires processing the code inside the loop. For this assertive code, the next statement to be processed is a call to Push. Before we present a proof rule to process a call to Push, first it is useful to understand the simpler function invocation rule.

Function Call Rule:

```
C \ code; Confirm Pre_F[x⇝u] and RP[v⇝ f(x)[x⇝
u]] ;
--------------------------------------------------
C \code; v := F(u); Confirm RP;
```

Where the context C includes the specification of operation F:

```
Operation  F(restores  x:T1): T2;
        requires Pre_F(x);
        ensures F = f(x);
```

The rule supposes that the specification of the function is in the context. The function restores and leaves its parameter x unchanged. The return value or the result is some function of the parameter x. Pre_F is the precondition (or the requires clause) for the function, and it must be satisfied before the function is called. Given mis function specification, suppose that the next statement to be processed is a function assignment v := F(u). The proof rule states that to prove the assertion RP after the assignment, it is sufficient to prove that the precondition for the call holds and that RP holds if v is replaced with the result of the function; of course, in the preconditions and postconditions, proper actual parameters must be substituted for formal parameters.

This function assignment rule is the one that needs to be applied to handle the assignment statements in the binary search code, given at the beginning of this article. The "expression assignment rule" for the assignment statement v := E in Ref. 2 is just a special case of function assignment rule, and it assumes expression assignment does not involve any precondition checking, such as for overflows.

Simple Integer Expression Assignment Rule:

```
C \ code; Confirm RP[v ⇝ E] ;
________________________________________
C \code; v := E; Confirm RP;
```

To handle the call to Push in the same code, an operation call rule is needed. In the simple case, the output is expressed as a function of the inputs in the ensures clause and the rule is similar to the one for invoking functions:

Simple Operation Call Rule:

```
C \ code; Confirm Pre_P[ x ⇝ u, y ⇝ v]
   and RP[v ⇝ f(#x,#y)[#x ⇝ u, #y ⇝ v]] ;
________________________________________
C\ code; P(u,v); Confirm RP;
```

Where the context includes the specification of operation P:

```
Operation  P(alters  x: T1, updates  y: T2);
          requires  Pre_P;
          ensures y = f(#x, #y);
```

The ensures clause of Push "S = <#E> o #S" in the Stack_Template specification in Fig. 1 is such that the output value (S) is expressed directly in terms of the inputs (#S and #E). So the simple operation call rule can be applied for the call Push(Next_Entry, S_Reversed) in the example assertive code. After replacing #E and #S in the expression <#E> o #S with, respectively, Next_Entry and S_Reversed, we have Next_Entry o S_Reversed, so we need to replace any S_Reversed in the Confirm assertion with (Next_Entry o S_Reversed). In addition, we need to confirm the requires clause of Push (after proper substitutions), which leads us to the assertive code below where the modified clauses are shown *italicized*.

Assertive code after processing the call Push(Next_Entry, S_Reversed):

```
Remember;
         ...
         Pop(Next_Entry, S);
Confirm
         ((|S_Reversed| <  Max_Depth) and
         (#S = (Rev(<Next_Entry> o  S_Reversed) o  S) and  (|S| <  ?P_Val)));
```

Next, the verification system must process the procedure call Pop(Next_Entry, S). This process is the case of a more general call to an operation where the ensures clause is not expressed as a function of the input values. In fact, the specification might be relational, and there might be many outputs for the same inputs. So we have to prove the Confirm assertion after the call for whatever outputs result from the call, as long as the outputs satisfy the ensures clause. To maintain the difference between variables before and after a procedure call—in which they are possibly altered—the name ?X is used for the value of the variable X after the call. The new variables are implicitly, quantified, universally, which leads us to the general operation call rule shown below.

Operation Invocation Rule:

```
C \ code; Confirm Pre_ P[y ⇝ b]   and
          (Post_P[x ⇝ a,  y ⇝ b]    implies
          RP[a ⇝ a, b ⇝ b]);
________________________________________
C \ code; P( a, b); Confirm RP;
```

Where the context C includes the specification of Operation P:

```
Operation P(replaces x, updates y);
          requires Pre_P;
          ensures Post_P;
```

In Ref. 6, Kulczycki et al. explain how to generalize the operation call rule even more to address calls with repeated arguments and how to pass parameters without introducing aliasing. For this article the rule above is adequate. Application of the rule to the call to Pop in our example leads to the following assertive code after the substitution of actual parameters for formal ones and to use of new names to distinguish values after the call.

Assertive code after processing the call Pop(Next_Entry, S):

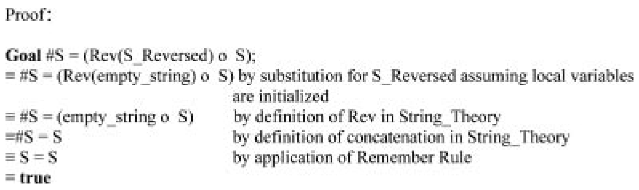
```
Remember;
Assume  |S| <= Max_Depth;
Assume true;
         Var S_Reversed:Stack;
         Var Next_Entry:Entry;
Confirm #S = (Rev(S_Reversed) o  S);
Change S, S_Reversed,  Next_Entry;
Assume (#S = (Rev(S_Reversed) o  S) and  ?P_Val = |S|);
Confirm true;
Assume |S| /= 0;
Confirm
         ((|S| >  0)  and  (S = (<?Next_Entry> o  ?S)  implies
                  ((|S_Reversed| <  Max_Depth) and
                  (#S = (Rev((<?Next_Entry> o  S_Reversed)) o  ?S) and
                  (|?S| <  ?P_Val)))));
```

Our assertive code at this point has no executable statements and two assertions to be confirmed. For ease of explanation, we separate the assertive code and its proof into two parts: The first part corresponds to the base case and confirms the requirement that the invariant holds at the beginning of the while loop. The second part corresponds to the inductive part of the proof of the invariance of the loop invariant.

Assertive code for establishing the invariant just before the loop:

```
Remember;
Assume |S| <= Max_Depth;
Assume true;
         Var S_Reversed:Stack;
         Var Next_Entry:Entry;
Confirm #S = (Rev(S_Reversed) o  S);
```

The proof of the Confirm assertion to show that the invariant Lodz before the loop is given below.



```
Proof:

Goal #S = (Rev(S_Reversed) o  S);
= #S = (Rev(empty_string) o  S) by substitution for S_Reversed assuming local variables
                                 are initialized
= #S = (empty_string o  S)       by definition of Rev in String_Theory
=#S = S                          by definition of concatenation in String_Theory
≡ S = S                          by application of Remember Rule
= true
```

After applying rules for Assume and Confirm clauses to prove the second confirm assertion, we have the following resulting assertive code where the underlined clauses need to be proved.

```
Assertive code for proving the invariant:

Remember;
Assume  |S| <= Max_Depth;
Assume true;
        Var S_Reversed:Stack;
        Var Next_Entry:Entry;
Change S, S_Reversed,  Next_Entry;
Confirm ((#S = (Rev(S_Reversed) o  S) and  ?P_Val = |S|) implies
             (|S| /= 0 implies
                    ((|S| >  0) and  (S = (<?Next_Entry> o  ?S) implies
                          ((|S_Reversed| <  Max_Depth) and
                          (#S = (Rev(<?Next_Entry> o  S_Reversed) o  ?S) and
                          (|?S| <  ?P_Val)))))));
```

After the application of the appropriate rules, the assertion can be proved mechanically by an automated theorem prover, such as Isabelle (7). Because of space considerations, we do not present additional steps of simplification, except to note mat only names change in the confirm assertion to be proved. The Change statement will have the effect of changing names S to ??S (because ?S is already used in the assertion to be proved) and S_Reversed to ?S_Reversed. No Next_Entry exists in the assertion, so no changes are to be made for that variable. By design, after these substitutions, the resulting assertion is devoid of names S_Reversed or Next_Entry, so the variable initialization clause has no effect. With the stripping off of # signs on handling of the remember statement, the resulting assertion to be proved is similar to what needs to be confirmed above, except that the names have changed. So we consider the same assertion as in the assertive code above without name changes, and we simply outline how the obligations can be discharged by a mechanical prover using suitable theorems.

```
Proofs:

Goal (|S| > 0);
≡ true                    by previous implication fact that |S| /= 0 and definition of "| |" in
                          String_Theory

Goal (|?S| <  ?P_Val);
≡ (|?S| <  |S|)            by replacement using implication fact ?P_Val = |S|
≡ (|S - 1| <  |S|)         by replacement using implication fact S = <?Next_Entry> o ?S;
≡ true

Goal #S = (Rev((<?Next_Entry> o  S_Reversed)) o  ?S);
≡ Rev(S_Reversed) o S = Rev(<?Next_Entry> o S_Reversed) o ?S
                          by replacement using implication fact #S = (Rev(S_Reversed) o S
≡ Rev(S_Reversed) o  S = Rev(S_Reversed) o  (<?Next_Entry> o  ?S)
                          by definition of Rev from String_Theory and reassociation of
                           concatenation
≡ Rev(S_Reversed) o  S = Rev(S_Reversed) o   S
                          by replacement using implication fact S = (<?Next_Entry> o  ?S)
≡ true
```

```
Goal |S Reversed| <  Max_Depth;
≡ |Rev(S_Reversed)| < Max_Depth
                          by definition of Rev in String_Theory
≡ |#S| - |S| < Max_Depth
                          by definition of concatenation and length in String_Theory from
                          assumption #S = (Rev(S_Reversed) o S
≡ |#S| <= Max_Depth
                           by proof that |S| > 0
≡ true
                           by constraint that |#S| <= Max_Depth

≡ true
```

Thus, the proposed implementation of Flip has been verified fully with respect to the Flip and Stack specifications assuming that the proof rules presented and discussed here, as a collection, are sound and that all logical steps described here have been checked by a sound, mechanical proof-checking system. The process described here is scalable in that Flip does not need to be reverified for each implementation of Stack_Template: It is verified once for all against the Stack_Template specification. Furthermore, this process is scalable in that client programs using Flip would be verified with respect to Flip's specification: The verification of this Flip implementation need not be (and should not be) revisited with each new call to Flip.

With the proof rules used above, it is also possible to attempt verification on the binary search implementation discussed in the introduction of this article. To verify the binary search algorithm, the code must first be specified properly. Annotations for the while loop must also be included. Then, assuming suitable specification of integer and array operations, the verifier would follow the process discussed in this article, but produce an improvable assertion indicating that either an error exists or that mechanical proof was impossible.

SOUNDNESS AND COMPLETENESS

The development of proof rules, such as the ones described in this article, that can be applied mechanically to assertive programs to establish their correctness is a significant step toward formal reasoning about computer programs. However, two important questions about such a proof system need to be addressed. One of these questions is both obvious and absolutely vital; the other is more subtle, but nevertheless important. The vital issue—whether the rules are sound—can be expressed informally by the question, "Might the rules permit one to prove that a program is correct when, in fact, it is not." The second, more subtle, issue—whether the rules satisfy the completeness property—can be expressed informally by the question, "Are the rules adequate to prove the correctness of every valid program?"

To answer these questions about soundness and completeness, a formal system for verification must define semantics for assertive programs, in addition to the proof rules for establishing correctness. The semantics define the intuitive notion of program *validity*. To define the meaning of "valid" formally, denotational semantics are defined based on the states of a program. Typically, states are described as mappings from variable names to values, but in general, these mappings will need to be relations. To formalize the validity of assertive programs involving specifications, it is necessary to enhance the state space with, three special status denoted by, say, *MW*, *VC*, and $\perp$ Here, *VC* stands for "Vacuously Correct," and it is the result when one of the assumptions of the code fails. For example, the Flip code assumes Push works properly, so it goes to state *VC* and becomes vacuously correct, if Push fails to satisfy its guarantees. *MW* stands for "Manifestly Wrong," and it is the result when an assertive program starts in a normal state but fails to meet one of its obligations. This obligation may be its ensures clause or the requirement of one of the called operations. For example, the Flip code needs to call Pop properly and not pass it an empty stack. If it fails that obligation or fails to reverse a stack, then it goes to *MW*. The symbol, $\perp$ is used to designate "spinning," i.e., the state of a program that has gone into an infinite loop. Once a program has entered any one of these three special states, it remains in that state.

An assertive program is valid if, for all starting states that are normal, the program does not enter *MW* or $\perp$. This explanation corresponds to "total correctness," because it includes the requirement that the program terminate. For partial correctness, validity simply requires that a program not enter the state *MW*.

Using these semantics, soundness is proven inductively by establishing for each proof rule that if its hypotheses are valid semantically, then its conclusion line must also be valid semantically. To examine the completeness question, we need to assume validity of the conclusion and then show that the hypotheses are valid. Of course, here we are talking about relative completeness as defined in the literature.

RELATED WORK

Various aspects of formal verification have received much attention in the literature. An excellent summary of many of the current areas of research in verification may be found in Leavens et al. (8). Principles of reasoning used in this article in the context of RESOLVE notation may be found in Refs. 9–11. Also see the "Formal Specification" article for related specification issues.

Some verification efforts are integrated, whereas some others address specific aspects of verification. An integrated method of verification is based on refinement. This process consists of refinement between levels of abstraction that are based on abstraction relations. Starting from higher levels of abstraction (written as a specification) through refinement a correct lower level result (such as an implementable solution) is developed. Verification then becomes the process of checking the correctness of refinement steps. The Vienna Development Model (VDM) is based on this process (12,13). Each step of refinement creates proof obligations that show the refinement process does not alter the meaning of the original specification.

PVS is both a specification language and a theorem prover (14,15). The included specification language is based on higher order logic and provides a type system. The specification language is accompanied closely by an interactive proof system that together provides the ability to complete verification of large systems.

"Why" is a software verification tool (16). It is directed toward construction of functional programs with assertions, though imperative constructs such as iteration are available. The focus is on typically built-in types, such as arrays rather than modularization or generic data abstractions. Tools associated with the "Why" system can be used to generate verification conditions, similar to the ones given in this article.

Model checking is often used as an alternative to full verification of behavior. Typically, the goal is to check whether (in the context of verification) the model (or implementation) has certain properties (the specification) (17). Property verification is an area of model checking that verifies that certain specific characteristics (or properties) are evident in the implementation. An excellent summary of model checking efforts as well as a specific system for model checking Java programs using JPF (Java Path Finder) can be found in Ref. 18. Symbolic execution principles have been employed in SLAM, which is a model checking system for C programs (19). Verification of safety specifications (20) is an area of ongoing research in property verification.

Research into verification of existing languages must deal with situations, such as aliasing, that greatly complicate modular reasoning. Using Isabelle, a theorem prover (7), Verisoft provides an integrated system for full verification of CO programs, a subset of the C language (20). By design, CO precludes several inherent verification difficulties that exist with the C language, such as aliasing. Correct pointer manipulation, on the other hand, is one goal of the ESC-Java effort (4).

Much research also exists on modular verification of object-oriented programs. Leino et al. and Muller et al. have dealt with verification of pointer behavior for object-oriented programs (4,21). JML, short for Java Modeling Language, is a specification language for Java. In JML, subclasses must have stronger specifications (stronger postconditions, weaker preconditions) than those of their superclass (22,23). Although the initial focus of JML has been on specification and run-time assertion checking, more recent efforts include verification. A precursor to JML is Larch that provides a two-tiered style of specification that requires specifications written in two languages: the Larch Interface Language and the Larch Shared Language (24). Some programs specified using Larch have beeen checked using LP, the Larch Prover. LSL specifications are algebraic. For more details on algebraic specifications, including an example, please see the article "Formal Specification."

ACKNOWLEDGMENTS

This work is funded in part from grants CCR-011381, DMS-0701187, and DUE-0633506 from the U.S. National Science Foundation and by a grant from NASA through the SC Space Grant Consortium. We thank Bill Ogden for his role in developing the proof rules given in this article. Our sincere thanks are due to Bruce Weide and the anonymous referees for their careful reading of this manuscript and for their suggestions for improvement. The assertions in this article have been generated mechanically using the RESOLVE verifier available at www.cs.clemson.edu/∼resolve.

FORMAL SPECIFICATION

A formal specification of a software component is a mathematical description of the component's behavior. The specification of a component tells its users, or clients, what it does and lets its implementers know what behavior needs to be provided. A specification does not indicate or dictate the details of a how a component is or should be implemented. When the specification is formal, it serves as an unambiguous contract between component users and implementers, which can reduce significantly the costs of software integration and testing that result from miscommunication between users and developers of components in large-scale software development. A formal specification is essential to achieve formal verification (see the article "Formal Program Verification"), whose goal is to prove that an implementation is correct with respect to its specification. Most current techniques for formal specification focus on specifying the *functional* behavior of a software component, but specification of *performance* behavior is becoming just as important.

INTRODUCTION TO FORMAL SPECIFICATION

A specification describes some essential aspect of the software's behavior, such as functionality or performance, without divulging or prescribing implementation details. For a simple example, consider the following Sort operation on Queues:

> **Operation** Sort(Q: Queue); **ensures** In_Order(Q) **and** Is_Permutation(#Q, Q);

Just like programming languages, specification languages have well-defined syntax and semantics. The specification above is given in RESOLVE, which is an integrated programming and specification language (1,2). A behavioral description of sorting in other specification languages may differ syntactically, but the essence of the specified behavior would be the same. For example, some specification languages use different keywords, (e.g., *post* instead *of ensures* clause) to express behavior. Some use alternative notations (e.g., Q and Q′ in the ensures clause instead of #Q and Q) to distinguish the values of parameters before and after operations. A variety of other specification notations, including Larch (3), VDM (4), and Z (5), are summarized in a later section of this article. We have chosen RESOLVE for this article because it is designed to support both full specification and verification of behavior, serving to explain not only specification principles in this article, but also verification principles in the related article "Formal Program Verification". RESOLVE also includes notations for specifying performance behavior, which is an emerging area of importance.

In the specification of the Sort operation, the value of the parameter Q is updated. In general, specifications of such operations may include a *requires* clause that specifies the precondition of the operation, i.e., what must be true in the program state just before the operation begins for the operation call to be legal. In the current case, the Sort operation has no requires clause, which means that the caller can invoke it on any Queue. The *ensures* clause specifies the postcondition of the operation. It indicates what a correct implementation will guarantee just after the operation as long as the caller satisfies the preconditions at the time of the call. In this case, a correct implementation of the Sort operation makes two guarantees: All elements of the resulting Q will be "in order," *and* the current value of Q (i.e., its resulting value at the end of the operation) is a permutation of the incoming or previous value of Q, denoted by #Q. The functions In_Order and Is_Permutation are mathematical functions defined on (the abstract values of) Queues. Although the above specification describes the behavior of the Sort operation, it is not biased toward or based on any one implementation technique. A programmer can implement the operation using any comparison-based sorting algorithm, such as insertion sort, quicksort, or merge sort.

Benefits of Specification

The specification of an operation can be viewed as a contract between the client and the imple-menter of the operation.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

The contract indicates the rights and responsibilities of both parties. The client has a responsibility to satisfy the precondition before invoking the operation, whereas the implementer has a responsibility to satisfy the postcondition if the precondition is met. The same notion of a contract also applies to components and their specifications.

A formal specification is necessary to allow a software developer to prove mathematically that program code is correct with respect to the specification. Although the goal of full program verification is the most fundamental one, formal specification can benefit software developers in other ways as well. In his article "Seven Myths of Formal Methods" (6), Anthony Hall noted that merely developing a formal specification for their project "helped us to clarify the requirements, discover latent errors and ambiguities, and make decisions about functionality at the right stages." Formal specifications can be checked for consistency or completeness even before the code is written, allowing developers to catch certain mistakes early in the development cycle. Developers can use the specifications as unambiguous requirements for their program code, and once the code is written, static checking tools (7) and runtime assertion checkers (8) may be employed to detect a variety of errors.

Informal, Lightweight, and Full Specification

Specifications can be either formal or informal, and the use of one does not preclude the other. Informal specifications use natural language, pictures, or real-world metaphors to describe a component. An informal specification for the sort operation may simply comprise one-line comments for the preconditions and postconditions, as in the following code:

Operation Sort(Q: Queue); **ensures** (* the elements of Q are in sorted order *);

The signature of the operation alone is not a specification because—apart from the appropriately chosen name—it does not describe the behavior of the operation. A good example of a well-organized library of informal specifications is the online documentation for the Java API. These documents indicate how each class or interface behaves. Java interfaces, in contrast, indicate only the signatures of the methods that implementing classes must provide. Some specification languages, such as the Java Modeling Language (JML) (9), allow informal descriptions to be written as comments in syntactic slots where formal assertions are typically required. This process allows programmers to keep their specifications organized when they may not have the resources to write full formal descriptions.

Although informal specifications can give programmers a quick understanding of how a component can be used, they have at least two drawbacks. First, the descriptions they provide are often imprecise, ambiguous, or incomplete. This issue can prevent a client from fully understanding or making proper use of a component. Second, informal descriptions cannot be understood by programming tools such as static checkers and runtime assertion checkers. For example, static checkers such as ESC/Java (7) can use JML specifications to help statically detect potential programming errors and errors in specifications. Tools that perform runtime assertion checking (8,10) determine whether a particular execution of the program is consistent with the machine-readable specifications. Also, tools exist for generating verification conditions (see the article "Formal Program Verification") and for theorem proving [such as PVS (11) or Isabelle/HOL (12)]. New tools continue to be developed that use formal specifications to assist in program testing, debugging, and verification.

A lightweight specification is a formal specification that captures only some aspects of the behavior of an operation or a component. Lightweight specifications vary in their difficulty and utility. At one end are specifications that are extremely simple, but easy to check, such as a specification of an Enqueue operation that merely asserts that the length of the resulting queue is one element longer (10). An alternative lightweight specification might specify that a given sequence of operations does not create cycles or null-pointer accesses (3). In general, lightweight specifications are useful in runtime assertion checking and extended static checking, but their utility is limited in full verification. In contrast to lightweight specification, full specification requires attention to a full range of specification features, including mathematical models for all types, computational bounds, invariants for all loops, and abstraction relations for all implementations. These and other specification features are described below. Full specifications are necessary for full verification of program behavior.

Specification-Based Reasoning

A fundamental principle of component-based software development is that a component should be usable solely on the basis of its specification. Figure 1 shows a design-time diagram of a software system in which circles represent component specifications and rectangles represent implementations (or realizations) of the specifications. A realization will typically use and therefore depend on other components, but reasoning about the correctness of the realization should be modular; i.e., it should only involve the specifications (not the implementations) of reused components. In Fig. 1, for example, to reason that the Queue_Based realization of Messenger is correct, the

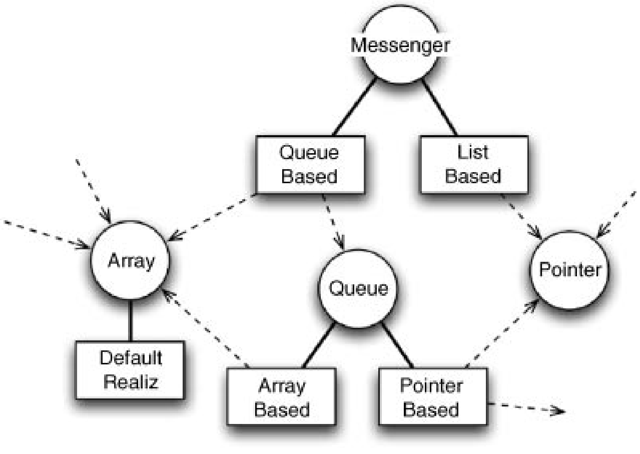

Figure 1. A design-time diagram to illustrate specification-based reasoning.

details of how the Queue specification is implemented should not be necessary. One result of this specification-based style of reasoning is that a developer may substitute one implementation of a component for another without affecting the functional behavior of the system. For example, a straightforward array-based implementation of the Queue component can be substituted with a circular array implementation, and only the performance of the system—not the behavior—will change. Modular or specification-based reasoning is necessary if reasoning about software systems is to be scalable.

SPECIFICATION OF A TYPICAL COMPONENT

This section illustrates the specification of a typical software component. A specification may be model-based or algebraic. We use a model-based style for the central example in this article, deferring a discussion of an algebraic approach to a later section that summarizes various other specification efforts. In a model-based approach, a mathematical model is used to explain each programming type whether it is built in or user defined. Each variable has an abstract value based on the mathematical model of its type, and preconditions and postconditions are written for each operation using that model.

Specification for a Queue Component

Figure 2 shows a model-based specification for a Queue component. The Queue example is sufficiently complex to illustrate the basic ideas of formal specification.

```
Concept Queue_Template (type Entry; evaluates Max_Length: Integer);
    uses String_Theory;
    requires Max_Length > 0;

Type Family Queue is modeled by Str(Entry);
    exemplar Q;
    constraints | Q | ≤ Max_Length;
    initialization ensures | Q | = 0;

Operation Enqueue(alters E: Entry; updates Q: Queue);
    requires | Q | < Max_Length;
    ensures Q = #Q o ⟨#E⟩;

Operation Dequeue(replaces E: Entry; updates Q: Queue);
    requires | Q | > 0;
    ensures #Q = ⟨E⟩ o Q;

Operation Length(restores Q: Queue): Integer;
    ensures Length = | Q |;

Operation Rem_Capacity(restores Q: Queue): Integer;
    ensures Rem_Capacity = ( Max_Length – | Q | );

Operation Swap_Front(updates E: Entry; updates Q: Queue);
    requires | Q | > 0;
    ensures ∃α: String(Entry) ∍ #Q = ⟨E⟩ o α and Q = ⟨#E⟩ o α;

Operation Clear(clears Q: Queue);
    end Queue_Template;
```

Figure 2. A specification for a bounded Queue.

The Queue_Template specification in Fig. 2 is generic—it is parameterized by an Entry type and an integer, Max_Length, which dictates the upper bound for a Queue. It must be properly instantiated with appropriate arguments before it can be used. The specification requires that the expression the user passes as an argument for Max_Length (during instantiation) must be a positive integer. The *uses* clause lists the dependencies. Here, the specification uses String_Theory—a purely mathematical compilation unit that contains properties and definitions related to mathematical strings, including those used in this specification. Automated tools depend on mathematical units when type checking mathematical expressions in specifications, as discussed in a later section in this article, and for generating verification conditions for formal verification.

In RESOLVE, the state space always consists of the abstract values of the currently defined variables. The abstract value space for a type is defined in the specification that provides it. For example, the *type family* declaration in the Queue_Template concept introduces the programming type Queue and associates mathematical strings of entries as the space for the values of Queue variables. Therefore, users can reason about a programming variable of type Queue as a mathematical string of entries. In this concept, the term *type family* is used instead of just *type* because the concept (and, therefore, the type) is generic until it is instantiated, so the declaration of Queue here encompasses an entire family of types. The notion that a programming variable can be viewed abstractly as a pure mathematical value is central to model-based specification and simplifies specification-based reasoning. All variables, even those of basic types, have an abstract (mathematical) interpretation. For example, an array variable may be viewed as a mathematical function from natural numbers to its contents, and an integer variable may be viewed as a mathematical integer, with suitable constraints to capture computational bounds.

The *exemplar* declaration in Queue_Template introduces a variable Q of type Queue to describe properties that hold for any arbitrary Queue variable. For example, the *constraints* clause immediately following the exemplar declaration indicates that the length of any Queue must always be less than Max_Length. Like the requires and ensures clauses, the constraints clause is a mathematical expression. Therefore, the type of Q in the constraints clause is a mathematical string of entries. The String_Theory math unit imported by the uses clause defines the bar outfix operator $|\alpha|$ as the length of string α. The *initialization ensures* clause indicates that each newly declared Queue has a length of zero. The only string that has a length of zero is the empty string, so this is the same as saying that all newly declared Queue objects can be viewed abstractly as empty strings.

A good component specification should provide a suitable set of operations. Together, the operations should be complete functionally, yet minimal. Guidelines for this core set of operations that we call primary operations are given in Ref. 13. To manipulate Queue variables, the current concept describes five operations: Enqueue, Dequeue, Length, Rem_Capacity, Swap_Front, and Clear.

A variety of specification parameter modes appear in the operation signatures. These modes are unique to the RESOLVE specification language, and they have been conceived especially to make specifications easier to understand. The Enqueue operation, for example, specifies its Queue parameter in the *updates* mode, allowing the ensures clause to indicate how it will be modified. In contrast, it lists the Entry parameter in the *alters* mode and indicates only that the Entry may be modified, but it does not indicate how. From this specification, a client knows only that the resulting Entry contains a valid but unspecified value of its type. Therefore, an implementer of Enqueue is not forced to copy the Entry. Copying a variable of an arbitrary type may be expensive, so this specification also allows the implementer to swap Entries, which can be done in constant time (14).

When a parameter is specified in the *replaces* mode, as in the Dequeue operation, its value will be replaced as specified in the ensures clause, regardless of what value it had when the operation was called. Again, this design makes it unnecessary to copy and return the item at the front of the queue, allowing more efficient swapping to be used.

The *restores* parameter mode used in the specification of Length indicates that the value of the parameter after the operation is the same as the value of the parameter before the operation, although the code for the operation may change it temporarily. A restored parameter Q adds an implicit conjunct to the ensures clause that $Q = \#Q$. If a parameter is specified to be in the *preserves* mode, it may not be modified during the operation. In other words, the preserves mode specifies that the concrete state as well as the abstract state remains unmodified, whereas the restores mode specifies only that abstract state remains unmodified. Function operations (operations with return values) should not be side-effecting, so typically all their parameters must be restored or preserved.

The *clears* parameter mode indicates that, after the operation, the parameter will have an initial value. For this reason, the Clear operation does not need an ensures clause: Its only purpose is to give the queue an initial value, which is specified by the clears parameter mode.

The specifications of the operations are given using the requires and ensures clauses. The requires clause of the Enqueue operation states that the length of the incoming Queue Q must be strictly less than Max_Length. The ensures clause states that the new Queue Q has a value equal to the string containing only the old value of E concatenated with the old value of Q. A variable inside of angle brackets, such as $\langle \#E \rangle$, denotes the unary string containing the value of that variable. A small circle represents string concatenation, so $\alpha \circ \beta$ denotes the concatenation of strings α and β. The angle brackets and the concatenation operator are defined in String_Theory.

As an example, suppose $P = \langle \Psi, \Delta, \Phi \rangle$ is a Queue of Tree objects whose maximum length is ten, and suppose $X = \Xi$ is a Tree. Before a client invokes the operation Enqueue(X, P), he is responsible for ensuring that the length of the Queue parameter is strictly less than ten. Since the length of P in our example is three, he can invoke the operation knowing that after the call, $P = \#P \circ \langle \#X \rangle$, or $P = \langle \Psi, \Delta, \Phi \rangle \circ \langle \Xi \rangle = \langle \Psi, \Delta, \Phi, \Xi \rangle$. Since the Entry X is specified in alters mode, the client knows only that X has a valid value of its type: It may be Δ, it may be Ξ, or it may be some other Tree value.

The RESOLVE language has an implicit frame property (15) that states that an operation invocation can only affect parameters to the operation—represented here by P and X. Therefore, the client knows that no other variables in the program state will be modified. This simple rule is possible in RESOLVE, but not necessarily in other languages, such as Java, because in RESOLVE, common sources of aliasing are avoided (for example, by using swapping rather than reference assignment).

Reasoning about the Dequeue operation is similar to reasoning about the Enqueue operation. The Length operation is a function. Like most function operations, this operation has no requires clause. The ensures clause states that $\text{Length} = |Q|$, indicating that the return value of the function is just the length of Q. The Swap_Front operation allows the front Entry of a Queue to be examined (and returned with a second call), without displacing it.

The Queue_Template specification can be implemented in variety of ways. However, users of Queues can ignore those details because all they need to know is described in the specification unambiguously. This developmental independence is crucial for large-scale software construction.

Mathematical Types and Type Checking in Specifications

Specifications that import mathematical types to explain program types give rise to two kinds of typing for the same variable, depending on whether the variable is used in a programming or a mathematical context. Specification languages include mathematical types for this purpose. Extensible specification languages allow new types to be defined and composed from other types. Typical mathematical types include booleans, natural numbers, integers, real numbers, sets, strings, functions, and relations. This small set of types can be composed and reused to specify a variety of computing concepts. For example, mathematical strings can be used in specifying a variety of programming concepts, such as stacks, queues, priority queues, and lists.

Mathematical types, definitions, and appropriate theorems involving those definitions may be described in mathematical theory units that themselves must be robust enough to allow specifications to be built on top of them. For example, the definitions of the string-forming outfix operator "⟨ ⟩" and string concatenation operator "o," both of which are used in the specification of Queue_Template, are given in Fig. 3 from the String_Theory mathematical unit.

…
Definition $\langle x\text{: } \Gamma \rangle\text{: Str}(\Gamma) = \text{ext}(\Lambda, x)$;

Inductive Definition $(s\text{: Str}(\Gamma)) \text{ o } (t\text{: Str}(\Gamma))\text{: Str}(\Gamma)$ **is**
(i) $s \text{ o } \Lambda = \Lambda$;
(ii) $\forall x\text{: } \Gamma,\ s \text{ o } (\text{ext}(t, x)) = \text{ext}(s \text{ o } t, x)$;
…
Inductive Definition $|s\text{: Str}(\Gamma)|$: **N is**
…

Figure 3. Example mathematical definitions in String_Theory.

The mathematical unit String_Theory defines strings over some set Γ, which is a local (mathematical) type used to represent an arbitrary set. Strings are syntactically identified to be the mathematical type Str using two definitions: Λ, the empty string, and ext, a function that extends a string with an object of type Γ. A comprehensive string theory that defines these and other mathematical string notations has been specified in RESOLVE, but its inclusion here is beyond the scope of this article.

When programming objects appear in assertions in specifications, their mathematical types are used rather than their programming types. For the purposes of type checking of these mathematical assertions, we need only know the signatures and types of the definitions involved. For example, the ensures clause of Enqueue "Q = #Q o ⟨#E⟩" is checked for type consistency starting with the values of #Q and #E. The type of #Q evaluates to Str(Entry), and #E has type Entry. The string-forming operator ⟨ ⟩ applied to #E returns an expression of type Str(Entry). The concatenation operator o applied to #Q and ⟨#E⟩ also yields an expression of type Str(Entry). This is compared with the left-hand side of the equality and the type of Q, which also has type Str(Entry). The types match, and the statement is found to be consistent. For another example, if Stacks and Queues are both modeled by mathematical strings of entries, then an ensures clause such as "S = #Q o ⟨x⟩" (where x is of type Entry) would type-check correctly even if S were a Stack and Q were a Queue.

SPECIFICATION OF ASSERTIONS WITHIN IMPLEMENTATIONS

The use of mathematical assertions is not confined to component specifications. Assertions such as abstraction relations, representation invariants, and loop invariants are forms of internal implementation-dependent specifications that need to be supplied along with code. They serve two purposes. First, they help human programmers. They formally document the design intent of the implementers, and they facilitate team development (within an implementation) and ease later maintenance and modification. Second, the assertions are necessary for automated program verification systems that cannot, in general, deduce these assertions that capture design intent.

To illustrate the role and use of implementation-specific, internal specifications, a portion of an array-based implementation for Queue_Template is given in Fig. 4. The Queue data type is represented by a record with one array field (Contents) and two integer fields (Front and Length). The Contents array holds the elements of the Queue, Front is the index of the array that holds the first element in the Queue, and Length is length of the Queue.

```
Realization Circular_Array_Realiz for Queue_Template;

    Type Queue = Record
            Contents: Array 0..Max_Length – 1 of Entry;
            Front, Length: Integer;
        end;

    conventions 0 ≤ Q.Front < Max_Length and
                0 ≤ Q.Length < Max_Length;
    correspondence
```

$$\textbf{Conc}.Q = \prod_{k=Q.Front}^{Q.Front+Q.Length-1} \langle Q.Contents(k \textbf{ mod } Max\_Length)\rangle;$$

```
  Procedure Enqueue(alters E: Entry; updates Q: Queue);
      Q.Contents((Q.Front + Q.Length) mod Max_Length) :=: E;
      Q.Length := Q.Length + 1;
  end Enqueue;

   (* implementation of other Queue operations *)

end Circular_Array_Realiz;
```

Figure 4. A portion of an array-based implementation of Queues.

The conventions clause—the representation invariant—indicates properties that must hold before and after the code for each exported (i.e., not private) Queue operation. The conventions here indicate that both the Front and the Length fields must always be between zero and the value of the Max_Length variable from the Queue_ Template. The correspondence clause—the abstraction relation—plays a fundamental role in specification-based reasoning. It defines the value of the conceptual Queue (**Conc**.Q) as a function of the fields in the Queue's representation. In this abstraction relation, the Π notation indicates string concatenation over a range of values. The relation states that the conceptual Queue is the mathematical string resulting from the concatenation from k = Q. Front to Q.Front + Q. Length − 1 of the unary strings whose elements are given by expression Q.Contents(k **mod** Max_Length). For example, if Max_Length = 5, Contents = [Ψ, Δ, Φ, Θ, Ξ], Length = 3, and Front = 3, then the conceptual Q would be ⟨Contents(3)⟩ o ⟨Contents(4)⟩ o ⟨Contents(0)⟩ = ⟨Θ, Ξ, Ψ⟩. Note that, in this implementation, some elements in the array have no effect on the conceptual value of the Queue. For example, an array value of [⟨Ψ, Γ, Ω, Θ, Ξ⟩] in the above example would yield the same conceptual Queue value. The Π notation is defined such that when the index at the top is smaller than the one at the bottom, it becomes the empty string. This is the reason in the initial state when Front and Length are set to 0 that the conceptual Queue corresponds to the empty string as specified in the initialization ensures clause.

To understand how the representation invariant and abstraction relation are used in reasoning, consider the implementation of the Enqueue operation given in Fig. 6. Let the representation value of the Queue parameter Q be as described above: Q.Contents = [Ψ, Δ, Φ, Θ, Ξ] and Q.Length = Q.Front = 3. Suppose that the element E that

```
Enhancement Sort_Capability (definition (x: Entry) ≾ (y: Entry): B)

            Insert_In_Order(E, Temp);
        end;
        Q :=: Temp;
    end Sort;

    Operation Insert_In_Order(alters E: Entry; updates Q: Queue);
        requires | Q | < Max_Length and Is_Conformal_with(≾, Q);
        ensures Is_Conformal_with(≾, Q) and Is_Permutation(#Q o ⟨E⟩, Q);
    Procedure
        (* procedure body goes here. *)
    end Insert_In_Order;

    end Insertion_Sort_Realiz;
```

Figure 6. An implementation for the Queue sort operation.

we want to enqueue has a value of Ω. The conceptual value of the Queue, $\langle\Theta, \Xi, \Psi\rangle$, indicates how the Queue is viewed by someone reading the concept or specification. Therefore, when we check the precondition and postcondition as it is given in the concept, we have to use the abstraction relation to translate the representation value of Q into its conceptual value. This instance of the representation is consistent with all the preconditions of the Enqueue operation. The representation invariant is satisfied, since Length and Front are both between 0 and 4. The precondition of the operation is satisfied, since the length of the conceptual Queue, $\langle\Theta, \Xi, \Psi\rangle$, is strictly less than Max_Length. The implementation of Enqueue first swaps Contents(3 + 3) **mod** 5 = Contents(1) with E, so that Contents(1) becomes Ω and E becomes Δ. Then it increases Length by one so that Length becomes 4. Thus, after the procedure, Q.Contents = $[\Psi, \Omega, \Phi, \Theta, \Xi]$, Q.Length = 4, Q.Front = 3, and E = Δ. This result is consistent with the representation invariant, since Q.Length = 4 is still strictly less than Max_Length = 5. The conceptual value of Q is now $\langle\Theta, \Xi, \Psi, \Omega\rangle$, and the ensures clause, Q = #Q o $\langle$#E$\rangle$, is satisfied since $\langle\Theta, \Xi, \Psi, \Omega\rangle = \langle\Theta, \Xi, \Psi\rangle$o$\langle\Omega\rangle$.

When at least one realization has been implemented for a concept, a developer can create a usable factory or facility by instantiating the concept and indicating the realization that will be used to implement it. Variables can then be declared using any type defined in this way. The code below shows how this is done in RESOLVE:

Facility Int_Queue_Fac is Queue_Template(Integer, 500) **realized** by Circular_Array_Realiz; $\cdots$**Var** Q Int_Queue_Fac. Queue;

A Queue Sorting Enhancement

Figure 5 gives an example of an enhancement for sorting a Queue. In RESOLVE, an enhancement is a way to add additional functionality to a concept without altering the concept specification or its implementations. The enhancement Sort_Capability specifies a *secondary* operation. The use of secondary operations facilitates data abstraction and information hiding and allows developers to keep the number of primary operations in a component to a minimum. The Sort operation can be implemented using a combination of Queue primary operations without directly depending on the internal details of any particular Queue implementation.

The Sort_Capability enhancement is generic. It is parameterized by a mathematical definition of the relation $\precsim$, which takes two parameters of type Entry and returns a Boolean value. The requires clause states that $\precsim$ must be total and transitive (i.e., a total preordering), ensuring that the entries can be sorted. The specification of the sort operation itself is the same as that given in the beginning of this article, except that we have used the idea of "conformal" a higher order predicate: A string Q is conformal with the ordering $\precsim$, if it is arranged according to that order. Both the predicates used in the specification, namely Is_Conformal_with and Is_Permutation, are defined in the mathematical unit String_Theory (imported by Queue_Template).

Figure 6 gives one possible implementation of the Sort operation—an insertion sort. The insertion sort implementation takes a programming operation, Are_Ordered, as a parameter. Any operation can be passed into the implementation as long as it has the same signature as Are_Ordered and has an ensures clause that is consistent with the ensures clause of Are_Ordered. The Are_Ordered operation simply provides a means to check programmatically whether two Entry variables are ordered according to the mathematical definition of $\precsim$.

The developer of an implementation involving a loop must give an invariant for the loop, which is introduced here via the **maintaining** clause. A loop invariant is an assertion that (i) must be an invariant, i.e., true at the beginning and end of each iteration of the loop, and (ii) must be strong enough to help establish the postcondition of the operation.

The loop invariant given in the procedure body for the sort operation is "Is_Conformal_with($\precsim$, Temp) and Is_Permutation(#Q, Q o Temp)." Proving that this invariant is true at the beginning and end of each iteration is done by a verification tool using induction (see the article "Formal Program Verification"). Here, we explain informally why the given assertion is an invariant for this particular instance. Consider a Queue of Trees Q whose value at the beginning of the procedure is $\langle\Theta_7, \Xi_4, \Psi_6\rangle$, where Tree T_i represents a Tree with i nodes, and the Trees are ordered based on the number of nodes they have. We can refer to the incoming value of Q at any state in the procedure as the old value of Q, or #Q. At the beginning of the first loop iteration, Temp has an initial value of its type, so that $\mathrm{Q} = \langle\Theta_7, \Xi_4, \Psi_6\rangle$ and Temp = $\langle\ \rangle$. The loop invariant is true since Temp is in agreement with the order and $Q\ \mathrm{o\,Temp} = \langle\Theta_7, \Xi_4, \Psi_6\rangle\ \mathrm{o}\ \langle\rangle = \langle\Theta_7, \Xi_4, \Psi_6\rangle = \mathrm{Q}$. The body of the loop dequeues the first Tree, Θ_7, from Queue Q and inserts it, in the correct order, into Temp, so at the end of the first loop iteration, $\mathrm{Q} = \langle\Xi_4, \Psi_6\rangle$ and $\mathrm{Temp} = \langle\Theta_7\rangle$. The loop invariant is true since Temp is in order and $Q\ \mathrm{o\,Temp} = \langle\Xi_4,\ \Psi_6,\ \Theta_7\rangle\mathrm{O}\langle\ \rangle = \langle\Xi_4, \Psi_6, \Theta_7\rangle$ is a permutation of #Q. The program state at the beginning of the second iteration is the same as the program state at the end of the first iteration, so the loop invariant remains true. During the second iteration, Ξ_4 is dequeued from Q and inserted in order into Temp so that $\mathrm{Q} = \langle\Psi_6\rangle$ and $\mathrm{Temp} = \langle\Xi_4, \Theta_7\rangle$. The loop invariant holds again since $Q\ \mathrm{o\,Temp} = \langle\Psi_6\rangle\mathrm{o}\langle\Xi_4, \Theta_7\rangle = \langle\Psi_6, \Xi_4, \Theta_7\rangle$ is a permutation of #Q. At the end of the final iteration, $\mathrm{Temp} = \langle\Xi_4, \Psi_6, \Theta_7\rangle$, and $\mathrm{Q} = \langle\rangle$, so the invariant still holds.

A verification tool will also use the invariant to prove the postcondition: that the new Queue value is conformal with the given order and a permutation of the old Queue value. The general case is easy to explain, so we do not restrict ourselves here to $\#\mathrm{Q} = \langle\Theta_7, \Xi_4, \Psi_6\rangle$. At the end of the loop, we know that the loop condition, Length(Q) /= 0, is false and that the loop invariant is true. Therefore, we know that Q is empty, Temp is in order, and Temp is a permutation of Q. When we swap the values of Temp and Q, Q is in order and Q is a permutation of #Q, which is what we needed to show.

Another use of specification in this procedure is the decreasing clause. The decreasing clause introduces a progress metric, which is used to prove that the loop terminates. The progress metric is a natural number that must decrease with each iteration of the loop. Since natural numbers cannot be negative, a proof that the metric decreases implies that the loop terminates (see thie article "Formal Verification"). In the example where $\#\mathrm{Q} = \langle\Theta_7, \Xi_4, \Psi_6\rangle, |\mathrm{Q}| = 2$ at the end of the first iteration, 1 at the end of the second, and 0 at the end of the third. Progress metrics are also used to show termination for recursive procedures.

The following code is an example of a facility declaration that includes the sort enhancement:

Facility Int_Queue_Fac is Queue_Template(Integer, 500) **realized** by Circular_Array_Realiz **enhanced** by Sort_Capability($\leq$) **realized** by Insertion_Sort_Realiz(Int_Less_Eq); .

PERFORMANCE SPECIFICATION

Although specification of functionality has received much attention, specification of performance characteristics, such as time and space requirements, are also necessary for reliable software engineering. When multiple implementations of the same specification occur, developers can use the performance specifications to choose one over the other depending on the needs of their application. This flexibility is essential, since different implementations provide tradeoffs and no single implementation of a concept is likely to be appropriate universally. Just as formal specifications of functionality are necessary for mechanized verification, formal specifications of performance are necessary for verification of performance correctness, which is a key requirement for embedded and other critical systems. In this article, we only show specifications of duration (time requirements) for components using the Queue example. For more details, including analysis of space requirements, please see Ref. 16.

In RESOLVE, performance specifications are given through the profile construct. Figure 11 shows a part of a performance profile called QSC for a class of "space conscious" Queue implementations that keep the internal array free of unutilized garbage (16). The profile in the figure does not make any assumptions about the generic terms Entry and Max_Length. Consequently, its expressions are written using these terms. Although a profile is implementation dependent, it should be free of nonessential implementation details. This capability is provided using a *defines* clause. This clause allows a profile to use constants ($\mathrm{QSC_I}$, $\mathrm{QSC_{I1}}$, $\mathrm{QSC_E}$, $\mathrm{QSC_D}$, $\mathrm{QSC_{Sfe}}$, etc.), whose values will come from the implementation. $\mathbf{R}^{\geq 0.0}$ indicates that their values must be positive real numbers. For each operation, a profile supplies the time necessary to execute the operation using a *duration* clause.

In Fig. 7, the duration expression for initialization is the summation of two terms. The first term, $\mathrm{QSC_I}$, is an implementation-based overall constant overhead. The second term is calculated in two steps. First, the sum of $\mathrm{QSC_{I1}}$ (an implementation-based constant overhead for each Entry) and Entry.**I_Dur** (duration to create an initial valued Entry) is calculated. Then the sum is multiplied by Max_Length to obtain the total time to initialize every Entry in the array structure that is used to represent the Queue internally.

To understand the duration expression for Enqueue, consider the following implementation of the Enqueue

```
Profile QSC short_for Space_Conscious for Queue_Template;
    defines
      $QSC_{I}$, $QSC_{I1}$, $QSC_{E}$, $QSC_{D}$, $QSC_{Sfe}$, $QSC_{L}$, $QSC_{RC}$, $QSC_{C}$: $\mathbf{R}^{\geq 0.0}$;
    Type Family Queue;
        initialization
            duration $QSC_{I}$ + ($QSC_{I1}$ + Entry.I_Dur) * Max_Length;

    Operation Enqueue(alters E: Entry; updates Q: Queue);
        ensures Entry.Is_Init(E);
        duration $QSC_{E}$;

    Operation Dequeue(replaces R: Entry; updates Q: Queue);
        duration $QSC_{D}$ + Entry.I_Dur + Entry.F_Dur(#R) ;

  ...
```

Figure 7. Part of a duration profile for bounded Queue implementations.

operation, which assumes that the Queue is implemented as space-conscious circular array:

```
Procedure Enqueue(alters E Entry; updates Q Queue);
Q.Contents((Q.Front + Q.Length) mod. Max_ Length) :=: E;
Q.Length := Q.Length + 1; end Enqueue;
```

In this implementation, the Enqueue procedure performs the following actions: It accesses a record a total of five times; it swaps an array element once; and it performs one integer assignment, two additions, and a mod operation (Fig. 12). Therefore, for this implementation of the Enqueue operation, QSC_E, used in the profile in Fig. 12, is given the following definition:

$$\text{Definition } QSC_E\text{: } R^{\geq 0.0} = \text{Dur}_{\text{Call}}(2) + 5\cdot\text{Record.Dur} + \text{Array.Dur}_{:=:} + \text{ Int.Dur}_{:=:} + 2.\text{ Int.Dur}_{+} + \text{ Int.Dur}_{\text{mod}};$$

In this expression, $\text{Dur}_{\text{Call}}(2)$ denotes the time to call an operation with two arguments. The duration expression of Dequeue is slightly more complex because it involves initialization of a new Entry variable and a variable finalization.

SUMMARY OF VARIOUS FORMAL SPECIFICATION EFFORTS

The RESOLVE specification language has been used in developing an extensive component library, teaching graduate and undergraduate courses (17,18), and developing commercial software (19). Several other specification languages have found wide use. Formalism is a shared objective of all these languages. This section contains a summary of various efforts.

The Z notation specification language, which was developed at Oxford University Computing Laboratory, is based on set theory and first-order predicate logic (5). A Z statement value can be either true or false and cannot be undefined. Like RESOLVE, Z is typed language: Every variable has a type, reducing errors in specification. For smaller problems, the mathematical notation can be understood easily, but specifications become unattractive as the problem size increases. This obstacle is overcome by introducing schema notation. A schema replaces several statements with a single statement, and it can be composed of several other schemas. This gives Z a modular structure. Just as Z provides logical operators on predicates, it also provides matching operators for schemas. Z specification statements are human readable and, in general, nonexecutable. Z provides both formatting and type-checking tools. Many systems have been built using Z specification, including hardware systems, transaction processing systems, communication systems, graphics systems, HCI systems, and safety-critical systems (20).

VDM-SL (4,21,22) is a model-oriented specification language that originated in the IBM Laboratory in Vienna. It uses propositional calculus and predicate logic. VDM-SL functions do not have side effects and are defined by their signature and preconditions and post-conditions. The Vienna Development Method (VDM) is a program development method based on VDM-SL and tool support. Its object-oriented version is called VDM++. The VDM development cycle starts with an abstract specification and ends with an implementation. The cycle is based on two steps: data reification and operation decomposition. *Data reification* (a VDM term commonly known as data refinement) involves the transition from abstract to concrete data types and the justification of this transition. A reification step is taken if behavior of the reifying and original definitions is guaranteed to be the same. A concrete definition of a function is said to reify or satisfy its abstract definition if for all arguments of the required type satisfying the precondition, the transformation process yields results that are of the required type and satisfy the postcondition.

RAISE (Rigorous Approach to Industrial Software Engineering) is a formal method technique based on VDM (23). It has been used to specify and develop software systems for industrial use. RSL, the specification language of RAISE, supports concurrent and sequential programming features (24).

Larch (3,25) is one of the earlier specification languages and is designed as a family of languages with two tiers of specification: The top tier is a *behavioral interface specification language* (BISL), and the bottom tier is the *Larch Shared Language* (LSL), which is an algebraic style specification language. The LSL is language-independent and is used to describe the mathematical vocabulary used in the preconditions and postcondition specifications. LSL specifications are algebraic rather than model-based. Instead of using mathematical types to model programming types, they introduce a set of axioms that together define the behavior of the component. Figure 8 gives a portion of a Queue specification similar to the one in Ref. 3. In the specification, E is the type for elements in the queue and C is the queue type. Functions are declared using the keyword *introduces*, and their behaviors are defined through the axioms in the *asserts* clause. For additional examples of LSL specifications, see Ref. 3.

Using the shared language, BISL is designed for a given programming language to specify both the interface and the behavior of program modules in that language. The modules are implemented in a particular programming language. Since a BISL is based on a specific programming language, the specification is

```
Queue (E, C): trait
    introduces
        empty: → C
        enqueue: E, C → C
        front: C → E
        dequeue: C → C
        length: C → Int
        isEmpty: C → Bool
        …
    asserts
        C generated by empty, enqueue
        ∀ q: C, e: E
            …
            front(enqueue(e, q)) == if q = empty then e else front(q);
            dequeue(enqueue(e, q)) ==
            if q = empty then empty else enqueue(e, dequeue(q));
            length(empty) == 0;
            length(enqueue(e, q)) == length(q) + 1;
            isEmpty(q) == q = empty;
        …
```

Figure 8. A portion of an LSL specification for a queue.

easy to understand and use. Currently, the available BISLs are Larch/CLU for CLU, Larch/Ada for Ada, LCL for ANSI C, LM3 for Modula-3, Larch/Smalltalk for Smalltalk-80, Larch/C++ for C++, and Larch/ML for Standard ML. Different features of BISL, such as abstraction, side effects, exception handling, name visibility, concurrency, and iterators, depend on how these features are handled by the specific programming language. The LSL checker and LP (Larch Prover) can be used to check Larch statements. First, the LSL checker is used to check the consistency of LSL specification statements and to help generate proof obligation statements. LP uses proof by induction or contradiction to show the correctness of newly created statements. LP is an interactive proof assistant that supports all of the Larch languages.

JML is a BISL tailored for Java (9,26). In JML, specification statements are written just before the header of the method using the Design-by-Contract (DBC) approach. JML specifications are written as special comments to the source file. Hence, it is easier for the programmer to understand than special-purpose mathematical notations. JML can be used with DBC, runtime assertion checking, static checking, specification browsing, and formal verification using theorem prover tools. In JML, inheritance relationships must adhere to the notion of behavioral subtyping: The specifications of the methods in a class must conform to the specifications of the methods they override in the parent class, which ensures that an object of a given type can always be substituted for an object of the parent type without violating the contract described by the specification (27). The Spec# language is similar in spirit to JML but is designed to be used with C# (28).

Other well-known specification languages include Euclid, Eiffel, ANNA, and SPARK. The Euclid programming language, based on Pascal, was developed for system programming and program verification (29–31). Eiffel is designed to support lightweight specifications (10). It was one of the first languages to facilitate run-time assertion checking. ANNA, a language extension of Ada, was designed to develop annotations so that formal methods of specification and documentation can be applied to Ada programs (32). SPARK is also based on Ada and is designed to be used for safety-critical applications (33).

LAMBDA-CALCULUS

INTRODUCTION

The λ-calculus is an abstract language and system of rules for *higher order programming,* in the sense that in this calculus one can represent programs that modify other programs, as well as programs that operate on numbers.

It was invented in 1928 by an American logician, Alonzo Church, as part of a logical system in which he hoped to describe the foundations of mathematics. This larger system turned out to be inconsistent and was abandoned, but the λ-calculus at its core survived, and Church's group found that, using it, they could give a precise definition of what computability meant. From this definition, they discovered the first rigorous proof that certain important problems could never be solved by computer. (It was published in 1936, see Ref. 1.)

But until the 1970s, λ-calculus had very little use in actual computing, as most practical programming languages were only first order.

Since then, however, many higher-order programming languages have been developed. They incorporate either a form of λ-calculus or something equivalent to it, and earlier studies of λ-calculus have helped to show what these languages can do. Roughly speaking, techniques can be tried out and developed on λ-calculus, and then applied to the more complex practical languages.

To give the reader the flavor of λ-calculus as quickly as possible, we shall describe here its simplest, "pure," form, but with the warning that most applications use more complicated variants.

Additional information on λ-calculus is available in many websites and books on computing, as well as in the introductory account by Hindley and Seldin [2] and the comprehensive book by Barendregt [3].

SYNTAX OF λ-CALCULUS

An arithmetical expression such as "x^2+3" defines a function of x; Church denoted this function by

$$\lambda x\cdot x^2+3$$

Associated with this notation is a rule: for all numbers n,

$$(\lambda x\cdot x^2+3)(n)=n^2+3$$

Church's notation is useful in dealing with expressions that contain more than one variable: For example, the expression "$x+2y$" can be viewed as defining either a function of x, with y held constant, or a function of y, with x held constant. In the λ-notation, these two functions are easily distinguished; they are called, respectively,

$$\lambda x\cdot x+2y,\quad \lambda y\cdot x+2y$$

We have

$$\begin{aligned}(\lambda x\cdot x+2y)(n)&=n+2y\\(\lambda y\cdot x+2y)(n)&=x+2n\end{aligned}$$

Church's λ-notation led to a formal language, whose expressions are called λ-*terms* and are intended to denote operators or programs or mathematical functions.

Definition 1 (λ-terms). (Ref. 2, Def. 1.1.) Assume given an infinite sequence of variables $x, y, z, x_1, y_1, z_1, x_2, y_2, z_2, \ldots$ (to denote arbitrary programs or operators). Then λ-*terms* are constructed as follows:

(a) each variable is a λ- term;
(b) from any λ- terms M and N, construct a new λ-term $(M\,N)$ (to denote the application of operator M to input N);
(c) from any variable x and λ-term M, construct a new λ-term $(\lambda x\cdot M)$ (to denote the function of x that M defines).

Notation 2. A term (MN) is called an *application* and $(\lambda x\cdot M)$ an *abstraction*. (In mathematics the application of M to N is usually called "$M(N)$"; the reason it is called "(MN)" in λ-calculus is merely a historical accident.) To denote arbitrary λ-terms, we shall use capital letters. We shall write

$$M\equiv N$$

to mean that M is the same term as N. Parentheses and repeated λs will often be omitted in such a way that, for example,

$$\begin{gathered}M\,N\,PQ\equiv(((M\,N)P)Q),\\ \lambda xyz\cdot MN\equiv(\lambda x\cdot(\lambda y\cdot(\lambda z\cdot(MN))))\end{gathered}$$

In the rest of this section, let x, y, z, u, v be any distinct variables.

Examples of λ-terms:

(a) $(\lambda x\cdot(xy))$,
(b) $((\lambda y\cdot y)(\lambda x\cdot(xy)))$,
(c) $(x(\lambda x\cdot(\lambda x\cdot x)))$
(d) $(\lambda x\cdot(yz))$

In (c) there are two occurrences of λx in one term; this is allowed by the definition of "λ-term," although discouraged in practice. In (d), there is a term of form $(\lambda x\cdot M)$ such that x does not occur in M; this is allowed, and such terms denote constant-functions.

To show how λ-terms are used as programs, some more apparatus is needed. We shall just give a brief sketch.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Definition 3 (Free and bound variables). (Ref. 2, Def. 1.11.) Any occurrence of a variable x in a term $\lambda x \cdot M$ is said to be *bound* by the λx. The x in λx is said to be *binding and bound*. Any nonbound occurrence in a term is said to be *free*. The set of all variables that occur free in a term P is called

$$FV(P)$$

A *combinator* or *closed term* is a term in which no variable occurs free.

Warning. When free or bound variables are mentioned, it is really *occurrences* of variables that are meant. A variable can have bound occurrences and free occurrences in the same term. For example, consider the term

$$P \equiv (\lambda \upsilon \cdot x)(\lambda y \cdot yx(\lambda x \cdot y \upsilon x))$$

In this term, the leftmost υ is bound and binding, the other υ is free, the leftmost two x's are free, the other two x's are bound, and all three y's are bound. Also

$$FV(P) = \{\upsilon, x\}$$

Definition 4 (Substitution). (Ref. 2, Def. 1.12.) For any terms M, N and any variable x, define $[N/x]\,M$ to be the result of substituting N for each free occurrence of x in M, and changing any λy's in M to prevent variables free in N from becoming bound in $[N/x]\,M$. In detail:

(a) $[N/x]x \equiv N$;
(b) $[N/x]y \equiv y$ (assuming $y \not\equiv x$);
(c) $[N/x](PQ) \equiv [N/x]P[N/x]Q$;
(d) $[N/x](\lambda x \cdot P) \equiv \lambda x \cdot P$;
(e) $[N/x](\lambda y \cdot P) \equiv \lambda y \cdot P$ if $x \notin FV(P)$;
(f) $[N/x](\lambda y \cdot P) \equiv \lambda y \cdot [N/x]P$ if $x \in FV(P)$ and $y \notin FV(N)$;
(g) $[N/x](\lambda y \cdot P) \equiv \lambda z \cdot [N/x][z/y]P$ if $x \in FV(P)$ and $y \in FV(N)$;
(Here z is a variable chosen to be $\notin FV(NP)$.)

Example. Let $M \equiv \lambda y \cdot yx$.

$$\begin{array}{llll} \text{If } N \equiv x\upsilon: & [(x\upsilon)/x](\lambda y \cdot yx) & \equiv \lambda y \cdot [(x\upsilon)/x](yx) & \text{by (f)} \\ & & \equiv \lambda y \cdot y(x\upsilon) & \text{by (a)} - \text{(c)} \\ \text{If } N \equiv xy: & [(xy)/x](\lambda y \cdot yx) & \equiv \lambda z \cdot [(xy)/x](zx) & \text{by (g)} \\ & & \equiv \lambda z \cdot z(xy) & \text{by (a)} - \text{(c)} \end{array}$$

Remark. If (g) were omitted from the definition of substitution, then we would have the undesirable fact that, although $\lambda y \cdot x$ and $\lambda \upsilon \cdot x$ both denote the same operator (the constant-operator whose output is always x), they would come to denote different operators when υ was substituted for x:

$$[\upsilon/x](\lambda y \cdot x) \quad \text{would be } \lambda y \cdot \upsilon, \quad [\upsilon/x](\lambda \upsilon \cdot x) \quad \text{would be } \lambda \upsilon \cdot \upsilon$$

Informally speaking, terms that differ only by changing bound variables have the same meaning. For example, $\lambda x \cdot x$ and $\lambda y \cdot y$ both denote the identity-operator. The process of changing bound variables is defined formally as follows.

Definition 5 (Changing bound variables, α-conversion). (Ref. 2, Def. 1.17.) If $y \notin FV(M)$, we say

$$(\alpha) \quad \lambda x \cdot M \equiv_{\alpha} \lambda y \cdot [y/x]M$$

If P changes to Q by a finite (perhaps empty) series of replacements of form (α), we say

$$P \equiv_{\alpha} Q$$

The relation $\equiv_{\alpha}$ can be proved symmetric (i.e. if $P \equiv_{\alpha} Q$ then $Q \equiv_{\alpha} P$) cf. Ref. 2, Lemma 1.19.

The λ-calculus analog of computation is defined as follows.

Definition 6 (β-contraction, β-reduction). (cf. Ref. 2, Def. 1.24.) A term of form

$$(\lambda x \cdot M)N$$

is called a β-*redex*. (It represents an operator applied to an input.) If it occurs in a term P, and we replace one occurrence of it by

$$[N/x]M$$

then we say that we have *contracted* that occurrence of it. If this contraction changes P to a term P', then we say

$$P \rightarrow_{\beta} P'$$

A finite (perhaps empty) or infinite series of contractions and changes of bound variables is called a β-*reduction*. If it is finite and changes P to Q, then we say that P β-*reduces to* Q or

$$P \twoheadrightarrow_{\beta} Q$$

Example. Here are some reductions; the redex contracted at each step is underlined. In (c) the reduction is infinite, even though the term never changes.

$$\begin{array}{llll} \text{(a)} & \underline{(\lambda x \cdot ((\lambda y \cdot xy)u))(\lambda \upsilon \cdot \upsilon)} & \rightarrow_{\beta} & \underline{(\lambda y \cdot (\lambda \upsilon \cdot \upsilon)y)u} \\ & & \rightarrow_{\beta} & \underline{(\lambda \upsilon \cdot \upsilon)u} \\ & & \rightarrow_{\beta} & u. \\ \text{(b)} & (\lambda x \cdot \underline{((\lambda y \cdot xy)u)})(\lambda \upsilon \cdot \upsilon) & \rightarrow_{\beta} & \underline{(\lambda x \cdot xu)(\lambda \upsilon \cdot \upsilon)} \\ & & \rightarrow_{\beta} & (\lambda \upsilon \cdot \upsilon)u \\ & & \rightarrow_{\beta} & u. \\ \text{(c)} & \underline{(\lambda x \cdot xx)(\lambda x \cdot xx)} & \rightarrow_{\beta} & \underline{(\lambda x \cdot xx)(\lambda x \cdot xx)} \\ & & \rightarrow_{\beta} & \cdots. \end{array}$$

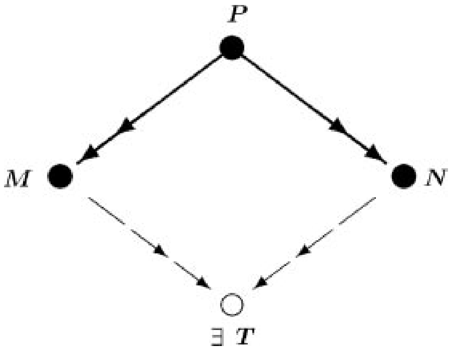

Figure 1. Church-Rosser theorem.

Definition 7 (β-normal form). A term N that contains no β-redexes is called a β-*normal form* or β-*nf*. If $M \twoheadrightarrow_\beta N$, then N is called a β-*normal form of M*.

Not every term has a β-normal form; in fact, Example (c) above shows that

$$(\lambda x \cdot xx)(\lambda x \cdot xx)$$

has none. Examples (a) and (b) above raise the question of whether a term can have more than one β-normal form. In fact it cannot, except for changes of bound variables. This result is a consequence of the following general theorem.

Theorem 8 (Church-Rosser theorem for β-reduction). (cf. Ref. 2, Thm. 1.32.) If $P \twoheadrightarrow_\beta M$ and $P \twoheadrightarrow_\beta N$ (see Fig. 1), then a λ-term T exists such that

$$M \twoheadrightarrow_\beta T, \quad N \twoheadrightarrow_\beta T$$

The Church-Rosser theorem implies that no term P can have more than one β-normal form, as follows. Suppose P could be reduced to two normal forms N_1 and N_2. Then by the theorem, N_1 and N_2 could both be reduced to a term T. But N_1 and N_2 contain no redexes, because they are normal forms. Hence, their reductions to T must have no contractions, only perhaps changes of bound variables. Thus N_1, N_2 and T must be identical except for bound variables.

In Definition 7, N is often called *the* β-normal form of M.

Note 9 (Some combinators). Here are some of the most commonly used combinators, with their standard names and reduction properties. {In this table, "X", "Y", "F", and "G" denote arbitrary λ-terms.}

Note 10 (Functions of many variables). A λ-term F represents an operator that accepts an input X and produces an output that we call *(FX)*. But in mathematics, some functions such as addition need two inputs before they can produce an output. No such functions are given in λ-calculus. However, mathematical many-place functions can be represented indirectly by one-input operators if we choose these operators to be higher order (i.e., operators whose outputs are other operators). For example, let *f* be a 2-place function that accepts numbers m, n as inputs and produces an output-number $f(m, n)$. Define a corresponding one-input operator f^* as follows. First, to each input-value m there corresponds a one-input operator f_m such that, in standard mathematical notation,

$$f_m(n) = f(m, n) \quad \text{for all}\, n$$

Then define f^* by setting

$$f^*(m) = f_m \quad \text{for all}\, m$$

This gives, for all m, n,

$$(f^*(m))(n) = f_m(n) = f(m, n)$$

In the computing community, the act of representing *f* by f^* is often called *currying*, after Haskell Curry, who was one of the contributors to λ-calculus. (Although Curry never claimed it to be his own idea.)

Note 11 (Computable functions). (cf. Ref. 2, Ch. 4.) If the combinators $\overline{0}, \overline{1}, \overline{2}, \ldots, \overline{n}, \ldots$ in Note 9 are taken to represent the numbers 0, 1, 2, …, n, …, then certain other combinators represent mathematical functions or operators. For example, let

$$\overline{Add} \equiv \lambda uvxy \cdot ux(vxy) \quad \overline{Mult} \equiv \lambda uvx \cdot u(vx)$$

Then, it can be shown that, for all natural numbers m and n,

$$\overline{Add}\,\overline{m}\,\overline{n} \twoheadrightarrow_\beta \overline{m+n} \quad \overline{Mult}\,\overline{m}\,\overline{n} \twoheadrightarrow_\beta \overline{m \times n}$$

$\mathbf{I} \equiv \lambda x \cdot x$	(identity combinator):	$\mathbf{I}X \twoheadrightarrow_\beta X$
$\mathbf{B} \equiv \lambda xyz \cdot x(yz)$	(composition),	$\mathbf{B}FGX \twoheadrightarrow_\beta F(GX)$
$\mathbf{C} \equiv \lambda xyz \cdot xzy$	(commutator),	$\mathbf{C}FXY \twoheadrightarrow_\beta FYX$
$\mathbf{K} \equiv \lambda xy \cdot x$	(constant-forming),	$\mathbf{K}XY \twoheadrightarrow_\beta X$
$\mathbf{S} \equiv \lambda xyz \cdot xz(yz)$	(substitution & composition),	$\mathbf{S}FGX \twoheadrightarrow_\beta FX(GX)$
$\mathbf{W} \equiv \lambda xy \cdot xyy$	(doubling),	$\mathbf{W}FX \twoheadrightarrow_\beta FXX$
$\mathbf{Y} \equiv (\lambda ux \cdot x(uux))(\lambda ux \cdot x(uux))$	(fixed-point combinator, cf. Ref.2 §3B),	$\mathbf{Y}F \twoheadrightarrow_\beta F(\mathbf{Y}F)$
$\overline{0} \equiv \lambda xy \cdot y$	(to represent zero),	$\overline{0}FX \twoheadrightarrow_\beta X$
$\overline{n} \equiv \lambda xy \cdot x^n y$	(to represent number n),	$\overline{n}FX \twoheadrightarrow_\beta F^n X$

where

$$F^n X \equiv F(F(\ldots(FX)\ldots)) \text{ with } n \text{ “}F\text{”s}$$

In general, a k-argument function f of natural numbers is said to be *represented* or λ-*defined* by a λ-term M when

$$M\overline{n_1}\ldots\overline{n_k} \twoheadrightarrow_\beta f(n_1,\ldots,n_k)$$

for all natural numbers $n_1, \cdots, n_k$. It can be proved that every function that is computable (by any of the standard idealized computers in the literature, such as a Turing machine) is λ-definable.

In this sense, all computable functions can be programmed in λ-calculus.

TYPES IN λ-CALCULUS

Types are expressions that are intended to denote sets: When a program or function or operator f changes members of a set denoted by σ to members of a set denoted by τ, we may say that f has the *type*$(\sigma \to \tau)$. Types were introduced into λ-calculus by Church in Ref. 4; he assigned to every variable a unique type and constructed composite typed terms by two rules, which may be written in modern notation as follows:

$$\left\{\begin{array}{l}\text{(i) from typed terms} M^{(\sigma\to\tau)} \text{ and} N^{\sigma}\text{, construct } (M^{(\sigma\to\tau)}N^{\sigma})^{\tau}\\ \text{(ii) from a variable} x^{\sigma} \text{ and term} M^{\tau}\text{, construct } (\lambda x^{\sigma}\cdot M^{\tau})^{\sigma\to\tau}\end{array}\right\} \qquad (1)$$

Systems of λ-calculus in which types are part of a term's construction in this way are called *Church-style* systems. In such a system, for example, the expression $(\lambda x \cdot x)$ is not a term; but, for every type τ, there is a variable v^τ from which we can build a term

$$(\lambda v^\tau \cdot v^\tau)^{\tau\to\tau}$$

Roughly speaking, for every definable set a Church-style system has an identity-operator on that set, but it does not have a "universal" identity operator.

In contrast, in a *Curry-style* system, the λ-terms are constructed without types, and types are assigned to terms by formal rules (as in Definition 13 below). For example, in such a system, $(\lambda x \cdot x)$ is a term and it receives an infinite number of types:

$$a\to a,\ b\to b,\ (a\to b)\to(a\to b) \quad \text{etc.} \qquad (2)$$

Also in the Curry style, types may contain parameter-symbols called *type-variables;* if a is a type-variable, then all the types in Equation (2) can be obtained from the single type $a\to a$ by substitution; $a\to a$ is called a *principal type* of $(\lambda x \cdot x)$.

Many different type-systems are based on many varieties of λ-calculus, and some of these are intermediate between these two styles.

To show one type-system in more detail, we shall here describe a simple Curry-style system, which is designed for use with functions of natural numbers {0, 1, 2, 3, ...}. It is a variant of system $\mathrm{TA}_\lambda^\to$ in Ref. 2, Ch. 12 and of system λ → -*Curry* in Ref. 5, §3.

Definition 12 (Simple types). (cf. Ref. 2, Def. 11.1.) Let **N** be a symbol to denote the set of all natural numbers; we shall call **N** a *type-constant*. Let $a, b, c, \ldots$ be a sequence of other symbols; we shall call them *type-variables*. Then, *types* are expressions constructed from type-constants and type-variables by this rule:

$$\text{from any types } \sigma, \tau, \text{ construct } (\sigma\to\tau) \qquad (3)$$

Examples. The following are types:

$$a,\quad \mathbf{N},\quad (a\to b),\quad (a\to\mathbf{N}),\quad ((\mathbf{N}\to a)\to(b\to\mathbf{N}))$$

Notation. Greek letters ρ, σ, τ, will denote arbitrary types. Parentheses may be omitted from types in such a way that, for example,

$$\rho\to\sigma\to\tau \equiv (\rho\to(\sigma\to\tau))$$

Definition 13 (System $\mathbf{TA}_\lambda^\to$). (cf. Ref. 2, Def. 12.6.) A *type-assignment formula* or *TA-formula* is any expression M: τ, where M is a λ-term (as in Definition 1), and τ is a type.

$\mathrm{TA}_\lambda^\to$ has the following three rules. Roughly speaking, each rule means that from the expressions above the line, one may deduce the expression below. Deductions are built as trees, with one formula at the bottom and assumptions at the tops of branches. (See Ref. 2, §§12.1–12.6 for details; $\mathrm{TA}_\lambda^\to$ is very like Gentzen's "Natural Deduction" systems in logic, cf. Ref. 6.)

$$(\to e),\ \text{the} \to\text{-elimination rule}: \quad \frac{M:\sigma\to\tau \quad N:\sigma}{(MN):\tau,}$$

$$(\to i),\ \text{the} \to\text{-introduction rule}: \quad \frac{\begin{array}{c}[x:\sigma]\\ \vdots\\ M:\tau\end{array}}{(\lambda x\cdot M):(\sigma\to\tau),}$$

$$(\equiv_\alpha),\ \text{rule of bound variables}: \quad \frac{M:\tau \quad M\equiv_\alpha N}{N:\tau.}$$

Explanation. Rule (→ i) means that if we already have made a deduction of M: τ from x: σ and perhaps a set Γ of other assumptions not containing x, then we can deduce, from Γ alone, the statement $(\lambda x \cdot M) : (\sigma\to\tau)$. Also, after we use rule (→ i), we enclose the assumption $x:\sigma$ in brackets wherever it occurs in the deduction-tree above M: τ, to show that it is now no longer regarded as an assumption. It is now called a *cancelled* or *discharged* assumption (Cf. Ref. 2, §12.1.). So a deduction grows in two ways, by adding new conclusions at the bottom, and by adding brackets to assumptions. A deduction with all assumptions discharged is called a *proof*.

Example. Let $\mathbf{S}\equiv \lambda xyz\cdot xz(yz)$ and let ρ, σ, τ be any types. Fig. 2 shows a proof of

$$\mathbf{S}:(\rho\to(\sigma\to\tau))\to((\rho\to\sigma)\to(\rho\to\tau))$$

Note that each assumption is undischarged at the start of the deduction and then becomes discharged later.

$$\dfrac{\dfrac{\dfrac{\dfrac{\dfrac{[x : \rho\to(\sigma\to\tau)]\ [z:\rho]}{xz:\sigma\to\tau}\,(\to\mathrm{e}) \quad \dfrac{[y:\rho\to\sigma]\ [z:\rho]}{yz:\sigma}\,(\to\mathrm{e})}{xz(yz):\tau}\,(\to\mathrm{e})}{\lambda z\cdot xz(yz):\rho\to\tau}\,(\to\mathrm{i})\ \text{(discharge both occurrences of “}z:\rho\text{”)}}{\lambda yz\cdot xz(yz):(\rho\to\sigma)\to(\rho\to\tau)}\,(\to\mathrm{i})\ (\text{dis. “}y:\rho\to\sigma\text{”})}{\lambda xyz\cdot xz(yz):(\rho\to(\sigma\to\tau))\to((\rho\to\sigma)\to(\rho\to\tau))}\,(\to\mathrm{i})(\text{dis. “}x:\rho\to(\sigma\to\tau)\text{”})$$

Figure 2.

Definition 14. If $x_1,\ldots,x_n$ are distinct variables and there is a deduction of M: τ with all assumptions discharged except those in the set $\{x_1\colon \rho_1, \ldots, x_n\colon \rho_n\}$, then we say the formula M: τ has been *deduced from* $\{x_1\colon \rho_1, \ldots, x_n\colon \rho_n\}$, or

$$x_1 : \rho_1, \ldots, x_n : \rho_n \vdash M : \tau$$

In the special case that $n = 0$ (i.e. that there exists a proof of M: τ), we say

$$\vdash M : \tau$$

For additional reading on λ-calculus with types we recommend Ref. 5 for a survey and comparison of several systems, Ref. 2 Chs. 10–13 for introductions to some of these, or Ref. 7 for a comprehensive and computer-oriented textbook.

λ-CALCULUS IN COMPUTER SCIENCE

The λ-calculus can be considered the smallest commonly used universal programming language. Quoting Peter Landin [8]: “Whatever the next 700 programming languages turn out to be, they will surely be variants and extensions of λ-calculus.”

In this section, we will survey more interesting developments of computer science in which the λ-calculus has played a crucial role. Our main source for the historical information will be Cardone and Hindley [9].

Computability Theory

As we mentioned in Note 11, one can represent numbers and computable functions on numbers by λ-terms. We gave λ-terms to represent two standard mathematical functions, but we did not show how to λ-define the predecessor function, which is much more tricky. Indeed, when Kleene, who was a student of Church, showed to his teacher a λ-definition he had constructed for the predecessor function, Church conjectured that all intuitively computable functions must be λ-definable (Ref.10, P.186). This intuition of Church led to what came to be known as “Church’s Thesis”:

> λ-*definability exactly captures the informal notion of effective computability*.

In fact, Kleene analyzed the notion of λ-definability and showed that every recursive function can be coded (by means of “normal forms”) into the λ-calculus [11, 12]. Church related the notion of effective computability to that of recursive function and hence, to λ-definability. He proved at the same time that the question of the equivalence of two λ-terms (not in normal-form) is undecidable [1]. Immediately after the work of Church but independently of it, Turing introduced his machine approach to computation and proved the undecidability of the halting problem [13]. Then, learning of Church’s work, he proved the equivalence between his notion of computability and that of λ-definable function [14].

Functional Programming

At the end of the 1950s, John McCarthy at Stanford University proposed the first functional language, *LISP* (LISt Processing) [15]. He wrote: “To use functions as arguments, one needs a notation for functions, and it seemed natural to use the λ-notation of Church.” *LISP* allows the reduction of a β-redex (see Definition 6)

$$(\lambda x \cdot M)N$$

only if N is a *value* (i.e., either a λ-abstraction or a constant). Usually such a β-redex is called a β_υ-redex [16]. Moreover, *LISP* does not allow reduction under a λ-abstraction (as we did in Example (b) after Definition 6); and substitution in *LISP* captures free variables, that is, clauses (f)-(g) of Definition 4 are replaced by:

$$(\mathrm{f}') \quad [N/x](\lambda y \cdot P) \equiv \lambda y \cdot [N/x]P$$

where any occurrences of y that may be free in N (l.h.s.) are captured by the λ-abstraction in the r.h.s. This difference is usually expressed by saying that the λ-calculus uses *static binding*, whereas *LISP* uses *dynamic binding*. New *LISP* dialects (*Common LISP* [17], *SCHEME* [18], etc.) use static binding. *LISP* today is a family of computer programming languages used in artificial intelligence, Web development, finance, computer science education, and a variety of other applications.

Although *LISP* is an untyped language, *ML* (Meta-Language) is a functional programming language based on type assignment for λ-calculus (cf. Definition 14): The programmer can write untyped programs, but the compiler will either infer types or return an error message [19, 20]. Several languages are in the *ML* family today: *SML* (Standard ML) [21], and *CAML* (Categorical Abstract Machine Language) [22]. *ML’s* applications include language design and manipulation (compilers, analyzers, theorem provers), bioinformatics, financial systems, a genealogical database, and a peer-to-peer client/server program.

Evaluation Strategies

Examples (a) and (b) after Definition 6 showed that the same λ-term can be reduced in two different ways by choosing different β-redexes to contract. The Church-Rosser Theorem for β-reduction (Theorem 8) shows that this choice does not influence the final result, if any. But it can influence the number of contractions and hence affect efficiency, because for example:

$$\begin{aligned}\underline{(\lambda x\cdot xx)((\lambda y\cdot y)(\lambda z\cdot z))} &\rightarrow_\beta \underline{(\lambda y\cdot y)(\lambda z\cdot z)}((\lambda y\cdot y)(\lambda z\cdot z))\\ &\rightarrow_\beta \underline{(\lambda z\cdot z)((\lambda y\cdot y)(\lambda z\cdot z))}\\ &\rightarrow_\beta \underline{(\lambda y\cdot y)(\lambda z\cdot z)}\\ &\rightarrow_\beta (\lambda z\cdot z)\end{aligned}$$

while

$$\begin{aligned}(\lambda x\cdot xx)\underline{((\lambda y\cdot y)(\lambda z\cdot z))} &\rightarrow_\beta \underline{(\lambda x\cdot xx)(\lambda z\cdot z)}\\ &\rightarrow_\beta \underline{(\lambda z\cdot z)(\lambda z\cdot z)}\\ &\rightarrow_\beta (\lambda z\cdot z)\end{aligned}$$

Furthermore, the choice of β-redexes can lead either to a terminating or to a diverging computation, as in:

$$\begin{aligned}\underline{(\lambda xy\cdot y)((\lambda z\cdot zz)(\lambda z\cdot zz))} &\rightarrow_\beta (\lambda y\cdot y)\\ (\lambda xy\cdot y)\underline{((\lambda z\cdot zz)(\lambda z\cdot zz))} &\rightarrow_\beta (\lambda xy\cdot y)\underline{((\lambda z\cdot zz)(\lambda z\cdot zz))}\\ &\rightarrow_\beta (\lambda xy\cdot y)\underline{((\lambda z\cdot zz)(\lambda z\cdot zz))}\\ &\rightarrow_\beta \cdots\end{aligned}$$

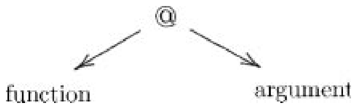
In the first reductions of both the above examples, we chose always to contract the left-most outer-most β-redex, whereas in the second reductions we chose always the left-most outer-most β_υ-redex.

An *evaluation strategy* is a systematic way of indicating which β-redex or β_υ-redex to contract in an arbitrary λ-term. The two strategies shown above are called, respectively, *call-by-name* and *call-by-value* [16]. They correspond respectively to call-by-name and call-by-value parameter passing in procedures of programming languages. For example, considering the procedure $square(x) = x \times x$, the evaluation of $square(2+1)$ when x is a call-by-name parameter gives $(2+1)\times(2+1)$, whereas when x is a call-by-value parameter, it gives $square(3)$.

An interesting strategy is that of *lazy evaluation*, which increases efficiency by waiting until the last possible moment to evaluate a term and by never reducing under an abstraction. This strategy allows one also to deal with infinite data structures. For example, one could construct a function that creates the infinite list of Fibonacci numbers. The calculation of the nth Fibonacci number would be merely the extraction of that element from the infinite list. The entire infinite list would never be calculated, only the values that influence a particular calculation. *MIRANDA* [23] and *HASKELL* [24] are examples of lazy functional programming languages.

The study of evaluation strategies for λ-calculus strongly influenced the implementation of functional programming languages.

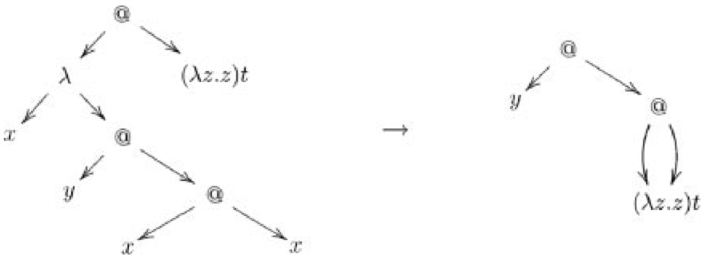
Various other techniques have been developed to get more efficient implementations; we just mention here *graph reduction* [25]. In graph reduction, a λ-term is represented as a directed graph without cycles:



and duplicated computation of shared subterms is avoided by duplicating arrows in the graph. For example, the contraction

$$(\lambda x\cdot y(xx))((\lambda z\cdot z)t) \rightarrow y(((\lambda z\cdot z)t)((\lambda z\cdot z)t))$$

is written as



The efficiency of graph reduction is enhanced when a functional program is translated to a fixed set of functions without free variables (*combinators*) [26] or when a functional program is translated to a set of functions without free variables and the members of the set are selected to be optimal for that program (*super combinators*) [27].

Thanks to these techniques and to the computational power of modern computers, functional languages have achieved a degree of practicality that was previously the prerogative of imperative languages.

Semantics

ALGOL 60 (ALGOrithmic Language) [28] was an imperative language designed in 1960 by the Working Group 2.1 of IFIP (International Federation for Information Processing). Peter Landin translated the core of *ALGOL 60* into λ-calculus extended with assignment [29]. This translation was the first formal semantics of a real programming language.

Two key problems of programming language semantics are:

- the semantics of looping constructs (**while, until**, . . . statements), and of recursive procedures, requires the solution of recursion equations. For example Euclid's algorithm is a recursive procedure: $gcd(n,m) = \textbf{if}\ m = 0\ \textbf{then}\ n\ \textbf{else}\ gcd(m, n\ \textbf{modulo}\ m)$
- (higher order) procedures can receive other procedures as arguments, so the meaning of a procedure must be both a function and an argument.

These problems arise also in giving the semantics of λ-calculus, because:

- recursion equations can be solved using the fixed-point combinator (see Note 9 and [Ref. 2, Corollary 3.3.1]);
- each λ-term can appear either in function or in argument position, so its meaning must be both a function and an argument.

Dana Scott gave the first actual model of λ-calculus in 1969. He solved the domain equation

$$\mathcal{D} = [\mathcal{D} \rightarrow \mathcal{D}]$$

in the category of complete lattices and continuous functions [30], and his model became the basis of the denotational semantics of programming languages [31].

Introductions to models of λ-calculus in general and Scott's model in particular can be found in Ref. 3, Chs. 5 and 18–20, and Ref. 2, Chs. 14–16 .

More recently, the λ-calculus provided models of biological phenomena [32]. Moreover the λ-calculus of objects (i.e., a λ-calculus enriched with suitable operators) was used to give the semantics of, and to study the types of, object-oriented languages [33]. Last, we mention that a linear and reversible λ-calculus with constants can represent atomic quantum logic gates [34].

Proofs and Programs

It is easy to check that by erasing λ-terms from the rules of the system $\mathrm{TA}_{\lambda}^{\rightarrow}$ of Definition 13 and omitting type-constants, we get the intuitionistic logic of implication. This observation is at the basis of the *Curry-Howard isomorphism* [35, 36], which involves the following correspondences:

types	⇔	logical formulas
closed terms	⇔	proofs
β-reduction	⇔	cut elimination

Certified Programming is centered on the Curry-Howard isomorphism. The key idea in fact is that the development of a program to satisfy a specification is the same as finding a proof of a logical formula. In this way, the program obtained comes with its correctness proof. The typed λ-calculus is used as a programming language, a specification language and a programming logic. For example, a constructive proof of the sentence "for all pairs of integers n_1, n_2 there is an integer m such that $m = n_1 + n_2$" is a program that computes the sum of two integers. (Usually, the programs obtained in this way are fairly large and, for efficiency, methods of deleting noncomputational parts are currently being studied.)

In the late 1960s, N. G. de Bruijn started the *AUTOMATH* (AUTOmated MATHematics) project [37], which was based on a λ-calculus with *dependent types* (types which can contain terms). He designed a language for expressing complex mathematical theories in such a way that a computer can verify a proof's correctness. The full textbook "Grundlagen der Analysis" of E. Landau has been translated into this language and verified by computer (Part D of Ref. 38).

In *Martin-Löf's Constructive Type Theory* [39–41] the following identifications can be made:

- a is an element of the set τ
- a is a proof of the proposition τ
- a is an object with the type τ
- a is a program with the specification τ
- a is a solution to the problem τ.

Martin-Löf developed his type theory (based on a λ-calculus with dependent types) between 1970 and 1980 as a foundational language for mathematics. He designed a functional programming language that includes its own logic.

The PRL (Proof/Program Refined Logic) Project [42] focuses on implementing computational mathematics and on providing logic-based tools that help to automate programming. A proof of a logical formula is compiled into an executable and certified code (essentially a λ-term). *Nuprl* (pronounced "new pearl") [43] is a family of proof development systems for the incremental verification of software systems' properties. Martin-Löf's type theory strongly influenced the development of Nuprl.

Coc (Calculus of Constructions) [44] combines dependent types with universal quantification on type variables. It is a higher-order typed λ-calculus in which types are first-class values: it allows one to define functions from, say, integers to types and types to types, as well as functions from integers to integers. Coc is the basis of *Coq* [45], which is a proof assistant that

- handles mathematical assertions,
- mechanically checks proofs of these assertions,
- helps to find formal constructive proofs,
- extracts a certified program from the constructive proof of its formal specification.

Coq is written in the *OCAML* (Objective Caml) [46] system, which is the main implementation of the *CAML* language.

MIDDLEWARE FOR DISTRIBUTED SYSTEMS

MIDDLEWARE IS PART OF A BROAD SET OF INFORMATION TECHNOLOGY TRENDS

Middleware represents the confluence of two key areas of information technology (IT): distributed systems and advanced software engineering. Techniques for developing distributed systems focus on integrating many computing devices to act as a coordinated computational resource. Likewise, software engineering techniques for developing component-based systems focus on reducing software complexity by capturing successful patterns of interactions and creating reusable frameworks for integrating these components. Middleware is the area of specialization dealing with providing environments for developing systems that can be distributed effectively over a myriad of topologies, computing devices, and communication networks. It aims to provide developers of networked applications with the necessary platforms and tools to (1) formalize and coordinate how parts of applications are composed and how they interoperate and (2) monitor, enable, and validate the (re)configuration of resources to ensure appropriate application end-to-end quality of service (QoS), even in the face of failures or attacks.

During the past few decades, we have benefited from the commoditization of hardware (such as CPUs and storage devices), operating systems (such as UNIX and Windows), and networking elements (such as IP routers). More recently, the maturation of software engineering focused programming languages (such as Java and C++), operating environments (such as POSIX and Java Virtual Machines), and enabling fundamental middleware based on previous middleware R&D (such as CORBA, Enterprise Java Beans, and SOAP/Web services) are helping to commoditize many common-off-the-shelf (COTS) software components and architectural layers. The quality of COTS software has generally lagged behind hardware, and more facets of middleware are being conceived as the complexity of application requirements increases, which has yielded variations in maturity and capability across the layers needed to build working systems. Nonetheless, improvements in software frameworks (1), patterns (2,3), component models (4), and development processes (5) have encapsulated the knowledge that enables COTS software to be developed, combined, and used in an increasing number of real-world applications, such as e-commerce websites, avionics mission computing, command and control systems, financial services, and integrated distributed sensing, to name but a few.

Some notable successes in middleware for distributed systems include:

- Distributed Object Computing (DOC) middleware (6–10) (such as CORBA, Java RMI, SOAP), which provides a support base for objects that can be dispersed throughout a network, with clients invoking operations on remote target objects to achieve application goals. Much of the network-oriented code is tool generated using a form of interface definition language and compiler.
- Component middleware (11) (such as Enterprise Java Beans, the CORBA Component Model, and .NET), which is a successor to DOC approaches, focused on composing relatively autonomous, mixed functionality software elements that can be distributed or collocated throughout a wide range of networks and interconnects, while extending the focus and tool support toward lifecycle activities such as assembling, configuring, and deploying distributed applications.
- World Wide Web middleware standards (such as web servers, HTTP protocols, and web services frameworks), which enable easily connecting web browsers with web pages that can be designed as portals to powerful information systems.
- Grid computing (12) (such as Globus), which enables scientists and high-performance computing researchers to collaborate on grand challenge problems, such as global climate change modeling.

Within these middleware frameworks, a wide variety of services are made available off-the-shelf to simplify application development. Aggregations of simple, middleware-mediated interactions form the basis of large-scale distributed systems.

MIDDLEWARE ADDRESSES KEY CHALLENGES OF DEVELOPING DISTRIBUTED SYSTEMS

Middleware is an important class of technology that is helping to decrease the cycle time, level of effort, and complexity associated with developing high-quality, flexible, and interoperable distributed systems. Increasingly, these types of systems are developed using reusable software (middleware) component services, rather than being implemented entirely from scratch for each use. When implemented properly, middleware can help to:

- Shield developers of distributed systems from low-level, tedious, and error-prone platform details, such as socket-level network programming.
- Amortize software lifecycle costs by leveraging previous development expertise and capturing implementations of key patterns in reusable frameworks, rather than rebuilding them manually for each use.
- Provide a consistent set of higher-level network-oriented abstractions that are much closer to application and system requirements to simplify the development of distributed systems.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

- Provide a wide array of developer-oriented services, such as logging and security that have proven necessary to operate effectively in a networked environment.

Middleware was invented in an attempt to help simplify the software development of distributed computing systems, and bring those capabilities within the reach of many more developers than the few experts at the time who could master the complexities of these environments (7). Complex system integration requirements were not being met from either the *application perspective*, in which it was too hard and not reusable, or the *network or host operating system perspectives*, which were necessarily concerned with providing the communication and endsystem resource management layers, respectively.

Over the past decade, middleware has emerged as a set of software service layers that help to solve the problems specifically associated with heterogeneity and interoperability. It has also contributed considerably to better environments for building distributed systems and managing their decentralized resources securely and dependably. Consequently, one of the major trends driving industry involves moving toward a multi-layered architecture (applications, middleware, network, and operating system infrastructure) that is oriented around application composition from reusable components and away from the more traditional architecture, where applications were developed directly atop the network and operating system abstractions. This middleware-centric, multi-layered architecture descends directly from the adoption of a network-centric viewpoint brought about by the emergence of the Internet and the componentization and commoditization of hardware and software.

Successes with early, primitive middleware, such as message passing and remote procedure calls, led to more ambitious efforts and expansion of the scope of these middleware-oriented activities, so we now see a number of distinct layers taking shape within the middleware itself, as discussed in the following section.

MIDDLEWARE HAS A LAYERED STRUCTURE, JUST LIKE NETWORKING PROTOCOLS

Just as networking protocol stacks are decomposed into multiple layers, such as the physical, data-link, network, and transport, so too are middleware abstractions being decomposed into multiple layers, such as those shown in Fig. 1.

Below, we describe each of these middleware layers and outline some of the technologies in each layer that have matured and found widespread use in COTS platforms and products in recent years.

Host Infrastructure Middleware

Host infrastructure middleware leverages common patterns (3) and best practices to encapsulate and enhance native OS communication and concurrency mechanisms to create reusable network programming components, such as reactors, acceptor-connectors, monitor objects, active objects, and component configurators (13,14). These components abstract away the peculiarities of individual operating systems, and help eliminate many tedious, error-prone, and nonportable aspects of developing and maintaining networked applications via low-level OS programming APIs, such as Sockets or POSIX pthreads. Widely used examples of host infrastructure middleware include:

- The Sun Java Virtual Machine (JVM) (15), which provides a platform-independent way of executing code by abstracting the differences between operating systems and CPU architectures. A JVM is responsible for interpreting Java bytecode and for translating the bytecode into an action or operating system call. It is the JVM's responsibility to encapsulate platform details within the portable bytecode interface, so that applications are shielded from disparate operating systems and CPU architectures on which Java software runs.

Figure 1. Layers of middleware and surrounding context.

- .NET (16) is Microsoft's platform for XML Web services, which are designed to connect information, devices, and people in a common, yet customizable way. The common language runtime (CLR) is the host infrastructure middleware foundation for Microsoft's .NET services. The CLR is similar to Sun's JVM (i.e., it provides an execution environment that manages running code and simplifies software development via automatic memory management mechanisms, cross-language integration, interoperability with existing code and systems, simplified deployment, and a security system).
- The Adaptive Communication Environment (ACE) (13,14) is a highly portable toolkit written in C++ that encapsulates native OS network programming capabilities, such as connection establishment, event demultiplexing, interprocess communication, (de)marshaling, concurrency, and synchronization. The primary difference between ACE, JVMs, and the .NET CLR is that ACE is always a compiled interface rather than an interpreted bytecode interface, which removes another level of indirection and helps to optimize runtime performance.

Distribution Middleware

Distribution middleware defines higher-level distributed programming models whose reusable APIs and components automate and extend the native OS network programming capabilities encapsulated by host infrastructure middleware. Distribution middleware enables clients to program distributed systems much like stand-alone applications (i.e., by invoking operations on target objects without hard-coding dependencies on their location, programming language, OS platform, communication protocols and interconnects, and hardware). At the heart of distribution middleware are request brokers, such as:

- The OMG's Common Object Request Broker Architecture (CORBA) (6) and the CORBA Component Model (CCM) (17), which are open standards for distribution middleware that allows objects and components, respectively, to interoperate across networks regardless of the language in which they were written or the platform on which they are deployed. The OMG Real-time CORBA (RT-CORBA) specification (18) extends CORBA with features that allow real-time applications to reserve and manage CPU, memory, and networking resources.
- Sun's Java Remote Method Invocation (RMI) (10), which is distribution middleware that enables developers to create distributed Java-to-Java applications, in which the methods of remote Java objects can be invoked from other JVMs, possibly on different hosts. RMI supports more sophisticated object interactions by using object serialization to marshal and unmarshal parameters as well as whole objects. This flexibility is made possible by Java's virtual machine architecture and is greatly simplified by using a single language.
- Microsoft's Distributed Component Object Model (DCOM) (19), which is distribution middleware that enables software components to communicate over a network via remote component instantiation and method invocations. Unlike CORBA and Java RMI, which run on many OSs, DCOM is implemented primarily on Windows.
- SOAP (20), which is an emerging distribution middleware technology based on a lightweight and simple XML-based protocol that allows applications to exchange structured and typed information on the Web. SOAP is designed to enable automated Web services based on a shared and open Web infrastructure. SOAP applications can be written in a wide range of programming languages, used in combination with a variety of Internet protocols and formats (such as HTTP, SMTP, and MIME), and can support a wide range of applications from messaging systems to RPC.

Common Middleware Services

Common middleware services augment distribution middleware by defining higher-level domain-independent services that allow application developers to concentrate on programming business logic, without the need to write the "plumbing" code required to develop distributed systems by using lower-level middleware directly. For example, application developers no longer need to write code that handles naming, transactional behavior, security, database connection, because common middleware service providers bundle these tasks into reusable components. Whereas distribution middleware focuses largely on connecting the parts in support of an object-oriented distributed programming model, common middleware services focus on allocating, scheduling, coordinating, and managing various resources end-to-end throughout a distributed system using a component programming and scripting model. Developers can reuse these component services to manage global resources and perform common distribution tasks that would otherwise be implemented in an ad hoc manner within each application. The form and content of these services will continue to evolve as the requirements on the applications being constructed expand. Examples of common middleware services include:

- The OMG's CORBA Common Object Services (CORBAservices) (21), which provide domain-independent interfaces and capabilities that can be used by many distributed systems. The OMG CORBAservices specifications define a wide variety of these services, including event notification, logging, multimedia streaming, persistence, security, global time, real-time scheduling, fault tolerance, concurrency control, and transactions.
- Sun's Enterprise Java Beans (EJB) technology (22), which allows developers to create n-tier distributed systems by linking a number of pre-built software services—called "beans"—without having to write much code from scratch. As EJB is built on top of Java technology, EJB service components can only be implemented using the Java language. The CCM

(17) defines a superset of EJB capabilities that can be implemented using all the programming languages supported by CORBA.

- Microsoft's .NET Web services (16), which complements the lower-level middleware .NET capabilities and allows developers to package application logic into components that are accessed using standard higher-level Internet protocols above the transport layer, such as HTTP. The .NET Web services combine aspects of component-based development and Web technologies. Like components, .NET Web services provide black-box functionality that can be described and reused without concern for how a service is implemented. Unlike traditional component technologies, however, .NET Web services are not accessed using the object model-specific protocols defined by DCOM, Java RMI, or CORBA. Instead, XML Web services are accessed using Web protocols and data formats, such as HTTP and XML, respectively.

Domain-Specific Middleware Services

Domain-specific middleware services are tailored to the requirements of particular domains, such as telecom, e-commerce, health care, process automation, or aerospace. Unlike the other three middleware layers, which provide broadly reusable "horizontal" mechanisms and services, domain-specific middleware services are targeted at vertical markets. From a COTS perspective, domain-specific services are the least mature of the middleware layers today. This immaturity is due partly to the historical lack of distribution middleware and common middleware service *standards*, which are needed to provide a stable base upon which to create domain-specific services. As they embody knowledge of a domain, however, domain-specific middleware services have the most potential to increase system quality and decrease the cycle time and effort required to develop particular types of networked applications. Examples of domain-specific middleware services include the following:

- The OMG has convened a number of Domain Task Forces that concentrate on standardizing domain-specific middleware services. These task forces vary from the *Electronic Commerce Domain Task Force*, whose charter is to define and promote the specification of OMG distributed object technologies for the development and use of electronic commerce and electronic market systems, to the *Life Science Research Domain Task Force,* who do similar work in the area of life science, maturing the OMG specifications to improve the quality and utility of software and information systems used in life sciences research. There are also OMG Domain Task Forces for the health-care, telecom, command and control, and process automation domains.
- The Siemens Medical Solutions Group has developed *syngo*. (See http://www.syngo.com), which is both an integrated collection of domain-specific middleware services as well as an open and dynamically extensible application server platform for medical imaging tasks and applications, including ultrasound, mammography, radiography, magnetic resonance, patient monitoring systems, and life support systems. The *syngo* middleware services allow health-care facilities to integrate diagnostic imaging and other radiological, cardiological, and hospital services via a black-box application template framework based on advanced patterns for communication, concurrency, and configuration for business and presentation logic supporting a common look and feel throughout the medical domain.

OVERARCHING BENEFITS OF MIDDLEWARE

The various layers of middleware described in the previous section provide essential capabilities for developing and deploying distributed systems. This section summarizes the benefits of middleware over traditional non-middleware approaches.

Growing Focus on Integration Rather than on Programming

This visible shift in focus is perhaps the major accomplishment of currently deployed middleware. Middleware originated because the problems relating to integration and construction by composing parts were not being met by *applications*, which at best were customized for a single use; *networks*, which were necessarily concerned with providing the communication layer; or *host operating systems*, which were focused primarily on a single, self-contained unit of resources. In contrast, middleware has a fundamental integration focus, which stems from incorporating the perspectives of both OSs and programming model concepts into organizing and controlling the composition of separately developed components across host boundaries. Every middleware technology has within it some type of request broker functionality that initiates and manages intercomponent interactions.

Distribution middleware, such as CORBA, Java RMI, or SOAP, makes it easy and straightforward to connect separate pieces of software together, largely independent of their location, connectivity mechanism, and the technology used to develop them. These capabilities allow middleware to amortize software lifecycle efforts by leveraging previous development expertise and reifying implementations of key patterns into more encompassing reusable frameworks and components. As middleware continues to mature and incorporate additional needed services, next-generation applications will increasingly be assembled by modeling, integrating, and scripting domain-specific and common service components, rather than by being programmed from scratch or requiring significant customization or augmentation to off-the-shelf component implementations.

Focus on End-to-End Support and Integration, Not Just Individual Components

There is now widespread recognition that effective development of large-scale distributed systems requires the use of COTS infrastructure and service components. Moreover, the usability of the resulting products depends heavily on the weaving of the properties of the whole as derived from its parts. In its most useful forms, middleware provides the end-to-end perspective extending across elements applicable to the network substrate, the platform OSs and system services, the programming system in which they are developed, the applications themselves, and the middleware that integrates all these elements together.

The Increased Viability of Open Systems Architectures and Open-Source Availability

By their very nature, distributed systems developed by composing separate components are more open than systems conceived and developed as monolithic entities. The focus on interfaces for integrating and controlling the component parts leads naturally to *standard* interfaces, which, in turn, yields the potential for multiple choices for component implementations and open engineering concepts. Standards organizations, such as the OMG, The Open Group, Grid Forum, and the W3C, have fostered the cooperative efforts needed to bring together groups of users and vendors to define domain-specific functionality that overlays open integrating architectures, forming a basis for industry-wide use of some software components. Once a common, open structure exists, it becomes feasible for a wide variety of participants to contribute to the off-the-shelf availability of additional parts needed to construct complete systems. As few companies today can afford significant investments in internally funded R&D, it is increasingly important for the IT industry to leverage externally funded R&D sources, such as government investment. In this context, standards-based middleware serves as a common platform to help concentrate the results of R&D efforts and ensure smooth transition conduits from research groups into production systems.

For example, research conducted under the DARPA Quorum, PCES, and ARMS programs focused heavily on CORBA open systems middleware. These programs yielded many results that transitioned into standardized service definitions and implementations for CORBA's real-time (9,18), fault-tolerant (23,24), and components (17) specifications and productization efforts. In this case, focused government R&D efforts leveraged their results by exporting them into, and combining them with, other on going public and private activities that also used a standards-based open middleware substrate. Before the viability of common middleware platforms, these same results would have been buried within a custom or proprietary system, serving only as the existence proof, not as the basis for incorporating into a larger whole.

Advanced Common Infrastructure Sustaining Continuous Innovation

Middleware supporting component integration and reuse is a key technology to help amortize software lifecycle costs by leveraging previous development expertise (e.g., component middleware helps to abstract commonly reused low-level OS concurrency and networking details away into higher-level, more easily used artifacts). Likewise, middleware also focus efforts to improve software quality and performance by combining aspects of a larger solution together (e.g., component middleware combines fault tolerance for domain-specific elements with real-time QoS properties).

When developers need not worry as much about low-level details, they are freed to focus on more strategic, larger scope, application-centric specializations concerns. Ultimately, this higher-level focus will result in software-intensive distributed system components that apply reusable middleware to get smaller, faster, cheaper, and better at a predictable pace, just as computing and networking hardware do today, which, in turn, will enable the next generation of better and cheaper approaches to what are now carefully crafted custom solutions, which are often inflexible and proprietary. The result will be a new technological paradigm where developers can leverage *frequently used common components*, which come with steady innovation cycles resulting from a multi-user basis, in conjunction with *custom domain-specific components*, which allow appropriate mixing of multi-user low cost and custom development for competitive advantage.

KEY CHALLENGES AND OPPORTUNITIES FOR NEXT-GENERATION MIDDLEWARE

This section presents some of the challenges and opportunities for next-generation middleware. One such challenge is in supporting new trends toward distributed "systems of systems," which include many interdependent levels, such as network/bus interconnects, embedded local and geographically distant remote endsystems, and multiple layers of common and domain-specific middleware. The desirable properties of these systems of systems, both individually and as a whole, include predictability, controllability, and adaptability of operating characteristics with respect to such features as time, quantity of information, accuracy, confidence, and synchronization. All these issues become highly volatile in systems of systems, because of the dynamic interplay of the many interconnected parts. These parts are often constructed in a similar way from smaller parts.

Many COTS middleware platforms have traditionally expected static connectivity, reliable communication channels, and relatively high bandwidth. Significant challenges remain, however, to design, optimize, and apply middleware for more flexible network environments, such as self-organizing peer-to-peer (P2P) networks, mobile settings, and highly resource-constrained sensor networks. For example, hiding network topologies and other deployment details from networked applications becomes harder (and often undesirable) in wireless sensor networks because applications and middleware often need to adapt according to changes in location, connectivity, bandwidth, and battery power. Concerted R&D efforts are therefore essential to devise new middleware solutions and capabilities that can fulfill the requirements of these emerging network technologies and next-generation applications.

There are significant limitations today with regard to building the types of large-scale complex distributed systems outlined above that have increasingly more stringent requirements and more volatile environments. We are also discovering that more things need to be integrated over conditions that more closely resemble a dynamically changing Internet than they do a stable backplane. One problem is that the playing field is changing constantly, in terms of both resources and expectations. We no longer have the luxury of being able to design systems to perform highly specific functions and then expect them to have life cycles of 20 years with minimal change. In fact, we more routinely expect systems to behave differently under different conditions and complain when they just as routinely do not. These changes have raised a number of issues, such as end-to-end-oriented adaptive QoS, and construction of systems by composing off-the-shelf parts, many of which have promising solutions involving significant new middleware-based capabilities and services.

To address the many competing design forces and runtime QoS demands, a comprehensive methodology and environment is required to dependably compose large, complex, interoperable distributed systems from reusable components. Moreover, the components themselves must be sensitive to the environments in which they are packaged. Ultimately, what is desired is to take components that are built independently by different organizations at different times and assemble them to create a complete system. In the longer run, this complete system becomes a component embedded in still larger systems of systems. Given the complexity of this undertaking, various tools and techniques are needed to configure and reconfigure these systems so they can adapt to a wider variety of situations.

An essential part of what is needed to build the type of systems outlined above is the integration and extension of ideas that have been found traditionally in network management, data management, distributed operating systems, and object-oriented programming languages. But the goal for next-generation middleware is not simply to build a better network or better security in isolation, but rather to pull these capabilities together and deliver them to applications in ways that enable them to realize this model of adaptive behavior with tradeoffs between the various QoS attributes. The payoff will be reusable middleware that significantly simplifies the building of applications for systems of systems environments. The remainder of this section describes points of emphasis that are embedded within that challenge to achieve the desired payoff:

Reducing the Cost and Increasing the Interoperability of Using Heterogeneous Environments

Today, it is still the case that it costs quite a bit more in complexity and effort to operate in a truly heterogeneous environment, although nowhere near what it used to cost. Although it is now relatively easy to pull together distributed systems in heterogeneous environments, there remain substantial recurring downstream costs, particularly for complex and long-lived distributed systems of systems. Although homogeneous environments are simpler to develop and operate, they often do not reflect the long-run market reality, and they tend to leave open more avenues for catastrophic failure. We must, therefore, remove the remaining impediments associated with integrating and interoperating among systems composed from heterogeneous components. Much progress has been made in this area, although at the host infrastructure middleware level more needs to be done to shield developers and end users from the accidental complexities of heterogeneous platforms and environments. In addition, interoperability concerns have largely focused on data interoperability and invocation interoperability. Little work has focused on mechanisms for controlling the overall behavior of integrated systems, which is needed to provide "control interoperability." There are requirements for interoperable distributed control capabilities, perhaps initially as increased flexibility in externally controlling individual resources, after which approaches can be developed to aggregate these into acceptable global behavior.

Dynamic and Adaptive QoS Management

It is important to avoid "all or nothing" point solutions. Systems today often work well as long as they receive all the resources for which they were designed in a timely fashion, but fail completely under the slightest anomaly. There is little flexibility in their behavior (i.e., most of the adaptation is pushed to end users or administrators). Instead of hard failure or indefinite waiting, what is required is either *reconfiguration* to reacquire the needed resources automatically or *graceful degradation* if they are not available. Reconfiguration and operating under less than optimal conditions both have two points of focus: individual and aggregate behavior. To manage the increasingly stringent QoS demands of next-generation applications operating under changing conditions, middleware is becoming more adaptive and reflective. *Adaptive middleware* (25) is software whose functional and QoS-related properties can be modified either (1) *statically* (e.g., to reduce footprint, leverage capabilities that exist in specific platforms, enable functional subsetting, and minimize hardware/software infrastructure dependencies or (2) *dynamically* (e.g., to optimize system responses to changing environments or requirements, such as changing component interconnections, power levels, CPU/network bandwidth, latency/jitter, and dependability needs.

In mission-critical distributed systems, adaptive middleware must make such modifications dependably (i.e., while meeting stringent end-to-end QoS requirements). Reflective middleware (26) techniques make the internal organization of systems, as well as the mechanisms used in their construction, both visible and manipulable for middleware and application programs to inspect and modify at run time. Thus, reflective middleware supports more advanced adaptive behavior and more dynamic strategies keyed to current circumstances (i.e., necessary adaptations can be performed autonomously based on conditions within the system, in the system's environment, or in system QoS policies defined by end users.

Advanced System Engineering Tools

Advanced middleware by itself will not deliver the capabilities envisioned for next-generation distributed systems. We must also advance the state of the system engineering tools that come with these advanced environments used to build and evaluate large-scale mission-critical distributed systems. This area of research specifically addresses the immediate need for system engineering tools to augment advanced middleware solutions. A sample of such tools might include:

- *Design time tools*, to assist system developers in understanding their designs, in an effort to avoid costly changes after systems are already in place (which is partially obviated by the late binding for some QoS decisions referenced earlier).
- *Interactive tuning tools*, to overcome the challenges associated with the need for individual pieces of the system to work together in a seamless manner.
- *Composability tools*, to analyze resulting QoS from combining two or more individual components.
- *Modeling tools for developing system models* as adjunct means (both online and offline) to monitor and understand resource management, in order to reduce the costs associated with trial and error.
- *Debugging tools*, to address inevitable problems that develop at run time.

Reliability, Trust, Validation, and Assurance

The dynamically changing behaviors we envision for next-generation middleware-mediated systems of systems are quite different from what we currently build, use, and have gained some degrees of confidence in. Considerable effort must, therefore, be focused on validating the correct functioning of the adaptive behavior and on understanding the properties of large-scale systems that try to change their behavior according to their own assessment of current conditions before they can be deployed. But even before that, long-standing issues of adequate reliability and trust factored into our methodologies and designs using off-the-shelf components have not reached full maturity and common usage, and must therefore continue to improve. The current strategies organized around anticipation of long lifecycles with minimal change and exhaustive test case analysis are clearly inadequate for next-generation dynamic distributed systems of systems with stringent QoS requirements.

TAKING STOCK OF TECHNICAL PROGRESS ON MIDDLEWARE FOR DISTRIBUTED SYSTEMS

The increased maturation of, and reliance on, middleware for distributed systems stems from two fundamental trends that influence the way we conceive and construct new computing and information systems. The first is that IT of all forms is becoming highly commoditized (i.e., hardware and software artifacts are getting faster, cheaper, and better at a relatively predictable rate). The second is the growing acceptance of a network-centric paradigm, where distributed systems with a range of QoS needs are constructed by integrating separate components connected by various forms of reusable communication services. The nature of the interconnection ranges from the very small and tightly coupled, such as embedded avionics mission computing systems, to the very large and loosely coupled, such as global telecommunications systems.

The interplay of these two trends has yielded new software architectural concepts and services embodied by middleware. The success of middleware has added new layers of infrastructure software to the familiar OS, programming language, networking, and database offerings of the previous generation. These layers are interposed between applications and commonly available hardware and software infrastructure to make it feasible, easier, and more cost effective to develop and evolve systems via reusable software. The past decade has yielded significant progress in middleware, which has stemmed, in large part, from the following:

Years of Iteration, Refinement, and Successful Use. The use of middleware is not new (27,28). Middleware concepts emerged alongside experimentation with the early Internet (and even its predecessor the ARPAnet), and middleware systems have been continuously operational since the mid-1980s. Over that period of time, the ideas, designs, and (most importantly) the software that incarnates those ideas have had a chance to be tried and refined (for those that worked), and discarded or redirected (for those that did not). This iterative technology development process takes a good deal of time to get right and be accepted by user communities and a good deal of patience to stay the course. When this process is successful, it often results in *standards* that codify the boundaries, and *patterns and frameworks* that reify the knowledge of how to apply these technologies, as described in the following subsections.

The Maturation of Open Standards and Open Source. Over the past decade, middleware standards have been established and have matured considerably, particularly with respect to mission-critical distributed systems that possess stringent QoS requirements. For instance, the OMG has adopted the following specifications in recent years: (1) *Minimum CORBA* (29), which removes nonessential features from the full OMG CORBA specification to reduce footprint so that CORBA can be used in memory-constrained embedded systems; (2) *Real-time CORBA* (18), which includes features that enable applications to reserve and manage network, CPU, and memory resources more predictably end-to-end; (3) *CORBA Messaging* (30), which exports additional QoS policies, such as timeouts, request priorities, and queuing disciplines, to applications; and (4) *Fault-tolerant CORBA* (23), which uses entity redundancy of objects to support replication, fault detection, and failure recovery. Robust implementations of these CORBA capabilities and services are now available from multiple suppliers, many of whom have adopted open-source business models. Moreover, the scope of open systems is extending to an even wider range of applications with the advent of emerging standards, such as the Real-Time Specification for Java (31), and the Distributed Real-Time Specification for Java (32).

The Dissemination of Patterns and Frameworks. Also during the past decade, a substantial amount of R&D effort has focused on developing *patterns* and *frameworks* as a means to promote the transition and reuse of successful middleware technology. Patterns capture successful solutions to commonly occurring software problems that occur in a particular context (2,3). Patterns can simplify the design, construction, and performance tuning of middleware and applications by codifying the accumulated expertise of developers who have confronted similar problems before. Patterns also raise the level of discourse in describing software design and programming activities. Frameworks are concrete realizations of groups of related patterns (1). Well-designed frameworks reify patterns in terms of functionality provided by the middleware itself, as well as functionality provided by an application. A framework also integrates various approaches to problems where there are no a priori, context-independent, optimal solutions. Middleware frameworks (14) can include strategized selection and optimization patterns so that multiple independently developed capabilities can be integrated and configured automatically to meet the functional and QoS requirements of particular applications.

In the brief space of this article, we can only summarize and lend perspective to the many activities, past and present, that contribute to making middleware technology an area of exciting current development, along with considerable opportunity and unsolved challenging R&D problems. We have provided references to other sources to obtain additional information about ongoing activities in this area. We have also provided a more detailed discussion and organization for a collection of activities that we believe represent the most promising future directions for middleware. The ultimate goals of these activities are to:

1. Reliably and repeatably construct and compose distributed systems that can meet and adapt to more diverse, changing requirements/environments, and
2. Enable the affordable construction and composition of the large numbers of these systems that society will demand, each precisely tailored to specific domains.

To accomplish these goals, we must overcome not only the technical challenges, but also the educational and transitional challenges, and eventually master and simplify the immense complexity associated with these environments, as we integrate an ever-growing number of hardware and software components together via advanced middleware.

OPTIMIZING COMPILERS

INTRODUCTION AND MOTIVATION

Optimization is achieved by analyzing a given input program and applying a variety of code transformations to it. Which optimizing steps and code transformations may be applied depends on the semantics of the source programming language and the results of the analyses. Optimization is not performed on the source code but on a compiler-internal program representation; the form of the latter can significantly influence both the optimizations that can be applied as well as their effect. Some optimizations are essential on many systems, especially RISC architectures, without which programs would be very inefficient. There is no guarantee that an optimized program will execute faster, or that more extensive optimization will lead to an improvement in performance; however, improvement will typically occur, especially for large, complex programs with extensive datasets, in short, for just those programs in which manual analysis is difficult to carry out. Moreover, any manual analysis and modification of intermediate code carries with it the danger of accidentally changing the program's semantics. In contrast, the code transformations applied by an optimizing compiler are guaranteed to leave the semantics unchanged. Moreover, significant time savings can often be obtained by an optimizing compiler at very little cost, because the optimization phase of a compiler is typically executed only once and the program may be executed very many times. (Strictly speaking, the term "optimization" is, of course, a misnomer because it is almost guaranteed that the resulting object code is not optimal; however, for historical reasons, we will use the term "optimization" in its intended meaning of *program improvement*, with this caveat.)

There are many design choices facing the developers of an optimizing compiler. The ability of the system to improve a large variety of input programs may depend on the accuracy of the analysis performed. Yet the required analyses can be highly expensive and difficult to implement. Modern compilers typically perform optimizations in multiple phases, each with a distinct purpose. Typically, certain sequences of analyses and transformations are combined into an *optimization strategy* that is accessible via a compiler switch. Thus, the user may choose between several predefined collections of optimizations when the compiler is invoked.

Not all languages are created equal with regard to optimization. For example, the potential for aliasing of variables in a code can have a major impact on the outcome of optimization. As each program change requires us to reason about the state a program will be in at a given point during execution, if two variables may share the same memory location at some point, the analyses must consider how the desired transformation will affect each of them, which may severely limit the potential for optimizing a program, especially when translating programs written in languages that permit uncontrolled use of pointers (if these features are extensively exploited in the code).

BASIC OPTIMIZATIONS

A variety of well-known optimizations are useful for improving code written in many different programming languages and for execution on most modern architectures. As such, they are widely implemented. They include optimizations to eliminate statements that will never be executed (useless code); to replace certain operations by faster, equivalent ones (e.g., strength reduction); and to eliminate redundant computations, possibly by moving statements in the code to a new location that permits the results to be used in multiple locations subsequently. Examples of this last optimization include hoisting code from loops, so that it is executed just once, rather than during each loop iteration, and partial redundancy elimination, variants of which attempt to move statements so that an expression is computed once only in a given execution path. Another popular optimization called constant propagation attempts to determine all variable references that have a constant value no matter what execution path is taken, and to replace those references with that value, which, in turn, may enable the application of further optimizations.

These optimizations are generally known as *scalar optimizations*, because they are applied to scalar variables without regard to the internal structuring of a program's complex data objects, and thus consider the individual elements of arrays to be distinct objects. They may be applied to small program regions in the form of so-called peephole optimizations, but also to entire procedures or even beyond. In order to perform them on a given program, it is necessary to analyze and represent the structure of each procedure being translated in such a way that all of its possible execution paths are identified. The implementation must then efficiently identify all points in the code where a given optimization is applicable and perform the specified translation.

Data Flow Analysis

Collectively, the analysis required to perform this work is known as *data flow analysis* (DFA), which studies the flow of values of data objects throughout a program. The analysis that determines the structure of a program is known as control flow analysis (CFA). Intraprocedural CFA constructs a flowgraph (or program graph), a directed graph with a single entry node, whose nodes represent the procedure's basic blocks and whose edges represent transfers of control between basic blocks. Basic blocks are maximal length sequences of statements that can only be entered via the first and only be exited via the last statement; they partition a procedure. The single-exit property can be enforced on the flowgraph if it is needed. Loops, including

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

implicitly programmed loops, can be identified in the flowgraph and a variety of node orderings defined and computed that enable data flow problems to be efficiently applied to it. Although scalar optimizations can be performed easily within basic blocks, their application to an entire procedure gives them considerably greater power.

For example, consider the following fragment of pseudo code.

```
x := A[j] ;
z := 1;
if x < 4
   then z := x;
fi
c := z + x
```

Figure 1 shows a flowgraph representing the flow of control in these statements. Each node in the graph corresponds to one of its basic blocks. The edges represent the flow of control between them.

Many data flow optimizations are closely related to the so-called use-definition (UD) and definition-use (DU) chains. (In fact, below we introduce one way of representing a procedure internally that makes DU chains explicit in the code.) A UD chain links a use of a variable to the set of all definitions of that variable that may reach it (i.e., all possible sources of the value that will be used); a DU chain links a definition of a variable to all of its possible uses. For example, the value of x defined in the first statement of the above code is used three times subsequently (on lines 3, 4, and 6 of the text), so the DU chains will link the definition to each of these uses. UD analysis will link each of the uses to this definition. The interactions of a basic block with the remainder of a program may be modeled by identifying its *outward-exposed* variable definitions, those definitions that may have uses in other basic blocks, and its outward-exposed uses, those variable uses that are defined in other basic blocks and may be used by this block. For example, basic block B3 in Fig. 1(a) has an outward-exposed definition of variable c and outward-exposed uses of variables x and y. This information has many applications.

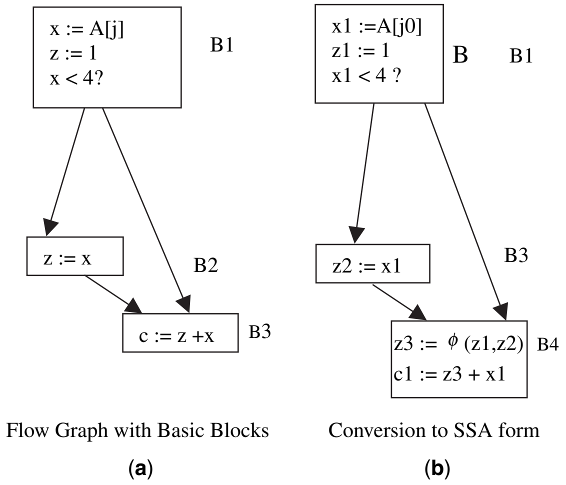

Figure 1. Representing control flow in a procedure.

Strategies for register allocation, for instance, may benefit from knowing which variables are live at the exit of a basic block. A variable is live if it may be used subsequently (i.e., if there is a path from the corresponding node in the flowgraph to a node with an outward-exposed use of that variable) and the path is definition-free for that variable. A variable that is not live should not be kept in a register. UD chains provide the required information. For example, x and z are live at the end of basic block B1 in Fig. 1(a), because they are subsequently used. The UD chains will link these uses of x and z to the definitions in B1.

Data Flow Problems

The task of determining all the points in the program where a specific optimization is applicable, or where a specific property holds, is known as a data flow problem. For example, the live variables problem may be solved by traversing a single-exit flowgraph, starting with its unique exit node, and propagating information on outward-exposed uses to nodes that precede them on paths from the start node. Any variable definition for which there is a subsequent outward-exposed use is live. The available expressions problem computes the expressions that are available on entry to a basic block. It requires a traversal of the flowgraph that begins with the start node and then visits subsequent nodes after all nodes that may precede them have been visited. The analysis gathers the expressions that are computed in a basic block and are outward-exposed (i.e., the variables used in the computation have not been redefined) and combines them with the expressions reaching this basic block that are preserved (i.e., the variables used in that computation have not been redefined). If there is an outward-exposed use of the same expression within the associated code, the resulting set of expressions will be available in the successor nodes of the callgraph. If there is an outward-exposed use of the same expression within the associated code, the computation is redundant and may be eliminated. For example, if we assume that Fig. 1(a) is part of a larger flowgraph, then the expression z+x will be available to a successor node of B3 if and only if neither of these variables have been redefined in the interim (*and* all paths to the node pass through B3). Any computation of z+x in such nodes is redundant and may be eliminated. There are a variety of approaches to detect and handle redundant computations in practice.

Data flow problems may be classified as *top-down* or *bottom-up* problems, depending on the order of information propagation. Live variables analysis is a bottom-up problem, and the available expressions computation is an example of a top-down problem. They may also be classified as *existence* problems or *all* problems. In the former case, the task is to find a path satisfying a given property; in the latter, the property must hold for all paths. For a variable to be live, we only need identify one path with an outward-exposed use that reaches the node in question; so it is an existence problem. In contrast, the available expressions problem is an all problem, because the expression is only available (and hence redundant) at a given point in the code if it is available no matter what execution path was taken to reach that point.

Techniques for Solving Data Flow Problems

The practical solution of data flow problems was enhanced by a strategy that exploits the fact that they can be modeled by monotone data flow systems (MDSs). A semilattice is used to represent data flow information and monotone functions model the way data flow information is modified when control passes through a basic block in the procedure. Virtually all data flow problems may be elegantly formulated in terms of MDSs; the associated solution mechanism is a simple iterative fixpoint algorithm whose implementation is efficient and very reasonable in its memory requirements for many data flow problems. In order to apply the iterative algorithm to a given data flow problem, this problem must be classified as either top down or bottom up; it must be formulated in terms of information to be computed at each node of the flowgraph, which is typically a set of variables, variable references, or statements. The effect a basic block has on the information computed for the nodes preceding it (or succeeding it, in the case of bottom-up problems) must be specified. Finally, it must be specified how information sets are merged when two paths meet in the flowgraph. Then the algorithm will begin at either the start (top-down) or exit (bottom-up) node of the flowgraph, compute the specified information, and propagate that information to the nodes succeeding or preceding it, respectively. This information will be updated and the resulting set propagated in the same direction. The presence of loops and, therefore, cycles in the flowgraph necessitates that this process be repeated on the current data until no more changes in information are observed. For example, the live variables problem begins by computing the set of variables in a basic block that have outward-exposed uses, which are passed to preceding nodes in the flowgraph, where all those that remain outward-exposed are augmented with those that have outward-exposed uses in that basic block and, in turn, are propagated. More powerful strategies using so-called interval analysis exist; they require considerably more implementation effort, but execute faster and make it easier to incrementally update data flow information. Both the iterative algorithm and the interval analysis expect a flowgraph to represent a procedure.

Typical Data Flow Optimizations

Among the many other optimizations that have been defined and are applied to basic blocks and procedures is copy propagation, which replaces a variable with one that is equivalent to it. Constant folding evaluates expressions at compile time when their operands are known to be constant, and is especially applied when they are integers. Common subexpression elimination and value numbering are two subtly different techniques that support the identification and removal of computations that are unnecessary because the values have already been determined. Partial redundancy elimination is a more powerful approach to handling this problem and is increasingly preferred over these alternatives. Bounds checking elimination is important for programming languages where it must be tested whether array references are within the defined range of index values. Loop-invariant code motion finds computations that produce the same result each time a loop is executed and moves them out of the loop. Some optimizations are performed multiple times, which is especially true with respect to dead code elimination, because during the course of applying transformations, the compiler may introduce code that is not needed and that can be subsequently removed. The compiler must also be able to simplify algebraic and logical expressions, both to reduce the work of computing them, but also to facilitate the implementation of those optimizations that require them to be compared or evaluated.

New Approaches to Data Flow Analysis

A relatively new approach to performing optimizations on a procedure requires the prior conversion of the program to a static single assignment (SSA) form. This representation makes the DU chains explicit by requiring that variables be defined once only. It is achieved by renaming variables and by introducing so-called join (ϕ) functions at any point in the code where two or more definitions may reach a single use. It is possible to optimize this representation to minimize the number of join functions required. In Fig. 1(b), we show the SSA form of the flowgraph given in standard form in Fig. 1(a). It uses a ϕ function in basic block B3 to indicate that the value of z may come from either B1 or B2.

The SSA representation makes several optimizations, including strength reduction, partial redundancy elimination, and constant propagation, easier to specify and more efficient to implement in comparison with the techniques described above; its use is growing. However, it is relatively hard to perform alias analysis on this representation. A compiler is likely to convert code to SSA form only temporarily during the overall optimization process.

INTERPROCEDURAL OPTIMIZATIONS

The strategies described above are typically applied to the individual procedures of a program. However, it is also possible to optimize code across procedure boundaries. The growing use of structured programming techniques has led to the increased modularization of programs, which may consist of a large number of relatively small procedures; thus, it has become important to consider how to improve code in a way that takes procedure and function invocations into account. Interprocedural analysis (IPA) is the name given to techniques that gather information about the calling relationships between different program units, and optimizations based on them are called interprocedural optimizations.

Interprocedural Analysis

Just as the flowgraph is the basis for optimizations within a procedure, so the callgraph is the foundation for interprocedural optimizations. This data structure is designed to represent the relationships between the procedures and functions of a program. The nodes of the callgraph represent the individual program units; there is a directed edge between nodes if and only if the procedure corresponding to the source invokes the procedure corresponding to the sink at least once. A traditional callgraph has only one edge between a pair of nodes per direction, no matter how often the sink procedure is called, and thus provides less information about the paths that are taken through a program than does a (procedure's) flowgraph; alternative multigraph representations of the calling sequences represent each invocation separately and thus provide additional information. In order to perform interprocedural optimizations, the actual arguments at each callsite must also be saved. It is possible to augment this information with details that help identify those sequences of calls, or call chains, that may occur at run time.

The only tricky part of constructing a call graph occurs when procedures are passed as arguments to other procedures. An example of this is given in Fig. 2 and is based on one given by Muchnik. Here, procedure m invokes g twice, but it is not reflected directly in the call graph where there is one edge from m to *g*. In turn, procedure g makes two calls, one to procedure j and one to procedure p. But p is a variable: Our analysis of the code shows that it will be associated with h, so that g actually calls j and h. Edges are inserted accordingly. Procedure h calls i, and thus we add an edge from caller to callee. Procedure j calls a, which again is not an actual procedure, so we must determine which values it may assume at run time. Our code inspection shows that it may only be associated with i, so we must insert an edge from j to i in the call graph. We now determine that procedure i invokes g and add a corresponding edge to the call graph in order to complete it. Note that nodes in the call graph correspond to actual procedures and procedure parameters do not occur in it.

```
procedure m ( )
begin
    call g( )
    call g( )
end

procedure g( )
begin
 procedure   p
    p:= h
    call p( )
    call j( i )
end

procedure h ( )
begin
    call( i )
end

procedure i( )
begin
    call g( )
end

procedure j(a)
 Procedure    a
begin
    call a( )
end
```

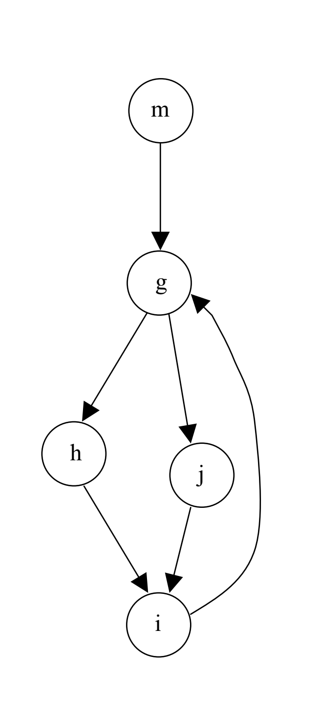

Figure 2. Program with procedure variables and resulting call graph.

Strategies for Interprocedural Optimization

A compiler generally translates an input code one procedure at a time (known as separate compilation). Strategies for applying optimizations interprocedurally must take this fact into account, and thus they are often separated into analysis phases that identify call sites and build the callgraph and a transformation phase that occurs after some analyses have been applied to each procedure individually, possibly spread among several phases of compilation to support other kinds of optimization, such as that described in the Array and Loop Optimizations Section, or possibly only shortly before the final code generation.

Purpose of Interprocedural Optimization

One reason that interprocedural analysis might produce superior results is that, without it, worst-case assumptions must be made with respect to the impact of procedure calls during (intraprocedural) DFA: It must be assumed that the call modifies every variable that is visible to both it and the calling procedure, including every global variable. Thus IPA can be used to improve the results of standard DFA. It may also be used explicitly to improve code that spans multiple procedures. Before we give examples of more sophisticated uses of IPA, we describe some of the simpler optimizations. At the end of this section, we consider the limitations of IPA.

Reducing Runtime Cost of Procedure Invocations

There are some interprocedural optimizations that may be implemented and carried out with relatively little effort. Each time a procedure is called at run time, information essential to the execution of the caller must be saved, the execution environment for the callee must be set up and control transferred. Upon its termination, the caller's environment must be restored, which incurs nontrivial overheads. Several optimizations are able to reduce these overheads, either directly or by reducing the number of procedure calls. One popular optimization in the latter category is known as procedure inlining: It replaces a procedure call in the code by the suitably adapted body of the procedure. If the call is made within a loop, this may sometimes lead to considerable savings. Unfortunately, however, it has proved to be very hard to come up with a good strategy for performing this optimization in general. If applied too frequently, the size of the object code may increase substantially, introducing other overheads. Strategies to control its application may take into account the frequency with which a call is expected to be executed, the length of the procedure's code, its location relative to the program hotspots, or some combination of these.

Advanced Interprocedural Optimization

A sophisticated compiler may be able to improve performance of a program by moving code between procedures or by applying basic optimizations on code that spans multiple procedures. For instance, code hoisting might extract code from a procedure into its calling procedures, or vice versa. As an example of the latter, register allocation might be performed between procedures in the late stages of compilation. If constant propagation proves that one or more arguments to a procedure assume constant values at a given callsite, it might be possible to exploit this information to create a particularly fast, specialized version of the procedure for that callsite.

Limitations of Interprocedural Analysis

One of the main purposes of interprocedural analysis is to determine which data are accessed, generally subdivided into the tasks of determining what values are defined and which are used, as the result of a given procedure invocation. Note that this determination also depends on the data accessed by those procedures that are invoked by the one under consideration. One of the difficulties with interprocedural analysis and optimizations based on it is that it is, in general, impossible to represent precisely the information gathered by IPA. For instance, a procedure may include several different possible execution paths, each of which accesses a different region of an array. When the compiler summarizes the impact of this procedure, it will combine this information and assume that all of the array elements that may be accessed on some path will indeed be accessed, as it has no way of knowing which of these paths will be executed. Moreover, it may be impossible to represent precisely the set of array elements that may be accessed, and the compiler must always be conservative. A variety of approaches to representing these regions has been proposed, from simple array sections (representation via a lower bound, upper bound, and stride in each array dimension) via linearization of accesses, lists of accesses, and representation as a convex region. The more complex the representation, the more time it will take to compute the region corresponding to a procedure call. Yet the usefulness of some interprocedural optimizations rests heavily on obtaining maximum precision in this analysis.

ARRAY AND LOOP OPTIMIZATIONS

Data Dependence Analysis

The optimizations introduced above are applied to individual scalar variables and are unable to explicitly consider structured data objects such as arrays. In particular, they are unable to deal with subscripted variables or to analyze the data access patterns in loops, where a statement may be executed many times, each time reading and writing a different set of variables. As a result, important optimizations may be missed. Consider the following pseudo-Fortran code fragment:

```
DO I:=1:N
    S:=S+A[I]*B[I]
    B[I]:= 2*C[I] +A[I]
OD I
```

If one were to look only at the variables without differentiating individual vector elements, the code would appear as follows:

```
DO I:=1:N
    S:=S+A*B
    B:= 2*C+A
OD I
```

On the other hand, the ability to distinguish between different elements of the vectors A, B, and C permits us to recognize that the code can be executed in a very different order (something that would not be valid for the undifferentiated version):

```
DO I:=1:N
    S:=S+A[I]*B[I]
OD I
DO I:=1:N
    B[I]:= 2*C[I] +A[I]
OD I
```

The ability of the compiler to analyze accesses to structured data objects, especially arrays, in the presence of nonconstant subscript expressions is crucial for a number of advanced optimization techniques, the foundation of which is (data) dependence analysis. Dependence analysis is a collection of techniques that allow the automatic determination at compile time whether two references to an array will both refer to one or more elements of an array (i.e., whether the regions of the array accessed by them will overlap). If they do not overlap, the compiler is free to reorganize the code in these statements as desired to optimize it. If they do, and one of them defines the variable, then it is essential that the relative order of those accesses be maintained. Indeed, the results of this analysis will enable the compiler to determine whether certain code transformations are semantically valid (produce the same results) in a specific context.

Numerous dependence tests have been developed and published; they are either exact or approximate. Exact tests determine precisely whether there is a dependence. Approximate tests will test for a condition whose validity implies that there is a dependence; if the condition is not satisfied, one assumes that a dependence is present. (known as a “nonfatal” assumption: It may be that, in fact, no dependence is present even though the condition is not satisfied; however, because the presence of a dependence merely impedes the application of a code transformation, not being able to transform the code will leave the semantics unchanged. We may simply miss out on some possible optimization, which an exact test would have allowed us to carry out.) Exact tests tend to be computationally intensive, if not infeasible, which is why approximate tests are commonly used in compilers dedicated to this type of optimization (typically vectorizing and parallelizing compilers).

Code Transformations

Once a complete dependence analysis for a given code has been carried out, code transformations can be applied. Paramount is, of course, that the semantics of the code not be affected by these transformations. As loops tend to account for a significant portion of the computation time of many programs, most code transformations focus on loops and arrays. Very common are loop distribution (replacing one big loop by several smaller ones—see for example, the code fragment above) and loop interchange (where the inner and the outer loop of a loop nest are interchanged—see the examples in I/O Management Section). Other code transformations are the wavefront method, replication and alignment, loop fusion and fission, and strip mining. These techniques were designed with specific objectives in mind, typically automatic vectorization or parallelization.

Vectorization

Vectorization is the attempt to produce "vector code," which is really pipelined code: What is conceptually a vector operation, for example, A[1:N]: = B[1:N]+C[1:N], is implemented as a pipeline of N operations A[i]: = B[i]+C[i]. A vectorizing compiler takes ordinary scalar code and produces equivalent vector code, which is typically done automatically, with no or very little user intervention. Semantically valid code transformations are applied to the given program in order to obtain code that can be vectorized. Automatic vectorization has been spectacularly successful, so much so that today very little manual vectorization is done. A good rule of thumb is that through vectorization, a program may run perhaps five or more times faster than the corresponding scalar version, which should require no more than 5% of the development cost of the original scalar program.

Parallelization

The resounding success of automatic vectorization raised expectations that automatic parallelization is similarly feasible, which proved to be quite unrealistic. Although the fundamental ideas are similar, the granularity of parallel code must be coarser ("more" must be executed) than that of vector code, because the start-up costs of a pipeline are much lower than those of a process or even a lightweight thread. As a result, automatic parallelization has not delivered on its promise, in spite of almost two decades of intensive work.

Language Support

One way in which people have attempted to avoid the difficulties encountered by automatic parallelization is to employ language support, some of which has always occurred in conjunction with vectorization where vectorization directives indicated to a compiler knowledge of the programmer that the compiler did not have or was unable to acquire. For example, an approximate test might be unable to exclude the possibility of a dependence, thereby impeding a possible optimization, while the programmer, alerted to this difficulty, may know that no dependence is present and can indicate this dependence to the compiler via a vectorization directive. Parallelizing compilers must rely on this type of language support to a much greater extent, given the much greater difficulties in parallelizing code automatically.

I/O MANAGEMENT

Motivation

In conventional programming, source code is compiled by a compiler; then the resulting object code is turned over to a run-time support system operating under the operating system (OS). This OS knows very little to nothing about the given program; in contrast, a compiler, especially a high-performance compiler, knows a good deal about the program. This knowledge is especially useful if the program is a "regular" program, such as one involved in many aspects of scientific computation. The information we are interested in is routinely collected by the compiler (in other words, the information collected is neither special nor unusual) and consists mainly of dependence information, which in turn determines which code transformations are semantically valid for a given program fragment.

It is instructive to keep a few key numbers in mind: Access to a single number residing in main memory today takes a few nanoseconds; if the same number resides on magnetic disk, access to it may require tens of milliseconds. Thus, if we fail to keep a number in main memory, which is needed sometime later, it may take 10 million times longer to get to it! Note that the corresponding factor for cache misses is less than 10 (caches are typically less than ten times faster than main memory); the same holds for bank conflicts (it takes four to six cycles to access an item, so pipelining accesses, which banks facilitate, will speed things up by at most that value).

It is important to understand that effective I/O management requires knowledge that is routinely available to a compiler, but is not accessible to the OS. Specifically, it is at the compiler level that decisions are made how to map multidimensional arrays into the one-dimensional memory space. It is at the compiler level where it can be determined whether certain code transformations preserve the semantics of a given source code. Both of these aspects are of crucial importance to the efficiency of I/O, as the following examples indicate.

Example 1. Bank conflicts: Assume that memory is organized in 64 banks and that one memory access takes four clock cycles. Consider the following code:

```
DO I:=1:65536:S
  A[I]:=I*I
OD I
```

where A is an array of size 1:65,536 and S may assume different integer values. It is important to understand the way in which array elements are mapped to memory banks: While the first array element, A[1] resides in some arbitrary bank, say bank b, the next element, A[2], resides in the next bank, namely bank b+1, A[3] in bank b+2, and so on, until the bank number exceeds 64, in which case one starts with bank 1. Now, if S is 64, it follows that every array element accessed by this code resides in bank b; therefore, each access will take four clock cycles. However, if S = 1, it is obviously possible to pipeline the accesses, resulting in an overall time requirement of essentially one cycle per access (altogether, we need 65,539 cycles to retrieve 65,536 elements). It should be clear that it is the value of S that creates problems in this case. However, consider the following code (under the exact same assumptions):

```
DO I:=1:1024
  DO J:=1:1024
    A[I,J]:=I*I
  OD J
OD I
```

Let us assume the mapping of the two-dimensional array A occurs in column-major order (as is the case for all Fortran-based languages). In this case, one can verify that each array access requires almost exactly **four** cycles: The code accesses the array A in rows, and given the stated assumptions, all the elements of any row reside in the same memory bank. Intriguingly, if the array were mapped in row-major order, or alternatively, if the code were replaced through loop interchange by the (completely equivalent) code

```
DO J:=1:1024
  DO I:=1:1024
    A[I,J]:=I*I
  OD I
OD J
```

the access cost per array element would be **one** clock cycle.

Example 2. Virtual memory management: Consider the following code fragment (similar to the last of Example 1):

```
DO J:=1:65536
  DO I:=1:65536
    A[I,J]:=I*I
  OD I
OD J
```

Assume Virtual Memory Management (VMM) is used, with an active memory set size of 1024 pages and a pure LRU replacement strategy (the page **L**east **R**ecently **U**sed is replaced whenever the active memory set size is exceeded). Furthermore, assume that a page holds exactly 2048 elements of the array A; consequently, 2M (or 2,097,152) pages are needed to hold A. As the active memory set is relatively small, it should be clear that paging will occur. Exactly how much depends, however, on the mapping of the 2-D array A into the memory space: If the mapping is in row-major order, every page will be retrieved exactly once, resulting in 2M page transfers. On the other hand, if the mapping is in column-major order, the first 1024 elements of the first row will each correspond to a page; initializing A[1,1025] will invoke the replacement function, because only 1024 pages can be accommodated, the page corresponding to A[1,1] will be displaced, which proceeds until the end of the first row is reached; then the second row of A is initialized. At this point, one observes that the page corresponding to A[1,1] is also that of A[2,1]; unfortunately, this page had been replaced long ago and must now be installed again. The upshot of this process is that, for each array element, a page has to be installed; as there are more than 4 billion (4,294,967,296) elements, the difference, in numbers of pages transferred, between the row-major and the column-major mappings amounts to a factor of 2048.

Several observations are in order: First, the vast majority of programmers are not aware of the mapping function that is employed (in spite of the rule of thumb that Fortran uses column-major and all other languages row-major). Second, and more important for our discussion, a compiler could easily determine that a loop interchange is semantically valid; therefore, if the language dictates column-major mapping (where we would need over 4 billion page transfers), the interchange of the I and the J loops would result in an equivalent code, but one that requires only about 2 million page transfers! Note that this interchange can only be done at the compiler level; once things are turned over to the OS, the context within which page transfers occur has been lost and with it the ability of restructuring accesses in semantically valid ways.

Automatic Minimization of Memory Bank Conflicts

Let us first look at memory bank conflicts. Given a program, together with information about memory mapping, number of cycles required to access main memory, and number of memory banks, a compiler can carry out an analysis (at compile time) of the number and type of bank conflicts that the program causes. This analysis is based on the assumption that the dimensions of the arrays are known at compile time (true for many languages, including Fortran and C). There are two ways in which a compiler can attempt to reduce bank conflicts, by changing the shape of arrays, and by inserting a filler of an appropriate length.

Changing the Shape of an Array. Consider the second code fragment of Example 1 above, assuming column-major mapping. Although, of course, it is possible to do a loop interchange in this case, matrix multiplication, for example, will require access by rows and by columns; therefore, this approach would not work in general. However, one can redefine the shape of the matrix; instead of defining it as (1:1024, 1:1024), one could define it as (1:1025, 1:1024), assuming the mapping is column-major. (If the mapping is row-major, the array should be defined as (1:1024, 1:1025).) In this way, traversing a row will not result in bank conflicts, as now A[1,1] is in bank 1, A[1,2] is in bank 2 (instead of in bank 1, as before the reshaping), and so on. Note that it is only the definition of the array that must be changed; all of the code manipulating the array remains completely unaffected. Furthermore, the amount of "wasted" memory is relatively small, one single column (or row). This process can be done at compile time, driven by the bank conflict analysis (in other words, if the analysis indicates a significant amount of conflicts, the reshaping operation is carried out and the resulting code is subjected to a bank conflict analysis; if the reshaped version has fewer conflicts than the original one, the new version is used, otherwise the original is restored).

Inserting a filler. Consider the code fragment

```
S:=0
DO I:=1:1024
     S:=S+A[I]*B[I]
 OD I
```

where we assume as before that we have 64 banks and each access takes four cycles. Moreover, we assume that the two arrays are of size 1024 and are declared in a way that causes them to be allocated contiguously in main memory. One can easily see that A[1] and B[1] will end up in the same bank, and so will A[2] and B[2], A[3] and B[3], and so on, which causes a significant amount of conflicts, which the compiler can determine at compile time. Inserting a filler of length 4 between the two arrays causes these conflicts to evaporate, as now A[1] will be in bank 1, but B[1] in bank 5; similarly, A[2] will be in bank 2 and B[2] in bank 6, A[3] in bank 3 and B[3] in bank 7, and so on. Again, the memory bank conflict analysis of the compiler can drive this process. More sophisticated analyses can also be carried out, taking into account the fact that the length of the filler can be varied as required. In this example, any length between 4 and 60 would work, allowing the compiler to consider and combine constraints imposed by other code fragments.

Automatic Minimization of Block Transfers: I/O Profiling

The code transformations referred to in the Code Transformations Section can be carried out with the objective of minimizing I/O, instead of vectorization or parallelization, which can be visualized by considering the Example 2 above for column-major mapping. It should be obvious that significant savings in I/O can be achieved provided a loop interchange is semantically valid. For this purpose, it is necessary to first establish the I/O profile of a given program, which can be done automatically at compile time and provides a measure of the amount of I/O occurring during execution. Based on the dependence analysis, the compiler can now carry out semantically valid code transformations, with the goal of reducing I/O. The resulting modified code is again I/O profiled; if the new version has a better I/O profile than the original one, it is retained, otherwise different code transformations are applied. In this way, it can either be established that the original program was already I/O efficient, or else a more I/O efficient program is obtained.

Compiler-Driven I/O Management

It should be clear from the previous paragraphs that all techniques described can be carried out automatically on the basis of information that is available to the compiler (at compile time). In fact, it is not very difficult to comprehend that the compiler has significantly more knowledge about the program (access patterns, use of complex structures and arrays, etc.) than the operating system. Therefore, it should also be obvious that I/O management is best accomplished by the compiler. In other words, it should be the compiler that determines which blocks are to be transferred between disk and main memory or between main memory and cache, not the OS. This gives rise to compiler-driven I/ O management, which will likely play an increasingly important role because external memory devices, primarily magnetic disk drives, have not increased in access speed over the past decade or so (and there is no indication that this trend will change), while CPUs have become significantly faster. This fact implies that more and more formerly CPU-bound programs will become I/O-bound, emphasizing the increasing need for intelligent I/O management.

LOW-LEVEL OPTIMIZATIONS

Among the most important optimizations applied in practice are those that attempt to examine and improve a version of the program that is a representation of the actual machine code that will be generated. At this low level, it is possible to analyze the use of data and to assign registers carefully, and to examine the sequences of instructions generated and consider how they will be mapped to the hardware resources. The use of such information to improve the selection and ordering of instructions, as well as details of the assignment of data to registers, is highly machine-specific. For instance, if it is known that it takes a certain number of cycles to load an integer into a register and the generated code uses an integer in the instruction immediately following a load, then the compiler might attempt to reorder the instructions so that other work is performed while the value is being loaded. Similarly, knowledge of the time it takes to handle a branch in the code might permit the insertion of other instructions in order that cycles are not wasted. Other low-level optimizations will already have attempted to optimize the number of branches required by the code. They may also attempt to perform branch prediction, which attempts to determine the most likely path that will be taken at run time, or may attempt to identify sequences of code that may be translated in a particularly efficient way on the target machine. Such *machine idioms* may be very short sequences of code, often the combination of two instructions into a single instruction in the target machine's instruction set.

Register Allocation

Possibly the best-known low-level optimization is register allocation. The purpose of register allocation is to make the best possible use of registers, a limited set of highest-speed memory locations that allow for the most efficient machine instructions to be applied. Note that some architectures require that all data used as operands be in registers.

As with most optimization problems, there is no practical algorithmic solution to the problem of assigning variables optimally to registers, and thus heuristics are used to provide approximate solutions instead. The standard approaches to dealing with this issue require an analysis of the live range of variables (i.e., the determination of the code region where a variable is referenced), which is used to construct a so-called *interference graph* to represent variables and their live ranges. Nodes correspond to variables and there is an edge between a pair of nodes if and only if their live ranges overlap. If there is no edge between a pair of nodes, it will be possible to assign them to the same register, because they are needed at different times during execution. On the other hand, if there is an edge, then we need different registers to hold the current values of the variables involved. By associating a distinct color with each hardware register, we may equate the problem of assigning distinct registers to these variables with the problem of coloring the interference graph in such a way that no connected nodes have the same color. In practice, several approaches have been proposed to find colorings for the interference graph, typically by simplifying this graph (by removing nodes and the edges from them) until one is found for which the given hardware-dependent number of registers can indeed provide such a mapping. As there are seldom sufficient registers to hold all live variables simultaneously, the mapping is typically achieved by spilling registers, the term given to the storing of values temporarily in memory until they can be restored to a register. Spillage will occur for all variables whose nodes were eliminated from the graph during the construction of a solution. The increase in instruction-level parallelism, or potential to exploit multiple functional units simultaneously, has increased the need for more variables to be in registers at any given time, and has made it harder to provide good solutions to this optimization problem.

Instruction Scheduling

Instruction scheduling refers to the ordering of machine instructions for execution, which is complicated by the need to keep a number of different functional units busy during execution. As this order obviously also affects the live range of the variables referenced, the scheduling of instructions is not independent of register allocation, and this interdependence is one of the difficulties of low-level optimization.

Typically, a machine will permit the independent, concurrent execution of specific kinds of instructions and it is the job of this phase in compilation to determine independent sets of computations that can be fed to the corresponding functional units simultaneously. An obvious limiting factor in this scheduling is the occurrence of a branch in the code; a variety of approaches have been proposed to help the machine carry out useful work despite those branches, including speculative techniques that guess at the branch that will be taken and begin to perform the work in that execution path. If the guess turns out to be incorrect, work is needed to undo the instructions performed.

Many current machines permit software pipelining, which is analogous to hardware pipelining, and performance improvements are obtained by overlapping the execution of distinct operations, which is typically most useful for loops, in which a set of instructions is repeated many times and in which data reuse may be high and the reuse distance known. The instruction scheduling required to facilitate software pipelining may be supported by loop unrolling, in which the body of a loop is increased by replicating the code (with suitable adaptation) for a given number of loop iterations known as the unroll factor. That is, there will be fewer loop iterations, but each of them will have more code and presumably higher levels of reuse of certain data objects. If the unroll factor chosen is too large, then the data required might not fit into cache, which is likely to offset any performance gains provided by this approach, so the unroll factor must be carefully chosen.

Emerging ideas on instruction scheduling consider how this process can be supported by having additional “helper” threads to determine the branches that will be taken, or to prefetch data to avoid some of the inevitable delays when instructions cannot be reordered in such a way that stalls (or waits) are offset.

PRACTICAL CONSIDERATIONS

Optimizing compilers are ordinary compilers with a well-developed optimization phase. There are often various options to select, depending on what optimizations are to be attempted. Clearly, no optimization should be performed if the program is not yet debugged or in its final form. It is important to view optimization as an investment: Carrying out the required analyses comes at a cost, namely the time the compiler requires to complete them. Unless there is a reasonable expectation that this investment will bring an acceptable return, it makes no sense to do optimization. For example, a program that is used once and whose execution time is short is not a good candidate for optimization. On the other hand, a program that is executed frequently and runs for long periods should probably be extensively optimized.

Another point that must be stressed is that optimization typically will reduce the running time of a program by a constant factor. This factor may be quite attractive, say 60%, but it will not grow asymptotically. To illustrate, consider two methods of sorting n numbers, one taking $4n\log_2(n)$ instructions, the other $n^2/4$ instructions. In this case, the advantage of the first method increases with n. Optimization does not work in this manner—if it saves 60% of a given program, this percentage will remain essentially unchanged and independent (for the most part) of the size of the input.

Finally, we note that a “good” optimizing compiler is by no means one that attempts to apply all possible analyses and code transformations. Indeed, such a compiler would be extremely costly to use because all this work will require a great deal of time and effort. As a result, a large number of programs would never be able to recover the investment in optimization through a reduction of the aggregate running time (taken over the life of the program). Instead, a good optimizing compiler tends to be one that applies a limited number of strategies very efficiently. In this way, a much larger number of programs can benefit properly from optimization.

OUTLOOK

As the complexity of hardware continues to grow, the need for re-evaluation and further development of optimization strategies is great. Current challenges include the need to enable code to exploit increasing levels of architectural parallelism at a low level, and to take the impact of a variety of new hardware and operating system mechanisms for multithreading into account. The widespread proliferation of a variety of handheld devices and telecommunications applications has led to the broader use of Java as a programming language and the necessity of choosing combinations of interpretation and dynamic compilation to minimize download time, execution time, memory usage, and power consumption. Multisite and grid computing has led to interest in the portability of code and thus to optimization at run time (or a separation of basic translations from the major optimizations). These ideas have given impetus to the exploitation of dynamic optimization for traditional languages, as well as the somewhat simpler gathering of profile data by a compiler and its use in a feedback loop that aims to improve the application of optimizations, possibly in a manner that is specific to a single execution. There are costs associated with the replacement of code fragments during execution, as well as the more obvious cost of any dynamic instrumentation needed to determine the suitability of such replacement, which is an area of active research and development. With the continued innovation in computer architectures and the growth in size of applications, computer jobs, and system configurations, we expect to see innovations in the area of compiler optimization for some time to come.

P

PARAMETER PASSING

Modern programming languages use various techniques to pass parameters to a function (or method). We discuss the techniques used in some of the more popular programming languages in current use, namely C, C++, Ada, Java, and C#, and mention some techniques found in other languages.

INTRODUCTION

Suppose our programming language defines a function:

```
int idx = 1;
int arr[ ] ={ 37, 12, 17 } ;
// Array of length 3, indices 0...2
void foo ( int param )
{
  idx++;
  param++;
  print ( param ) ; // What is printed here?
}
```

In this example, as in all others, the parameters that are listed with the function declaration are the *formal parameters*. The parameters supplied in the function call are the *actual arguments* (sometimes also known as the *actual parameters*). The function can be invoked as shown below:

```
foo ( arr[ idx ] ) ; // What happens to arr?
```

The natural question, of course, is to ask what is printed on the last line of function `foo`, and what are the array contents that are printed after invoking `foo`?

Of course, experienced programmers will answer easily the question in the language of their choice, but the answer depends on the underlying decisions made in the design of the particular programming language that dictates how the parameters are actually being passed. For instance, here are some possible scenarios (all of which add one to `idx`):

1. `param` is simply a copy of `arr[ 1]`. In this case, `param` is initially 12 and is incremented, and the value 13 is printed. However, `arr[ 1]` (and thus the remainder of `arr`) are unchanged.
2. `param` is a synonym for `arr[ 1]`. In this case, `arr[ 1]` is incremented to 13.
3. `param` is a synonym for `arr[ idx]`, and since `idx` is incremented to 2, `param++` increments `arr[ 2]`.

Because all of the above results could plausibly be the desired outcome, each programming language provides mechanisms to achieve at least one of these results. Needless to say, the example above, with just one integer parameter and a few lines of code, is fairly simple. Thus, a full programming language will have many complications and subtleties that are beyond the scope of this article. The remainder of this article describes the most common parameter passing mechanisms in five fairly similar languages that are in common use today: C, C++, Ada, Java, and C#. We also briefly mention parameter passing in other languages.

PARAMETER PASSING IN C

Call-By-Value

Before discussing call-by-value in C, it is helpful to explain how values are treated in C (and similar languages such as C++). C makes use of the notion of two types of values: an L-value and an R-value. In C, an L-value is an expression that refers to a region of storage that can be examined and stored into. An R-value refers to a data value that is stored at some address in memory. A literal constant can serve as an R-value. Variables in C, such as `x`, `*p`, or `a[ i]` have two values: the L-value (address) and the R-value (contents of that address).

In C, all parameters to functions are passed using the mechanism of call-by-value. In call-by-value, the actual argument is copied into the formal parameter (this is Scenario 1 in the example in the introduction). So in call-by-value, the formal parameter is a new local variable that is initialized with the R-value of the actual argument. Call-by-value has some limitations.

The first limitation is that call-by-value is expensive if used on parameters that are large. Because C is not an object-oriented language, most parameters are primitive types or pointer variables. Thus, they are inexpensive to copy. In original C, `struct` types (i.e., aggregates) could not be passed as a parameter, and instead they are passed indirectly by passing a pointer to the `struct`. Modern C does allow passing of `struct` types; however, because of the cost of copying, `struct` types are almost always passed by using a pointer. Arrays could theoretically be expensive to pass via call-by-value, but in C this is not an issue because arrays in C are represented by a pointer variable that points at a suitably large block of memory. What is being passed is not the array but is the address of the large block of memory that stores the array items. (Unfortunately this means that an additional parameter that represents the array size must also be passed, or some other mechanism must be used.) Similarly, strings are actually arrays of characters, and pointer variables are used.

The second limitation is that call-by-value does not allow the function to change the actual argument, which makes routines such as `swap`, which would swap its two parameters, impossible to write directly.

Call-By-Passing Pointers

In C, as described in the previous section, arrays and strings are passed by using a pointer to the block of memory in which they are stored, as are `struct`s. Call-by-value guarantees that the value of the pointer variable is used, so after the call returns, the pointer variable will be viewing the same block of memory, but the contents of the block of memory can change. This mechanism is also useful for writing routines, such as `swap`, that change two variables. Sample code is shown below:

```
void swap( int *px, int *py )
{
  int tmp = *px;
  *px = *py;
  *py = tmp;
}
```

In this routine the two parameters represent the addresses (i.e., the L-values) of the two integers that are being swapped. To invoke `swap`, we simply pass in two addresses (L-values) as shown in the following fragment.

```
int x = 5;
int y = 7;
swap( &x, &y );
```

Call-By-Macro Expansion

Another alternative in C is the use of preprocessor macros. These macros technically are not functions, and have significant differences from functions. Because they look enough like functions and are often used like functions, we describe its parameter passing mechanism.

In the *call-by-macro expansion*, the actual arguments are *substituted textually* in the macro body in all places where the corresponding formal parameters appear. Then the macro body replaces the macro call. Thus, in C, given the macro:

```
#define CUBE( a ) ( (a) * (a) * (a) )
```

the statement

```
y = CUBE( x + 3 ) * 5;
```

is interpreted as

```
y = ( (x + 3) * (x + 3) * (x + 3) ) * 5;
```

Scenario 3, as described in the Introduction, can be implemented straightforwardly in C if macros and the comma operator are used:

```
#define foo(param) (idx++,param++,print(param))
```

Macros have some distinct advantages over functions, but also they have some tremendous liabilities. On the positive side, macro parameters are typeless (one can pass an `int`, `double`, etc. as a parameter). Macros avoid the overhead of a copy, which can save time (but not as much time as was the case in the 1970s, at the height of C's popularity). The time savings was the original motivation for the use of macros. Macros can be used to evade call-by-value restrictions. Macros can also be used for very tricky code in which several parameters can be combined to form a resulting string that can then be the name of a variable. The major problem with macros is that they are not semantically equivalent to function calls. Most obviously, without the excessive parenthesis shown in the macros the programmer runs the risk of the macro expansion generating code that is wrong because of precedence rules. For instance, with no parenthesis, the macro is interpreted as

```
y = x + 3 * x + 3 * x + 3 * 5
```

Even with parenthesis, macro arguments are evaluated as many times as needed in the expansion, so for instance `CUBE(sin(theta))` calls the expensive `sin` function three times, thus losing any speed benefit that might have accrued. And if the macro argument contains a side effect, as in `CUBE(++x)`, the macro call is unpredictable but definitely not the same as a corresponding function call.

An additional concern with macros has to do with problems that can arise when variables in the macro expansion collide with variables in the function that contains a call to the macro. In this article's last section, we see *call-by-name*, which was prominently used in Algol 60. Call-by-name uses variable capture to avoid these issues.

PARAMETER PASSING IN C++

C++ is designed for the most part as a superset of C, so all parameter passing idioms described for C are valid in C++. However, because passing pointers and using macros are notoriously error-prone, C++ provides alternatives that are much safer than the corresponding C constructs.

Inline Optimization

In C++, functions can be declared inline. When the compiler inlines a function call, the effect is that the function call is replaced by the body of the function, with the formal parameters replaced carefully by the actual arguments. However, if a formal parameter is used more than once, it is evaluated only once, and its value is saved and reused for the subsequent occurrences. This process makes an inline function semantically equivalent to a normal function call, differentiating it from a macro expansion.

When a C++ function is declared inline, the declaration is considered nonbinding advice to the compiler. If the body of the function is not suitably compact, or the actual arguments are not relatively simple (or are aliased), the compiler is likely to avoid the optimization.

Call-By-Reference

In call by reference, the formal parameter is a synonym (alias) for the evaluated argument (they have the same L-values). A formal parameter that is declared with an `&` is considered to be passed using call-by-reference semantics.

Thus, Scenario 2 in the Introduction can be implemented with the following code:

```
void foo( int & param )
{
   idx++;
   param++;
   print( param ); // What is printed here?
}
```

When the call to foo is made, as before:

```
foo( arr[ idx ] ); // What happens to arr?
```

param becomes another name for arr[1] (because idx is 1 at the time of the call). Call-by-reference makes it easy to write a swap routine without using pointer variables:

```
void swap( int & x, int & y )
{
   int tmp = x;
   x = y;
   y = tmp;
}
```

In this routine, the two parameters represent the two integers that are being swapped. To invoke swap, we simply pass in two integers as shown in the following fragment:

```
int xx = 5;
int yy = 7;
swap( xx, yy );
```

Call-by-reference requires that the actual argument be a modifiable L-value (i.e., it can be assigned to; thus objects that we declared with const are not acceptable arguments) and of the same type, or in the case of inheritance, the actual argument can be a public subclass of the formal parameter type. Call-by-reference is typically implemented by the compiler by passing invisibly the address of the actual argument, and then by dereferencing the pointer variable that is received by the function.

Call-By-Reference to a Constant

In C, when large aggregates need to be passed to a function, a pointer variable is used to pass the address of the aggregate, rather than an entire copy of the aggregate. But working with pointer variables is clumsy. Consider the following code:

```
int binarySearch( vector<int> arr, int x )
{ /* implementation not shown */ }
```

In this code, even though binarySearch is a fast operation (using $O(\log N)$ time), the code will require $O(N)$ time because call-by-value will mandate a copy of the N-element vector that is passed as the first parameter. An alternative, supported in other older languages such as Pascal, is pass by reference:

```
int binarySearch( vector<int> & arr, int x )
{ /* implementation not shown */ }
```

This code will be much faster because it avoids the copy of the vector. However, it is NOT semantically equivalent. If the implementation resizes arr, or makes a change to arr, the original version will not reflect a change in the actual argument, whereas the new version will. In addition, the original version works with constant (i.e., immutable) vectors; the new version does not. Both problems are solved using call-by-reference to a constant:

```
int binarySearch( const vector<int> & arr, int x )
{ /* implementation not shown */ }
```

In this code, the actual argument is still being passed by reference. However, in the scope of binarySearch, arr is treated as a constant. Thus attempts to resize or change arr will result in a compiler error. Consequently there is a guarantee that when binarySearch returns, the actual argument will not have been changed (it is possible to trick the compiler by using type casts to remove the const, but doing so requires at least some effort).

Call-by-reference to a constant also is sometimes known as *call-by-constant reference.*

C++ Parameter Passing Summary

For the most part, parameter passing in C++ either uses call-by-value (the default), call-by-reference, or call-by-reference to a constant. Macros are now rarely used, and modern optimizing compilers perform inline optimization whether or not it is requested by the programmer. The decision on which parameter passing mechanism to use is critical, and the following table summarizes the general principles on which mechanism is appropriate:

Call-by-reference	Actual argument **may need to be changed.** In this case, it does not matter what is the type of the actual argument.
Call-by-value	Actual argument **should not be changed**, and **copy cost is minimal**. The actual argument is usually a primitive or pointer type or a class type that is unusually easy to copy.
Call by reference to a constant	Actual argument **should not be changed**, and **copy cost is expensive**. The actual argument is a class type such as vector.

PARAMETER PASSING IN ADA

Ada's approach to parameter passing is somewhat different from C++'s approach. In C++, when we have an actual argument that we want to be sure will not be changed by the function, the programmer will declare that either call-by-value or call-by-reference to a constant is used, because either mechanism provides (for the most part) the guarantees that we want. However, the programmer must make a decision on whether a copy of the actual argument should be made (call-by-value) or hidden pointers should be used (call-by-reference to a constant). Ada takes the position that this choice is best left to the compiler. The programmer should specify simply that the formal parameter should be "read only."

Thus, in Ada, parameters are passed in one of three modes, representing roughly "read only," "read and write," and "write only." These parameters are `in`, `in out`, and `out`, respectively. The default mode is `in`.

A second difficulty is that in the call `bar(x,y)`, there is no way to tell, without looking at the signature of `bar`, whether it is possible that `x` and `y` can be changed in the call. Ada avoids this problem by differentiating between "functions" and "procedures." A function in Ada must have a return value, and the caller cannot ignore the return value. A procedure in Ada cannot have a return value. Ada requires that all parameters to functions are `in` parameters. Thus, it is guaranteed that the actual arguments to a function will not be changed during the execution of the function call, and it is easy to distinguish between a function and a procedure. However, as in C++, in a procedure call, there is no way to tell how parameters are being passed without looking at the procedure's signature.

In Mode

The formal parameter is a constant and permits only reading of the value of the associated actual parameter. The formal parameter cannot be assigned to (so it cannot appear on the left-hand side of an assignment statement). If the parameter is a primitive, then a copy is made. Otherwise, a reference is used. Thus, the Ada compiler makes these decisions that can cause significant performance problems for C++ programmers.

In Out Mode

The formal parameter is not a constant and permits both reading and writing the value of the associated actual parameter. The formal parameter can appear on both sides of an assignment statement.

If the parameter is large, then the compiler will probably elect to pass by reference, as in C++. Arrays are passed this way, and some types are required by the language specification to be passed by reference.

Call-By-Value Return

However, if the parameter is a primitive, then the language specification requires that a copy is made when the procedure commences (recall that all function parameters are passed using `in` mode). When the procedure returns, the current state of the formal parameter is copied back into the actual argument. This is known as call-by-value return, or sometimes as copy-in, copy-out.

In most circumstances, call-by-value return and call-by-reference achieve the same semantic result as allowing the actual argument to be changed by the procedure. However, there are some subtle cases, many of which involve parameter aliasing, when call-by-value return and call-by-reference give different results. Consider the following contrived example:

```
u : integer := 5;
procedure silly( x: in out integer ) is
begin
 u := 0;
 x := x + 1;
end silly;
```

Suppose we invoke `silly(u)`. Using call-by-reference as the parameter passing mode would set `u` to 1. However, the result is different if call-by-value return is used, because since `x` will be a copy of `u`, the value of `x` prior to the procedure return will be 6 and then that value is copied back to `u`.

The Ada Language Specification allows the compiler to choose either method to pass record types using *in out* mode, and thus in the presence of aliasing, the compiler's choice affects the behavior of the program. Ada programs that rely on knowing which parameter passing mechanism has been chosen by the compiler are considered nonportable. The program above is portable because, as was mentioned, primitive types must use call-by-value return to pass `in out` parameters.

Out Mode

In early versions of Ada, the compiler permitted only to write the value of the associated actual parameter, and the formal parameter could appear only on the left-hand side of an assignment statement. This rule was relaxed, so now the formal parameter is a variable and may be assigned values; however, its initial value should be considered undefined (because if the initial value is important, then `in out` is the correct parameter passing mode). Technical issues involve the idea that the actual argument is undefined, but might be partially constructed, and its partial initialization should not be lost. As a result, parameter passing is similar to `in out` parameters.

Named Parameters

The print procedure shown below is typical of procedures that have lots of parameters: Many of the parameters have the same type, and it is difficult to remember the order of the parameters. The normal way of invoking the procedure is to use positional parameters: The caller must list the parameters in the same order that the function does. If the caller of the procedure supplies the last parameters in the wrong order, the program will still compile, unless parameters of different types are interchanged. Obviously this procedure is prone to error.

```
procedure print( file_name : String;
                 indent : integer;
                 line_len : integer;
                 lines_per_page : integer );
```

Ada allows the use of named parameters. For instance the following calls are all acceptable:

```
print( file_name => "foo.txt", indent => 5,
       line_len => 72, lines_per_page => 62 );
```

```
print( file_name => "foo.txt", indent => 5,
       lines_per_page => 62, line_len => 72 );
print( lines_per_page => 62, indent => 5,
       line_len => 72, file_name => "foo.txt" );
```

Each actual argument is associated specifically with a formal parameter; the order does not matter. It is also possible to mix the positional arguments and the named arguments, but the positional arguments must all come first, and in their correct positions. So it is customary to make sure the most important formal parameters are specified first in the signature. Here are examples of a valid mixed parameter call:

```
print( "foo.txt", line_len => 72, indent => 5,
   lines_per_page => 62 );
print( "foo.txt", indent => 5,
   lines_per_page => 62, line_len => 72 );
print( "foo.txt", 5,
   lines_per_page => 62, line_len => 72 );
```

PARAMETER PASSING IN JAVA

In Java, the only parameter passing mechanism available is call-by-value. For value types (which are primitive types, only), the value is copied. For reference types (which are everything else, including strings, arrays, and collections), this means that the value of the reference variable, rather than the entire object being referenced, is copied. Thus, the copy is never expensive.

As in C, a mechanism exists to evade the call-by-value restriction and to simulate call-by-reference. In Java, because the state of the object that is being accessed by the formal parameter's reference variable can always be changed, information can be passed back to the caller by embedding it in an object and passing a reference to the object. Sometimes the object is simply an array of length 1. Other times it is a more complex entity. Some routines, such as `swap`, are impossible to write cleanly in Java.

PARAMETER PASSING IN C#

The C# model is similar to the Java model, with a few additions. As in Java, a distinction exists between value types and reference types, and although value types can include types that are not primitives (known as `struct` types), the general expectation still exists that parameter passing using call-by-value should never be expensive. Thus, almost all parameter passing in C# is similar to Java and the default is call-by-value.

However, C# also allows call-by-reference. Both the formal parameter and actual arguments must be preceded with the keyword `ref` (if exactly one of the parameter/argument pair contains `ref`, it is an error). Here is sample C# code for `swap`:

```
void swap( int ref x, int ref y )
{
  int tmp = x;
  x = y;
  y = tmp;
}
```

In this routine, the two parameters represent the two integers that are being swapped. To invoke `swap`, we simply pass in two integers as shown in the following fragment.

```
int xx = 5;
int yy = 7;
swap( ref xx, ref yy );
```

Requiring the `ref` prior to the actual argument solves C++'s problem that in C++, the caller cannot distinguish a parameter passed using call-by-reference from call-by-value or call-by-constant reference without seeing the corresponding function signature.

C# also provides `out` parameters that behave somewhat like in Ada. As with `ref` parameters, the keyword `out` must be used prior to the formal parameter and the actual argument. The compiler will assume that the `out` formal parameter is uninitialized on entry to the function and will verify that it is definitely assigned before the function return.

PASSING A FUNCTION AS A PARAMETER

All of the languages that we have examined provide the ability to pass a function (or procedure) as a parameter to a function (or procedure). In all cases, the syntax is definitely nontrivial, but one of two competing philosophies is as follows.

1. Pass a pointer to the function as a parameter (C, C++, Ada).
2. Embed the function inside a class type, and pass a reference (or copy) of the class type as a parameter (C++, Ada, Java, C#). This idea is often known as a *function object.*

Passing a Pointer to a Function in C, C++, and Ada

Passing the pointer is generally considered an inferior solution; among the languages we have examined, this solution is most appropriate in C. The following function applies function `func` to every element in array `input` and produces the answer in the corresponding slots of array `output`:

```
void evaluate( const double input[ ],
               double output[ ],
               int n, double (*func) (double x))
{
  int i = 0;
  for( i = 0; i < n; i++ )
    output[ i ] = (*func) ( input[ i ] );
}
```

The onerous syntax for a pointer to function in C can be simplified in modern C with:

```
void evaluate( const double input[ ],
               double output[ ],
               int n, double func( double x ))
{
  int i = 0;
  for( i = 0; i < n; i++ )
    output[ i ] = func( input[ i ] );
}
```

In either case, the following code fragment computes some square roots and logarithms:

```
double arr[ ] ={ 8.5, 7.9, 4.2, 7.3 } ;
double roots[ 4 ] ;
double logs[ 4 ] ;
evaluate( arr, roots, 4, sqrt );
evaluate( arr, logs, 4, log10 );
```

This code also works, unchanged in C++, but as mentioned it is considered by modern C++ programmers to be an inferior solution to the one shown later that makes use of function objects. The same basic logic can be used in Ada95, as shown in the following code:

```
with Text_IO; use Text_IO;
with Numerics.Elementary_Functions;
    use Numerics.Elementary_Functions;
procedure Function_Pointers is
    type Array_Type is array( Integer range <> )
       of Float;
    type Math_Func is access function (X : Float) :
       Float;
procedure Evaluate( Input : Array_Type;
                    Output : out Array_Type;
                    func : Math_Func ) is
begin
  for( I in Input’ range ) loop
    Output[ I ] := Func.all( Input[ I ] );
  end loop;
end Evaluate;

begin
  Arr : Array_Type(1..4 ) :={ 8.5, 7.9, 4.2, 7.3} ;
  Root : Array_Type( 1..4 );
  Logs : Array_Type( 1..4 );
  Evaluate( Arr, Roots, Sqrt’ access );
  Evaluate( Arr, Logs, Log’ access );
end Function_Pointers;
```

Function Objects in Ada, Java, and C#

In these languages, functions are passed to parameters by embedding each function in a class type, and then by creating an instance of the class type. Then, a reference to the object (containing the function) can be passed as a parameter. In these languages, inheritance in the form of an interface is used to specify the signature of the function being passed. Here is a Java example:

```
interface MathFunctionObject
{
  double func( double x );
}
class FunctionPointers
{
   public static void evaluate
                        ( double[ ] input,
                          double[ ] output,
                          MathFunctionObject f )
   {
     for( int i = 0; i < input.length; i++ )
       output [ i ] = f.func( input[ i ] );
   }
   public static void main( String[ ] args )
   {
     double  [ ] arr ={ 8.5, 7.9, 4.2, 7.3 } ;
     double  [ ] roots = new double[ 4 ] ;
     double  [ ] logs = new double[ 4 ] ;

     evaluate( arr, roots, new SqrtObject( ) );
     evaluate( arr, logs, new Log10Object( ) );
   }
   private static class SqrtObject
                  implements MathFunctionObject
   {
     public double func( double x )
       { return Math.sqrt( x ); }
   }
   private static class Log10Object
                  implements MathFunctionObject
   {
     public double func( double x )
       { return Math.log10( x ); }
   }
}
```

Function Objects in C++

In C++, inheritance is replaced by template expansion and overloading of `operator()`. The syntactic tricks are that `evaluate` is expanded once for each function object type and `func.operator()` is replaced by simply `func`.

```
template <typename MathFunctionObject>
void evaluate( const vector<double> & input,
               vector<double> & output,
               MathFunctionObject func )
{
  for( int i = 0; i < input.size( ); i++ )
    output[ i ] = func( input[ i ] );
}
class SqrtObject
{
  public:
    double operator() ( double x ) const
      { return sqrt( x ); }
} ;
class Log10Object
{
  public:
```

```
  double operator() ( double x ) const
    {  return log10( x ); }
};

int main( )
{
   vector<double> arr( 4 );
   arr[ 0 ] = 8.5; arr[ 1 ] = 7.9;
   arr[ 2 ] = 4.2; arr[ 3 ] = 7.3;
   vector<double> roots( 4 );
   vector<double> logs( 4 );

   evaluate( arr, roots, SqrtObject( ) );
   evaluate( arr, logs, Log10Object( ) );
}
```

Passing Functions in Functional Languages

In other languages, particularly functional languages such as Scheme, ML, or Haskell, functions are treated as just another kind of value and do not require the baroque syntax of the languages we have illustrated in this section.

ADDITIONAL FEATURES

Two interesting features that are somewhat common are the use of *default parameters* and *variable numbers of arguments*.

Default Parameters

Default parameters are found in both C++ and Ada. In these languages, formal parameters can be provided with default values that will be used if the actual argument is omitted.

Here is a C++ example:

```
double myLog( double n, int base = 10 )
{
    return log10( n ) / log10( base );
}
```

In this example, the call `myLog(n,2)` is valid, and so is `myLog(n)`. In the later case, base will be presumed to be 10. Significant rules exist regarding when and where default parameters can be used, and the parameters do not mix well with other features, such as inheritance. The Ada code is comparable with its C++ equivalent.

Because many languages support function overloading (allowing the same function name to be used as long as parameter signatures differ), default parameters are not essential and can be viewed as strictly a syntactic convenience.

Variable Arguments

Variable argument lists, in which an unknown number of actual arguments can be passed, are found in C, C++, C#, and later versions of Java (starting with Java 5). In all instances, zero or more "known" actual arguments are passed, followed by the "unknown" group. Strictly speaking, variable arguments are a convenience, because one can always achieve the same effect by using an array to encapsulate the unknown group of actual arguments. Not surprisingly, then, Java 5 and C# take a similar approach in which the unknown actual arguments are accessed by an array. Here is example code for implementing a variable argument `max` function in Java:

```
public static int max( int first, int ... rest )
{
   int maxValue = first;
   for( int i = 0; i < rest.length; i++ )
     if( rest[ i ] > maxValue )
        maxValue = rest[ i ];
   return maxValue;
}
```

The same idiom is used in C#, via `params` arrays:

```
int max( int first, params int[ ] rest )
{
   int maxValue = first;
   for( int i = 0; i < rest.Length; i++ )
     if( rest[ i ] > maxValue )
        maxValue = rest[ i ];
   return maxValue;
}
```

In both languages, these functions support calls such as `max(3,5,2,1,4)`, `max(3,5)`, and `max(3)`. Also supported is `max(3,new int[ ]{ 5,2} )`, which illustrates how the compilers are really handling the situation (and how similar C# and Java really are).

C and C++ use a significantly uglier strategy of invoking macros that manipulate the runtime stack. The calls to the macros are platform independent, although the implementation of the macros obviously is not.

PARAMETER PASSING IN OTHER LANGUAGES

Call-By-Name

Call-by-name is a parameter passing mechanism that is most associated with the influential 1960s programming language, Algol-60. In call-by-name, the actual arguments are substituted in the macro body in all places where the corresponding formal parameters appear. Although this sounds exactly like call-by-macro expansion, which is used in C (and also C++), the important difference is that the substitution is not textual. Rather, it is *capture avoiding*, meaning that care is taken to ensure that actual arguments and local function variables that have identical names are treated differently. For instance, if the actual argument is `arr[ idx]` and the function also contains a local variable named `idx`, when `arr[ idx]` is substituted for all occurrences of the formal parameter, `idx` represents the variable in the caller's context, rather than the local variable named `idx` in the function. This is done using a structure known as a *thunk*.

Call-by-name has two desirable properties. First, if an actual argument is not actually needed in the function, it is not evaluated. Here is a simple example:

```
int foo( bool cond, int x, int y )
{
    if( cond )
        return x;
    else
        return y;
}
```

Consider either of the following calls: `foo(true,u,1/u)` or `foo(false,loop(u),bar(u))`. In the first call, if u is 0, the C parameter passing mechanism, which is call-by-value, will cause a divide-by-zero error. But using call-by-name, because the formal parameter y is never needed, no divide-by-zero will occur. In the second case, if function `loop` is nonterminating, if call-by-value is used, then `foo` never finishes (actually it never starts). With call-by-name, `loop` is never called. This process makes it easier to prove program properties mathematically.

The second desirable property is that it allows functions to be passed as parameters via a mechanism known as *Jensen's device*. The classic Algol example is given by the following Algol code:

```
real procedure SIGMA(x, i, n);
   value n;
   real x; integer i, n;
begin
   real s;
   s := 0;
   for i := 1 step 1 until n do
      s := s + x;
   SIGMA := s;
end
```

To find the sum of the first 15 cubes, we can call `SIGMA(i*i*i,i,15)`. In this call, formal parameter x is replaced with `i*i*i`.

Unfortunately, call by name has some significant problems. First, it can be challenging to write even seemingly simple routines like `swap`, because of the potential of calls such as `swap(v,arr[ v])`. With call-by-name, once v is changed in the `swap` routine, it will be impossible to change the correct element in `arr`. Second, the implementation of thunks is somewhat cumbersome. And third, actual arguments are reevaluated every time the corresponding formal parameter is used, which can be very inefficient. Consequently, although Algol 60 was itself an extremely influential language, and introduced call-by-value parameter passing which is still used today, call-by-name parameter passing has not stood the test of time, and is mostly of historical interest.

Call-by-Need

Call-by-need is like call-by-name, except that when an actual argument is evaluated, its value is saved, in a process called *memoization*. If the formal parameter reappears, rather than reevaluating the actual argument, the saved value is used. In imperative languages, such as all of the languages described earlier in this article, this strategy does not work, because the value of the actual argument could change because of side effects. However, in purely functional languages, with no effects, call-by-need produces the same results as call-by-name, with each actual argument evaluated at most once (and sometimes not at all). In addition, routines such as swapping are not expressible anyway, and thus call-by-need can be practical, and is in fact implemented in some functional languages, most notably *Haskell*.

SUMMARY

Although parameter passing seems like a simple topic, in reality, many options and subtleties can emerge. One appeal of functional languages is the relatively simple syntax involved in parameter passing. C and Java limit parameter passing to call-by-value and have standard workarounds to allow call-by-reference to be simulated, and to pass functions. Ada's parameter passing is nice because it distinguishes between the mode (in, out, or in out) rather than the underlying implementation used to achieve the effect. C++ has the most complex parameter passing mechanisms, including the unfortunate requirement for the programmer to choose between call-by-value and call-by-reference to a constant. C# parameter passing blends features from Java, Ada, and C++, combining the best features.

PROGRAM TRANSFORMATION: WHAT, HOW, AND WHY

WHAT: THE MANIPULATION OF COMPLEX VALUES

A typical computer program consists of a sequence of instructions that manipulate values belonging to a variety of *simple* data types. In this context, a data type is considered to be simple if its values have a simple syntactic structure. Integers, reals, Booleans, strings, and characters are all examples of simple data types. In contrast, when viewed as a value, the sequence of characters that make up a program written in a high-level language such as Java or C++ can be seen as having a highly complex syntactic structure.

Informally speaking, a good litmus test for determining whether a particular value is simple is to consider the complexity of user-defined methods capable of reading in such a value from a file, storing this value internally within a program, and writing this value to a file. Thinking along these lines reveals that typical computer languages provide input/output (I/O) support for simple types (e.g., getc, read, input1, inputN, put, print, and write) as well as primitive support for basic operations on these types (e.g., equality comparison, relational comparisons, addition, and subtraction).

A similar level of support is generally not provided for values having syntactic structures that cannot be directly modeled in terms of simple values. Thus, as the structure of the data becomes more complex, a greater burden is placed on the programmer to develop methods capable of performing desired operations (e.g., I/O, equality comparison, internal representation, and general manipulations). In the limit, the techniques employed for structure recognition include the development of domain-specific parsers, reuse of general-purpose context-free parsers such as LL, LALR, LR parsers (1), and even state-of-the-art parsers such as Scannerless Generalized LR (SGLR) parsers (2,3). The values constructed by these tools are typically output using sophisticated algorithms such as abstract pretty printers (4,5).

Parsers such as LL, LALR, LR, and SGLR parsers all ultimately make use of powerful parsing algorithms for recognizing the structure of a sequence of symbols. From a theoretical perspective, these parsing algorithms are capable of recognizing the class of languages known as context-free languages. This class of languages is interesting because it represents the most complex class that can be efficiently recognized by a computer using general-purpose algorithms. The syntactic structure of modern programming languages typically fall in the class of context-free languages or slight variations thereof (6).

Figure 1 gives an example of an extended-BNF grammar fragment describing the syntactic structure of a simple imperative language we will call *Imp*. The directives *%LEFT_ASSOC ID* and *%PREC ID* are used to declare and assign precedence and associativity to operations and productions in the grammar (for more on precedence and associativity, see Ref. 1). These assignments allow portions of the grammar that would otherwise be ambiguous to be uniquely parsed. Informally summarized, the language described by the grammar fragment defines an *Imp* program as consisting of a single block containing a statement list. In turn, a statement list consists of zero or more labeled statements. A label may be optionally associated with a statement. A statement can either be a block, one of three different kinds of "if" statements, a "while" loop, an assignment, a "goto" statment, or a statement called "skip" whose execution does nothing (i.e., "skip" is a no-op). Programs written in this language can be parsed using an LALR parser that has been extended with associativity and precedence.

As a result of their context-free roots, the structure of character sequences corresponding to typical computer programs can be modeled in terms of a tree structure (also known as a term structure). Tree structures come in two basic flavors: parse trees, which literally reflect the structure described by the context-free grammar used to define the programming language, or abstract syntax trees, which capture the essence of the structure described by the context-free grammar (for more on extended-BNF grammars and abstract syntax, see Ref. 7). More compact internal representations such as directed acyclic graphs (DAGs) are also possible; but a discussion of these representations lies beyond the scope of this article.

HOW: EQUATIONAL REASONING – THE ESSENCE OF PROGRAM TRANSFORMATION

Program transformation concerns itself with the manipulation of programs. Conceptually speaking, a (program) transformation system accepts a *source program* as its input data and produces a transformed program known as a *target program* as its output data. Thus, a transformation system treats programs in much the same way that traditional programs treat simple data. In general, systems that share this view of programs-as-data are called *meta-programming systems*. A compiler is a classic example of a meta-programming system.

In spirit, the goal in program transformation is to manipulate programs using techniques similar to the techniques used by mathematicians when they manipulate expressions. For example, in mathematics, the expression $x \wedge true$ can be simplified to x. Similarly in Java, the sequence of assignments $x = 5; x = x$ can be simplified to

Figure 1. A grammar fragment of a simple imperative language called Imp.

the single assignment $x = 5$. In Boolean algebra, the expression $e1 \vee e2$ is equivalent to $e2 \vee e1$ for any arbitrary Boolean expressions $e1$ and $e2$. However, in Java, Boolean expressions are conditionally evaluated[1] and, as a result, $e1 \| e2$ is not equivalent to $e2 \| e1$ (consider the evaluation of the Boolean expression $true \| 4/0 < 5$). On the other hand, in Java, a conditional statement of the form *if (BE) stmt*$_1$; *else stmt*$_2$; is equivalent to *if (!(BE)) stmt*$_2$; *else stmt*$_1$; for any Java Boolean expression *BE* and Java statements *stmt*$_1$ and *stmt*$_2$. Having seen a few examples of manipulation, let us take a more detailed look at how mathematical expressions can be manipulated in general through a process known as *equational reasoning*.

Equational Reasoning: A Technique for Mathematical Manipulation

In mathematics, there are axioms (i.e., laws) and theorems stating how expressions of a certain type (e.g., Boolean expressions) can be manipulated. Axioms and theorems are oftentimes given in the form of equations relating two syntactically distinct expressions. Figure 2 gives a standard set of axioms defining a Boolean algebra.

The axioms for Boolean algebra provide us with the basis for manipulating Boolean expressions. In mathematics, when manipulating a mathematical expression, a common goal is the *simplification* of that expression. In math classes, problems are often given in which the goal is to simplify an expression until it can be simplified no further. This activity is referred to as *solving* the expression, and the simplified form of the expression is called the *answer*. In the context of equational reasoning, such an *answer* is called a *normal form*. For example, the *normal form* of $7 * 7 + 1$ is 50. In this article, we will use the terms *rewriting* and *simplification* interchangeably.

In addition to expression simplification, in mathematics, one is also interested in knowing whether one expression is equal to another expression. This activity is known as *theorem proving*. Theorems have the general form: $e1 = e2$ *if cond*, where *cond* defines the conditions under which $e1 = e2$ holds. In the degenerative case, where $e1 = e2$ always holds, one may drop the conditional portion and simply write the theorem as $e1 = e2$.

Suppose that one is interested in knowing whether $or(b, b) = b$ is a theorem, where $or(b, b)$ is the prefix form of the Boolean expression $b \vee b$. How does one go about proving such a theorem? One approach for proving a theorem of the form $e1 = e2$ is to separately try to *rewrite* $e1$ and $e2$ into their normal forms and then compare the results. A variation of this idea is to pick whichever term $e1$ or $e2$ is more complex and rewrite it in the hopes that it can be simplified to the other term. Having said that, we will view the proof of $or(b, b) = b$ in terms of a simplification problem. In particular, we are interested in rewriting the expression $or(b, b)$ to b, which conveniently already happens to be in its normal form, thereby proving the theorem $or(b, b) = b$. The proof of $or(b, b) = b$ is shown in Fig. 3. An important thing to note about the sequence of "simplifications" that are applied to $or(b, b)$ is that they are anything but simple. It turns out that, in the context of first order logic, there is no universal definition for the notion of *simplification* that can be used to prove all theorems. Indeed, it is well known that theorem proving in the realm of first-order logic is, in fact, undecidable. The implications of this observation is that the complete automation of Boolean simplification is not realistic.

Operationally, the simplifications shown in Fig. 3 are accomplished through a process known as *equational reasoning*, which is based on equational logic (8). Informally

[1] This form of evaluation is also referred to as short-circuiting.

Commutativity

$$or(x, y) = or(y, x)$$
$$and(x, y) = and(y, x)$$

Identity

$$or(x, false) = x$$
$$and(x, true) = x$$

Distributivity

$$or(x, and(y, z)) = and(or(x, y), or(x, z))$$
$$and(x, or(y, z)) = or(and(x, y), and(x, z))$$

Complement

$$or(x, not(x)) = true$$
$$and(x, not(x)) = false$$

Figure 2. The standard axioms for a Boolean algebra.

stated, equational reasoning is the notion that "equals may be substituted for equals"(8). The axioms of Boolean algebra shown in Fig. 2 provide us with an initial set of equal quantities in the form of equations, and it is instances of these axioms that are used in the proof shown in Fig. 3.

Equational reasoning is a cornerstone of mathematics and is an indispensable tool at the mathematician's disposal when it comes to reasoning about expressions. In theory, the concepts and mechanisms underlying equational reasoning should also be adaptable to reason about and manipulate programs. Just as in mathematics, in computer science there are axioms and theorems stating how program structures belonging to a given language relate to one another. Realizing this fact, our original definition of *program transformation* can be refined as follows:

> *Program transformation involves the discovery and development of suitable axioms and theorems and their application to programs in accordance with the laws of equational logic to achieve a particular goal.*

The Mechanism of Equational Reasoning

In order to consider manipulating programs in the way mathematicians manipulate expressions, it is helpful to first analyze and abstract the techniques and concepts underlying equational reasoning. In addition, we are interested in knowing the extent to which various techniques and processes can be automated. Ideally, we are aiming for a fully automated system that, when presented with a program and a goal (e.g., simplification), will produce an output program satisfying that goal.

Variables and Matching. In equational reasoning, the *variable* plays an important role. For example, the axioms in Fig. 2 make use of the variables x, y, and z. Variables allow equations to be written that capture general relationships between expression structures. *Matching* (8) is an activity involving variables that is very important in equational reasoning. Let *e* denote an expression we are interested in manipulating, and let $e1 = e2$ denote the equation we are considering using to manipulate *e*. Matching allows us to determine whether *e* is an instance of e_1 or e_2. For example, in the proof in Fig. 3 it is possible to rewrite *or*(*b, b*) to *and*(*or*(*b, b*), *true*) using the equation *and*(*x, true*) $=$ *x* and realizing that *or*(*b, b*) is an instance of *x* (i.e., the variable *x* can denote a quantity like *or*(*b, b*)). Similarly, it is possible to rewrite the expression *or*(*b, and*(*b, not*(*b*))) to *or*(*b, false*) by using the equation *and*(*x, not*(*x*)) $=$ *false* and realizing that the subexpression *and*(*b, not*(b)) is an instance of *and*(*x, not*(*x*)).

Let *e* denote an expression that may contain one or more variables and let *t* denote an expression containing no variables. We will write $e \ll t$ to denote the attempt to *match* *e* with *t*. We will refer to $e \ll t$ as a *match equation*. A match equation is a Boolean-valued test that either succeeds, or fails. If a match equation succeeds, then it means that *t* is an instance of *e*, which more specifically means that there exist values that when substituted for the variables in *e* will produce the expression *t*. For example, if we substitute *b* for *x* in the expression *and*(*x, not*(*x*)), we get *and*(*b, not*(*b*)), thus *and*(*x, not*(*x*)) $\ll$ *and*(*b, not*(*b*)) succeeds under the substitution $x \mapsto b$. Substitutions are abstractly denoted by the symbol σ. The act of replacing the variables in an expression *e* as defined by is known as *applying* the substitution σ to *e* and is written $\sigma(e)$.

Matching-related concepts have been heavily researched. Under suitable conditions, it is appropriate to use more powerful algorithms to construct an expression that is an instance of two other expressions. These algorithms include *unification* (9), *AC-matching* (10), *AC-unification* (11), and even *higher-order unification and matching* (12).

Equation Orientation, Confluence, and Termination. Given an expression *t*, a crucial aspect of equational reasoning is how one makes the decision regarding which equation should be used to simplify *t* or one of its subexpressions. In the realm of rewriting, the complexity of the decision-making process has been simplified by orienting equations. For example, instead of writing $e_1 = e_2$, one would write $e_1 \rightarrow e_2$. An oriented equation of the form $e_1 \rightarrow e_2$ is called a *rewrite rule*. The orientation $e_1 \rightarrow e_2$ constrains the equational reasoning process to the replacement of instances of e_1 by instances of e_2 and not the other way around[2].

Orienting equations into rewrite rules greatly simplifies the task of deciding which rewrite rule should be applied to a given term. However, equation orientation does not eliminate the decision altogether. In general, expressions still exist to which two or more competing rules apply (see the next subsection for more details on rule application). Under such conditions, we say that the rules *interfere* with one another. The simplest example of a pair of interfering rules are two rewrite rules having identical left-hand sides (e.g., $e_1 \rightarrow e_2$ and $e_1 \rightarrow e_3$). Ideally, we would like to have a set of rules that do not interfere with each other, or at least know that if rules do interfere with one another the interference somehow does not matter. A consequence of the notion of "interference not mattering" is that the normal form for an

[2] A discussion of the techniques used to decide how equations should be oriented lies beyond the scope of this article.

$or(b, b)$	Given
$and(or(b, b), true)$	*Identity*: $x \rightarrow and(x, true)$ where x is $or(b, b)$
$and(or(b, b), or(b, not(b)))$	*Complement*: $true \rightarrow or(x, not(x))$ where x is b
$or(b, and(b, not(b)))$	*Distributivity*: $and(or(x, y), or(x, z)) \rightarrow or(x, and(y, z))$ where x is b, y is b and z is $not(b)$
$or(b, false)$	*Compliment*: $and(x, not(x)) \rightarrow false$ where x is b
b	*Identity*: $or(x, false) \rightarrow x$ where x is b

Figure 3. An example of axiom-based manipulations of Boolean expressions.

expression, when it exists, must be unique. In general, rule sets having the property of "interference not mattering" are said to be *confluent* or equivalently *Church–Rosser* (8,13). Formally, the *Church–Rosser* property is defined as $e_1 \overset{*}{\leftrightarrow} e_2 \Rightarrow e_1 \downarrow e_2$. Informally, this property means that expressions that are equal can always be *joined* through the application of rewrite rules (i.e., oriented equations) in the (Church–Rosser) rule set. In other words, given a rule set R, we say that two expressions can be *joined* if they both can be rewritten to the same expression using only the rewrite rules found in R.

An important result concerning the confluence/Church–Rosser property is that it is possible to mechanically check whether a rule set possesses this property. It is also possible in certain cases to convert a rule set that is not confluent into an equivalent rule set that is confluent (8).

Confluence is a highly desirable property for a rule sets to possess because it implies that the decision of which order rules should be applied during the course of an equational reasoning session is immaterial. Thus, the algorithm driving the equational reasoning process is trivial, one simply applies rules where ever and whenever possible secure in the knowledge that the rewriting process will always arrive at the same *normal form*, when it exists.

When does a normal form not exist? Given a confluent rule set, the only circumstances under which a normal form does not exist is if the rule set is nonterminating. For example, consider the rule set consisting of the single rule $x \rightarrow f(x)$. This rule set is trivially confluent but is nonterminating and therefore produces no normal forms. Using this rule set to "simplify" the expression b will yield the nonterminating sequence of rewrites $b \rightarrow f(b) \rightarrow f(f(b))) \rightarrow \ldots$. A rule set is said to be *terminating* if every simplification sequence eventually produces a normal form. The combination of confluence and termination let us conclude that all expressions have a normal form and that their normal forms are unique.

In general, the problem of showing that a rule set is terminating is undecidable. However, in practice one can often show that a particular rule set is terminating. As a result of the highly desirable properties of rule sets that are confluent and terminating, the termination problem is a heavily researched area in the field of rewriting (8).

Rule Extensions and Application. The basic notion of a rewrite rule can be extended in two important ways. The first extension allows a label to be associated with a basic rewrite rule. The result is called a *labeled rewrite rule*. Labeled rewrite rules typically have the form *label*: $lhs \rightarrow rhs$, where lhs and rhs are expressions. A transformation system supporting labeled rewrite rules allows the option of labeling rewrite rules and treats a reference to a label as a shorthand for a reference to the rule.

In the second extension, a labeled rewrite rule can be extended with a condition. The result is called a *labeled conditional rewrite rule*. Conditions can take on a number of forms, but all ultimately can be understood as a Boolean condition that enables or prohibits a rewrite rule from being applied. Consider the rule $x/x \rightarrow 1$ *if* $x \neq 0$. In this article, a labeled conditional rewrite rule has the form *label*: $lhs \rightarrow rhs$ *if condition*. We will also only consider a restricted form of condition consisting of Boolean expressions involving *match equations* as defined in the variables and matching subsection.

Let r denote an arbitrary rewrite rule and let e denote an expression. If r is used as the basis for performing a manipulation of e, we say that r is applied to e, which is what we mean when we say *rule application*. More specifically, when using a conditional rewrite rule of the form $lhs \rightarrow rhs$ *if cond* to simplify an expression t, one first evaluates the Boolean expression $lhs \ll t \wedge cond$. If this Boolean expression evaluates to *true* and produces the substitution σ, then t is *rewritten* to rhs', where $rhs' = \sigma(rhs)$ is the instance of rhs obtained by applying the substitution σ to the expression rhs.

Program Fragments as "Expressions". Thus far, we have given an overview of the mechanisms underpinning rewriting. However, we have not said much about notations for describing expressions. When manipulating Boolean expressions, the choice of notation is fairly straightforward. One can, for example, write a Boolean expression in infix form $e_1 \vee e_2$ or in prefix form $or(e_1, e_2)$. How do these ideas translate to program structures? One possibility is to express code fragments in prefix form. However, there are some disadvantages to such an approach. One disadvantage is that there is some notational complexity associated with prefix forms because it is not how we write programs in general. This conceptual gap holds in the realm of Boolean algebra as well. For example, most readers will probably find $x \vee y \wedge z$ to be more readable than $or(x, and(y, z))$. This problem is amplified as the complexity of the structure expressed increases (and code fragments can have a complex structure). To address the comprehensibility problem, we will express code fragments in an infix form that we call a *parse expression* (14,15). A parse expression is essentially a shorthand for a parse tree and assumes that the syntax of the programming language has been defined by an extended-BNF. In general, a parse expression has the form $B[\![\alpha']\!]$, where B is a nonterminal in the gram-

Figure 4. Rewrite rules capable of transforming Imp source programs into equivalent target programs.

mar and the derivation $B \overset{+}{\Rightarrow} \alpha$ is possible. The difference between α as it occurs in the derivation and α' as it occurs in the parse expression is that in α' all nonterminal symbols have been subscripted, making them *variables*. In particular, when we say *variable* we mean a symbol that can participate in matching as described.

Let us consider the grammar fragment for Imp shown in Fig. 1. The parse expression $\mathit{assign}\llbracket \mathit{id}_1 = E_1\rrbracket$ denotes a parse tree whose root is the nonterminal *assign* and whose leaves are id_1, $=$, and E_1. As id_1 and E_1 are variables, this parse expression denotes the most general form of an assignment statement. The expression $\mathit{assign}\llbracket \mathit{id}_1 = E_1\ \mathit{op}_1\ E_2\rrbracket$ denotes a less general form of an assignment in which an identifier id_1 is bound to an expression $E_1\, \mathit{op}_1\, E_2$, that is, an expression containing a least one binary operator.

Matching works for parse expressions just as would be expected. For example, the match equation $\mathit{assign}\llbracket \mathit{id}_1 = E_1\rrbracket \ll \mathit{assign}\llbracket x = 5 + 4\rrbracket$ succeeds with the substitution $\mathit{id}_1 \mapsto \mathit{id}\llbracket x\rrbracket$ and $E_1 \mapsto E\llbracket 5 + 4\rrbracket$. Similarly, the match equation $\mathit{assign}\llbracket \mathit{id}_1 = E_1\ \mathit{op}_1\ E_2\rrbracket \ll \mathit{assign}\llbracket x = 5 + 4\rrbracket$ also succeeds with the substitution $\mathit{id}_1 \mapsto \mathit{id}\llbracket x\rrbracket, E_1 \mapsto E\llbracket 5\rrbracket$, and $E_2 \mapsto E\llbracket 4\rrbracket$. We are now ready to look at a more concrete example of program transformation.

Example: A Pseudo-Compiler for Imp

A compiler takes a source program as input and produces an assembly program as output. As such, a compiler is a meta-programming system. In this section, we look at an example of how an Imp program can be partially compiled via rewriting. The goal in our example is to take an Imp *source program* and transform it into an Imp *target program*. We claim, without proof, that the rewrite rules presented for accomplishing this goal are both confluent and terminating. The normal form of an Imp *source program* is an Imp *target program*, and it can be obtained by the exhaustive application of the labeled conditional rewrite rules shown in Fig. 4.

In order to be considered a *target program*, an Imp program should satisfy the following properties:

- All expressions in the target program should be *simple expressions*. An expression is a *simple expression* if it satisfies one of the following properties: (1) the expression consists solely of a base value (i.e., either an integer or an identifier), (2) the expression consists of a binary operation involving two base values (e.g., $15 + 27$), or (3) the expression consists of a unary operation on a base value (e.g., $!(x)$). All other expressions are not simple.
- A target program may contain no "*while*" *loops*.

[3] The ability to generate a *new* identifier name is supported by most program transformation systems.

$\boxed{x = 3 + 4}$ $\Longrightarrow$

```
LOAD 3, R1
LOAD 4, R2
ADD R1, R2, R3
STORE R3, x
```

Figure 5. An example of how an assignment statement in an Imp target program can be transformed into a sequence of assembly instructions.

- A target program may contain no *"if-then"* or *"if-then-else"* statements, which makes the *"if" statement* the only remaining conditional construct.
- The Boolean expression associated with the *"if" statement* must be an identifier (e.g., it may not be an expression of the form e1 *op* e2).

As a result of their simple structure, Imp target programs are similar to assembly programs. In fact, Imp target programs are just one step away from assembly programs and can be transformed into assembly programs on a statement by statement basis. Figure 5 gives an example of how an assignment statement can be directly transformed into a sequence of assembly instructions.

We hope the reader is convinced by this concrete example that the bulk of the general transformation from Imp target programs to assembly code is straightforward. Thus, we return our attention to the problem of transforming Imp source programs into Imp target programs.

Figure 6 shows an Imp source program and the target program that is obtained after applying the labeled conditional rewrite rules given in Fig. 4. In Fig. 4, the rewrite rules *assign_simplify1*, *assign_simplify2*, and *assign_simplify3* collectively account for the three cases that need to be considered when simplifying an expression in the context of an assignment statement. The rule *assign_simplify1* is a conditional rule that removes (unnecessary) outermost parenthesis from an expression. The rule *assign_simplify2* transforms the assignment of an identifier to a negated expression into a sequence of two assignment statements, provided the negated expression is not a base value. For example, the assignment $x = !(3 < 4)$ will be transformed to $x\_1 = 3 < 4; x = !(x\_1)$, where x_1 is a *new* identifier. Notice that to carry out this kind of manipulation, one must have the ability to generate a *new* (heretofore unused) identifier. In the rewrite rules shown, this functionality is realized by the function *new*, which we do not discuss further in this article[3]. And lastly, note that without the conditional check $\neg\,(E_1 \ll E[\![base_1]\!])$, the rule *assign_simplify2* would be nonterminating.

The rule *assign_simplify3* transforms an assignment statement containing a nonsimple expression (e.g., an expression containing two or more binary operators) into a sequence of three assignment statements. For example, the assignment $x = 4 + 5 * 6 * 7$ would be rewritten into the assignment sequence $x\_1 = 4$; $x\_2 = 5 * 6 * 7; x = x\_1 + x\_2$. Notice that the assignment $x\_2 = 5 * 6 * 7$ still contains a complex expression and will again be simplified by the *assign_simplify3* rule. In the rule *assign_simplify3*, the parse expression $stmt\_list[\![id_1 = E_2\, op_1 E_3; stmt\_list_1]\!]$ denotes a statement list whose first statement is the assignment of the form $id_1 = E_2\, op_1\, E_3$. Analysis of the problem shows that matching this structure is a necessary but not sufficient condition to ensure that an expression is not simple. In order for an expression to be not simple, it must also not be the case that both E_2 and E_3 are *base* structures. Formally, this property is captured in the conditional portion of *assign_simplify3* by the Boolean expression $\neg\,(E_2 \ll E[\![base_2]\!] \wedge E_3 \ll E[\![base_3]\!])$. The remaining portion of the condition $id_2 \ll new \wedge id_3 \ll new$ is

```
{
  x = 27;
  while x! = 1 do {
    if x mod 2 == 0 then { x = x div 2;}
    else { x = 3 * x + 1; };
}
```

$\Longrightarrow$

```
{  x = 27;
   skip;
   L_1 : x_8 = x != 1;
   y_3 = !( x_8 );
   if y_3 goto L_2;
   {  x_11 = x mod 2;
      x_12 = 0;
      x_10 = x_11 == x_12;
      y_9 = !( x_10 );
      if y_9 goto L_4;
      { x = x div 2; };
      goto L_5;
      L_4 : {
         x_6 = 3 * x;
         x_7 = 1;
         x = x_6 + x_7;
      };
      L_5 : skip;
   };
   goto L_1;
   L_2 : skip;
}
```

Figure 6. An Imp source program and an equivalent Imp target program.

responsible for binding the variables id_2 and id_3 to *new* identifier names (e.g., $id_2 \mapsto id[\![x\_1]\!]$).

The remaining rules in Fig. 4 make use of notational constructs similar to those we have just discussed. The rules *jump1*, *jump2*, and *jump3* are respectively responsible for rewriting "*if-then*" statements, "*if-then-else*" statements, and "*while*" loops into equivalent sequences consisting of "*if-statements*", *labels*, "*goto*" statements, and "*skip*" statements. Here, the "*skip*" statement is used to provide a point, beyond a given block, to which a "goto" can jump. In many cases, additional optimizing transformations can be applied to remove unneeded "skip" statements. However, the "*skip*" statement cannot be removed entirely (consider the case where the last portion of a program is a block that one wants to jump over).

And lastly, the *simplify_if* rule makes sure that the Boolean condition associated with an "*if*" *statement* consists of a base value.

Program Transformation Frameworks

The Equation orientation, confluence, and termination subsection mentioned that confluence and termination are highly desirable properties for rule sets because the problem of deciding which rule to apply then becomes immaterial. Unfortunately, when transforming programs it is often the case that rewrite rules are created that are neither confluent nor terminating and cannot be made so. Under these conditions, if transformation is to succeed, explicit control must be exercised over when, where, and how often rules are applied within a term structure. A specification of such control is referred to as a *strategy*, and systems that provide users with constructs for specifying control are known as *strategic programming systems*.

The control mechanisms in a strategic programming system fall into two broad categories: *combinators* and *traversals*. The computational unit in a rewrite system is the *rewrite rule*. Similarly, the computational unit in a strategic programming system is the *strategy*. A strategy can be inductively defined as follows:

- A rewrite rule is a strategy.
- A well-formed expression consisting of strategies, combinators, and traversals is a strategy.

Of central importance to a framework exercising explicit control over the application of rules is the ability to observe the outcome of the application of a rule to a term. Specifically, to exercise control, a system needs to be able to answer the question "Did the application of rule *r* to term *t* *succeed* or *fail*?" In summary then, a strategic programming system can be thought of as a rewriting system that has been extended with mechanisms for explicitly controlling the application of rules where the notion of *failure* plays a central role.

Strategic Combinators. A *combinator* is an operator (generally unary or binary) that can be used to compose one or more *strategies* into a new *strategy*. Let s_1 and s_2 denote two strategies. Typical combinators include

- *sequential composition* denoted $s_1; s_2$. The application of $s_1; s_2$ to a term t will first apply s_1 to t and then apply s_2 to the result.
- *left-biased choice* denoted $s_1 <+ s_2$. When applied to a term t, the strategy $s_1 <+ s_2$ will first try to apply s_1 to t; if that succeeds and produces the result t', then t' is the result of applying $s_1 <+ s_2$ to t. Otherwise, s_2 is applied to t. If this application succeeds and produces t'' as it's result, then t'' is the result of applying $s_1 <+ s_2$. However, if the application of s_2 to t fails, then the application of $s_1 <+ s_2$ is said to fail.
- *right-biased choice* denoted $s_1 +> s_2$. The strategy $s_1 +> s_2$ is equivalent to $s_2 <+ s_1$.
- *nondeterministic choice* denoted $s_1 + s_2$. If both s_1 and s_2 can be applied to a term t, then s_1 or s_2 is nondeterministically chosen and applied to t. If only one strategy can be applied, that strategy is selected, and if both strategies do not apply, then the application of $s_1 + s_2$ to the term t fails.

Traversals. The combinators described in the previous subsection provide the ability to discriminate and sequence the application of strategies to a term. When a strategy contains a combinator, the application of that strategy to a term is defined with respect to the structure of the strategy, irrespective of the structure of the term. In contrast, a *traversal* focuses on the structure of the term, but does not consider the structure of the strategy. Broadly speaking, a traversal specifies the order in which a term and its subterms are visited. Thus, a traversal can be understood as a mechanism for sequencing term structures. Typically, when a term is visited, some action is performed like the application of a strategy to the term.

Some traversals capture sequencing notions that are broadly applicable across a wide range of applications. Such traversals are called *generic traversals*. A typical and very useful generic traversal is one that performs a top-down left-to-right traversal of a tree structure and uniformly applies a given strategy to all subtrees encountered. Another generic traversal is one that performs a bottom-up left-to-right traversal of a tree structure. And a third generic traversal is one in which the traversal is stopped after the first successful application of a given strategy. Other generic traversals have been identified in the literature (14,16,17).

In some cases, the notion of generic traversal has direct analogies with traditional models of computation. For example, a top-down (outside-in) approach to evaluation corresponds to a lazy evaluation style where functions are applied to arguments without (first) evaluating the arguments.

In contrast, a bottom-up (inside-out) approach corresponds to a strict evaluation where the arguments to functions are evaluated before functions are applied.

Strategic Frameworks. In addition to the combinators and traversals, strategic programming frameworks may contain a variety of additional features. These features can include (1) the ability to create rewrite rules and strategies dynamically (14,15,18), (2) the ability to define strategy application via *congruences*(16,19), and (3) constructs that allow user-defined generic traversals to be created (14,18).

ELAN (16), TL (14), the ρ-calculus (14), the S'_{γ}-calculus, and Stratego (20) are examples of strategic programming frameworks. Of these frameworks, ELAN and Stratego have implementations, and a dialect of TL is implemented in a system called HATS (21).

WHY: APPLICATIONS

Abstractly, a program transformation system can be viewed as a system that transforms a *source program* into a *target program*. In Ref. 22, an excellent overview is given of a wide variety of software-related activities that can be approached from a transformation-oriented perspective. Activities are broadly classified as either belonging to the category of *rephrasing* or *translation*. In this section, we present a taxonomy similar to the one given in Ref. 22, but with a greater emphasis placed on semantics. In particular, our taxonomy is motivated by the relationship between the semantic models necessary to understand the source and target programs. Within this classification system, we identify seven major bi-directional goals of program transformation:

- *Clarity*. This goal focuses on separation and encapsulation of functional and behavioral concerns.
- *Efficiency*. This goal focuses on changing the resource usage of an executing program. Resources of primary concern are time and space.
- *Computability*. This goal focuses on the translation between noncomputable and computable program representations. Technically speaking, the goal of a compiler is to take a source program that cannot be directly executed on a computer and translate it into a target program that can be executed on a computer. In most cases, this goal involves moving between semantic models at two different levels of abstraction.
- *Simplicity*. This goal focuses on transforming a source program to a target program where the semantic model for the source program is either a subset or superset of the semantic model of the target program.
- *Functionality*. This goal focuses on changing the functional behavior of the source program. The semantic model for the source and target program are the same.
- *Translation*. This goal focuses on transforming a source program into an equivalent target program having a different syntax and generally a different semantic model. Here, both semantic models are roughly at the same level of abstraction.
- *Computation*. This goal focuses on using transformations to perform computations, that is, one is interested in some form of evaluation of a program or expression.

Transformations that Shift between Semantic Models

Compilation is a classic example of a fully automatic transformation whose source and target programs are understood with respect to different semantic models. The goal is *computability*. Source programs define computations that are typically understood in terms of semantic models containing high-level concepts such as variables, data structures, and recursion whereas target programs define computations that are understood in terms of semantic models consisting of registers, memory locations, bytes, and bits.

Synthesis and *refinement* are two examples of activities in which source programs having specification-like characteristics are transformed into executable implementations. The goal is *computability*. Transformations in this realm are typically not fully automatic (otherwise they would be called compilers) and require some form of attention on a per problem basis. Specification languages can, and oftentimes do, make use of constructs that are not computable. Thus, the semantic shift between source and target programs can be dramatic.

Migration is an activity in which a program written in one language is transformed into an equivalent program written in another language where both the source and target languages are roughly at the same level of abstraction (e.g., C++ and Java). The goal is *translation*. Such transformation can involve subtle shifts in semantic models. For example, the expression $(x{+}{+}){+}x$ has a precise semantics in Java and is, technically speaking, undefined C++.

Aspect-oriented programming is a paradigm in which cross cutting aspects of software are defined separately (23,24). These aspects are then *woven* into a base program that can then be compiled and executed in a traditional fashion. The *weaving* of aspects into a program is typically approached from a transformation-oriented perspective. The goal in *weaving* is *translation*.

Transformations that Remain within a Single Semantic Model

In *partial evaluation* (25), knowledge that a general-purpose source program will be used in a context where one or more of its inputs are fixed is used as the basis for transformation. The goal is *computability*. In particular, the target program produced is one in which all computations that can be performed statically have been carried out, which oftentimes results in a dramatic improvement in the efficiency of the resulting program.

Desugaring is an activity in which the goal of transformation is *simplification*. In desugaring, the target program that is produced belongs to a language that is a strict subset of the language of the source program. The pseudo-compiler example given earlier is an example of a desugaring transformation.

Renovation is an activity focusing on altering the behavior of a software system that is currently in use. The goal is *functionality*. The need for *renovation* is driven by changing requirements that are placed on the software.

Program *optimization* is a highly researched area in computer science. The goal in optimization is *efficiency*. Optimizations can occur at a variety of abstraction levels. A classic example can be found in Ref. 26 where an exponential algorithm for calculating Fibonacci numbers is transformed into a linear time algorithm. Well-known optimizations include constant propagation, constant folding, strength reduction, and common subexpressions elimination (1).

In the following sections, we take a more in-depth look at two transformational activities that are, in some sense, at the opposite ends of the conceptual spectrum.

Refactoring. When developing software, it is common to reach a point where some unanticipated structural or functional dependencies make the resulting software architecture difficult to understand or resistant to future modification. When such a point is reached, programming effort needs to be expended to "clean up" the software. *Refactoring* is the term used to describe general techniques and methods that can be used to "clean up" software. More formally stated, the goal of refactoring is to restructure software to make it clearer (e.g., improving its design) while preserving its functionality. In contrast, the goal in *obfuscation* is to make software harder to understand.

Examples of refactoring range from simple to complex and include:

- *Identifier renaming.* The goal of identifier renaming is to give a identifier a new name that more accurately describes its purpose.
- *Method extraction.* The goal of method abstraction is to abstract a sequence of statements into a method.
- *Object-oriented generalization.* The goal of generalization is to identify a collection of classes that share common features (e.g., methods and fields) and to migrate these common features to a super class.
- *Object-oriented specialization.* The goal of object-oriented specialization is to identify a class containing a general abstraction whose realization consists of a number of distinct special cases. When such a class is discovered, a number of subclasses should be generated and each special case should be migrated into its own subclass.

Ideally, refactoring is accomplished by carrying out a sequence of small transformations each of which are so simple that they are "obviously" correctness-preserving. In addition to simplicity, these transformations also should build on one another in a cumulative fashion. Under these circumstances, a sequence of simple transformations can have an overall effect that results in a dramatic refactoring of the program. In many cases, refactoring is subjective activity. As a result, the ideal refactoring system is one that has an interactive dimension to it allowing users to actively participate in the refactoring process. Furthermore, such a system should support an undo operation that allows refactorings to be retracted, thereby allowing a variety of refactoring possibilities to be explored.

William Opdyke's PhD thesis (27) is generally cited as the first major work that extensively looks at software refactoring as an area of research in its own right. However, in spite of this origination, the importance and implications of refactoring were not fully appreciated until popularized by Martin Fowler et al. in a book titled *Refactoring–Improving the Design of Existing Code* (28). Since then, software refactoring has become widespread. A number of tools are available to help software developers perform refactorings. Among these tools are Transmorgrify, Eclipse, RECODER, and RefactorIT. Refactoring has also been identified as an essential component of extreme programming (29).

The Evaluation of λ-expressions. Functional programming languages have their origins in a formalism known as the λ-calculus (30). The syntax of the λ-calculus is extremely simple. The elements of the language of λ-calculus are called λ-expressions or expressions for short. A λ-expression can be a constant, a variable, the application of one λ-expression to another λ-expression, or a λ-abstraction of the form $(\lambda\, id.E)$, where *id* is an identifier and E is a λ-expression.

The λ-calculus is a powerful notation for describing general-purpose computation. In fact, it has been shown that any computable function can be described in terms of a λ-calculus expression. In this framework, computation consists of the evaluation of λ-expressions. The goal in an evaluation is to simplify a λ-expression until it can be simplified no further. If such a point is reached, we say the expression is in its *normal form*.

The manipulation of λ-expressions is governed by the three axioms shown below. The first two axioms make use of an operation that substitutes a value for all free occurrences of a variable within a λ-expression. Let E denote a λ-expression, let x a variable, and let v denote a value (i.e., a λ-expression). The expression $E[x \mapsto v]$ denotes the instance of E that is obtained by replacing all free occurrences of x in E by v. The first and third axioms make use of the ability to determine whether a variable *occurs free* within a λ-expression. The formal definitions of $E[x \mapsto v]$ and *occurs free* are straightforward but lie beyond the scope of this article. For more information, see Ref. 30.

- **Axiom 1.** *Alpha-conversion (variable renaming).* $\lambda x.E \underset{\alpha}{\leftrightarrow} \lambda y.\ E[x \mapsto y]$*provided* y *does not occur free in* E.
- **Axiom 2.** *Beta-conversion (function application).* $(\lambda x.E_1)E_2 \underset{\beta}{\leftrightarrow} E[x \mapsto E_2]$.
- **Axiom 3.** *Eta-conversion (redundant layers of λ-abstraction).* $(\lambda x.F\,x) \underset{\eta}{\leftrightarrow} F$ *provided* x *does not occur free in* F *and* F *is a λ-abstraction.*

The equivalences in these axioms can be oriented from left to right to form corresponding *reductions* or rewrite rules. A λ-expression is simplified by applying reductions until the *normal form* of the expression is reached. When reducing λ-expressions, the workhorses of reduction are the rewrite rules derived from the second and third axioms, and a λ-expression to which these rules can be applied is called a *redex*.

An important corollary to a famous theorem known as the *Church–Rosser Theorem* states that normal forms for λ-expressions are unique (up to variable renaming). Given the knowledge of the uniqueness of normal forms, an interesting question to ask is: "Given a λ-expression E, can the normal form of E be reached by applying reductions in any order to any subexpression of E?" A second *Church–Rosser* theorem states that one is guaranteed to reach the normal form of a λ-expression (if it exists) by always reducing the left-most, outer-most redex, and only applying α-conversion when needed to avoid the *name capture problem* (see Ref. 30 for more on the name capture problem).

SUMMARY AND CONCLUSION

In this article, *program transformation* is defined as a mechanism for manipulating programs (and other software artifacts) having its roots firmly grounded in *equational reasoning*. On an intuitive level, equational reasoning can be thought of as the notion that “equals can be replaced by equals” (3). Formalization of this notion makes use of concepts such as (1) *matching/unification*, (2) *confluence*, and (3) *termination*. The practical adaptation of the ideas underlying equational reasoning to the realm of meta-programming (i.e., program transformation) requires the use of parsing technology to automatically recognize the complex term structures that are typically possessed by computer programs. These term structures can be defined using context-free grammars and can be stored internally by the transformation system as (1) *parse trees*, which directly reflect the structure defined by the grammar; (2) *abstract syntax trees*, which capture the essence of the structure described by the context-free grammar; or even (3) DAGs.

Applications lending themselves to a transformational perspective can be found in numerous areas including: compilation, refactoring, synthesis, refinement, and even computation.

Interest in program transformation is driven by the idea that, through their repeated application, a set of simple rewrite rules can affect a major change in a software artifact. From the perspective of dependability, the explicit nature of transformation exposes the software development process to various forms of analysis that would otherwise not be possible.

RAPID PROTOTYPING

INTRODUCTION: WHY RAPID PROTOTYPING IS NEEDED

Explicit process models for software development have evolved in response to various problems encountered in the development of large, complex software systems. These problems include cost/schedule overruns and the production of systems that do not operate as specified or do not meet customer needs. Process models have converged on rapid prototyping methods to reduce the risks of software misdevelopment.

Before process models were made explicit, software development suffered from chaotic implementation without comprehensive, prior, requirements analysis or design. Formulating requirements that accurately represent the needs of customers is a limiting factor in the success of software, particularly for large systems that serve diversified user communities. Different people have partially overlapping and sometimes contradictory viewpoints on different aspects of the requirements that are associated with their particular job functions. Requirements analysts must create precise, formal models of unfamiliar problems, based on imprecise communication with system stakeholders, each of whom only has a partial understanding of the system requirements. The situation is worse for applications where computers are being introduced for the first time. The new system fundamentally may redefine the job functions of the customers so that the introduction of the system can cause changes in the job functions it is intended to support. The full impact of a proposed software requirement, therefore, can be very difficult to predict and assess.

The accuracy of the transition from fluctuating informal views of the problem to a fixed formal model is fundamentally uncertain. Ideally, we would like to have dynamic formal models that can be adapted easily to changing situations. Reasonably accurate approximate models can be created by using an iterative guess/check/modify cycle that relies on prototype demonstrations and customer feedback to converge to a consensus about the requirements. The purpose of system and software prototyping is to help customers understand and criticize the proposed systems and to explore the possibilities that computer solutions can bring to their problems in a timely and cost effective manner. Measurements of prototypes can reduce uncertainty about the properties of a proposed design before it is implemented and support assessments of suitability, feasibility, performance, relative merits of alternative designs, and impact on stakeholder organizations.

The main incentive for using prototypes is economic: Scale models and prototype versions of most systems are much less expensive to build than the final versions. Prototypes, therefore, should be used to evaluate proposed systems if acceptance by the customer or the feasibility of development is in doubt. As complexity of the proposed system increases, so does the probability of requirements errors creeping into the specification and the cost of implementing the system. Software prototyping is an appropriate tool for increasing the probability of project success and for potentially reducing cost in such situations.

WHAT IS RAPID PROTOTYPING?

A prototype is an executable model of a proposed system that accurately reflects a chosen subset of its properties, such as display formats, functionality, or response times. Prototypes are useful for formulating and validating requirements, resolving technical design issues, and speeding up development of proposed systems. Rapid prototyping refers to the capability to create a prototype with significantly less effort than it takes to produce an implementation for operational use.

RELATION TO THE FINAL SYSTEM

Prototypes can be developed either to be thrown away after producing sought insight or to evolve into the product version of the software. A tradeoff exists between these approaches, where the choice depends on the context of the effort.

A software prototype may not satisfy all constraints on the final version of the system. For example, the prototype may

- provide only a subset of all the required functions,
- be expressed in a more powerful or more flexible language than the final version,
- run on a machine with more resources than the proposed target architecture,
- be less efficient in both time and space than the final version,
- be limited in capacity (databases may be implemented in main memory),
- not include the full facilities for error checking and fault tolerance, and
- not have the same degree of concurrency as the final version.

Such simplifications often are introduced to make the prototype easier and faster to build. To be effective, partial prototypes must have a clearly defined purpose that determines what aspects of the system must be reproduced faithfully and which ones safely can be neglected.

The Throw-Away Approach

The main advantage of the throw-away approach is that it enables the use of special-purpose languages and tools even if they introduce limitations that would not be acceptable in an operational environment or even if they are not capable of expressing and addressing the entire problem. The throw-away approach is most appropriate in the project

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

acquisition phase where the prototype is used to demonstrate the feasibility of a new concept and to convince a potential sponsor to fund a proposed development project.

The main disadvantage of a throw-away prototype is spending implementation effort on code that will not contribute directly to the final product. Also, the temptation exists to skip or abbreviate documentation for throw-away code. This temptation is harmful because the lessons learned from the prototyping effort may be lost if they are not recorded. Lack of documentation and degradation of the initial design simplicity may block the evolution of the prototype before it reaches a form that captures customer needs, with respect to the scope of the prototyping effort.

The Evolutionary-Build Approach

The evolutionary-build approach produces a series of prototypes in which the final version becomes the software product. This approach depends on special tools and techniques because usually it is not possible to put a prototype into production use without significant changes to its implementation to optimize the code and to complete all details. The conceptual models and designs contained in a prototype usually can be used in the final version. Precise specifications for the components of a prototype and clear documentation of its design, therefore, are critical for effective software prototyping, as are tools for transforming and completing designs and implementations.

RELATION TO THE SOFTWARE EVOLUTION PROCESS

Rapid prototyping should be an integral part of the software development and evolution process. Prototyping can reduce the amount of maintenance effort spent on correcting requirements errors after systems have been delivered. However, prototyping requires explicit planning for iterations because the feedback process generally needs several cycles to converge. To keep the process predictable and visible to project managers, schedule and budget for multiple cycles should be arranged at the outset.

RELATION TO SOFTWARE AUTOMATION

To be effective, prototypes must be constructed and modified rapidly, accurately, and inexpensively. They do not have to be efficient, complete, portable, or robust, and they do not have to use the same hardware, system software, or implementation language as the delivered system. The automated construction of programs is needed to support the evolutionary approach to rapid prototyping, and such tools can be very useful in this context even if the resulting programs are not very efficient.

RELATION TO OTHER DEVELOPMENT APPROACHES

Rapid prototyping is related to other development approaches that emphasize customer involvement and iterative development, such as agile programming, rapid application development, and the spiral model. The common theme is using customer feedback to ensure the system will solve the intended problems.

Agile programming is a specialization of incremental development that emphasizes the frequent delivery of working code and intensive communication with customers over detailed documentation and design. Some specific approaches in this category include extreme programming, Scrum, and Crystal. These approaches use deliverable code instead of prototypes to elicit customer feedback and requirements adjustments. They depend on the assumptions that the code can be modified cheaply and reliably and that this process can be done with minimal informal documentation. They work best on a small scale and with availability of intensive involvement of knowledgeable customers. Current agile approaches have relatively little automation support because of the informality of the designs and documentation.

Rapid Application Development was introduced in the 1980s as an approach to combine rapid prototyping and computer aided software engineering (CASE). Most CASE tools claim to support the approach, which is targeted at large-scale systems and seeks to capture requirements in forms that can enable tools to generate at least some parts of the code.

The Spiral Model was proposed in 1988 by Boehm. It seeks to develop large systems via a combination of risk assessment, prototyping, and incremental development. The approach seeks to mitigate several kinds of risks; the risks related to misunderstood requirements and to customer acceptance of the new system are addressed via prototyping.

RELATION TO REQUIREMENTS ENGINEERING

Typical challenges in requirements engineering involve dealing with ambiguity, incompleteness, inconsistency, and unstated requirements. Prototyping is one method for addressing these issues.

Communication between people with different areas of expertise is problematic because the people may be associating different meanings with the same terminology without realizing it. Specialized terms typically are well defined and clear to experts in each field but ambiguous in the wider context. Readers may not be aware of the specialized senses of the words and may assume their common meanings instead or assume different specialized meanings for the same word drawn from their own area of expertise. Prototyping provides concrete examples of proposed system behavior that can help expose this type of problem. By helping system stakeholders visualize how the proposed system will affect their jobs and responsibilities, prototype demonstrations also can elicit previously unstated requirements and expose incomplete descriptions that are likely to be interpreted differently by stakeholders and developers.

Inconsistencies arise naturally in requirements for systems with many different stakeholders, particularly if they have different responsibilities and associated conflicts of interest. The resulting conflicts and inconsistencies can be very difficult to identify if the documentation is lengthy. Because a prototype must be consistent with the requirements it seeks to demonstrate, constructing a prototype can provide early detection of inconsistencies that lie within the scope of the demonstration.

USER'S VIEW OF AN INTEGRATED PROTOTYPING ENVIRONMENT

A prototyping environment is a set of tools for supporting prototyping. The main functions that should be provided by an integrated prototyping environment are a convenient interface for formulating and viewing the specifications and design of a prototype, execution and analysis capabilities, support for evolution and reuse, and optimization capabilities.

The designer interface should provide decision support for the designer and a high-level model of the decisions that the designer must make so that major choices can be made explicitly and implied details can be supplied by a design management system. Such facilities are essential for reducing the amount of detail that a prototype designer must consider explicitly. Static analysis tools should help the designer assess prototype properties such as type consistency, feasibility of timing constraints, consistency between the levels of a hierarchical description, preconditions on input parameters and generic parameters, constraints on relative rates of producer and consumer processes, an absence of deadlocks in distributed and parallel systems, an absence of unhandled exceptions, and so forth.

Execution support should include methods for executing incomplete specifications and facilities for controlling, monitoring, measuring, and summarizing the results of execution, as well as debugging. Reusable components and default assumptions are needed to realize specified behavior if details of algorithms and data structures have not been given by the designer.

The environment should include a design database that supports the evolution of the prototype by managing the dependencies between the requirements and the prototype design, supporting change impact analysis, recording the history of the prototype development, coordinating concurrent updates to the design, and providing facilities for combining design alternatives in different combinations. Meaning-changing transformations also are important for supporting evolution.

Optimization facilities are needed to support the transition from the prototype version to the software product. Such facilities are needed to improve the performance of quick and simple first implementations of requirements within the scope of a prototype that are not covered by existing reusable components with mature implementations. This optimization process can be partially automatic and can be partially guided by the designer via annotations that provide implementation advice. Such annotations, in some cases, can enable the details of the product code to be generated automatically from the same source as the prototype, while allowing designers to tune the performance of the implementation by selectively overriding the default implementation methods used during the prototype execution with more sophisticated data structures and algorithms. Such facilities are essential for a mature, integrated prototyping environment because they enable product quality performance while preserving the flexibility inherent in a prototype description tailored to support system maintenance and rederivation.

SUPPORTING TECHNOLOGY FOR EFFECTIVE PROTOTYPING

Computer-aided prototyping depends on emerging technologies and is migrating gradually into practical use as these technologies mature. The relevant technologies involve the following, as explained below:

1. Prototyping languages
2. Execution support
3. Software reuse
4. Computer-aided design

Prototyping Languages

Rapid prototyping languages are used to create software prototypes, which are executable descriptions of simplified models of proposed software systems. They also support processes that document, analyze, and adjust the models. A prototyping language is used by both people and the software tools in a prototyping environment. To support the human users, a prototyping language should make it easy to write, understand, and modify the models. To support the tools, the language should be easy to analyze and transform to reflect requirement changes. An example of a prototyping language is prototype system description language (PSDL). PSDL provides a simple representation of system decompositions by using data flow diagrams that are augmented with nonprocedural control constraints and timing constraints (maximum response times, maximum execution times, minimum inter stimulus periods, periods of periodic operators, and deadlines). The language represents both periodic and data-driven tasks and both discrete (transaction-oriented) and continuous (sampled) datastreams.

A prototyping language should provide a simple computational model and primitives that match the problem domain as closely as possible. This goal can be met either via domain-specific prototyping languages or by providing domain-specific components and toolkits.

In addition to supporting an execution capability, languages used in prototyping must simplify the description of the software and capture specifications and requirements. Specifications and links to requirements are needed to record which aspects of the prototype are system requirements so that they can be distinguished from accidental consequences of execution support mechanisms. This distinction affects the presentation and analysis of prototype demonstrations and the transformation of stable prototypes into software products.

Execution Support Technology

Execution support for a prototyping language requires extending conventional translation techniques with transformations and application-specific techniques for automatically generating programs to allow the execution of incompletely specified facilities. This extension can be performed with the help of default assumptions for unspecified decisions and scheduling processes that meet real-time constraints.

Scheduling requires models of the target hardware configuration. Because the components of a prototype may not be fully optimized and may run on different hardware than the product version, demonstrations of prototypes with real-time constraints often require simulations that provide linearly scaled real-time performance that faithfully represents the behavior of the intended system, possibly at a reduced speed. In cases where control of the physical systems must be part of the demonstration, either suitably time-scaled models of the physical systems must be constructed or the software must be hosted on hardware that is sufficiently fast to run the simulations in actual real time to keep up with the dynamics of the real physical system.

Real-Time Scheduling

Prototyping of embedded software presents special challenges because such software often is associated with real-time constraints that must be met under all operating conditions. Concurrent control loops also are common in embedded systems. Explicit control over the scheduling of parallel tasks usually is necessary to guarantee that such hard real-time constraints can be met because the scheduling capabilities provided by most operating systems are somewhat removed from the level of support needed for implementing hard real-time systems. The execution support system for a prototyping language that addresses real-time systems, therefore, should provide higher-level facilities for scheduling real-time operations. No generally effective and universally accepted approach to real-time scheduling exists. Thus, the execution support system for a prototyping language should provide the designer with several choices of scheduling methods and should generate the code structures necessary to realize those methods in practice.

Program Transformations

Transformations that add detail are needed to execute incompletely specified components. Such transformations should supply reasonable default values for attributes necessary for execution if the designer does not specify them explicitly. This supply of default values is essential for rapidly testing and demonstrating partially completed prototypes.

The quality of the choices is less important than the ability to replace default assumptions. Quickly and easily with increasingly accurate alternatives, which can be drawn from predefined domain-specific toolkits and policies. For example, each data type can have a built-in default output representation as a string in a text box, with a selectable list of optional alternative representations. For numerical values, alternative representations such as gauges, plots, or moving graphics can enable visualization in different ways. Fine tuning can be done via controllable parameters.

Default values can be overridden explicitly to produce more accurate models of the system or to improve its performance. Default implementations can be created by simple or increasingly sophisticated techniques, such as interactively asking the user to supply values, using random selections from a fixed set of responses, using internet searches or responses from online games, using logic programming to simulate black-box specifications, or using transformation techniques to generate effective implementations from black-box descriptions.

Automated Program Construction

The prototyping systems with the highest levels of automation support have been designed for specific problem domains. Such prototyping systems have been developed for problem domains that include business information processing, user interfaces, computer languages, and real-time systems.

Generators for business information systems provide graphical interfaces to databases to define database schemas, queries, and reports by graphically defining table layouts. Many commercially available tools exist in this category.

Interface generation systems generate graphical user interfaces based on a set of predefined components, such as windows, menus, scroll bars, and buttons. These components are placed and adapted interactively.

Generators for language processors are based mostly on attribute grammars. These systems can generate various tools for computer languages based on a context-free grammar for the language, augmented with equations that define computed attributes for the nodes of the parse tree. This technology can be used to prototype tools for computer languages, including translators, interpreters, pretty printers, type checkers, dataflow analyzers, and so forth. Applications span programming languages, specification languages, and data definition languages for databases; they span hardware description languages and command languages for applications programs. Attribute grammar processors have been coupled to generators for syntax-directed editors and program transformation systems.

The most powerful systems are domain-specific and include built-in knowledge about effective solution methods for typical problems in the domain. This knowledge is typically materialized in the form of reusable components, special-purpose code generators, or inference engines with domain-specific rules for combining and adapting components. Many tools come with GUI generators and support rapid component composition via drag-and-drop interfaces that let users create annotated graphical pictures of the intended connection structure and then generate the corresponding connection and control code. For example, the CAPS system for prototyping real-time control systems uses a scheduling algorithm to find a schedule that meets the hard real-time constraints associated with the components and then generates the control module that connects the components and executes them according to the schedule. Other systems recognize interface mismatches and are capable of generating adapter code to correct some types of mismatches. For example, the AMPHION system for spacecraft mission planning automatically inserts transformations between different coordinate systems where they are needed to bridge the gaps between components that use different kinds of coordinates.

Software Reuse and Open Architectures

Software reuse is essential for rapid prototyping because it can enable the designer to avoid many details that have been considered previously. The environment should assist the designer in retrieving reusable components and in tailoring and combining available components to fulfill queries that do not exactly match any of the reusable components explicitly stored in the software base. Reuse can be applied at the levels of code (algorithms and data structures), design (system decompositions), and requirements models (domain-specific concepts). A difficulty with this approach is the cost of obtaining suitable components, re-engineering them to be reusable in wider contexts, and ensuring that they can be interconnected without conflicts.

Open architectures are useful for enhancing the effectiveness of reuse for software prototyping and system evolution. An architecture is the common structure of a family of systems that span a particular problem domain. This structure consists of subsystem slots, their organization and interconnections, and the constraints, protocols, and standards associated with the slots and connections. A subsystem slot is a place in the architecture that can be filled with a plug-in component that conforms to the associated constraints, protocols, and standards. An architecture is open if the details of the architecture are known publicly and have been specified accurately enough to enable any component or connector that meets the given constraints to be used together with any combination of other components that satisfy the architecture to form a properly working system. Open architectures define families of reusable plug-compatible components and create associated market incentives for many vendors to create such components. They support flexible systems in prototyping that can be reconfigured by swapping components for other plug-compatible components with different characteristics.

Computer-Aided Design

Computer-aided design relevant to prototyping includes configuration management, integration of subsystems, high-level debugging, explanations, and optimization. Many of these design processes are amenable to a model-based generation approach, in which many details are derived automatically from simplified high-level models.

System Integration

The individual subsystems that comprise a large system commonly are developed by different teams of developers. Integration tools can aid the process of combining such subsystems by supporting validation of the decomposition before to dividing up the work and can be used for comparison purposes when assessing whether delivered subsystems conform to their requirements. Both testing and proof technologies are relevant to this validation process.

High-Level Debugging

A mature prototyping environment should support debugging and error handling at the level of abstraction provided by the prototyping language. Errors and failures during prototype execution should be mapped from the underlying programming-language level to the level of the prototype language to keep low-level programming details from intruding when the designer tests and demonstrates a prototype.

Explanations

Justifications for decisions made by the tools should be available as a feedback mechanism for the designer in cases where the automated design completion procedures fail. Such a failure explanation facility is needed to support systematic computer-aided design in situations where complete automation is not possible.

CONCLUSION

Ideally, prototyping should be integrated with the process that produces the final implementation. To produce deliverable software, prototyping tools should provide optimization capabilities to produce programs whose efficiency is comparable to the designs of competent programmers. This goal generally is feasible only in the context of specific application domains that have mature solution techniques. The beginnings of the required technologies are visible: Correctness-preserving transformations and performance-estimation techniques can be used to guide derivation strategies that systematically produce efficient implementations.

In the longer term, prototyping systems will have reasoning capabilities and extensive knowledge bases that may include generic models of the problem domain, common goals of customers, common system structures, and generators producing specifications and code for classes of software components. Facilities for supporting formal verification of prototype decompositions are desirable to ensure that the proposed decompositions are viable, especially if the subcomponents are to be built by different developers.

REQUIREMENTS SPECIFICATION AND ANALYSIS

The first step in engineering a software system is to understand what the system should do—this is referred to as the specifications of the requirements for the software system or, alternatively, as requirements specifications or software requirements specifications (SRS). Once the requirements have been specified, very often the next step is to analyze them to update, modify, and prioritize the requirements so that the software development team develops a better understanding of the system to be developed, the constraints on the system, and initial estimates on cost and schedule for developing the system—this step is referred to as requirements analysis. Thus, requirements specification and analysis is a two-step process that is also iterative—analysis may lead to revised specifications that could entail additional analysis. Requirements specification and analysis is a phase in software engineering; from a software engineering perspective, the requirements specification and analysis phase is followed by the software design phase.

The requirements specification and analysis phase of a software project is the most important phase of software development and should not be omitted under any condition. More than half of software projects have failed because of errors in the requirements specification and analysis phase, and the cost for correcting errors committed during this phase increases exponentially as software system development progresses through the remaining phases of design, implementation, testing, and maintenance. It has been estimated (1), as shown in Fig. 1, that if an error detected and fixed during the requirements phase will incur a cost ratio of 1, then the same error if detected and fixed during the design phase will incur a cost ratio of between 3 and 6, during the implementation phase will incur a cost ratio of 10, during the development testing will incur a cost ratio of between 15 and 40, during the acceptance testing will incur a cost ratio of between 30 and 70, and if the error is detected and fixed when the system is under operation (or during the maintenance phase), the organization will incur a cost ratio of between 40 and 1000. Therefore, proper requirements specification and analysis is important during software development.

A basic rule of SRS development is to capture "what" the software system should do and never rush to the "how" the requirement is to be achieved—violation of this simple rule will lead to an early commitment to design without suitably exploring alternative designs. Even though this rule seems simple enough, the history of requirements specifications is replete with examples of breaches of this rule that may be a reason for the large number of software project failures—the temptation to rush to design or even implementation without first understanding the requirements is sometimes too much for software engineers. Thus, very often solutions are produced for the wrong problem or wrong solutions are produced for the actual problem!

Requirements for a software system can be classified into two types: functional and nonfunctional. Functional requirements specify what the system should do, whereas nonfunctional requirements specify the global characteristics of the software system. Thus, the requirement "*The input to the software system should be by means of a keyboard entry, mouse click, or stylus movement*" is a functional requirement, whereas "*The software system should have fast responses to user inputs*" is a nonfunctional requirement (NFR) since the "fast responses" requirement is usually not achievable by means of just a few components in the software system but is a globally observed characteristic of the software system. Functional requirements include requirements related to inputs, outputs, processes (or functions), and stored data for the new system. Functional requirements also capture the interfaces between the system and its users as well as the interfaces between systems. Nonfunctional requirements (also referred to as quality requirements or system attributes) capture requirements related to characteristics such as performance, usability, security, reliability, availability, maintainability, and portability; effort, budget, and schedule estimations; documentation and training needs; quality management; and constraints under which the final system may be expected to operate, for example, operating system, processing speed, network bandwidth, memory size, or implementation language.

An SRS typically includes

1. Verbal descriptions of functional and nonfunctional requirements.
2. Analysis artifacts such as requirements prioritization, dependencies, versioning, cost and staff size estimations, formulation of acceptance tests, and analysis of NFRs.
3. All associated models developed during analysis.

Not only does the SRS serve as the starting point for subsequent phases of software development, SRS also often serves as a legal contract between the software developing organization and the customer who will actually be purchasing and/or using the software.

The process of developing software requirements and analyzing them is illustrated in Fig. 2, and the focus during this phase is on the customers and users of the proposed software system. The process starts invariably with an understanding of the current system and its problems—the current system may be manual or computerized. This task is also called problem analysis. The techniques to help with this task include the PIECES (performance, information, economics, control, efficiency, and service) framework, Ishikawa diagrams (also called fish-bone diagrams), study of forms and documentation used with the current system, interviews with users of current system, and observations of use of the current system. The outputs of this task include the problem statement and system improvement objectives

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

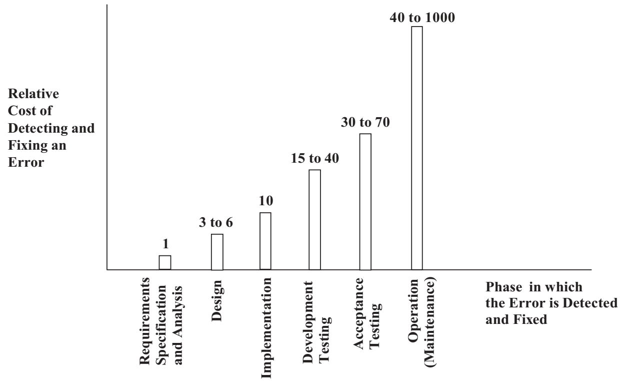

Figure 1. Relative costs of detecting and fixing an error in different software development phases (not drawn to scale).

that are used during the second task to guide elicitation of requirements from the users and customers. Usually, a subtle distinction is made between a user (also called an end user) and a customer. Customer is the organization or person(s) who will be paying for the software or sponsoring the software project, whereas users are the actual users of the software system who will be interacting with the software for the benefit of their organization; of course, customers may be users as well. The most important technique to elicit requirements is interviewing, but recently JRP (joint requirements planning) and discovery prototyping have emerged as supplementary techniques. The outputs of this task include notes, minutes, voice recordings, and updated prototypes. The third task uses the outputs of requirements elicitation to develop the initial SRS that documents the requirements using any combination of tabular listing, use-cases, and user stories. The first, second, and third tasks collectively form the requirements specifications step referred to earlier. The fourth task analyzes the initial SRS using reviews and customer/user clarifications to identify priorities, dependencies, versions, cost and manpower estimates, acceptance tests, and NFR analyses. The output of this task is the updated SRS. The fifth and final task models the requirements using any combination of UML (Unified Modeling Language) diagrams, ERD (Entity Relationship Diagrams) (2), DFD (Data Flow Diagrams), and formal methods. The output of the fifth task, also called logical design, is the updated SRS with models. The fourth and fifth tasks together form the requirements analysis step mentioned earlier. The SRS is now ready for the next phase of software development, namely, design, which is also called the physical design since implementation or physical aspects of the software system will have to be considered. As indicated in Fig. 2, the process is not linear but iterative; it is possible to go from one task to any of the earlier tasks whenever an error or omission is detected. Each technique is discussed in more detail in the subsequent sections. Typically, requirements specification and analysis phase lasts one third of the total project time and the durations of the individual tasks within this period are distributed almost evenly.

TASK 1: UNDERSTAND PROBLEMS WITH THE CURRENT SYSTEM

Very frequently the main driving force behind the development of new software systems is the set of problems faced by the end users in using the current system and processes, both of which may include a combination of manual and computerized aspects. Therefore, a good understanding of the problems with the current system will give the developers a set of measurable objectives that the new system

should satisfy. Examples of measurable objectives are "*Number of orders processed should increase by 10%*" or "*Response time decreases by 20%.*" These objectives can be achieved by fixing certain problems with the current system, and therefore, those problems provide not only opportunities for improving the current system but also serve as starting points for developing the requirements for the new and improved system. However, how does one identify the problems? The PIECES framework (3) is an excellent tool to document problems in an existing system—very frequently problems occur in the categories of performance, information, economics, control (and/or security), efficiency, and service. Other techniques include interviewing users of the current system, examining problem reports on the current system, and observing actual usage of the current system. When a large number of end users are involved, questionnaires may also be used. Once the problems are identified, they are documented in a problem statement matrix that lists the problems identified, the urgency of each problem, the monetary benefits in fixing each problem, and how each problem might be fixed such as, for example, by developing a new system or simply patching the existing one. Once the problems have been identified, it becomes necessary to determine their causes, and for this purpose, Ishikawa diagrams (also called fish-bone diagrams) (1) may be used. For each problem, an Ishikawa diagram is developed wherein the problem is mentioned along the main bone and the side bones represent categories under which causes for the problem may be grouped; the actual causes are listed off the side bones. Ishikawa diagrams help distinguish between symptoms and problems, and once all the problems are identified, a systematic effort may be undertaken to determine how the problems may be eliminated—called opportunities for improvement—and in this process, the preliminary requirements for the new system can be identified. As a result of this process, we develop the system improvement objectives matrix that lists, for each problem in the problem statement matrix, the probable causes and the measurable objectives for verifying the absence of the problem in the new system.

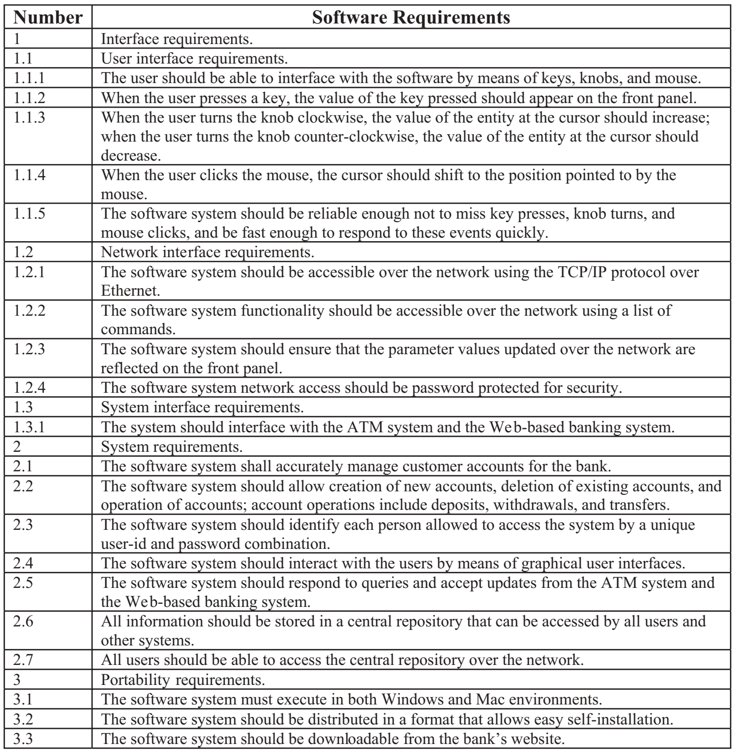
TASK 2: ELICIT REQUIREMENTS FOR NEW SYSTEM

As one might expect, software requirements are usually provided by the end users of the proposed software system. This process of gathering requirements from end users is called requirements elicitation. Even though elicitation seems like a simple activity, the trouble is that very frequently users are not sure of what they want (4)! Eliciting requirements should preferably be handled by software engineers well versed in communication and an understanding of human nature, because they will be required, quite often, to lead the process of elicitation by careful questioning of the end users. Interviews are the most common technique for eliciting requirements from end users. During interviewing, the questions necessary to elicit functional and nonfunctional requirements should be put to the end users. For example, questions such as "*What should the system do?*", "*What inputs will the system receive?*", "*What outputs should the system generate?*", and "*What are the data formats?*" are examples of questions that will help elicit functional requirements, whereas questions such as "*What is the maximum tolerable throughput of the system?*", "*What types of access control are required?*", "*What is the expected mean time between failures?*", "*What operating systems should the system work in?*", and "*What programming language will be used to implement the system?*" are examples of questions that will help elicit nonfunctional requirements. The user responses to these questions may be captured as notes or minutes on paper, or voice may be recorded digitally or on tapes. Important points to keep in mind are the types of questions to ask such as open-ended (for example, "*What is the maximum number of expected users for the system?*") and closed-ended (for example, "*Will the maximum number of expected users for the system be less than ten or between ten and hundred or more than hundred?*"), whether the interviews should be structured or unstructured, understanding body language since only about 7% information (1) is communicated verbally, and understanding proxemics or the relationship between people and space around them. When a large number of end users exists it may be cost effective to use questionnaires. An important factor in developing questionnaires is whether free-format questions or fixed-format questions need to be asked.

Another source of requirements are the physical forms and documents that are used for the existing system, including user manuals, filled-in forms used for data capture, standard operating procedures, notes, memos, e-mails, and forms capturing user feedback. Often, the new software system replaces physical forms and documents, and the requirements engineer will have to understand the form's contents and its usage, along with the processes listed in the documents to formulate requirements for the new software system.

JRP is another technique for eliciting requirements—JRP is part of the JAD (Joint Applications Development) philosophy that requires the relevant stakeholders (users and their managers) to participate in a workshop for collaboratively gathering the requirements. The JRP sessions are facilitated usually by an external moderator who ensures that the sessions focus on their objectives and not let egos dominate the proceedings. JRP requires attendance from the technical staff as well so that any requirements that may not be feasible may be immediately pointed out to the concerned users. JRP ensures that collective responsibility for system development occurs and that the users are actively involved in the development process, which encourages them to take ownership of the project.

The discovery prototype is yet another technique for eliciting requirements in which a small-scale working model (sometimes referred to as a "quick-and-dirty" implementation) of the proposed system is developed and given to the users to work with. Based on the philosophy that the users will understand the requirements once they actually see a working sample, the users are frequently able to better articulate their requirements based on their experiences with the prototypes. Discovery prototypes are useful in eliciting requirements that are not clearly understood (sometimes by the users themselves). It must be kept in mind that the prototypes cannot be considered as the first



Number	Software Requirements
1	Interface requirements.
1.1	User interface requirements.
1.1.1	The user should be able to interface with the software by means of keys, knobs, and mouse.
1.1.2	When the user presses a key, the value of the key pressed should appear on the front panel.
1.1.3	When the user turns the knob clockwise, the value of the entity at the cursor should increase; when the user turns the knob counter-clockwise, the value of the entity at the cursor should decrease.
1.1.4	When the user clicks the mouse, the cursor should shift to the position pointed to by the mouse.
1.1.5	The software system should be reliable enough not to miss key presses, knob turns, and mouse clicks, and be fast enough to respond to these events quickly.
1.2	Network interface requirements.
1.2.1	The software system should be accessible over the network using the TCP/IP protocol over Ethernet.
1.2.2	The software system functionality should be accessible over the network using a list of commands.
1.2.3	The software system should ensure that the parameter values updated over the network are reflected on the front panel.
1.2.4	The software system network access should be password protected for security.
1.3	System interface requirements.
1.3.1	The system should interface with the ATM system and the Web-based banking system.
2	System requirements.
2.1	The software system shall accurately manage customer accounts for the bank.
2.2	The software system should allow creation of new accounts, deletion of existing accounts, and operation of accounts; account operations include deposits, withdrawals, and transfers.
2.3	The software system should identify each person allowed to access the system by a unique user-id and password combination.
2.4	The software system should interact with the users by means of graphical user interfaces.
2.5	The software system should respond to queries and accept updates from the ATM system and the Web-based banking system.
2.6	All information should be stored in a central repository that can be accessed by all users and other systems.
2.7	All users should be able to access the central repository over the network.
3	Portability requirements.
3.1	The software system must execute in both Windows and Mac environments.
3.2	The software system should be distributed in a format that allows easy self-installation.
3.3	The software system should be downloadable from the bank's website.

version of the system and that their intent was requirements discovery only.

TASK 3: DEVELOP INITIAL SOFTWARE REQUIREMENTS SPECIFICATION

Tabular SRS

Typically, software requirements are listed in categories with each requirement given a unique number for easy reference. Figure 3 shows an example list of requirements for a hypothetical software system that manages accounts for a bank. The software requirements are categorized at the highest level into Interface Requirements, System Requirements, and Portability Requirements; under each category, the requirements are subcategorized—for example, under the Interface Requirements category, the subcategories include User Interface Requirements, Network Interface Requirements, and System Interface Requirements. The simplest way to capture the nesting of levels of software requirements is to use the nested decimal notation as shown in Fig. 3. Typically, a requirement that a software system should have (also called a mandatory or essential requirement) is indicated by using words such as "*shall*," "*should*," or "*must*," with the importance decreasing in this order—that is, a requirement with a "*shall*" is more important than a requirement with a "*should*," and this is more important than a requirement with a "*must.*" In practice, an organization may adopt its own conventions and follow it consistently—it should be noted that modality of terms used in SRS could be different from their usage in ordinary conversation. More importantly, requirements should be unambiguous, correct, consistent, verifiable, complete, and unique (5); an ambiguous requirement is not specific, for example, "*When the user presses the key and/or turns the knob the value displayed should be updated*" —here it is not clear what value should be displayed when both the key and the knob are turned at the same time; a consistent requirement does not conflict with another requirement; a correct requirement is within the domain of the software system, that is, it is a requirement of the software system and not an extraneous factor; a verifiable requirement is one that can be subsequently verified as having been included in the final completed software system; a complete set of requirements capture responses to all possible classes of inputs; and the uniqueness of requirements ensures the that they do not repeat either in the same or another form.

Figure 3 shows both functional and nonfunctional requirements. Requirement 1.1.5 and requirement 2.1 are nonfunctional requirements, whereas the others are functional requirements.

Use-Cases

Another technique for documenting requirements, which is increasingly becoming popular, is use-cases (6); this includes both the use-case diagram and the use-case narratives. The use-case diagram captures all the interactions between the software system and the external entities, whereas the use-case narrative captures the sequential processing of an interaction. Together, they define the scope of the system, give a detailed insight

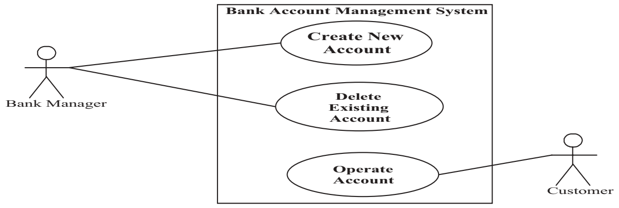

Figure 4. Modeling requirements with UML use-case diagrams.

into the software system to be developed, and allow more accurate effort and schedule estimates. Consider, for example, the use-case diagram shown in Fig. 4, where the stick figure represents a user in a specific role, also called an actor, interacting with a specific functionality or use-case of the software system represented by the oval shape. In Fig. 4, a *Bank Manager* actor exists, and its use-case is *Create New Account* that describes the sequence of activities occurring during interaction between the software system Bank Account Management System and the user *Bank Manager*. Also, it may be noted from Fig. 4 that the *Bank Manager* interacts with the use-case *Delete Existing Account* as well while the *Customer* interfaces only with the *Operate Account* use-case. More importantly, from the use-case diagram of Fig. 4, one may infer that the *Bank Manager* does not interact with the use-case *Operate Account* just as the *Customer* does not interact with the use-cases *Create New Account* and *Delete Existing Account*. Therefore, use-case diagrams also serve as a mechanism to define the scope of the system. Frequently use-cases and scenarios have been used interchangeably in the literature. However, a subtle difference does exist. A scenario is one instance of execution of the use-case, whereas a use-case is an abstract entity; therefore, one use-case can typically represent several scenarios of use. Also, one use-case may include one or more requirements for the software system.

The actual sequence of activities is described in the use-case narrative, an example of which is given in Fig. 5. The narrative of Fig. 5 captures the different ways the user *Bank Manager* can provide inputs to the system and receive outputs from the system, and it captures the detailed sequence of activities undertaken by the system in response to user inputs. Figure 5 is just one way of writing the use-case narrative—different formats are possible, including some that capture exceptional events, alternative events, and responses to multiple users (or, more appropriately, roles). Also, the details in the use-case narrative may be achieved iteratively over time—that is, the first version of the narrative may have only the intent of the use-case, the second version may have more details, the third even more details, and so on till all minutiae are uncovered in the final versions of the narrative. The details in a use-case may be modeled using UML activity diagrams during the modeling task.

Use Case Name	Create Bank Account	
Use Case ID	UC001	
Actor	Bank Manager	
Typical Course of Events	**Actor Action**	**System Response**
	1. The actor informs the system that a new account is to be created.	2. The system asks the user the type of account to be created.
	3. The actor informs the system the type of account to be created.	4. The system asks the user the account details.
	5. The actor enters the account details.	6. The system creates the new account and returns with the account number.

Figure 5. Use-case narrative for the use-case *Create Bank Account* in Fig. 4.

User Stories

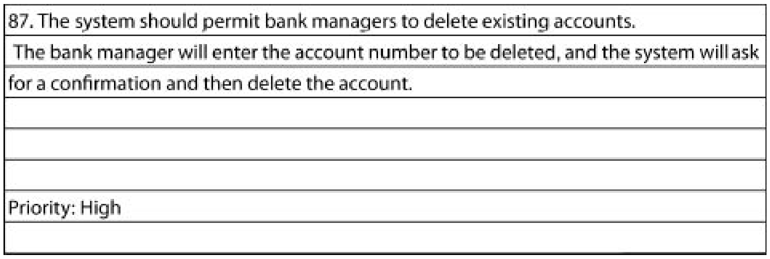
Another technique for capturing initial requirements is user stories (7)—a user story is a brief (usually about three sentences) description of an expected functionality written by the user. An example user story is given in Fig. 6. Each user story is usually captured on an index card and in many cases is written (actually handwritten) directly by the user or the domain expert using the language of the domain. That way it becomes a convenient medium to discuss business requirements with the users. Moreover, from a management perspective, each user story is given a unique number and a priority so that when the stack of user stories is collected, the scope of the system to be developed is well defined and the user stories may be prioritized for different iterations of the software system. In addition, since each user story is expected to take a fixed unit of time to implement, typically about a week, the schedule for the project can also be determined.

Decision Tables

Decision tables (1,8) are yet another technique for documenting requirements, although at a detailed level to capture business rules. Decision tables capture true or false values of conditions and their resultant effects on decisions. For example, if we have the following situation:

> *A bank account can be established only when the customer has both a social security number (SSN) and documented proof of residency; if the customer can electronically remit her salary to the account each month, then the monthly fee is waived; else a monthly fee is imposed.*

To make the decision whether a new account may be approved and, if so, whether a fee needs to be imposed, the decision table shown in Fig. 7 will be useful. In Fig. 7, *T* stands for a condition that is true, whereas *F* stands for a condition that is false, *X* represents an irrelevant condition (that is, it can be either true or false, but its value does not affect the decision), and the applicable decision is indicated with the *a* mark. Therefore, in only one situation can a new account be approved without a fee and that is when all three conditions (customer has SSN, customer has residency proof, and customer can remit salary electronically) are true; when the first two conditions are true, but the customer is unable to remit salary electronically, then a new account is approved but with a fee imposed; in all other cases, a new account is not approved.



87. The system should permit bank managers to delete existing accounts.

The bank manager will enter the account number to be deleted, and the system will ask for a confirmation and then delete the account.

Priority: High

Figure 6. Requirements capture using a user story.

TASK 4: ANALYZE REQUIREMENTS

The main purpose of requirements analysis is to refine the requirements collected during the requirements elicitation phase. Usually the requirements collected initially do not satisfy all the characteristics of being unambiguous, correct, consistent, verifiable, complete, and unique—the requirements may be considered "raw" that need to be refined and better understood for subsequent phases of software development. The chief technique for this purpose is reviewing the requirements. During reviews, teams of development personnel along with customers/users go over the SRS developed to determine errors and omissions. Any errors and omissions determined will have to be corrected before proceeding. Reviews can be used iteratively during this phase and can be applied to any artifact developed during the process of requirements specification and analysis. Other goals of requirements analysis include requirements prioritization, determining requirements dependencies, determination of versions, schedule formation, staff size determination, preliminary cost estimation, formulation of acceptance tests, and analyzing NFRs.

Requirements Prioritization

Even though at the end of the requirements specification phase we may have a list of all expected software requirements, it may not be feasible for the software development organization to implement all requirements in the very first version of the software, the chief reasons being the time constraints and the delays incurred because of the inevitable changes to software requirements. Therefore, only a subset of the requirements is usually delivered in the first version, and this subset includes only those requirements deemed most important by the customer and considered most feasible by the software development organization. Customers/users determine requirements priorities while their feasibilities are evaluated by the developers—thus, even though the customer, for example in Fig. 3, may state that requirements 1.1.1, 1.1.2, and 1.1.3 are more important than 1.1.4, the current state of hardware technology for the system may not incorporate a knob-based input; in this case, the developers may negotiate with the customer to provide only the requirements 1.1.1 and 1.1.2 with the first release and push requirements 1.1.3 and 1.1.4 to a subsequent release of the software system. An important aspect of negotiating with customers is to ensure that a "win–win" situation is reached for all concerned stakeholders.

Customer has SSN	T	F	F	T	T
Customer has residency proof	F	T	F	T	T
Customer can remit salary electronically	X	X	X	F	T
Bank account approved with fee				α	
Bank account approved without fee					α
Bank account not approved	α	α	α		

Figure 7. Documenting detailed business rules using decision tables.

Identifying Requirements Dependencies

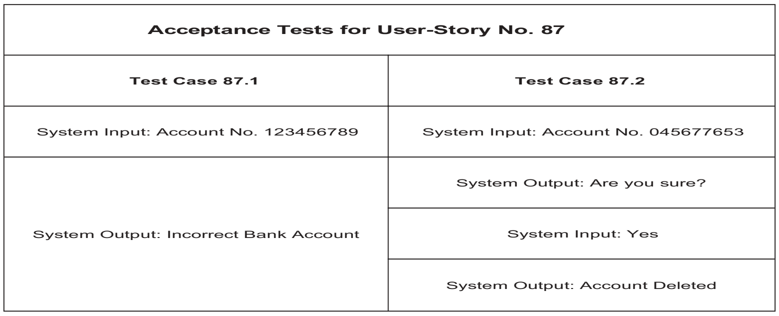
Requirements frequently have dependencies among themselves such that in order to fulfill one requirement, another requirement must have been fulfilled previously. For example, requirement 1.2.3 in Fig. 3 assumes that requirement 1.1.2 is already satisfied since front panel updating ability is a prerequisite for requirement 1.2.3; therefore, requirement 1.1.2 may need to be developed before requirement 1.2.3. Identification of such dependencies will also help with scheduling the software system development such that requirements upon which others are dependent are completed before the requirements that depend on them. When requirements are captured as use-cases, then the dependencies may exist among use-cases. Here the use-case upon which most other use-cases are dependent should be completed before the others.

Requirements Versioning

Prioritization of requirements and identification of their interdependencies can help identify the versioning requirements that determine the distribution of features (a feature is a use-case or a set of requirements) among the different versions of the software system. Therefore, for example, if a high-priority requirement is dependent on a low-priority one, it may be necessary to have the low-priority requirement along with the high-priority one as part of the first version of the system. Versioning assumes software development is based on an incremental process.

Schedule Formation

Versioning is closely tied to scheduling the software development project—thus, if the initial requirements identify the need for ten versions to accommodate all the features required by the customer, then by estimating the time needed to complete each version, an accurate schedule for the project may be developed. Since SRS frequently serves as a contract between the software development



Acceptance Tests for User-Story No. 87	
Test Case 87.1	Test Case 87.2
System Input: Account No. 123456789	System Input: Account No. 045677653
System Output: Incorrect Bank Account	System Output: Are you sure?
	System Input: Yes
	System Output: Account Deleted

Figure 8. Acceptance tests for the user story of Fig. 6 .

organization and the customer, determination of the schedule at this stage will allow the software organization to negotiate properly requirements and cost for the project. For example, using the process chosen for the project, if each version takes four months of development (design and implementation), then for ten versions and assuming sequential development, the project manager can quickly lay out a schedule lasting more than three years.

Staff Size Determination

Another objective of requirements analysis is to identify accurately the staffing requirements for the project—this will help the software organization quickly determine whether the expected schedule and cost can be satisfied or whether more negotiation with the customer is required. Since SRS frequently serves as a contract between the software development organization and the customer, it will be useful to consider staff size requirements at this stage itself. For determining staff size, if prior experience with the company's methodology indicates that a feature takes 10 person-days to design, implement, and test, then for ten features, 100 person-days will be required; based on versioning, which has already decided the approximate sequences of feature-sets to be delivered to the customer, the average staff size for development can be determined quickly.

Project Cost Estimation

Based on personnel requirements and expected length of the project, the project manager can develop or revise preliminary estimates for the budget so that the project benefits may be determined clearly. Again, since SRS frequently serves as a contract between the software development organization and the customer, it will be useful to identify or update project costs based on requirements so that, if needed, additional negotiation regarding requirements and schedule may be held between the two parties. For estimating project costs, past experience could serve as the guide; for example, if past experience indicates that each person-day costs $500, then a project requiring 100 person-days of effort will cost $50,000. However, cost estimation may also be performed using well-known models such as the COCOMO (Constructive Cost Models) that helps, especially COCOMO II (the latest version) (9), to calculate effort in terms of person-months during the requirements specification and analysis phase itself; therefore, if the cost per person-month is known, the project cost can be estimated.

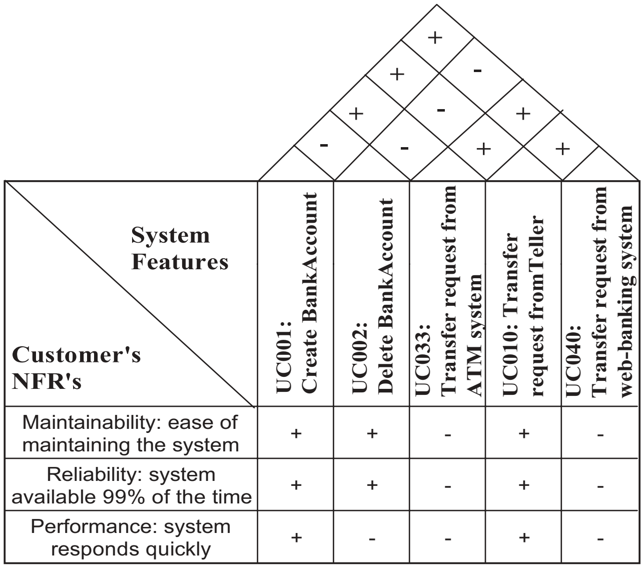
Formulating Acceptance Tests

Requirements analysis serves the very important purpose of developing acceptance tests that document the tests the user will execute on the final system for verifying that the system indeed satisfies the requirements—thus, for example, if we consider the user story shown in Fig. 6, the user may say that the acceptance tests shown in Fig. 8 will be executed to confirm the proper implementation of the user story. Development of acceptance tests during this phase will help clarify requirements and encourage proper design of software. For example, from the customer's acceptance tests, we can request the rules for identifying correct account numbers and, during design, develop a system that will first check that the entered account number is legal before continued processing.

Analyzing NFRs

Analyzing NFRs brings with it its own set of issues, chief among them being the inherent vagueness in defining NFRs. Although several techniques have been proposed, most seem to suffer from their own restricted definitions for the nonfunctional requirements they seek to analyze. However, from a wide applicability standpoint, two techniques stand out: the House of Quality and the NFR Framework. The House of Quality is part of the Quality Function Deployment process that was originally developed for the manufacturing industries in Japan and has been used for software requirements quality analysis as well. In its simplest form, the House of Quality is a matrix where rows represent the NFRs and the columns represent the technical aspects of the project that help achieve the NFRs, and at the intersection of each row and column, we identify the extent to which the technical aspects satisfy the customer's NFRs using qualitative measures such as strongly positive, positive, negative, and strongly negative. The "roof of the house" is the correlation between the technical factors themselves that captures the conflicting or synergistic interactions between the factors. The House of Quality may be extended with other aspects such as project planning and cost for achieving the NFRs. For example, for the bank account management system modeled in Fig. 4, if the user considers NFRs maintainability, reliability, and performance as being the most important, then an analysis of these NFR's using the House of Quality is presented in Fig. 9. In Fig. 9, the technical aspects considered are the two use-cases from Fig. 4, and the three additional use-cases identified for the system. In Fig. 9, we see that in the central part of the figure we denote how the use-cases affect the customer requirements—positive impacts are denoted by "+" whereas negative impacts are denoted by "–". Thus, for example, the use-case *UC033: Transfer Request From ATM System* has a negative influence on Performance, since two systems (the ATM system and the bank account management system) need to interface in order to complete this request, and such system interfaces are typically slower; however, the use-case *UC010: Transfer Request From Teller* has a positive influence on Performance, since only one system (the bank account management system) is involved and the required data are entered by the experienced teller. At the top of the figure, we indicate the trade-offs between the use-cases by using "+" to denote synergies and "–" to denote conflicts. Thus, *UC001: Create Bank Account* conflicts with *UC002: Delete Bank Account* since they are two opposing features with different constraints, whereas UC040 and UC010 synergize each other since developing one feature (UC040) helps in reducing dependence on the other (UC010). This information can be used for project planning, cost/effort determination, and use-case prioritization, and it can be captured in an extended version of Fig. 9.

Some drawbacks of the House of Quality technique include the inability to capture justifications and the flexibility to accommodate various definitions of NFRs. The NFR framework (10) addresses these drawbacks. The chief artifact of the NFR framework is the Softgoal Interdependency Graph (SIG), which captures all information pertaining to the achievement or otherwise of the NFRs. In a SIG, the NFRs are captured as NFR softgoals (depicted by a cloud-shape) that are to be achieved during the process of software development (we are concerned with the requirements specification and analysis), and three relationships are possible between NFR softgoals: AND (depicted by a single arc) means that the parent NFR softgoal is achieved only if all child softgoals of the AND-relationship are achieved; OR (depicted by a double arc) means that the parent NFR softgoal is achieved if even one of the child softgoals in the OR-relationship is achieved; and EQUAL relationship relates (by a line) one child to a parent and the parent is achieved if the child is achieved. Even though we used the word "achieved," the actual NFR framework term is satisfied, which means relative satisfaction and not absolute satisfaction. The system features are captured in the SIG by means of operationalizing softgoals (depicted by a dark-bordered cloud-shape), and the contributions of the operationalizing softgoals to the NFR softgoals are captured by contributions that come in four flavors: strongly positive (++), positive (+), negative (–), and strongly negative (– –). The contributions can be propagated up the SIG using well-defined propagation rules of the NFR framework. Finally, the reasons for the contributions (and, in fact, any element of the SIG) can be captured by means of argumentation softgoals (depicted by dashed-bordered cloud-shapes). The information in the House of Quality of Fig. 9 regarding two use-cases (UC001 and UC033) is captured easily by the SIG of Fig. 10—in this figure, the use-cases have been represented as operationalization softgoals (operationalizations refer to the artifacts currently under consideration that help achieve or deny NFR softgoals, and during the requirements specification and analysis phase, the artifacts could be requirements, use-cases, user stories, or decision tables). In Fig. 10, it may be noted that the argumentation softgoals capture justifications, the decomposition of the NFR softgoals (the AND–OR–EQUAL relationships) capture the definitions of the NFRs, and the propagation rules permit the determination of whether the NFRs are achieved, and, more importantly, they help identify the reasons in either case.



System Features / Customer's NFR's	UC001: Create BankAccount	UC002: Delete BankAccount	UC033: Transfer request from ATM system	UC010: Transfer request fromTeller	UC040: Transfer request from web-banking system
Maintainability: ease of maintaining the system	+	+	-	+	-
Reliability: system available 99% of the time	+	+	-	+	-
Performance: system responds quickly	+	-	-	+	-

Legend: "+" means positive influence (synergistic)
"–" means negative influence (conflicting)

Figure 9. Application of House of Quality to analyze nonfunctional requirements (NFRs).

TASK 5: MODEL REQUIREMENTS

Modeling helps to clarify requirements with the customers and users, so that the SRS is unambiguous, complete, and captures all essential requirements. Modeling is based on the premise that "a picture is worth a thousand words" and that information can be captured concisely using pictures. Modeling may be accomplished using modeling notations or formal logic.

Modeling Notations

Common modeling approaches include unified modeling language (UML) diagrams (11), data flow diagrams (DFDs) (1), and entity relationship diagrams (ERDs) (1). The common diagrams used for requirements analysis in UML include use-case model diagrams (as in Fig. 4), activity diagrams, class diagrams, sequence diagrams, and state charts. Noun-parsing of use-case narratives helps discover potential classes for developing class diagrams. DFDs are useful for modeling business processes and for capturing the interaction between manual and computerized processes (8). DFDs can be hierarchical with each level expand-

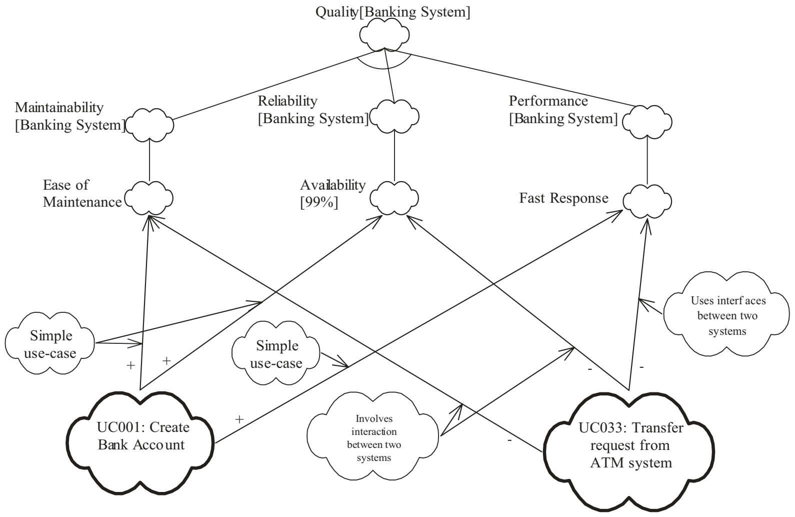


Figure 10. SIG of the NFR framework.

ing on the processes at a higher level—level 0 is the highest level and is called the context diagram, which considers the entire system as one black box; level 1 is the lower level that expands the black box of level 0; level 2 is the next lower level; and so on. A rule of thumb is to ensure that a higher level process is decomposed into at least five detailed processes at the lower level. ERDs can capture relationships between real-world entities in the problem domain and serve as an excellent technique to model data requirements for the domain. Petri nets have also been used to model requirements, but their semantics may be difficult for the average user to understand. Petri nets help to model concurrent activities where the order of occurrence is not important (12).

Formal Methods

Formal techniques for modeling requirements include first-order logic, temporal logic, Object Constraint Language, Z language, algebraic specifications, Specification and Description Language, and Software Cost Reduction (12). Formal techniques attempt to avoid problems associated with misinterpreting semantics of a model or inherent ambiguity in using natural languages (such as, for example, English) for documenting requirements. Again without going into details, it may be safely mentioned that practicality and scalability of these methods is limited even though claims have been made that for mission-critical systems these techniques are useful.

REQUIREMENTS MANAGEMENT

One of the major issues with requirements analysis is what to do when an error is discovered in the requirements—the error may be an incorrect requirement, ambiguous requirement, or even a missing requirement. The processes by which changes to the requirements specifications are handled fall under the category of requirements management. An important aspect of requirements management is ensuring that all stakeholders during the requirements phase always refer to the most updated set of requirements. Frequently a committee, called the Change Control Board, is formed to manage requirements, and all requests for changes need to be forwarded to this committee, which then decides on the necessity for the changes and, if required, updates the requirements and disseminates change notices.

Another facet to requirements management is the development of traceability tables where each traceability table relates requirements to an aspect of the system. Thus, for example, there could be a features traceability table, source traceability table, dependency traceability table, subsystem traceability table, and interface traceability table. The features traceability table relates each requirement to a feature (or functionality) of the system, the source traceability table relates each requirement to its source, the dependency traceability table indicates how requirements are dependent on each other, the subsystem traceability table relates each requirement to the subsystem the requirement applies to, and the interface traceability table captures the relationship between requirements and system interfaces.

TOOL SUPPORT FOR REQUIREMENTS SPECIFICATION AND ANALYSIS

The most important software tools for requirements specification are a word processor or spreadsheet software. Both of them help capture software requirements—the advantage with a word processor is that diagrams and detailed descriptions can be captured, whereas the main advantage of a spreadsheet software is that the requirements can be represented in tabular forms that help to add, delete, and modify requirements easily. Also, both tools help capture categorized or nested requirements. Some modeling environments such as IBM's Rational Requisite Pro (13) and Telelogic's System Architect (14) help draw use-cases and determine requirements dependencies. Drawing applications such as Smartdraw (15) and Microsoft Visio (16) have libraries for modeling requirements using UML, ERD, and

DFD notations. In order to capture different versions of requirements a configuration management tool such as open-source Concurrent Versions System (17) or IBM's Rational ClearCase (13) may be useful. Very often the versioning system is integrated with a Web-based system that is usually developed for each project so that interfaces for viewing and uploading the latest requirements are readily available. Sometimes, the Web-based repository serves as a bulletin board service as well so that all update notifications are issued at one place—the Web-based system then becomes a central repository for all data pertaining to the project including requirements.

DOORS (Dynamic Object Oriented Requirements System) (18) marketed by Telelogic is a tool for collaborative requirements management that helps capture, view, and update the latest requirements for a project. In addition, DOORS can help with change management and can be integrated with third-party application tools.

The Automated Requirements Measurement (ARM) (19) tool from NASA can evaluate requirements specified in the English language for words, including imperatives, directives, continuances, options, and weak phrases. These constructs are measured in terms of size, specification depth, readability, and text structure.

RESEARCH PROBLEMS IN REQUIREMENTS SPECIFICATION AND ANALYSIS

As stated, one of the important problems with the requirements specification and analysis phase is that users are frequently unable to articulate their needs—the roots for this problem may lie in an interdisciplinary area overlapping the fields of neuroscience, psychology, and cognition. A team of interdisciplinary researchers need to analyze the causes of this problem so that tools—both hardware and software—to better elicit requirements from people may be developed. Another problem is that of modeling requirements for communication among stakeholders (20)—current communication tools that use natural language such as English are prone to ambiguities, whereas a modeling language such as UML requires training for proper usage. Another issue that requires additional study is that of analysis paralysis, which refers to the problem of being in a state of perpetual analysis with no end to the phase in sight—the answer to the question "*When has enough analysis been done?*" is of considerable interest to practitioners (21). A very useful development in this area would be identification of conceptual patterns of user needs so that these concepts may be used as building blocks for developing requirements for new systems; in addition, these concepts may be used as a mechanism for communicating with users. For example, concepts such as human–machine interaction, data access, and networking seem to be common for most systems, and these could be designated as patterns that can be used for building new systems. Yet another research area is quantification of requirements quality (10) so that practitioners know when they are done—currently this field is in its infancy with tools such as ARM providing mainly syntactic metrics, but it needs to be developed to include semantic or conceptual levels.

SOFTWARE AGING AND REJUVENATION

INTRODUCTION

Several studies have now shown that outages in computer systems are more due to software faults than due to hardware faults (1,2). Recent studies have also reported the phenomenon of "software aging" (3,4) in which the state of the software degrades with time. The primary causes of this degradation are the exhaustion of operating system resources, data corruption, and numerical error accumulation, which eventually may lead to performance degradation of the software, crash/hang failure, or both. Some common examples of "software aging" are memory bloating and leaking, unreleased file-locks, data corruption, storage space fragmentation, and accumulation of round-off errors (3). Aging has not only been observed in software used on a mass scale but also in specialized software used in high-availability and safety-critical applications (4). This type of aging in operational software systems is different from code decay in software systems caused by maintenance (5,6). The former results in performance problems, system slow downs, and crashes, whereas the latter results in unrunnable or invalid software and maintenance-induced bugs.

As aging leads to transient failures in software systems, environment diversity, a software fault-tolerance technique, can be employed proactively to prevent degradation or crashes, which involves occasionally stopping the running software, "cleaning" its internal state or its environment and restarting it. Such a technique known as "software rejuvenation" was proposed by Huang et al. (4,7,8), [1] which counteracts the aging phenomenon in a proactive manner by removing the accumulated error conditions and freeing up operating system resources. Garbage collection, flushing operating system kernel tables, and reinitializing internal data structures are some examples by which the internal state or the environment of the software can be cleaned.

Software rejuvenation has been implemented in the AT&T billing applications (4). An extreme example of a system-level rejuvenation, proactive hardware reboot, has been implemented in the real-time system collecting billing data for most telephone exchanges in the United States (9). Occasional reboot is also performed in the AT&T telecommunications switching software (10). On reboot, called *software capacity restoration*, the service rate is restored to its peak value. On-board preventive maintenance in spacecraft has been proposed and analyzed by Tai et al. (11), which maximizes the probability of successful mission completion by the spacecraft. These operations, called *operational redundancy*, are invoked whether or not faults exist. Proactive fault management was also recommended for the Patriot missiles' software system (12,13). A warning was issued saying that a very long running time could affect the targeting accuracy. This decrease in accuracy was evidently due to overflow in the counter keeping track of time, during conversion from integer to real numbers. The longer the system ran continuously, the larger the error became. The warning, however, failed to inform the troops how many hours "very long" was and that it would help if the computer system was switched off and on every eight hours, which exemplifies the necessity and the use of proactive fault management even in safety critical systems. More recently, rejuvenation has been implemented in cluster systems to improve performance and availability (14–17). Two kinds of policies have been implemented taking advantage of the cluster failover feature. In the periodic policy, rejuvenation of the cluster nodes is done in a rolling fashion after every deterministic interval. In the prediction-based policy, the time to rejuvenate is estimated based on the collection and statistical analysis of system data. The implementation and analysis are described in detail in Refs. 14 and 15. A software rejuvenation feature known as process recycling has been implemented in the Microsoft IIS 5.0 web server software (18). The popular web server software Apache implements a form of rejuvenation by killing and recreating processes after a certain numbers of requests have been served (19,20). Software rejuvenation has been proposed for specialized transaction processing servers (21), cable and DSL modem gateways (22), in Motorola's Cable Modem Termination System (23), and in middleware applications (24) for failure detection and prevention. Automated rejuvenation strategies have been proposed in the context of self-healing and autonomic computing systems (25). Recently, recursive restarts and micro-reboot has been proposed to increase availability (26). Software rejuvenation (preventive maintenance) incurs an overhead (in terms of performance, cost, and downtime), which should be balanced against the loss incurred due to unexpected outage caused by a failure. Thus, an important research issue is to determine the optimal times to perform rejuvenation.

Here, we present two approaches for analyzing software aging and studying aging-related failures. The rest of this article is organized as follows: The next section describes various analytical models for software aging and to determine optimal times to perform rejuvenation. Measurement-based models are dealt with next, followed by discussion of the implementation of a software rejuvenation agent in a major commercial server, various approaches and methods of rejuvenation. The article concludes with pointers to future work.

[1] Although we use the by-now-established phrase "software aging," it should be clear that no deterioration of the software system per se is implied but rather the software appears to age due to the gradual depletion of resources (8). Likewise, "software rejuvenation" actually refers to rejuvenation of the environment in which the software is executing.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

ANALYTIC MODELS FOR SOFTWARE REJUVENATION

The aim of the analytic modeling is to determine optimal times to perform rejuvenation that maximizes *availability* or minimizes the *probability of loss* or minimizes the *mean response time of a transaction* (in the case of a transaction processing system), which is particularly important for business-critical applications for which adequate response time can be as important as system uptime. The analysis is done for different kinds of software systems exhibiting varied failure/aging characteristics.

The accuracy of a model-based approach is determined by the assumptions made in capturing aging. In Refs. 4,11,27–29, only the failures causing unavailability of the software are considered, whereas in Ref. 30 only a gradually decreasing service rate of a software that serves transactions is assumed. Garg et al. (31), however, consider both these effects of aging together in a single model. Models proposed in Refs. 4,27,28 are restricted to hypo-exponentially distributed time to failure. Those proposed in Refs. 11,29,30 can accommodate general distributions but only for the specific aging effect they capture. Generally distributed time to failure, as well as the service rate being an arbitrary function of time are allowed in Ref. 31. It has been noted (2) that transient failures are partly caused by overload conditions. Only the model presented by Garg et al. (31) captures the effect of load on aging. Existing models also differ in the measures being evaluated. In Refs. 11 and 29, software with a finite mission time is considered. In Refs. 4,27,28,31, measures of interest in a transaction-based software intended to run forever are evaluated.

Bobbio et al. (32) present fine-grained software degradation models, where one can identify the current degradation level based on the observation of a system parameter. Optimal rejuvenation policies based on a risk criterion and an alert threshold are then presented. Dohi et al. (33,34) present software rejuvenation models based on semi-Markov processes. The models are analyzed for optimal rejuvenation strategies based on cost as well as steady-state availability. Given a sample data of failure times, statistical non-parametric algorithms based on the total time on test transform are presented to obtain the optimal rejuvenation interval.

Basic Model for Rejuvenation

Figure 1 shows the basic software rejuvenation model proposed by Huang et al. (4). The software system is initially in a “robust” working state, 0. As time progresses, it eventually transits to a “failure-probable” state, 1. The system is still operational in this state, but can fail (move to state 2) with a non-zero rate. The system can be repaired and brought back to the initial state, 0. The software system is also rejuvenated at regular intervals from the failure probable state 1 and brought back to the robust state 0.

Huang et al. (4) assume that the stochastic behavior of the system can be described by a simple homogeneous continuous-time Markov chain (CTMC) (35). The CTMC is then analyzed and the expected system downtime and the expected cost per unit time in the steady state are computed. An optimal rejuvenation interval that minimizes expected downtime (or expected cost) is obtained.

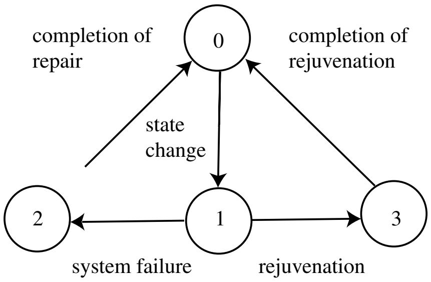

Figure 1. State transition diagram for rejuvenation.

It is not difficult to introduce the periodic rejuvenation schedule and to extend the CTMC model to the general one. Dohi et al. (33,34) developed semi-Markov models with the periodic rejuvenation and general transition distribution functions. Garg et al. (27) have developed a Markov Regenerative Stochastic Petri Net (MRSPN) model where rejuvenation is performed at deterministic intervals assuming that the failure probable state 1 is not observable.

Software Rejuvenation in Transactions-Based Software Systems

In Ref. 31, Garg et al. consider a transaction-based software system whose macro-states representation is presented in Fig. 2. The state in which the software is available for service (albeit with decreasing service rate) is denoted as state *A*. After failure, a recovery procedure is started. In state *B*, the software is recovering from failure and is unavailable for service. Lastly, the software occasionally undergoes rejuvenation, denoted by state *C*. Rejuvenation is allowed only from state *A*. Once recovery from failure or rejuvenation is complete, the software is reset to state *A* and is as good as new. From this moment, which constitutes a renewal, the whole process stochastically repeats itself.

The system consists of a server-type software to which transactions arrive at a constant rate. The effect of aging in the model may be captured by using decreasing service rate and increasing failure rate, where the decrease or the increase respectively can be a function of time, instantaneous load, mean accumulated load, or a combination of the above.

Two policies that can be used to determine the time to perform rejuvenation are considered. Under policy I, which is purely time-based, rejuvenation is initiated after a constant time δ has elapsed since it was started (or restarted). Under policy II, which is based on instantaneous load and

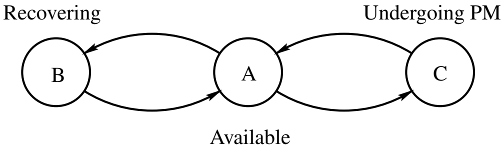

Figure 2. Macro-states representation of the software behavior.

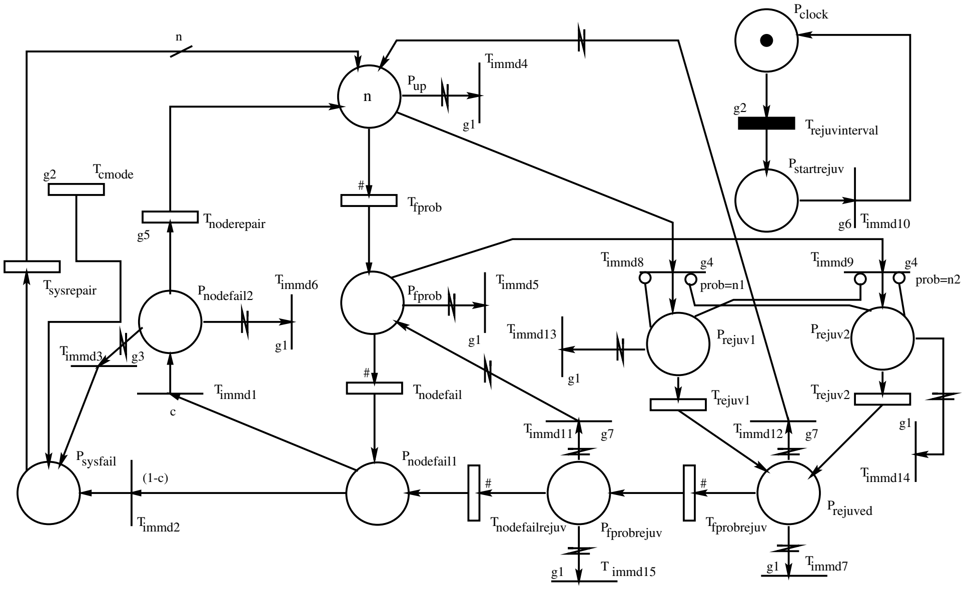

Figure 3. SRN model of a cluster system employing simple time-based rejuvenation.

time, a constant waiting period δ must elapse before rejuvenation is attempted. After this time, rejuvenation is initiated if there are no transactions in the system. Otherwise, the software waits until the queue is empty upon which rejuvenation is initiated. The goal of the analysis is to determine optimal values of δ (rejuvenation interval under policy I and rejuvenation wait under policy II) different objective functions such as the availability, the loss probability, and the mean response time.

Software Rejuvenation in a Cluster System

Software rejuvenation has been applied to cluster systems (14,16), which significantly improves cluster system availability and productivity. The Stochastic Reward Net (SRN) model of a cluster system employing simple time-based rejuvenation is shown in Fig. 3. The cluster consists of n nodes, which are initially in a "robust" working state, P_{up}. The aging process is modeled as a two-stage hypoexponential distribution (increasing failure rate) (35) with transitions T_{fprob} and $T_{noderepair}$. Place P_{fprob} represents a "failure-probable" state in which the nodes are still operational. The nodes then can eventually transit to the fail state, $P_{nodefail1}$. A node can be repaired through the transition $T_{noderepair}$, with a coverage c. In addition to individual node failures, there is also a common-mode failure (transition T_{cmode}). The system is also considered down when there are a ($a \leq n$) individual node failures. The system is repaired through the transition $T_{sysrepair}$.

In the simple time-based policy, rejuvenation is done successively for all the operational nodes in the cluster, at the end of each deterministic interval. The transition $T_{rejuvinterval}$ fires every δ time units depositing a token in place $P_{startrejuv}$. Only one node can be rejuvenated at any time (at places P_{rejuv1} or P_{rejuv2}). Weight functions are assigned such that the probability of selecting a token from P_{up} or P_{fprob} is directly proportional to the number of tokens in each. After a node has been rejuvenated, it goes back to the "robust" working state, represented by place $P_{rejuved}$, which is a clone place for P_{up} in order to distinguish the nodes that are waiting to be rejuvenated from the nodes that have already been rejuvenated. A node, after rejuvenation, is then allowed to fail with the same rates as before rejuvenation even when another node is being rejuvenated. Clone places for P_{upb} and P_{fprob} are needed to capture this result. Node repair is disabled during rejuvenation. Rejuvenation is complete when the sum of nodes in places $P_{rejuved}$, $P_{fprobrejuv}$, and $P_{nodefail2}$ is equal to the total number of nodes, n. In this case, the immediate transition T_{immd10} fires, putting back all the rejuvenated nodes in places P_{up} and P_{fprob}. Rejuvenation stops when there are $a-1$ tokens in place $P_{nodefail2}$, to prevent a system failure. The clock resets itself when rejuvenation is complete and is disabled when the system is undergoing repair. Guard functions ($g1$ through $g7$) are assigned to express complex enabling conditions textually.

For the analysis, the following values are assumed. The mean times spent in places P_{up} and P_{fprob} are 240 hrs and 720 hrs, respectively. The mean times to repair a node, to rejuvenate a node, and to repair the system are 30 mins, 10 mins, and 4 hrs, respectively. In this analysis, the common-mode failure is disabled and node failure coverage is assumed to be perfect. All the models were solved using the SPNP (Stochastic Petri Net Package) tool (36). The measures computed were expected downtime and the expected cost incurred over a fixed time interval. It is assumed that the cost incurred due to node rejuvenation is much less than the cost of a node or system failure since rejuvenation can be done at predetermined or scheduled times. In our analysis, we fix the value for $cost_{nodefail}$ at \$5,000/hr and the $cost_{rejuv}$ at \$250/hr. The value of $cost_{sysfail}$ is computed as the number of nodes, n, times $cost_{nodefail}$.

Figure 4 shows the plots for an 8/1 configuration (8 nodes including 1 spare) system employing simple time-based

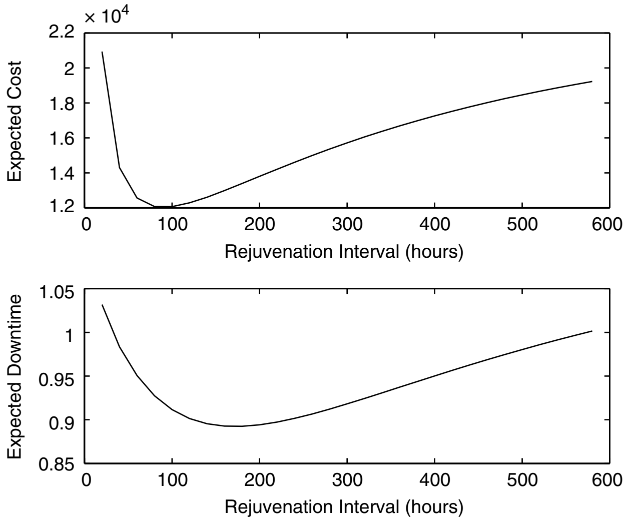

Figure 4. Results for an 8/1 cluster system employing time-based rejuvenation.

rejuvenation. The upper plot and lower plots show the expected cost incurred and the expected downtime (in hours), respectively, in a given time interval, versus rejuvenation interval (time between successive rejuvenation) in hours. If the rejuvenation interval is close to zero, the system is always rejuvenating and thus incurs high cost and downtime. As the rejuvenation interval increases, both expected downtime and cost incurred decrease and reach an optimum value. If the rejuvenation interval goes beyond the optimal value, the system failure has more influence on these measures than rejuvenation. The analysis was repeated for 2/1, 8/2, 16/1, and 16/2 configurations. For time-based rejuvenation, the optimal rejuvenation interval was 100 hours for the 1-spare clusters, and approximately 1 hour for the 2-spare clusters.

MEASUREMENT-BASED MODELS FOR SOFTWARE REJUVENATION

While all the analytical models are based on the assumption that the rate of software aging is known, in the measurement-based approach, the basic idea is to monitor and collect data on the attributes responsible for determining the health of the executing software. The data is then analyzed to obtain predictions about possible impending failures due to resource exhaustion.

In this section, we describe the measurement-based approach for detection and validation of the existence of software aging. The basic idea is to periodically monitor and collect data on the attributes responsible for determining the health of the executing software, in this case the UNIX operating system. Garg et al. (3) propose an approach for detection and estimation of aging in the UNIX operating system. An SNMP-based distributed resource monitoring tool was used to collect operating system resource usage and system activity data from nine heterogeneous UNIX workstations connected by an Ethernet LAN at the Department of Electrical and Computer Engineering at Duke University. A central monitoring station runs the manager program, which sends *get* requests periodically to each of the agent programs running on the monitored workstations. The agent programs, in turn, obtain data for the manager from their respective machines by executing various standard UNIX utility programs like *pstat*, *iostat*, and *vmstat*. For quantifying the effect of aging in operating system resources, the metric *Estimated time to exhaustion* is proposed.

In the time-based estimation method presented by Garg et al. (3), data was collected from the UNIX machines at intervals of 15 minutes for about 53 days. Time-ordered values for each monitored object are obtained, constituting a time series for that object. The objective is to detect aging or a long-term trend (increasing or decreasing) in the values. Only results for the data collected from the machine *Rossby* are discussed here.

First, the trends in operating system resource usage and system activity are detected using *smoothing* of observed data by *robust locally weighted regression*, proposed by Cleveland (3). This technique is used to get the global trend between outages by removing the local variations. Then, the slope of the trend is estimated in order to do prediction. Figure 5 shows the smoothed data superimposed on the original data points from the time series of objects for Rossby. Amount of *real memory free* (plot 1) shows an overall decrease, whereas *file table size* (plot 2) shows an increase. Plots of some other resources not discussed here

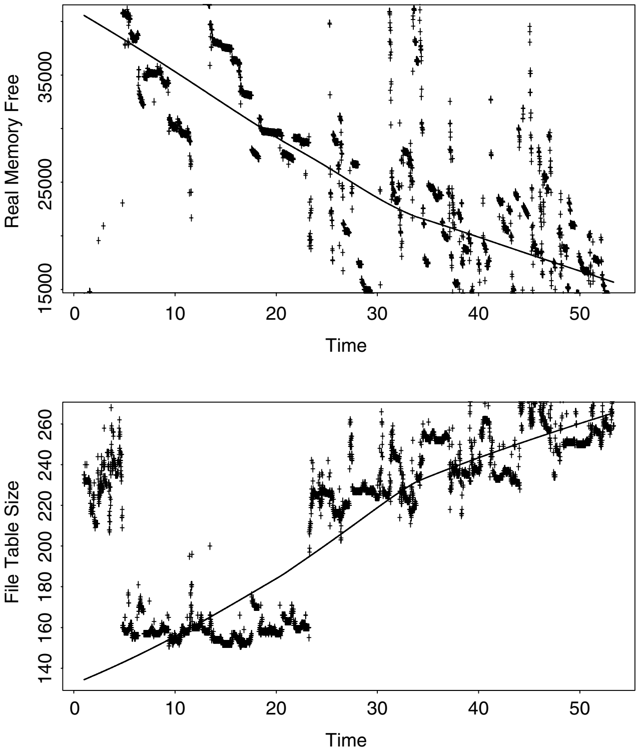

Figure 5. Non-parametric regression smoothing for Rossby objects.

Table 1. Estimated slope and time to exhaustion for Rossby, Velum, and Jefferson objects

Resource Name	Initial Value	Max Value	Sen's Slope Estimation	95% Confidence Interval	Estimated Time to Exh. (days)
Rossby					
Real Memory Free	40814.17	84980	−252.00	−287.75 : −219.34	161.96
File Table Size	220	7110	1.33	1.30 : 1.39	5167.50
Process Table Size	57	2058	0.43	0.41 : 0.45	4602.30
Used Swap Space	39372	312724	267.08	220.09 : 295.50	1023.50
Jefferson					
Real Memory Free	67638.54	114608	−972.00	−1006.81 : −939.08	69.59
File Table Size	268.83	7110	1.33	1.30 : 1.38	5144.36
Process Table Size	67.18	2058	0.30	0.29 : 0.31	6696.41
Used Swap Space	47148.02	524156	577.44	545.69 : 603.14	826.07

also showed an increase or decrease, which corroborates the hypothesis of aging with respect to various objects.

The seasonal Kendall test (3) was applied to each of these time series to detect the presence of any global trends at a significance level, α, of 0.05. With Z_α= 1.96, all values are such that the null hypothesis (H_0) that no trend exists is rejected for the variables considered. Given that a global trend is present and that its slope is calculated for a particular resource, the time at which the resource will be exhausted because of aging only is estimated. Table 1 refers to several objects on Rossby and lists an estimate of the slope (change per day) of the trend obtained by applying Sen's slope estimate for data with seasons (3). The values for real memory and swap space are in Kilobytes.

A negative slope, as in the case of *real memory*, indicates a decreasing trend, whereas a positive slope, as in the case of *file table size*, is indicative of an increasing trend. Given the slope estimate, the table lists the estimated time to failure of the machine due to aging only with respect to this particular resource. The calculation of the time to exhaustion is done by using the standard linear approximation $y = mx + c$.

The method discussed in Ref. 3 assumes that accumulated depletion of a resource over a time period depends only on the elapsed time. However, it is intuitive that the rate at which a resource is depleted is dependent on the current workload. In Refs. 37 and 38, a measurement-based model to estimate the rate of exhaustion of operating system resources as a function of both time and the system workload is discussed. The SNMP-based distributed resource monitoring tool described previously was used for collecting operating system resource usage and system activity parameters (at 10 min intervals) for over 3 months. Only results for the data collected from the machine Rossby are discussed here. The *longest* stretch of sample points in which no reboots or failures occurred were used for building the model. A semi-Markov reward model (39) is constructed using the data. First, different workload states are identified using statistical cluster analysis and a state-space model is constructed. Corresponding to each resource, a reward function based on the rate of resource exhaustion in the different states is then defined. Finally, the model is solved to obtain trends and the estimated exhaustion rates and time to exhaustion for the resources.

A methodology based on time-series analysis to detect and estimate resource exhaustion times due to software aging in a web server while subjecting it to an artificial workload is proposed in Ref. 19. The experiments are conducted on an Apache web server running on the Linux platform.

The analysis can be done using two different approaches: (1) building a univariate model for each of the outputs or, (2) building only one multivariate model with seven outputs. In this case, seven univariate models are built and then combined into a single multivariate model. First, the parameters are determined to determine their characteristics and build an appropriate model with one output and four inputs for each parameter—connection rate, linear trend, periodic series with a period of one week, and periodic series with a period of one day. The autocorrelation function (ACF) and the partial autocorrelation function (PACF) for the output are computed. The ACF and the PACF help us decide the appropriate model for the data (40). For example, from the ACF and PACF of *used swap space*, it can be determined that an autoregressive model of order 1 [AR(1)] is suitable for this data series. Adding the inputs to the AR(1) model, we get the ARX(1) model for used swap space:

$$Y_t = aY_{t-1} + b_1X_t + b_2L_t + b_3W_t + b_4D_t \tag{1}$$

where Y_t is the used swap space, X_t is the connection rate, L_t is the time step that represents the linear trend, W_t is the weekly periodic series, and D_t is the daily periodic series. After observing the ACF and PACF of all the parameters, we find that all of the PACFs cut off at certain lags. So all the multiple input single output (MISO) models are of the ARX type, only with different orders, which gives great convenience in combining them into a multiple input multiple output (MIMO) ARX model, which is described later.

In order to combine the MISO ARX models into a MIMO ARX model, we need to choose the order between different outputs, which is done by inspecting the CCF (cross-correlation function) between each pair of the outputs to find out the leading relationship between them. If the CCF between parameter A and B gets its peak value at a positive lag k, we say that A leads B by k steps and it might be possible to use A to predict B. In our analysis, there are

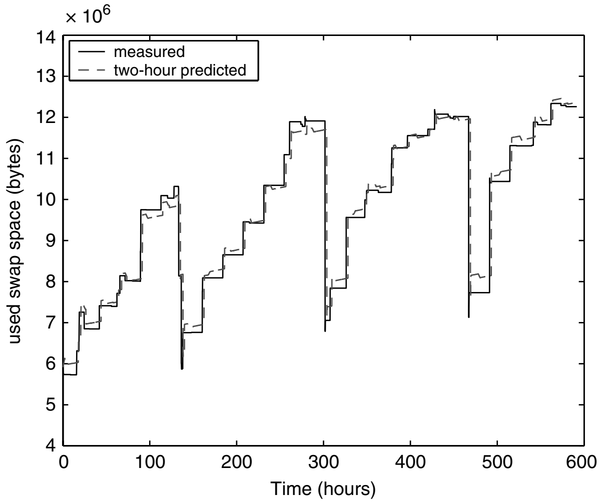

Figure 6. Measured and two-hour-ahead predicted used swap space.

21 CCFs that need to be computed. And, in order to reduce the complexity, we only use the CCFs that exhibit obvious leading relationship with lags less than 10 steps. The next step after determination of the orders is to estimate the coefficients of the model by the least squares method. The first half of the data is used to estimate the parameters and the rest of the data is then used to verify the model. Figure 6 shows the two-hour-ahead (24-step) predicted used swap space, which is computed using the established model and the data measured up to two hours before the predicted time point. From the plots, we can see that the predicted values are very close to the measured values.

In Ref. 8, a model is developed to account for the gradual loss of system resources, especially the memory resource. In a client-server system, for example, every client process issues memory requests at varying points in time. An amount of memory is granted to each new request (when there is enough memory available), held by the requesting process for a period of time, and presumably released back to the system resource reservoir when it is no longer in use. A memory leak occurs when the amount of allocated memory is not fully released. The available memory space is gradually reduced as such resource leaks accumulate over time. As a consequence, a resource request that would have been granted in the leak-less situation may not be granted when the system suffers from memory resource leaks. This model accommodates both the leak-free case and the leak-present case. The model relates system degradation to resource requests, releases or resource holding intervals, and memory leaks. These quantities can be monitored and modeled directly from obtainable data measurements (19).

Avritzer and Weyuker (10) monitor production traffic data of a large telecommunication system and describe a rejuvenation strategy that increases system availability and minimizes packet loss. Cassidy et al. (21) have developed an approach to rejuvenation for large online transaction processing servers. They monitor various system parameters over a period of time. Using pattern recognition methods, they come to the conclusion that 13 of those parameters deviate from normal behavior just before a crash, providing sufficient warning to initiate rejuvenation.

IMPLEMENTATION OF A SOFTWARE REJUVENATION AGENT

The first commercial version of a software rejuvenation agent (SRA) for the IBM xSeries line of cluster servers has been implemented with our collaboration (14–16). The SRA was designed to monitor consumable resources, estimate the time to exhaustion of those resources, and generate alerts to the management infrastructure when the time to exhaustion is less than a user-defined notification horizon. For Windows operating systems, the SRA acquires data on exhaustible resources by reading the registry performance counters and collecting parameters such as available bytes, committed bytes, non-paged pool, paged pool, handles, threads, semaphores, mutexes, and logical disk utilization. For Linux, the agent accesses the /proc directory structure and collects equivalent parameters such as memory utilization, swap space, file descriptors and inodes. All collected parameters are logged on to disk. They are also stored in memory preparatory to time-to-exhaustion analysis.

In the current version of the SRA, rejuvenation can be based on elapsed time since the last rejuvenation or on prediction of impending exhaustion. When using timed rejuvenation, a user interface is used to schedule and perform rejuvenation at a period specified by the user. It allows the user to select when to rejuvenate different nodes of the cluster, and to select "blackout" times during which no rejuvenation is to be allowed. Predictive rejuvenation relies on curve-fitting analysis and projection of the use of key resources, using recently observed data. The projected data is compared with prespecified upper and lower exhaustion thresholds, within a notification time horizon. The user specifies the notification horizon and the parameters to be monitored (some parameters believed to be highly indicative are always monitored by default), and the agent periodically samples the data and performs the analysis. The prediction algorithm fits several types of curves to the data in the fitting window. These different curve types have been selected for their ability to capture different types of temporal trends. A model-selection criterion is applied to choose the "best" prediction curve, which is then extrapolated to the user-specified horizon. The several parameters that are indicative of resource exhaustion are monitored and extrapolated independently. If any monitored parameter exceeds the specified minimum or maximum value within the horizon, a request to rejuvenate is sent to the management infrastructure. In most cases, it is also possible to identify which process is consuming the preponderance of the resource being exhausted, in order to support selective rejuvenation of just the offending process or a group of processes.

APPROACHES AND METHODS OF SOFTWARE REJUVENATION

Software rejuvenation can be divided broadly into two approaches as follows:

- **Open-loop approach:** In this approach, rejuvenation is performed without any feedback from the system. Rejuvenation, in this case, can be based just on elapsed time (periodic rejuvenation) (4,27) or instantaneous/cumulative number of jobs on the system (31).
- **Closed-loop approach:** In the closed-loop approach, rejuvenation is performed based on information on the system "health." The system is monitored continuously (in practice, at small deterministic intervals) and data is collected on the operating system resource usage and system activity. This data is then analyzed to estimate time to exhaustion of a resource that may lead to a component or an entire system degradation/crash. This estimation can be based purely on time and workload-independent (3,14), or it can be based on both time and system workload (37,38).

  The closed-loop approach can be further classified based on whether the data analysis is done offline or online. Offline data analysis is done based on system data collected over a period of time (usually weeks or months). The analysis is done to estimate time to rejuvenation. This offline analysis approach is best suited for systems whose behavior is fairly deterministic (37,38). The online closed-loop approach, on the other hand, performs online analysis of system data collected at deterministic intervals (14). Another approach to estimate the optimal time to rejuvenation could be based on system failure data (34).

This classification of approaches to rejuvenation is shown in Fig. 7.

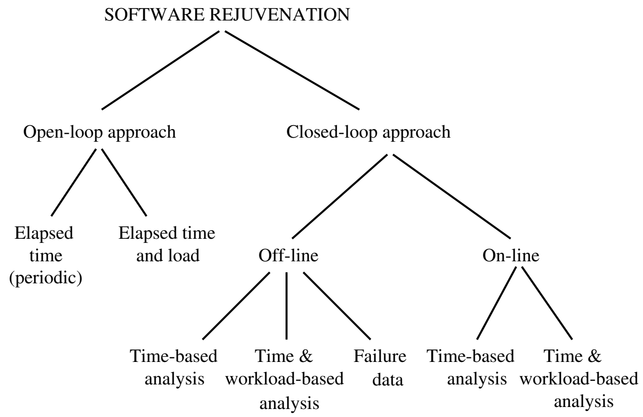

Figure 7. Approaches to software rejuvenation.

Rejuvenation is a very general proactive fault management approach and can be performed at different levels—the system level or the application level. An example of a system-level rejuvenation is a hardware-reboot. At the application level, rejuvenation is performed by stopping and restarting a particular offending application, process, or a group of processes, also known as a *partial rejuvenation*. The above rejuvenation approaches when performed on a single node can lead to undesired and often costly downtime. Rejuvenation has been recently extended for cluster systems, in which two or more nodes work together as a single system (14,16). In this case, rejuvenation can be performed by causing no or minimal downtime by failing over applications to another spare node.

CONCLUSIONS

In this article, various analytical models for software aging and to determine optimal times to perform rejuvenation were described. Measurement-based models based on data collected from operating systems were also discussed. The implementation of a software rejuvenation agent in a major commercial server was then briefly described. Finally, various approaches to rejuvenation and rejuvenation granularity were discussed.

In the measurement-based models presented in this article, only aging due to each individual resource has been captured. In the future, one could improve the algorithm used for aging detection to involve multiple parameters simultaneously, for better prediction capability and reduced false alarms. Dependencies between the various system parameters could be studied. The best statistical data analysis method for a given system is also yet to be determined.

SOFTWARE ARCHITECTURE

INTRODUCTION

During the 1990s, architectural design emerged as an important subfield of software engineering. Practitioners have come to realize that having a good architectural design is a critical success factor for complex system development. A good architecture can help ensure that a system will satisfy key requirements in such areas as performance, reliability, portability, scalability, and interoperability. A bad architecture can be disastrous.

Practitioners have also begun to recognize the value of making explicit architectural choices and leveraging past architectural designs in the development of new products. Today, there are numerous books on architectural design, regular conferences and workshops devoted specifically to software architecture, a growing number of commercial tools to aid in aspects of architectural design, courses in software architecture, major government and industrial research projects centered on software architecture, and an increasing number of formal architectural standards. Codification of architectural principles, methods, and practices has begun to lead to repeatable processes of architectural design, criteria for making principled tradeoffs among architectures, and standards for documenting, reviewing, and implementing architectures.

THE ROLES OF SOFTWARE ARCHITECTURE

What exactly is meant by the term “software architecture?” If we look at the common uses of the term “architecture” in software, we find that it is used in different ways, often making it difficult to understand what aspect is being addressed. Among the uses are: (1) the architecture of a particular system, as in “the architecture of system S contains components $C_1 \dots C_n$”; (2) an architectural style, as in “system S adopts a client-server architecture”; and (3) the general study of architecture, as in “there are many books on software architecture.”

Within software engineering, however, most uses of the term focus on the first of these interpretations. A typical definition is:

> The software architecture of a program or computing system is the structure or structures of the system, which comprise software elements, the externally visible properties of those elements, and the relationships among them (1).

Although numerous similar definitions of software architecture exist, at the core of all of them is the notion that the architecture of a system describes its gross structure using one or more views. The structure in a view illuminates a set of top-level design decisions, including things such as how the system is composed of interacting parts, where the main pathways of interaction are, and what the key properties of the parts are. Additionally, an architectural description ideally includes sufficient information to allow high-level analysis and critical appraisal.

Software architecture typically plays a key role as a bridge between requirements and code (see Fig. 1).

By providing an abstract description (or model) of a system, the architecture exposes certain properties while hiding others. Ideally, this representation provides an intellectually tractable guide to the overall system, permits designers to reason about the ability of a system to satisfy certain requirements, and suggests a blueprint for system construction and composition.

For example, an architecture for a signal processing application might be constructed as a dataflow network in which the nodes read input streams of data, transform that data, and write to output streams. Designers might use this decomposition, together with estimated values for input data flows, computation costs, and buffering capacities, to reason about possible bottlenecks, resource requirements, and schedulability of the computations.

To elaborate, software architecture can play an important role in at least six aspects of software development.

1. *Understanding:* Software architecture simplifies our ability to comprehend large systems by presenting them at a level of abstraction at which a system’s design can be easily understood (2–4). Moreover, at its best, architectural description exposes the high-level constraints on system design, as well as the rationale for specific architectural choices.
2. *Reuse:* Architectural design can support reuse in several ways. Current work on reuse generally focuses on component libraries. Architectural design supports, in addition, both reuse of large components (or subsystems) and also frameworks into which components can be integrated. Such reusable frameworks may be domain-specific software architectural styles (5,6), component integration standards (7), and architectural design patterns (8).
3. *Construction:* An architectural description provides a partial blueprint for development by indicating the major software components and dependencies between them. For example, a layered view of an architecture typically documents abstraction boundaries between parts of a system’s implementation, clearly identifying the major internal system interfaces, and constraining what parts of a system may rely on services provided by other parts (2).
4. *Evolution:* Software architecture can expose the dimensions along which a system is expected to evolve. By making explicit the “load-bearing walls” of a system, system maintainers can better understand the ramifications of changes, and thereby more accurately estimate costs of modifications. Moreover, architectural descriptions separate concerns about the functionality of a component from the ways in

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

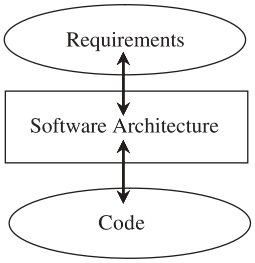

Figure 1. Software architecture as a bridge.

which that component interacts with other components, by clearly distinguishing between components and mechanisms that allow them to interact. This separation permits one to more easily change connection mechanisms to handle evolving concerns about performance and reuse.

5. *Analysis:* Architectural descriptions provide new opportunities for analysis, including system consistency checking (9,10), conformance to constraints imposed by an architectural style (11), conformance to quality attributes (12), dependence analysis (13), and domain-specific analyses for architectures built in specific styles (14–16).
6. *Management:* Experience has shown that successful projects view achievement of a viable software architecture as a key milestone in an industrial software development process. Critical evaluation of an architecture typically leads to a much clearer understanding of requirements, implementation strategies, and potential risks (17).
7. *Communication:* An architectural description often serves as a vehicle for communication among stakeholders. For example, explicit architectural design reviews allow stakeholders to voice opinions about relative weights of features and quality attributes when architectural tradeoffs must be considered (12).

PRECURSORS

The notion of providing explicit descriptions of system structures goes way back. In the 1960s and 1970s there were active debates about criteria on which to base modularization of software (18,19). Programming languages began to provide new features for modularization and the specification of interfaces.

In 1975, DeRemer and Kron (20) argued that creating program modules and connecting them to form larger structures were distinct design efforts. They created the first module interconnection language (MIL) to support that connection effort. In an MIL, modules import and export resources, which are named programming-language elements such as type definitions, constants, variables, and functions. A compiler for an MIL ensures system integrity using intermodule-type checking. Since DeRemer and Kron's proposal, other MILs have been developed for specific programming languages such as Ada and Standard ML, and have provided a base from which to support software construction, version control, and system families (21,22). Enough examples are available to develop models of the design space (23).

These early efforts to develop good ways to talk about system structures and to provide criteria for software modularization focused primarily on the problem of code organization and relationships between the parts based on interactions such as procedure call and simple data sharing. The key question was how to partition the software into units that could be implemented separately by software developers, and that would provide downstream benefits in support of extensibility, maintenance, and system understandability.

Today's view of software architecture builds on the insights and concepts from the early days of software structuring, but goes much further by also considering architectural representations that capture a system's run-time structures and behavior. By representing architectures as interacting components (viewed as actual run-time entities), these representations more directly facilitate reasoning about system properties such as performance, security, and reliability. Additionally, modern views of software architecture provide a much richer notion of interaction (than procedure call and simple data sharing), permitting new abstractions for the "glue" that allows components to be composed.

A NEW DISCIPLINE EMERGES

Initially, architectural design was largely an ad hoc affair. Architectural definitions relied on informal box-and-line diagrams, which were rarely maintained once a system was constructed. Architectural choices were made in an idiosyncratic fashion—typically by adapting some previous design, whether or not it was appropriate. Good architects, even if they were classified as such within their organizations, learned their craft by hard experience in particular domains and were unable to teach others what they knew. It was usually impossible to analyze an architectural description for consistency or to infer nontrivial properties about it. There was virtually no way to check that a given system implementation faithfully represented its architectural design.

However, despite their informality, architectural descriptions were central to system design. As people began to understand the critical role that architectural design plays in determining system success, they also began to recognize the need for a more disciplined approach. Early authors began to observe certain unifying principles in architectural design (24), to call out architecture as a field in need of attention (4), and to establish a working vocabulary for software architects (3). Tool vendors began thinking about explicit support for architectural design. Language designers began to consider notations for architectural representation (25).

Within industry, two trends highlighted the importance of architecture. The first was the recognition of a shared repertoire of methods, techniques, patterns, and idioms for structuring complex software systems. For example, the box-and-line-diagrams and explanatory prose that typically accompany a high-level system description often refer to such organizations as a "pipeline," a "blackboard-oriented design," or a "client-server system." Although these terms were rarely assigned precise definitions, they permitted designers to describe complex systems using abstractions that make the overall system intelligible. Moreover, they provided significant semantic content about the kinds of properties of concern, the expected paths of evolution, the overall computational paradigm, and the relationship between this system and other similar systems.

The second trend was the concern with exploiting commonalities in specific domains to provide reusable frameworks for product families. Such exploitation is based on the idea that common aspects of a collection of related systems can be extracted so that each new system can be built at relatively low cost by "instantiating" the shared design. Familiar examples include the standard decomposition of a compiler (which permits undergraduates to construct a new compiler in a semester), standardized communication protocols (which allow vendors to interoperate by providing services at different layers of abstraction), fourth-generation languages (which exploit the common patterns of business information processing), and user interface toolkits and frameworks (which provide both a reusable framework for developing interfaces and sets of reusable components, such as menus and dialog boxes).

Much has changed in the past two decades. Although there is wide variation in the state of the practice, broadly speaking, architecture is much more visible as an important and explicit design activity in software development. Job titles now routinely reflect the role of software architect; companies rely on architectural design reviews as critical staging points; and architects recognize the importance of making explicit tradeoffs within the architectural design space.

In addition, the technological basis for architectural design has improved dramatically. Three of the important advancements have been the development of architecture description languages and tools, the emergence of product line engineering and architectural standards, and the codification and dissemination of architectural design expertise.

ARCHITECTURE DESCRIPTION LANGUAGES AND TOOLS

The informality of most box-and-line depictions of architectural designs leads to a number of problems. The meaning of the design may not be clear. Informal diagrams cannot be formally analyzed for consistency, completeness, or correctness. Architectural constraints assumed in the initial design are not enforced as a system evolves. There are few tools to help architectural designers with their tasks.

To alleviate these problems, there have been a number of important developments. First has been the emergence of practitioner guidelines (2) and published standards for architectural documentation (26,27), which have helped to codify best practices and provide some uniformity to the way architectures are documented.

A second development has been the creation of formal notations for representing and analyzing architectural designs. Sometimes referred to as "Architecture Description Languages" or "Architecture Definition Languages" (ADLs), these notations usually provide both a conceptual framework and a formal language for characterizing software architectures (25,28). They also typically provide tools for parsing, displaying, compiling, analyzing, or simulating architectural descriptions.

Examples of ADLs include AADL (29), Acme (30), Adage (14), C2 (31), Darwin (16), Rapide (10), SADL (32), UniCon (33), Meta-H (34), and Wright (9). Although all of these languages are concerned with architectural design, each provides certain distinctive capabilities: AADL supports the design and analysis of real-time and embedded computer systems; Acme supports checking of conformance to architectural styles; Adage supports the description of architectural frameworks for avionics navigation and guidance; C2 supports the description of user interface systems using an event-based style; Darwin supports the analysis of distributed message-passing systems; Meta-H provides guidance for designers of real-time avionics control software; Rapide allows architectural designs to be simulated and has tools for analyzing the results of those simulations; SADL provides a formal basis for architectural refinement; UniCon has a high-level compiler for architectural designs that supports a mixture of heterogeneous component and connector types; and Wright supports the formal specification and analysis of interactions between architectural components.

Although these languages (and their tools) differ in many respects, a number of key insights have emerged through their development.

The first insight is that good architectural description benefits from multiple views, each view capturing some aspect of the system (2,26,27,35). Two of the more important classes of view are:

- **Code-oriented views**, which describe how the software is organized into modules and what kinds if implementation dependencies exist between those modules. Class diagrams, layered diagrams, and work breakdown structures are examples of this class of view; and
- **Execution-oriented views**, which describe how the system appears at run time, typically providing one or more snapshots of a system in action. These views are useful for documenting and analyzing execution properties such as performance, reliability, and security.

A second insight is that architectural description of execution-oriented views, as embodied in most of the ADLs mentioned earlier, requires the ability to model the following as first-class design entities:

- **Components** represent the computational elements and data stores of a system. Intuitively, they correspond to the boxes in box-and-line descriptions of software architectures. Examples of components include clients, servers, filters, blackboards, and databases. Components may have multiple interfaces, each interface defining a point of interaction between a component and its environment. A component may have several interfaces of the same type (e.g., a server may have several active http connections).

- **Connectors** represent interactions among components. They provide the "glue" for architectural designs, and they correspond to the lines in box-and-line descriptions. From a run-time perspective, connectors mediate the communication and coordination activities among components. Examples include simple forms of interaction, such as pipes, procedure call, and event broadcast. Connectors may also represent complex interactions, such as a client-server protocol or an SQL link between a database and an application. Connectors have interfaces that define the roles played by the participants in the interaction.
- **Systems** represent graphs of components and connectors. In general, systems may be hierarchical: Components and connectors may represent subsystems that have their own internal architectures. We will refer to these as *representations*. When a system or part of a system has a representation, it is also necessary to explain the mapping between the internal and external interfaces.
- **Properties** represent additional information (beyond structure) about the parts of an architectural description. Although the properties that can be expressed by different ADLs vary considerably, typically they are used to represent anticipated or required extra-functional aspects of an architectural design. For example, some ADLs allow one to calculate system throughput and latency based on performance estimates of the constituent components and connectors. In general, it is desirable to be able to associate properties with any architectural element in a description (components, connectors, systems, and their interfaces). For example, a property of an interface might describe an interaction protocol.
- **Styles** represent families of related systems. An architectural style typically defines a vocabulary of design element types as a set of component, connector, port, role, binding, and property types, together with rules for composing instances of the types. We will describe some of the more prominent styles later in this article.

To illustrate the use of these modeling constructs, consider the example shown in Fig. 2. The system defines an execution-oriented view of a simple string-processing application that extracts and sorts text. The system is described in a pipe-filter style, which provides a design vocabulary consisting of a filter component type and pipe connector type, input and output interface (port) types, and a single binding type. In addition, there would likely be constraints (not shown) that ensure, for example, that the reader/writer roles of the pipe are associated with appropriate input/output ports. The system is described hierarchically: *MergeAndSort* is defined by a representation that is itself a pipe-filter system. In complementary documentation, properties of the components and connectors might list, for example, performance characteristics used by a tool to calculate overall system throughput.

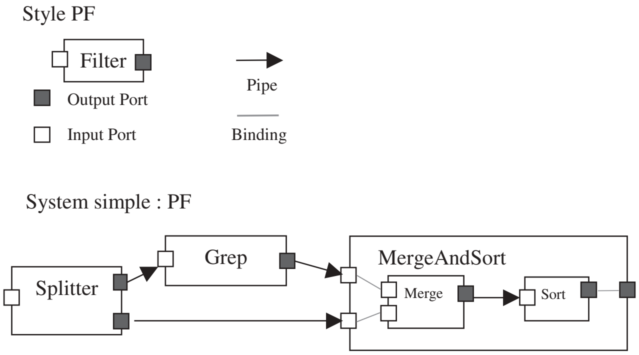

Figure 2. A system in the pipe-filter style.

PRODUCT LINES AND ARCHITECTURAL STANDARDS

As noted earlier, an important trend has been the desire to exploit commonality across multiple products. Two specific manifestations of that trend are improvements in our ability to create product lines within an organization and the emergence of domain-specific architectural standards for cross-vendor integration.

With respect to product lines, a key challenge is that a product line approach requires different methods of development. In a single-product approach, the architecture must be evaluated with respect to the requirements of that product alone. Moreover, single products can be built independently, each with a different architecture.

However, in a product line approach, one must also consider requirements for the *family* of systems and the relationship between those requirements and the ones associated with each particular instance. Figure 3 illustrates this relationship. In particular, there must be an up-front (and ongoing) investment in developing a reusable architecture that can be instantiated for each product. Other reusable assets, such as components, test suites, tools, and so on, typically accompany this approach.

Although product line engineering is not yet widespread, we are beginning to have a better understanding

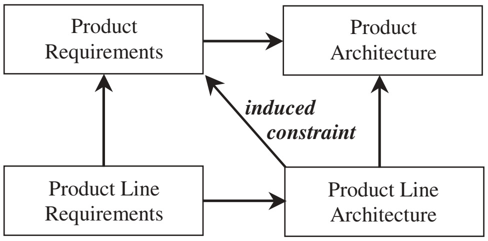

Figure 3. Product line architectures.

of the processes, economics, and artifacts required to achieve the benefits of a product line approach. A number of case studies of product line successes have been published (36,37). Moreover, organizations such as the Carnegie Mellon University's Software Engineering Institute are well on their way toward providing concrete guidelines and processes for the use of a product line approach (38).

Like product line approaches, domain-specific architectural standards for cross-vendor integration provide frameworks that permit system developers to configure a wide variety of specific systems by instantiating those frameworks. But more importantly, such standards support the integration of parts provided by multiple vendors. A number of these have been sanctioned as formal international standards (such as those sponsored by the Institute of Electrical and Electronics Engineers, Incorporated (IEEE) or the International Standards Organization (ISO)), whereas others are ad hoc or de facto standards promoted by one or more industrial leaders.

A good example of a formal standard is the High-Level Architecture (HLA) for Distributed Simulation (5). Initially proposed by the U.S. Defense Modeling and Simulation Office as a standard to permit the integration of simulations produced by many vendors, it now has become an IEEE Standard (IEEE P1516.1/D6). The HLA prescribes interface standards defining services to coordinate the behavior of multiple semi-independent simulations. In addition, the standard prescribes requirements on the simulation components that indicate what capabilities they must have, and what constraints they must observe on the use of shared services.

An example of an ad hoc standard is Sun's Enterprise Java-Beans (EJB) architecture (6). EJB is intended to support distributed, Java-based, enterprise-level applications, such as business information management systems. Among other things, it prescribes an architecture that defines a vendor-neutral interface to information services, including transactions, persistence, and security. It thereby supports component-based implementations of business processing software that can be easily retargeted to different implementations of those underlying services.

CODIFICATION AND DISSEMINATION

One early impediment to the emergence of architectural design as an engineering discipline was the lack of a shared body of knowledge about architectures and techniques for developing good ones. Today, the situation has improved, due in part to the publication of books on architectural design (1,8,24,26,36,39) and courses (40).

A common theme in these books and courses is the use of standard architectural *styles*. An architectural style typically specifies a design vocabulary, constraints on how that vocabulary is used, and semantic assumptions about that vocabulary (2,11). For example, a pipe-filter style might specify vocabulary in which the processing components are data transformers (filters) and the interactions are via order-preserving streams (pipes). Constraints might include the prohibition of cycles. Semantic assumptions might include the fact that pipes preserve order and that filters are invoked non-deterministically.

Other common styles include blackboard architectures, client-server architectures, event-based architectures, and object-based architectures. Each style is appropriate for certain purposes, but not for others. For example, a pipe-and-filter style would likely be appropriate for a signal processing application, but not for an application in which there is a significant requirement for concurrent access to shared data (41). Moreover, each style is typically associated with a set of associated analyses. For example, it makes sense to analyze a pipe-filter system for system latencies, whereas transaction rates would be a more appropriate analysis for a repository-oriented style.

The identification and documentation of such styles (as well as their more domain-specific variants) enables others to adopt previously defined architectural patterns as a starting point. In that respect, the architectural community has paralleled other communities in recognizing the value of established, well-documented patterns, such as those found in Ref. 42.

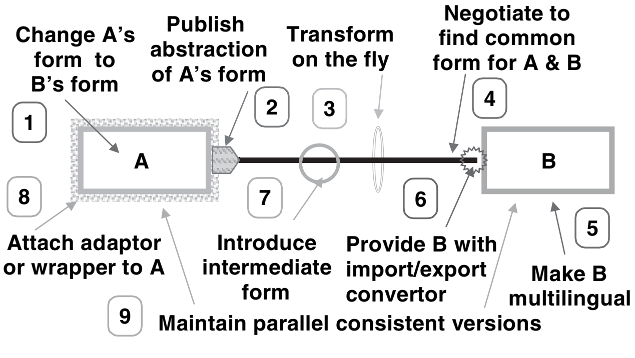
While recognizing the value of stylistic uniformity, realities of software construction often force one to compose systems from parts that were not architected in a uniform fashion. For example, one might combine a database from one vendor, with middleware from another, and a user interface from a third. In such cases, the parts do not always work well together—in large measure because they make conflicting assumptions about the environments in which they were designed to work (43), which has led to a recognition of the need to identify architectural strategies for bridging mismatches. Although we are far from having well-understood ways of detecting such a mismatch, and of repairing it when it is discovered, a number of techniques have been developed, some of which are illustrated in Fig. 4 (due to Mary Shaw).

RELATED AREAS

There are a number of closely related areas.

Software Development Methods

One of the hallmarks of software engineering progress has been the development of methods and processes for



Change A's form to B's form

Figure 4. Some mismatch repair techniques.

software development. Like software architecture, methods attempt to provide a path from requirements to code that eliminates some of the ad hoc development practice of the past.

Methods complement software architecture: The former attempt to provide a set of regular steps for software development, whereas the latter attempts to provide a basis for developing and analyzing certain design models along that path.

To the extent that they support conceptual design of systems, they also address architectural concerns. On the other hand, most methods tend to favor a particular architectural style. For example, object-oriented methods naturally favor architectural designs based on interacting objects, whereas other methods favor other styles.

Object-Oriented Design and Modeling

There are a number of parallels between the evolution of object-oriented design techniques and the trends of software architecture, outlined above.

- **Description Languages and Tools:** Object-oriented systems have long had design languages and tools to support their use. The Unified Modeling Language (UML) has emerged as a standard notation, unifying many of its predecessors (44). Increasingly, vendors are developing tools that take advantage of this technological standardization.
- **Product Lines and Standards:** Object-oriented frameworks have long been an important point of leverage in system development. In particular, component-oriented integration mechanisms, such as CORBA, .NET, and JavaBeans have played an important role in supporting integration of object-oriented parts. In other more domain-specific ways, frameworks like J2EE, VisualBasic, and MFC, have helped improve productivity in specific areas.
- **Codification and Dissemination:** There has been considerable work and interest in object-oriented patterns, which serve to codify common solutions to implementation problems (42).

Given these similarities, it is worth asking the following question: What are the important differences between the two fields? To shed light on the issue, it is helpful to view the relationship between architecture and object-oriented methods from at least three distinct perspectives.

1. *Object-oriented design as an architectural style:* This perspective treats the part of object-oriented development that is concerned with system structure as the special case of architectural design in which the components are objects and the connectors are procedure calls (method invocation). Some ADLs support this view, providing built-in primitives for inter-component procedure call.
2. *Object-oriented design as an implementation base:* This perspective treats object-oriented development as a lower-level activity, more concerned with implementation. Viewed this way, object modeling becomes one viable implementation target for any architectural design.
3. *Object-oriented design as an architectural modeling notation:* This perspective treats a notation such as UML as a suitable notation for all architectural descriptions (8,35,45). Proponents of this perspective have advocated various ways of using object modeling, including class diagrams, collaboration diagrams, and package diagrams (36,46,47). From this perspective, architecture is viewed as a sub-activity of object-oriented design.

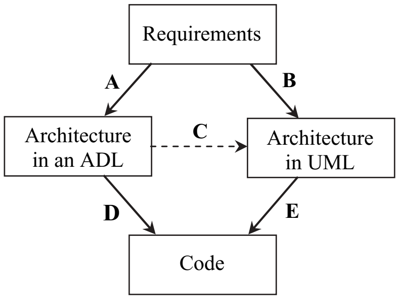

Figure 5. ADLs versus object modeling.

Elaborating on the relationship between ADLs and object-oriented modeling notations, such as UML, Fig. 5 shows some of the paths that might be followed. Path A-D is one in which an ADL is used as the modeling language. Path B-E is one in which UML is used as the modeling notation. Path A-C-E is one in which an architecture is first represented in an ADL, but then transformed into UML before producing an implementation.

Using a general-purpose modeling language such as UML has the advantages of providing a notation that practitioners are more likely to be familiar with and providing a more direct link to object-oriented implementations and development tools. But general-purpose object languages suffer from the problem that the object conceptual vocabulary may not be ideally suited for representing architectural concepts, and there are likely to be fewer opportunities for automated analysis of architectural properties.

Component-Based Systems

Component-based systems are closely related to object-oriented systems insofar as both are based on the construction of systems from encapsulated entities that provide well-defined interfaces to a set of services. However, most component-based systems have a strong intrinsic architectural flavor in that they are usually coupled with an integration framework that prescribes what kinds of interfaces the components must have and ways in which components can interact at run time (7).

From an architectural perspective, component-based systems such as .NET, CORBA, and J2EE define architectural styles that are predominantly object-oriented. In addition, they may support other forms of interaction such as event publish-subscribe. However, component integration standards typically go beyond architectural modeling by providing run-time infrastructure and (in many cases) considerable support for generating code from more abstract descriptions.

FUTURE PROSPECTS

The field of software architecture is one that has experienced considerable growth since the 1990s, and it promises to continue that growth for the foreseeable future. As architectural design matures into an engineering discipline that is universally recognized and practiced, there are a number of significant challenges that will need to be addressed. Many of the solutions to these challenges are likely to occur as a natural consequence of dissemination and maturation of the architectural practices and technology that we know about today. Other challenges develop because of the shifting landscape of computing and the needs for software: These challenges will require significant new innovations. This article has attempted to provide a high-level overview of the terrain, illustrating where software architecture has come over the past few years and outlining relationships between software architecture and other aspects of software engineering.

SOFTWARE COMPONENT REPOSITORIES

INTRODUCTION

In the past, reuse has primarily been the result of opportunistic success, where one program was able to take advantage of the efforts of another. A paradigm shift is needed from current software engineering and development practices to a software engineering process in which software reuse is institutionalized and becomes an inseparable part of the software development process. Reuse should be systematic, driven by a demand for software components identified as a result of domain analysis and architecture development. Reuse needs to be treated as an integral part of engineering and acquisition activities. It is essential that an organizational infrastructure be implemented to manage domains, define products and standards, establish ownership criteria, allocate investment resources, and direct the establishment and population of reuse repositories. An effective infrastructure will guide reuse activities to avoid duplication of effort, impose necessary standardization, and ensure repository population is user demand-driven.

WHAT IS SOFTWARE COMPONENT REPOSITORY?

A component repository system that supports software reuse (3) by helping programmers locate, comprehend, and modify components has three parts: a repository that contains components, an indexing and retrieval mechanism, and an interface for user interaction.

Usually, component repository capabilities include the following:

- Automated repository system with a graphical user interface (GUI) for browsing, searching and retrieval;
- Standard component description framework (e.g., to include purpose, functional description, certification level, key environmental constraints, historical results of usage, and legal restrictions);
- Effective classification scheme for each domain; and
- Thorough system and component documentation.

REPOSITORY MECHANISM

Each repository system should provide as much automated support to users as possible on identification, comparison, evaluation, and retrieval of similar reusable components. Support for adapting, transforming, and specializing components is desirable. It must also provide a range of support to users in locating and comparing the relative reusability of individual repository components. Furthermore, the system must be readily available to system developers if it is to be used, and it must support access from a variety of platforms. As the repository acquires a significant number of reusable software components (RSCs), an automated search and retrieval system becomes indispensable (4–6). Whatever tool is used, the repository must have a way to classify RSCs so that a user can quickly find what is wanted without frustration and delay. Sophisticated, expert system, knowledge-based approaches and new technologies for high-speed text search are the subjects of current research efforts.

Standard component description frameworks help ease the process of comprehension and comparison of similar components, and they include data such as relative numeric measures for reusability, reliability, maintainability and portability (7). Inclusion of testing and component documentation provides additional information to help the potential user gauge the effort required to tailor the component for reuse.

Effective classification schemes are essential to assist the user in locating and comparing repository components and to speed the process of identifying appropriate components for the task at hand (8,9). Finally, system and component documentation complete the cycle of evaluation and enable the reuser to determine which components have reuse potential with regard to specific requirements and to fully comprehend the process of obtaining components for reuse in a new application.

In addition, other equally important requirements have been identified that require resolution to support cohesive, wide reuse, including [1] integration of repository capabilities and procedures within the system development and acquisition process; [2] identification and support of specific requirements associated with the security and integrity of reusable components implementing trusted computing base (TCB) or other security capabilities; and [3] intercommunication and interoperabllity among diverse repository systems. Experience has shown that these requirements can only be resolved through the combination of developing new technologies, standard procedures, and evolution or revision of existing policies.

REPOSITORY RETRIEVAL

Component retrieval is a fundamental issue in software reuse. The retrieval process involves finding a component matching the desired functionality and making sure that the component satisfies required nonfunctional properties such as timing and resource constraints.

Precision and recall are two measures that have traditionally been used to evaluate methods for retrieving software components. Let Q be the set of items that should be returned in answer to the query and let R be the choice set actually returned. Then precision can be defined as $|R \cap Q|/|Q|$, which measures the ability to return only the relevant components. Recall can be defined as $|R \cap Q|/|R|$, which measures the ability not to miss relevant components. Desirable retrieval techniques should yield high precision and recall.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Classic Retrieval Approaches

The most classic approach to retrieval is to classify items by keywords and then search for items that have certain given keywords (10). Experience shows that this approach works poorly for retrieving software components from even moderately large repositories. One problem is that the user must be familiar with both the classification scheme and the particular repository. Also, it is very difficult to get both high precision and high recall. This situation suggests that, for ranked filtering, it would be most appropriate to use a small number of keywords.

Another classic approach is browsing. Browsing systems depend on links among the items to be searched and on the user following those links to find the desired item. Experience shows that browsing through large structures can be very frustrating and time-consuming. The problem is that the structure of the links often does not match the needs of most users and that different users may need different structures.

The Facet Approach

Prieto-Diaz (11) proposed using *facets*, which are groups of related terms in a subject area. For example, a facet to describe the functions performed by components might use terms chosen from *find, compare, sort, update, send, receive*, and so on. This approach provided a better description of UNIX components than a pure keyword approach because of its standardized structure. However, it still relies on an informal description of components, using a limited set of facets and terms. Facets also suffer from the same problem as the keyword approach.

AI Approaches

Artificial intelligence (AI) based approaches use a knowledge base and statistical information to retrieve reusable components, based on a keyword search from texts describing the components (12–14). However, because the characterization of the component behavior is completely informal, the behavior is unpredictable.

The Ontology-based Approach

Yen (15) used an ontology-based approach to facilitate browsing and effective search in a repository for embedded software. They developed a merging and echoing technique, which converts the ontology into a hierarchy suitable for browsing, but without the loss of critical semantics of the ontology. A search result categorization approach was developed to eliminate the problem of obtaining a large number of search results without reducing the recall factor. As the ontology approach can typically have many views, it may not be suitable for navigation and browsing.

Specification-based Approaches

Specification-based approaches use semantics for software component retrieval (16,17). The primary aim was to check that retrieved components yield the behavior specified in the user's query, therefore increasing the precision of retrieval. Zaremski and Wing (18) focused on specification matching, using the Larch/ML interface language to express pre- and post-conditions in first-order logic and the Larch prover to verify that candidate components satisfy these conditions. Various senses of matching are defined, but neither ranking nor partial semantic matching is considered.

In general, using formal specifications as search keys has two main problems. The first problem is practical: Not all users are sophisticated enough to write formal specifications, much less correct ones. The second problem is that semantic matching is very time-consuming, because some form of theorem proving must be done. As theorem proving requires unbounded time, practical implementations must impose time limits, which reduce recall.

Automated Retrieval

Luqi et al. (19) proposed an automated retrieval approach. In this approach, search is organized as a series of increasingly stringent filters on candidate components. They first filter components by comparing their signatures with that of the query, which is accomplished by signature matching, which looks for maps that translate the type and function symbols of the query into corresponding type and function symbols of candidate components. A first stage of signature filtering can compare pre-computed syntactic profiles of components with the profile of the query. These profiles are special data structures that support an efficient approximation of signature matching. Signature matches can be partial, in that only part of the functionality the user seeks may actually be available. Profile matching should be followed by full signature matching. To achieve high recall, filters in the early stages must eliminate only those components that are definitely not compatible with the query.

Finally, semantic filters rank components by how well they satisfy the equations in the query. In this process, equations that are logical consequences of the query specification are translated through the signature matches into equations whose proof is attempted in the candidate specifications. For greatest efficiency, it is desirable to restrict queries to be ground equations; these ground equations correspond to test cases and enable semantic matching to be efficiently decidable. The candidates in the choice set are ranked according to their likelihood of success. If the closest match is partial, the user will need to modify the closest matching component. This whole process can be made iterative.

Figure 1 shows the multi-level filtering architecture of the automated retrieval approach; the top line is to indicate user modification of the query in light of the final filtering results.

In comparing with other approaches, the automated retrieval approach has the following merits:

1. It can simultaneously achieve high precision and high recall (20).
2. It compares formal specifications of components using ground equation test cases as queries.
3. Users do not need to deal with formal specification notation, but instead can express queries in a

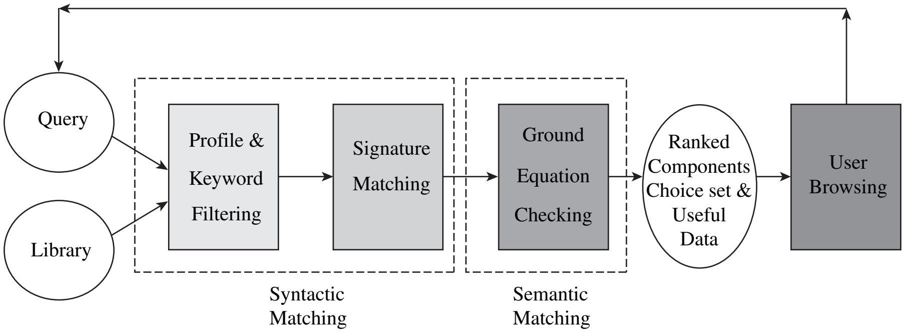

Figure 1. An organization model for software component search.

standard programming notation, which is automatically translated into algebraic notation.

4. It seeks to achieve both efficiency and effectiveness by imposing a series of increasingly stringent filters that use both syntactic and *partial* semantic information about components.
5. A rank is provided on components in the choice set, measuring how well they fit the user's query and enabling sorting by relevance.
6. Generic modules are allowed in the software base.
7. It addresses structuring the software base to facilitate search.
8. Users can give *selection criteria* to control the search and display of retrieved components.
9. Besides returning the ranked components, it also reports information to help the user reformulate the query in case no suitable component was found.

SOME REUSABLE SOFTWARE COMPONENT REPOSITORIES

Microsoft Repository

Microsoft Repository is composed of two major components: a set of ActiveX interfaces that a developer can use to define open information models and a repository engine that is the underlying storage mechanism for these information models (21). The repository engine sits on top of an SQL Server and Microsoft JET database system.

A tool developer can use Microsoft Repository to share and reuse components. To share components effectively, it is useful to share not only the executable image of a component but also descriptive information about the component and its configuration.

Microsoft Repository uses an SQL Server database to store object and relationship data. The repository engine is scalable from desktop-based to server-based solutions. The repository exposes information models by way of ActiveX objects and uses an SQL Server as a storage and query provider.

+1Reuse Repository

The +1Reuse system supports reuse repositories created and maintained by the user, project-wide "filtered" repositories under strict quality controls, and selective reuse. Selective reuse enables reuse of any submodel from an existing or re-engineered +1Environment projrect. In a sense, every +1Environment project is a reuse repository. Selective reuse significantly improves a user's ability to reuse all source code and documentation from all previous projects and at any granularity, which, to the best of our knowledge, is currently the only system to support this feature.

The +1Reuse system supports reuse of design, documentation, source code, header files, test cases, test shell scripts, expected test results, and modeling information.

The +1Reuse system was developed by +1 Software Engineering Co. in California (22). It is now running on Sun Workstation platforms under Solaris. The GUI is based on OpenWindows, Motif, and CDE.

ComponentSource Repository

ComponentSource provides a web-based repository for "off-the-shelf" reusable software components (23). It uses a taxonomy to structure components to facilitate retrieval. This taxonomy provides an effective way of locating generic components (domain-independent) that are well known to programmers and corresponds well with their intuition. ComponentSource has spent many years accumulating the world's largest online repository of quality software components and development tools. Every product that is listed on the site has first gone through a commercial and technical assessment process, to review such things as software and documentation quality, sample code, likely support issues, and the ongoing viability of the supplier.

Agora

The Component-Based Systems (CBS) Initiative at the Software Engineering Institute (SEI) developed the Agora software prototype to investigate the integration of search technology with component introspection to create a distributed, worldwide component repository.

Agora is a prototype component repository being developed by the SEI at Carnegie Mellon University (24,25). The objective of this work is to create an automatically generated, indexed, database of software components classified by component models (e.g., JavaBean, ActiveX, CORBA, Enterprise JavaBean). Agora combines introspection with Web search engines to reduce the costs of bringing software components to, and finding components in, the software marketplace.

The Agora search engine enhances existing but rudimentary search capabilities for Java applets. By using Java introspection, the Agora search engine can maintain a more structured and descriptive index that is targeted to the type of content (the component model) and the intended audience (application developers) than is supported by existing search engines. For example, information about component properties, events, and methods can be retrieved from Agora.

CAPS Software Reusable Component Repository

CAPS (Computer-Aided Prototyping System) is a research project developed by the Software Engineering Group at the Naval Postgraduate School (26). Initial implementation of CAPS software base was first explored in 1988 (27). An implementation of the software base was accomplished in 1991 by using ONTOS, an object-oriented database management system that provides an interface to C++ for customization and flexibility (28). The CAPS software base has been changing to a software component repository since 1998 (19). The CAPS component repository supports two critical functions: component storage and component retrieval. Much effort has been made to improve the component retrieval method (20,29). To the best of our knowledge, CAPS Repository is the only one that supports profile matching and signature matching. It simultaneously provides high precision and recall retrieval. The CAPS repository is still under construction. A prototype has been developed to verify the performance of the retrieval methods.

CONCLUSION

Web-based reuse is the current trend of software component repositories. Usually, the aim is to provide a service within a domain, organization, or area. This kind of repository is used in a wide scope. Another trend of component repositories is to be a part of an integrated CASE environment. The aim is to provide an integrated CASE environment for a software development organization. This kind of repository is generally used in a relatively narrow scope.

As suggested by Weisert (30), to guarantee successful software reuse, the software development organization must support a component repository, to which programmers contribute new components as byproducts of their projects, and from which other programmers will draw existing components for use in their projects.

SOFTWARE CYBERNETICS

INTRODUCTION

Separately, the concepts of software and cybernetics are well known and found as in the definitions extracted from an online dictionary.

Software (1). The programs and procedures required to enable a computer to perform a specific task, as opposed to the physical components of the system (hardware).

Cybernetics (1). The study of communication and control, typically involving regulatory feedback, in living organisms, in machines, and in organizations and their combinations, for example, in sociotechnical systems, computer-controlled machines such as automata, and robots.

As we can see from the definition above, cybernetics includes software that implements a control system but does not include the control of software itself, much less the control of the software development process. For example, the design of the software for a cruise control system of an automobile is considered part of cybernetics, but the design of a software/technique to regulate the behavior of another software system is not addressed in the scope of cybernetics. A new area is therefore needed to develop control systems with this purpose. It should be noted that the definition of control systems (as seen below) used in this new area remains unchanged.

Control Systems (1). A control system is a device or set of devices that manage the behavior of other devices. Some devices or systems are not controllable. A control system is an interconnection of components connected or related in such a manner as to command, to direct, or to regulate itself or another system. A control loop is a collection of instruments and control algorithms arranged in such a fashion as to regulate a variable at a setpoint or a reference value. The loop part of the name refers to the fact that most control loops make use of feedback in a continuous loop. These loops are referred to as closed-loop control. An open-loop controller does not directly make use of feedback. The most common control loop uses a feedback or PID controller.

Control theory has been successfully applied to solve problems in areas such as biology, management, and social sciences. The successful application of the same concepts to control/regulate the behavior of software systems and/or of the software development process (2) in all its aspects is what we now refer to as software cybernetics. Software cybernetics also includes principles and theories in software engineering that can be applied to control engineering. In this article we provide a definition of software cybernetics and delineate its scope. Research in software cybernetics has been applied to many distinct areas such as software development, adaptive software, network security, and fault tolerance; a brief description of these applications appears in this article.

Software cybernetics has been consistently expanding since its inception and the community is organizing itself mainly through the International Workshop on Software Cybernetics (IWSC). However, skepticism continues to exist as some reject the feasibility/use of regulating software systems or its development process by mathematical laws. Also, a belief exists that control is purely a continuous approach and overlooks the fact that discrete counterparts do exist for all continuous techniques. Moreover, even when a continuous approach is used to model the behavior of the object under consideration, a control technique can be applied at discrete time intervals. The difficulties in applying feedback control to software processes, for example, have been delineated by Lehman et al. (3). One of the difficulties they point out is the immaturity of software processes. They state, "...we need research to establish appropriate theories from which to derive necessary control mechanisms and experimentations to establish their settings and effects." Although this has not yet been fully accomplished, results from research on software cybernetics have moved a few steps toward this goal. Another aspect contributing to the slow development and adoption of control-theoretic concepts for software is the paucity of control-system researchers involved in software engineering. Again, software cybernetics offers an environment where collaboration among both areas can flourish.

DEFINITION AND SCOPE

According to Norbert Wiener (4), cybernetics refers to control and communication in man and humans in machines. Accordingly, one may define software cybernetics as control and communication in the software, its processes, and systems. However, this definition is not satisfactory for two reasons. First, it implies that software cybernetics should cover various ad hoc control activities in software engineering and various communication mechanisms in concurrent computing. It would be difficult to distinguish software cybernetics from the existing discipline of software engineering and the theories of concurrent computing. Second, the above definition rules out the possibility that the principles and theories of software engineering can be applied to control theories and engineering.

It is important to note that control is a well-established discipline, of which feedback and optimization are two central themes. In addition, a solid theoretical foundation has yet to be established for the existing discipline of software engineering. Therefore, we define software cybernetics as an emerging discipline that explores the *theoretically justified* interplay between software and control. More importantly, according to Cai et al. (5), software cybernetics addresses issues and questions that relate to (*1*) the formalization and quantification of feedback

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

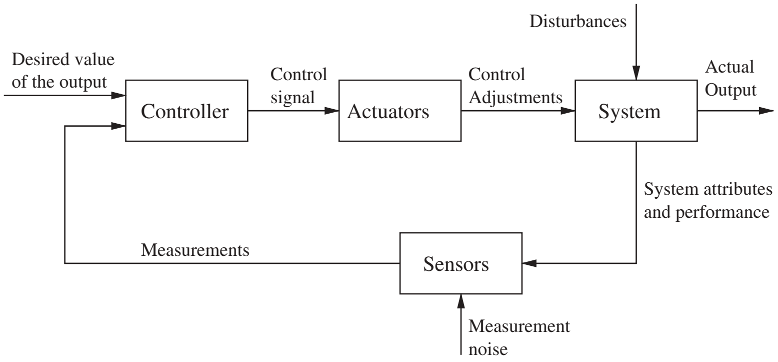

Figure 1. Typical feedback loop (5).

mechanisms in software processes and systems, (*2*) the adaptation of control theoretic principles to software processes and systems, (*3*) the application of the principles of software theories and engineering to control systems and processes, and (*4*) the integration of the theories of software engineering and control engineering. In response to these issues and questions, research subareas of software cybernetics can be divided into four classes: fundamental principles, cybernetic software engineering, cybernetic autonomic computing, and software-enabled control.

Figure 1 presents the structure of a typical closed feedback control loop (6). Although it is oriented towards physical systems, the same structure can be used to control software systems and software processes. The block labeled "System" in Fig. 1 can be mapped to a software system or software process as the object to be controlled, and the actuators could be exemplified as the process manager executing suggested changes (in case the object to be controlled is a software process), or the operating system allocating additional memory when the object under control is a software application. Clearly, the application of control requires quantification/qualification of the output variables to be controlled and the input values used to control them. This means that any measurable quantities/qualities with respect to software products and processes can be potentially controllable. For example, consider the control system proposed for the software system test phase by Cangussu et al. (7); the controller uses the model parameters and two inputs corresponding to the test manager's vectors to induce changes in the process. The control technique explicity requires that the user be able to quantify the values of the control inputs, and it implicitly requires—through the use of the model parameters—the data from which the model parameters were calibrated. This example illustrates that the data requirements of a particular application of software cybernetics are primarily dictated by the underlying model, with a small additional requirement in the specification of the expected model inputs.

It should be clear that software cybernetics is not the only overlap of software systems/software engineering with control theory. The implementation of a controller for a boiler system represents this overlap (software being used to implement a control mechanism). However, software cybernetics is more comprehensive and can be seen more as the mapping of software systems/software engineering concepts to concepts in control systems. For example, the use of control theory to regulate the amount of memory reserved for a cache system represents this mapping.

Fundamental Principles

The research area of fundamental principles (FP) is concerned with the fundamental questions and theoretical foundation of software cybernetics. Such questions are as follows: Can the software behavior be controlled? What role can feedback play in software processes and systems? How can software behavior be modeled in the framework of software cybernetics? Three specific topics should be addressed in this research area: modeling formalism, controllability and bisimulation, and feedback complexity and bisimulation.

Modeling Formalism. To address the question of whether software behavior can be controlled in a theoretically justified manner, it is important to examine how software behavior can be modeled. Three modeling formalisms have been proposed: formal models, dynamical system models, and controlled Markov chains. A typical formal model is the extended finite state machine (EFSM), which has been widely adopted to describe communication software behavior (8). It is interesting to note that an EFSM can be reformulated as a closed-loop control system comprising a controlled object and a controller (9). This implies that most software systems can be modeled as a control system.

Linear dynamic system models have been proposed to describe software testing process (7) and software service behavior (10). In the continuous-time domain, the model is in the form of Equation (1).

$$\begin{cases} \dot{x}(t) &= Ax(t) + Bu(t) \\ y(t) &= Cx(t) + Du(t) \end{cases} \tag{1}$$

where $x(t)$, $u(t)$, and $y(t)$ are state vector, control input, and output, respectively, and A, B, C, and D are matrices of appropriate dimension. The discrete-time counterpart of Equation (1) is given by Equation (2)

$$\begin{cases} x(k+1) = Ax(k) + Bu(k) \\ y(k) = Cx(k) + Du(k) \end{cases} \tag{2}$$

where k denotes the kth sampling instant.

Finally, controlled Markov chains have been proposed to describe the software testing process (11). The states in a controlled Markov chain are defined by software variables of interest such as the number of defects remaining in the software under test. As distinct testing actions are applied to the software under test, the software state transitions take place in accordance with a Markov law whose probability distributions depend on the applied testing actions.

Controllability and Bisimulation. Controllability is a fundamental concept in modern theories of control. Generally, a dynamic system is said to be controllable if a control input transforms the system from an arbitrary state to the zero state in a finite length of time (12). Furthermore, a (formal) language of a discrete-event system is said to be controllable if the prefix closure is invariant under the occurrence of uncontrollable events (13). On the other hand, bisimulation is a fundamental concept in process algebra and concurrent computing (14). It determines whether two processes in a computing system or two states in a state space are equivalent in some sense of actions and state transitions. Three classes of research have been delineated within the topic of controllability and bisimulation. The first class reveals that inherent relationships exist between controllability and bisimulation (15,16). This fact is surprising and supports the suggestion that control theories and computing theories may be put into a unified theoretical framework.

The second class of research is devoted to the introduction of bisimulation relations for conventional dynamic systems (17). It is shown that the abstract notion of bisimulation in the context of open maps may characterize the equivalence relations for discrete event systems, for conventional dynamic systems, as well as for hybrid systems (18,19). The third class of research is concerned with how to control a system so that the resultant closed-loop system bisimulates or approximately bisimulates another system in some sense (20).

Feedback Complexity and Limitation. It is well known in the control community that feedback is not a panacea for achieving control goals. There are limitations on the role that feedback can play (21). Normally, a closed-loop control system is composed of controller and a controlled object, which communicate with each other in a collaborative manner to achieve a given control objective. Feedback between the controller and the controlled object defines a kind of communication. On the other hand, the communication complexity theory is a well-established area in computer science, which is concerned with why communication is necessary for two collaborative agents to complete a given task (22). A natural question arises: Can feedback limitation be formulated in the context of communication complexity theory? This research topic remains largely unexplored.

Cybernetic Software Engineering

Cybernetic software engineering (CSE) treats software development as a control problem and applies control theoretic principles to guide software process improvements and quality assurance (23). Because a software development process is often divided into several phases such as requirement analysis, design, and testing, control theoretic principles are applied to individual phases.

Software Requirement Acquisition. Software requirement acquisition is an interactive process between the software development personnel and the user, and feedback is an intrinsic feature of the process. It is argued that the requirement acquisition process be treated as feedback requirements process control (RPC) system, where the requirements specification of the application serves as the object to be controlled (24). The RPC perspective can then be applied to assess the quality of the requirement acquisition process and to guide the corresponding process improvement. This research area is in its early stages of development.

Software Synthesis. Because most software systems can be treated as a control system, it is natural to raise the question whether control theories can help guarantee the correctness of software design solutions. A modest amount of research has been devoted to address this question where the control theories of discrete-event systems are applied. In the work of Marchand and Samaan (25), and Wang et al. (26) the software under synthesis, modeled by a polynomial dynamical system (PDS) serves as the required controller, whereas the operating environment serves as the controlled object. Sridharan et al. (27,28) applies the theory of supervisory control to synthesize the safety controllers for ConnectedSpaces, which is a collection of one or more devices, each described by its Digital Device Manual and reachable over a network. On the other hand, it is shown that software fault-tolerance can be treated as a robust supervisory control problem and the traditional idea of diverse redundancy can be avoided (29).

Software Test Management. A control mechanism has been used to regulate the behavior of the system test process. A mathematical model capturing the dominant behavior of the process has been developed (7). The parameters of the model are calibrated using data from the ongoing process by means of a least squares approach. A parametric control approach is then used to regulate the process and to correct problems such as schedule slippage. The approach has been statically validated using a Kronecker product to conduct a sensitivity analysis (30) and has also been successfully applied to a series of projects from large corporations (31).

Adaptive Testing. Adaptive testing is the software testing counterpart to adaptive control and is the outgrowth of the controlled Markov chain (CMC) approach to software testing. In the CMC approach, the software under test serves as the controlled object and is modeled by a controlled Markov chain, whereas the test strategy serves as the corresponding controller. The software under test and the test strategy make up a closed-loop feedback control system. Although the test strategy uses the test history to generate or select the next set of test cases to be applied to the software under test, adaptive testing implies that the underlying parameters in the test strategy be also updated online during testing by using the test history. It is shown that adaptive testing can be applied not only for software reliability improvements by removing the detected defects (11,32), but also for software reliability assessment by freezing the code of the software under test (33).

Cybernetic Autonomic Computing

Autonomic computing (referred to later as *CAC)* is an initiative launched by IBM (34). It is aimed at making computing systems self-managing, which implies that computing should be self-configuring, self-optimizing, self-healing, and self-protecting. By cybernetic automatic computing we refer to autonomic computing achieved by applying control-theoretic or cybernetic principles and methods. Moreover, computing systems are treated as a feedback closed-loop control system and thus should be self-stabilizing. Several research topics have been addressed in the literature as follows.

Software-Aging Control. Aging is a phenomena widely studied in hardware reliability community. Hardware systems tend to age because of physical deterioration such that the corresponding failure rate function behaves as a nondecreasing function of the operating time. In 1990s software systems also suffered from the aging phenomena (35,36). Software aging emerges as a result of computing resource contention, memory leakage, file-space fragmentation, and so on. It causes the computing systems to demonstrate performance degradation and then to hang, panic, and crash. This is particularly true for Web servers in the Internet environment. Three questions can be raised for software aging. First, what are the underlying aging mechanisms (37,38)? Second, how can software aging be modeled (39,40)? Finally, how can software aging be forecasted and controlled (41,42)? Software-aging control is an interesting research area deserving of additional investigation.

Adaptive Software. The environments where software products are executing today have considerably increased in complexity. The number of simultaneous users on distinct platforms with different resource constraints and the dynamic interaction among all of these elements constitute the basis for this complex and often open environment such as the Internet. Adaptive software operating in the environment of this kind identifies the changes in the environment, adjusts its internal architecture and/or parameters, and assesses its behavior to provide satisfactory quality of service. Feedback is an imperative kind of activity for adaptive software and a crucial problem is how to formulate, to quantify, and to optimize the underlying feedback mechanism. Three questions have been partially addressed in the literature. First, what architectures should be adopted for adaptive software (43,44)? Second, what control algorithms should be developed for adaptive software (45–47)? Finally, what quality attributes should be employed to assess adaptive software (48)? Adaptive software is a research topic in which control-theoretic principles and methods can play a fundamental role.

Self-Stabilizing Software. The notion of self-stabilization was introduced by Dijkstra in 1974 (49) and a many self-stabilizing computing algorithms has been reported in the literature (50,51). A system is said to be self-stabilizing if, regardless of its initial state, it is guaranteed to arrive at a legitimate state in a finite number of steps. This implies that self-stabilizing software can resume normal operation in the presence of transient software faults. Although it is observed that self-stabilization shares some concepts with self-management in autonomic computing (52), research on self-stabilizing software is still in early stages. This topic is important for two reasons. First, existing mainstream mechanisms for software fault-tolerance lack solid theoretical foundation (29) and self-stabilizing software may be considered as a new kind of fault-tolerant software that is theoretically justified. Second, the notion of self-stabilization is different from the traditional notion of Lyapunov's stability, and self-stabilizing software may lead to a new theory of stability.

Autonomic Computing Prototyping. Although autonomic computing systems are claimed to mimic the autonomic neurons in biological systems (53,54), the field of autonomic computing does not currently provide researchers with a clear idea of what is required to develop an autonomic computing system (48). What are the fundamental concepts and principles of autonomic computing? What are the qualitative and quantitative goals of autonomic computing? What are the architectures that autonomic computing systems should adopt? What are the computing models and algorithms that autonomic computing should be based on? All these questions should be addressed in the research works on autonomic computing. By autonomic computing prototyping we mean that these questions are addressed and examined by developing various prototyping systems. These systems can be observed in the various works presented at the international conferences on autonomic computing (55,56).

Software-Enabled Control

Software-enabled control (SEC) was initially a research program launched by the U.S. Defense Advanced Research Projects Agency (57,58). The motivation for SEC is twofold. First, conventional control systems, including adaptive control systems, and robust control systems, are often over-designed based on simplified models of system dynamics and well-defined operational environments. This leads to underperformance in normal environments and control vulnerabilities that arise in extreme environments such as damaged control surfaces for modern aircrafts. Second, developments in software technology have enabled new apparatus for control systems, including device networks, smart sensors, programmable actuators, and systems-on-a-chip. A challenge is how to design control and software, or how to exploit software and computation to achieve new control capabilities. This requires a new perspective of system dynamics. Besides conventional accounts of parameter uncertainty, noise, and disturbance, the new system dynamics should also take into account dynamic tasking, sensor and actuator reconfiguration, fault detection and isolation, and structural changes in plant model and dimensionality. It should also treat software as a dynamic system which has an internal state, time scales, transients and saturation points, responds to inputs, and produces outputs. SEC is now an established research area that shares the general idea of software cybernetics (57,58). In the following we identify three research topics that relate to SEC.

Control Software Architecture. Research in control software architecture is concerned with particular types of software architectures that fit well the implementation of complex control algorithms. There are two primary concerns. First, the control software of concern is mostly real-time embedded software. This is particularly true for airborne software of modern aircrafts. Second, monolithic structures should be avoided to reflect the closed-loop feedback feature of control systems (57,58). Overall, the control software architecture should follow the new perspective of system dynamics. An outgrowth of this research topic is the so-called open control platform (OCP) for Unmanned Aerial Vehicles (UAVs), which is an object-oriented software infrastructure that allows seamless integration of cross-platform software and hardware components in any control system architecture.

Software-Enabled Control Synthesis. The endeavor for software-enabled control was carried out mainly for modern aircrafts in general, and UAVs in particular. How to put flight control, flight management, task management, and software constraints into a unified framework is a grand challenge for computer science, control theory, and software engineering. For example, the distributed controller enabled by emerging real-time middleware support can consist of hierarchical systems, integrated subsystems, or independent confederated systems, such as multi-vehicle systems. It is unclear how to synthesize the required coordinated control algorithms.

Control Software Validation. Conventional software validation assumes that the underlying algorithms implemented by the software under validation are given a priori and are not adjusted online. For example, conventional software testing assumes that a test oracle is given a priori. However, this assumption is not true for software-enabled control that follows the new perspective of system dynamics. Control algorithms may be adjusted or even reconfigured in response to sensor/actuator failures or unexpected conditions. This may trigger the reconfiguration of control software to adopt an alternative software architecture. On the other hand, software reconfiguration in response to software component failures may require that control algorithms are updated to guarantee flight safety. There is a dynamic process of interactions between control algorithms and software systems. This imposes a challenge to software validation (57,58).

APPLICATIONS OF SOFTWARE CYBERNETICS

In this section we highlight applications developed within the research areas presented in Section 2. Since the majority of the research work falls within more than one of the areas from Section 2, we have organized the works by application area. The research topics are then individually categorized based on the four main software cybernetics research areas defined in Section 2 and are also listed below.

- Fundamental Principles (*FP*)
- Cybernetic Software Engineering (*CSE*)
- Cybernetic Autonomic Computing (*CAC*)
- Software-Enabled Control (*SEC*)

Process Management

By *process management* we refer to the work directed toward the task of bringing control-theoretic approaches to bear on the perennial problems of software process improvement and control. Xu et al. (24) have mapped the 66 key practice areas from the Requirements Engineering Good Practice Guide (59) to the corresponding parts of a typical control system (i.e., to actuators, sensors, etc.) and sketch an overview of the process of building a Requirements Process Controller. Their work falls in the *CSE* area.

Management of the construction phase of incremental software development is addressed by Miller (60), where a state-model of the construction phase is proposed, and an outline given of a control strategy based on model predictive control (MPC) (61). The control attempts to minimize the deviation between the actual progress and the schedule while balancing the cost of the control resources with the cost of schedule deviation. These projects can be characterized as part of FP and CSE areas.

Modeling and control of the system test phase (STP) of software development within a control-theoretic formalism has been addressed by Cangussu et al. (7,30) where a state-model is constructed for the STP and a partial eigenvalue-assignment control technique is proposed. The control technique presents a test manager with a set of options which will likely achieve the quality objectives by the schedule deadline. Miller et al. propose (62) a controller for the STP model based on MPC. This work can also be characterized as part of FP and *CSE* areas.

Buy and Darabi build upon their work on time-extended Petrinets (63,64) to construct a supervisory controller capable of enforcing constraints on a class of workflow processes. Workflows can be used to describe many processes, including those in software development. This work is best characterized by the area of CSE.

Padberg has studied the link between software process modeling and Markov Decision Theory (65), where a model of software development is proposed as a Markov Decision Process, and an optimal schedule is derived using a dynamic programming approach. CSE again is the best characterization of this work.

Software Development

Although body of work proposes architecture and design elements to support software cybernetic implementations, these elements are out-of-scope for the present survey.

Instead we focus on the *actual usage* of control-theoretic techniques and ideas.

The task of designing software can be aided by supervisory control techniques which commonly augment existing systems to impose constraints. Examples of design synthesis via supervisory control are given in Sections 3.1 and 3.4.

Software testing has also received considerable attention from the software cybernetics community (11). Cai et al. (32) view the software under test as a controlled object which is modeled by a controlled Markov chain. The testing strategy is synthesized as an optimal controller of the software under test. This body of work falls within the CSE area.

Research has also focused on the application of adaptation techniques to improve random testing. Chan et al. (66) propose an adaptive *center of gravity* constraint to pure random testing to improve the input domain coverage with fewer tests. Cai et al. (67) propose a dynamic partitioning of the input domain for random testing to improve the test selection process. As above, *CSE* characterizes this work.

Adaptive Software

Control-theoretic foundations for the construction of adaptive software have been studied (45–47). For example, a system identification technique is used to capture the behavior of a software application with respect to a specified resource usage (47). The derived model is then used to predict constraint violations and the software is adapted accordingly to avoid such violations. An increase in software robustness is achieved with this adaptation. The work on adaptive systems is better characterized by the *CAC* research area.

Safety

Software cybernetics has been used to address the enforcement of safety policies in collaborative environments. Sridharan et al. (27,28) propose a safety enforcement environment called “ConnectedSpaces” with a formalism for describing and exchanging the safety policy of a device within a ConnectedSpace. A form of supervisory control is then applied to achieve online generation of a safety controller for the ConnectedSpace that adapts as devices enter and exit the ConnectedSpace. This research project involves both areas of *FP* and *CSE*.

Adaptive software introduces its own safety concerns: Is it possible for the adaptation to fail and leave the system in a dangerous state? This issue is addressed by Liu et al. (68) where a stability monitor is constructed based on Lyapunov Stability Theory (69). The stability monitor determines whether the current data will prevent the adaptation process from converging (i.e., because of due to abnormal or incorrect data) and, if so, it prevents the data from reaching the adaptation routine. FP and CAC characterize these projects.

Networking

Techniques based on control theory have been applied to common problems in networking as well. Moerdyk et al. (70) propose a hybrid optimal controller based on MPC which achieves load-balancing in a cluster of computer nodes.

Tan et al. (71) propose a technique for handling high-bandwidth traffic aggregates (e.g., DOS attacks) by installing rate throttles in upstream routers and building control-theoretic algorithms to adaptively, robustly, and fairly set the throttle rates at the routers. CAC can be used to characterize the projects in this section.

Fault Tolerance

Software rejuvenation refers to the idea that software can repair its internal state to prevent a more severe future failure. A framework for adaptive software rejuvenation is proposed by Bao et al. (42) with examples given for monitoring and for adapting the rejuvenation schedule in response to resource loss (e.g., memory leaks.)

A self-stabilizing program is one which guarantees the arrival at a legitimate state after a finite number of steps, regardless of the initial state (49). Gouda and Herman (72) relate program adaptation to self-stabilization in the context of fault tolerance. The research areas of *CAC* and *SEC* characterize these projects.

Information Security

Venkatesan and Bhattacharya (73) propose a threat-adaptive security policy in which a trust model is developed as a finite state machine from a set of rules specifying how trust is to be adjusted. Depending on the level of trust, the system requires varying levels of authentication; the intent is to improve performance while retaining control over the access of untrusted users.

An approach to security quantification is proposed by Griffin at al. (74). A state-space representation of security is proposed, followed by a stochastic attack model. Analysis of the pair yields estimates of mean time-to-failure, the probability of reaching a particular fail-state, and a method of optimizing the security policy. *FP* and *CSE* are a good characterization for these work.

FUTURE DIRECTIONS

Many areas have already benefited from the use of control theoretical aspects but much more needs to be explored. There is always the alternative of increasing the number of areas where software cybernetics can be applied. This is naturally occurring as more and more researchers embrace the benefits of applying control techniques and theories within their research areas. The diverse areas surveyed in this article provide a clear indication of this phenomena. However, most of the research on software cybernetics can be considered to be in their preliminary stages and much more detailed solutions with a full body of results/concepts must be in place before software cybernetics can achieve a reasonable level of maturity.

For example, the work on software project management has been almost restricted to the final phases of the development process or more specifically to the testing phases. This occur because later phases are easier to quantify and less subjective than early phases of the development process. The lack of better and/or more precise quantification mechanisms to represent early phases are not only a matter of their subjectivity but also a matter of the immaturity of software engineering (3). Clearly, software cybernetics research in this area has to move toward all the phases of the development process until a full body of models and control mechanisms are in place to regulate the entire development process.

Another aspect to be considered is how software cybernetics will require the development of new techniques (or the adjustment of existing ones) used in control. For example, the quantification of noise is well understood and used when controlling physical systems. However, noise in software is difficult to quantify. Though most researchers make assumptions about noise (for example, assuming a white Gaussian (Normal) random noise (75), $\omega[n] \sim N[0, \sigma^2]$, of zero mean and variance σ^2 at an instant n to represent noise), we believe that there has not been a detailed study about the quantification of noise for software systems. The availability of such a study may lead to the development of new techniques to handle the specifics of software systems.

CONCLUDING REMARKS

Control theory is a tool that can be used to regulate systems and processes. Software systems do not operate in a static environment and many aspects of software (either at operating system, networking, or application level) need to be regulated to improve performance, increase reliability, and even regulate resource usage. Similarly, the same concepts can be applied to regulate the development process of a software product. Software cybernetics is therefore an area that brings together researchers from both the software and the control systems communities to develop solutions for these problems. The initial results of research projects on software cybernetics are an indication of the benefits of molding this new exciting area. Developments targeting network security, safety, testing process, and fault tolerance, among others, demonstrate this potential.

SOFTWARE EFFORT PREDICTION

INTRODUCTION

Empirical modeling to predict software development effort has been an important topic in software engineering studies for over 30 years. The basic underlying premise is that historical data about past projects can be employed as a basis to predict effort for future projects. For both engineering and management purposes, accurate prediction of effort is of significant importance, and to improve estimation accuracy is an important goal of most software organizations. A continuing pursuit exists to derive better techniques and models to improve predictive performance.

Until recently, the emphasis has been on algorithmic models that postulate some functional relationship between effort and significant project characteristics, and that are derived from project data using statistical techniques such as regression analysis. Some of these models incorporate tuning parameters so that the model can be adapted to different development environments. In recent years, an increased emphasis has been on the use of machine learning and on neural network approaches. Some of these have produced promising results. An important goal of these studies is to characterize projects by the features that have the most impact on effort and use them as independent variables in prediction models. For example, size, complexity, functionality, and so on all potentially are relevant attributes that impact effort.

Formally, the development of a predictive model can be seen as finding a functional mapping between a project's features, called inputs, and between effort, called output, that satisfies some predictive performance criterion. The data (D) and the function (f) can be represented as follows:

$$D = \{\mathbf{x}_i, y_i, \mathbf{x}_i\ R^d, y_i\ R, i = 1, 2, , n\} \tag{1}$$

and

$$y = f(x; \beta) + e \tag{2}$$

Here x denotes the software project features, d is the number of features, y is the effort, n is the number of projects in the dataset, β is the parameter set, and e is an error term. The derived model can be seen as a particular realization of the function in Equation (2) obtained by some modeling technique. The predictive performance of a model is evaluated by some accuracy measure or measures. Two measures employed commonly in software effort research are the mean magnitude of relative error (MMRE) and prediction at level υ, Pred (υ), defined as:

$$MMRE_i = \frac{1}{n}\sum_{i=1}^{n}\frac{|Actual\,Effort - Predicted\,Effort\,|}{Actual\,Effort} \tag{3}$$

$$PRED(\upsilon) = \frac{Number\,of\,estimates\,within\,(y \pm \upsilon y)}{n} \tag{4}$$

As the definitions imply, models with low MMRE and high Pred(υ) are preferred.

This article describes the main effort prediction techniques and discusses some issues that develop during the modeling process. The next section presents an overview of the commonly used models and some representative comparative studies. The prediction modeling process is described in the following section. An illustrative example is then used in the next section to derive support vector models from several industrial projects. Finally, some concluding remarks are presented.

MODELS AND COMPARISONS

A large number of effort prediction models (1) have been proposed. This section presents model groupings and provides highlights of commonly used models. Key findings from some comparative studies also are presented. The following represents selected studies and is not intended to be a review of the literature on effort estimation.

Model Categories

Most currently used models use historical data for parameter estimation. Based on the technology employed for model development, current models can be grouped into the following categories:

- Statistical
- Neural networks
- Machine learning

Statistical models are derived from historical data using statistical methods, mostly regression analysis. The statistical models were some of the earliest to be developed. Examples of the statistical models are provided in Refs. 2 and 3. Bayesian models have also been developed (4,5).

Neural network models formulate the prediction problem as developing a trained net to approximate the input-output mapping that is used to derive effort estimates for new projects.

The machine learning techniques used for software effort prediction modeling are rule induction, case-based

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

reasoning (CBR), neuro-fuzzy logic, and so on. Currently, a popular CBR approach is based on the Angel tool (6,7).

Another possible category is expert judgment, where the models are generated by experts. Experts are individuals with knowledge about the development environment and have experience with similar systems. Such approaches clearly are nonrepeatable and are biased. However, for local use, expert judgment can be a very effective and accurate effort estimation technique.

Effort Models

Some of the models from the above categories are summarized below, roughly in a chronological order.

Walston and Felix (2) developed one of the earlier cost models, based on data from IBM systems. They used primarily regression analysis for model fitting. Their basic model was Effort = 5.2(size)**0.91. This simple model was the basis of several later studies.

Putnam (8) proposed a lifecycle manpower distribution model based on his observations for many defense systems. This model had previously been used for hardware projects. Its parameters were determined from previous projects, adjusted for the characteristics of the new projects and new environments. Its analytical form facilitates the derivation of many useful project-related performance measures to monitor and to control resource allocation.

Boehm (9) developed the COCOMO model that is currently one of the most widely used models. It was based on data from 63 projects using a statistical approach and expert judgment. The primary project feature is its size in delivered source instructions. Its basic form is man-months = a*(KDSI)**b. The parameters a and b depend on the software development mode. The man-month estimate is then adjusted by 15 cost drivers. Subsequent revisions (10) and updates have incorporated many current trends and techniques in software development.

Function Points. Most of the algorithmic models use lines of code as an important software feature. However, size must be estimated by other means, which affects adversely the prediction accuracy of the model. To overcome this difficulty, Albrecht and Gaffney (11) use function points as a substitute for size. Function points can be derived from the requirements and the specification documents thus becoming available early in the lifecycle. In these models, effort is related directly or indirectly to function points.

Analogy. Estimation by analogy is a form of case-based reasoning. The key phases of estimation by analogy are the identification of a problem as a new case, the retrieval of similar cases from a repository, the reuse of knowledge derived from previous cases, and the suggestion of a solution for a new case. Several different algorithmic approaches can be used to assess similarity between new case and cases in the repository, for example, the k-nearest neighbor and the fuzzy similarity. Several case studies (6) have documented experiences with the use of analogy.

Neural network. Such models have been proposed within the past 10 years. Wittig and Finnie (12) employed a back-propagation training approach for a multi-layer perceptron network. Shin and Goel (13) developed radial basis function models using data from Bailey and Basili (3), whereas Lim (14) employed support vector machines (SVMs) on many datasets for effort-prediction modeling.

Comparative Studies

Over the past 15 years, several comparisons of modeling techniques have been reported. Key findings from some of these reports are summarized below. However, general conclusions cannot be drawn from such studies because almost every technique requires subjective decisions during the modeling process, which influence the results invariably. Nevertheless, such studies provide some interesting insights into the strengths and the limitations of the various techniques.

Sheppard and Schofield (7) studied the performance of analogy, of stepwise multiple regression, and of multiple regression on a large number of industrial projects developed in different environments for many applications. They found that their analogy approach had a superior performance as judged by MMRE and Pred(25) measures.

Briand et al. (15) presented the results of a comprehensive comparison of common effort estimation techniques. They compared predictive performance on multi-organization and company-specific data and found no significant difference with respect to modeling techniques. However, on their data, regression models outperformed analogy-based estimation.

Dolado (16) evaluated regression, neural networks, and genetic programming for effort estimation using several datasets and concluded that the improvements by machine learning techniques were not impressive.

Lim (14) developed SVM-based effort models for several datasets, (6,11,17,18). Their performance was superior to the models derived by multiple regression, stepwise multiple regression, and analogy (6) in terms of MMRE and Pred(25).

MODEL DEVELOPMENT PROCESS

Developing a prediction model consists of finding some expression for the function in Equation (2), generally called “function approximation” in modeling literature. Various models described above are manifestations of this approximation. The process to derive these functions depends on the chosen technique, but, at an abstract level, a common underlying process exists that is described below and shown in Fig. 1.

Modeling Approach

The first issue is to determine a modeling approach. This decision is governed by the application and the development environment as well as by the available data and by modeling expertise. Requirements of predictive perfor-

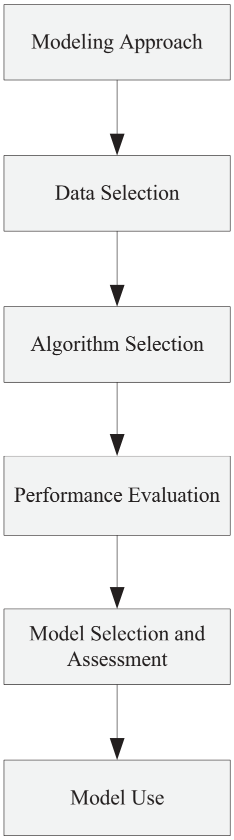

Figure 1. Model development process.

mance, ease of use, and model interpretability also affect this selection.

Data Selection

The modeling approach dictates data selection. For example, if a regression model is to be built, explicit data in the form of Equation (1) is required. The case is the same for neural network models. For case-based reasoning models, a case base and domain knowledge are required. Also, preprocessing of the data usually is necessary, which includes dealing with missing data, outliers, normalization, and data transformation, as well as with feature subset selection and with dimensionality reduction. Obviously, data selection has a major impact on model performance.

Algorithm Selection

An algorithm to determine model parameters is chosen to satisfy some desired speed and efficiency constraints. If a linear regression model is chosen, the algorithm is straightforward. For neural network modeling, several algorithms are available. Other decisions include the approach to determine network architecture, error tolerance, and training parameters. For CBR models, issues of distance measures, adjustment mechanism, and so on, are to be addressed. This process is nontrivial, which requires much insight into the algorithms and their tradeoffs. As examples, see Ref. 13 for radial basis function models and Ref. 19 for SVMs.

Performance Evaluation

By using measures such as MMRE and Pred(υ), multiple models usually are developed and their performance is evaluated. Some model validation approaches are employed for model comparison. One approach is to divide the data into training, validation, and test sets. Models are derived from the training set. Their performance is evaluated on the validation set and usually the best performing model is selected. If the dataset is of limited size, k-fold cross-validation is more appropriate. The data are divided into k groups of almost equal size. A model is developed from (k-1) sets and its performance is evaluated on the kth set. This process is repeated k times and the average of the k values is a measure of model performance. In the special case when the dataset is small, k = 1 is used and is called the leave-one-out cross-validation approach.

Model Selection and Assessment

Model performance on the test set is considered to be a measure of its generalization performance (i.e., its predictive performance on future projects). Other factors that are employed generally for model assessment are ease of use, meaningfulness, interpretability, and so on. Model complexity is also an important concern. A parsimonious model is almost always preferred because, among other things, it requires fewer data features for model development and use.

Model Use

The selected model is employed to predict the effort of new systems. Lessons learned are used to improve future predictions.

SUPPORT VECTOR MACHINE PREDICTION

SVM is a relatively new approach for effort estimation. It possesses some very nice mathematical properties and has shown promising performance in fields such as bioinformatics, medicine, and banking. SVM is a new type of learning algorithm based on statistical learning theory. Specifically, it represents an approximate implementation of the method of structural risk minimization, which states that the generalization error of a learning machine is bounded by the sum of its training error and a term that depends on its Vapnik–Chervonenkis dimension (20). A brief description of SVM is given below, followed by an illustrative example.

Support Vector Machine

Originally, SVMs were employed for linearly separable pattern classification tasks (i.e., for data that are linearly separable in the input space). Even though the above is unrealistic for most real-world applications, its treatment is helpful to understand the SVM fundamentals. For realistic situations, a high dimensional feature space is constructed by using an inner-product kernel $K(x,x_i)$. The input data are mapped into this feature space and the linear classification problem is solved in the feature space. Recently, this approach has been extended to solve nonlinear regression problems such as effort estimation modeling. In this context, the function in Equation (2) is nonlinear in the parameters and can be written as

$$y = f(x;\beta) \equiv \sum_{i=1}^{n} y_i \alpha_i K(x, x_i) \tag{5}$$

where for the Gaussian kernel is

$$K(x;x_i) = exp\{-\frac{1}{2\sigma^2}\|x - x_i\|^2\} \tag{6}$$

The dual problem to be solved for the above model is, given the project data of Equation (1), find the Langrange multipliers *ai*'s such that the following objective function is maximized (21).

$$Q(\alpha_i, \alpha_i') = \sum_{i=1}^{n} y_i(\alpha_i - \alpha_i') - \varepsilon\sum_{i=1}^{n}(\alpha_i + \alpha_i') - \frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n}(\alpha_i - \alpha_i')(\alpha_j - \alpha_j')K(\mathbf{x}_i, \mathbf{x}_j) \tag{7}$$

$$\text{subject to} \sum_{i=1}^{n}(\alpha_i - \alpha_i') = 0 \tag{8}$$

$$0 \le \alpha_i, \alpha_i' \le C, \quad i = 1, 2, , n \tag{9}$$

In the above, the kernel width σ, the penalty parameter C, and theVapnik loss function ε are to be specified by the user. These parameters are called the support vector hyperparamaters. Finally, the effort prediction model is

$$\hat{y} = \sum_{i=1}^{n} y_i \alpha_i K(\mathbf{x}, \mathbf{x}_i) \tag{10}$$

where the α_i's are between 0 and C and **x** are the features of the project for which effort is to be predicted. Thus, for specified σ, C, and ε, and for the software project data D represented by Equation (1), the necessary model parameters are derived by support vector regression, and Equation (10) is used to predict effort.

Illustrative Example

Data about some projects from Ref. 18 and reported in Ref. 6 are used here to develop support vector effort models. It consists of 77 projects, each with nine features (i.e., d = 9 and n = 77 for this data). The data was separated additionally into three groups of 44, 23, and 10 projects according to its development environment. The four datasets are labeled DE, DE1, DE2, and DE3, respectively.

The first step is to determine the support vector hyperparameters, which is an important problem and has been studied extensively in the literature (22). For this example, a new methodology proposed in Ref. 14 is used. It is called SVEG (Support Vector parameter selection using Experimental design-based Generating set search). SVEG combines ideas from the Design of Experiments and from the generated set of search areas. It consists of three steps, namely, to determine hyperparameter ranges, to define an experimental design in the hyperparameter space, and to conduct a generating set search. A central composite design is constructed based on the ranges of σ, C, and ε, determined according to the SVEG methodology. Then, a generating set is constructed and a generating set search is undertaken using the experimental design points as the initial settings for the search.

Performance measures MMRE and Pred(25) are obtained by the leave-one-out approach. Based on the values of these parameters, the support vector regression model is developed as described above. The predictive performance of the developed models is evaluated by generating a set search. Two models are selected, one with the smallest MMRE and another with the largest Pred(25). The average test errors of the selected models are listed in Table 1.

It is noted that the predictive performance improves if the data are from a homogeneous environment, as is the case for DE1, DE2, and DE3 compared with the DE performance. Also included in this table are the performance results from the models developed by stepwise multiple regression and the analogy reported in Ref. 6. From a comparative perspective, the SVEG has better performance on both measures for each dataset. Similar results were found for several other projects (14).

CONCLUDING REMARKS

This article addresses the issue of software effort prediction. To provide a perspective on the current state of practice and research, highlights about commonly used models and key findings from some comparative studies

Table 1. Prediction Performance for Example Data

	MMRE (%)			Pred(25) (%)

SOFTWARE INSTRUMENTATION

INTRODUCTION

Since the inception of computer systems, development of reliable (i.e., bug-free) and efficient (i.e., extracting maximum performance from the available hardware resources) software programs has been one of the major concerns for the developer/programmer community. Over time, the task of ensuring such reliability and efficiency has become progressively complex along with the software systems themselves. Consequently, to assist the individual coders, a set of tools and methods for program analysis, debugging, and profiling has been developed. Although such tools usually vary widely in their designs and intents, many of them are similar in that they employ a technique called *software instrumentation*, or simply *instrumentation*. Naturally, instrumentation has been an active area of research over the past few decades.

In its simplest form, instrumentation involves adding extra code to a program's text. The intent usually is to *monitor some kind of program behavior*—either for debugging or for optimization purposes. For example, a programmer who wants to optimize the execution time of a large program might first like to know the regions of code that are executed most of the time, and then go on to optimize those frequently executed sections (rather than naively trying to optimize the entire program–a large part of which might have been written to handle extremely rare error cases). To accomplish this task, the programmer at least needs to know how many times each *function* in the program has been invoked i.e., she/he needs to *monitor the function calling behavior of the program*. The simplest way to accomplish this is to employ manual instrumentation—that is, to add extra statements at the beginning of each function to increment a counter variable that corresponds to that function, and printing all the counters when the program exits.

The abovementioned manual strategy no longer remains viable as the size of the program grows (e.g., large programs with hundreds of functions) or as the complexity of the monitoring task increases (e.g., monitoring execution of each statement or each memory access rather than each function). Consequently, many program analysis tools have been developed over the years for automatic instrumentation of program code. Because manual instrumentation is employed mostly in ad-hoc basis without any general methodology or tool support, only automated instrumentation tools will be discussed in this article.

Before going into more details, it is necessary to define a few terms clearly that will be used throughout this article. As has been mentioned already, instrumentation means adding extra code to a program or modifying the program text—usually to monitor some program behavior for the purpose of performance analysis or debugging (some other uses of instrumentation will be introduced later in this article). The extra code added is termed as *instrumentation code*. When instrumentation code is added automatically by a tool, the tool is called an *instrumenter*. The application being modified through instrumentation is called the *target application*.

The rest of this article is organized as follows. In the next two subsections, the most important usages of instrumentation are introduced, and a classification of different instrumentation techniques is provided. Two major classes of instrumentation techniques are discussed in detail in the following two sections. Finally, the article is concluded with a brief summary.

Purposes of Instrumentation

Instrumentation techniques vary widely in their design and implementation. In the following, the different purposes for which instrumentation techniques are used will be introduced:

1. **Profiling, performance analysis, and program optimization.** Profiling and performance analysis involve identification of most computation-intensive sections of an application program, followed by the optimization of such sections by partial or complete rewriting. Computation-intensive sections of a program might correspond to coarse-grain program elements, such as complete *functions*, or might be more fine grained such as *loops, basic blocks*[1] or even individual *program statements* or instructions. The required information for performance analysis can be obtained by attaching counters to each program element of interest (i.e., functions or basic blocks) and incrementing them when the corresponding program element is executed. The extra code for initialization, incrementing, and printing of such counters can be added through instrumentation. A wide variety of profiling tools, such as UNIX prof and GNU gprof (2), MIPS Pixie (3) and QPT (4), use instrumentation for various profiling tasks such as *basic block counting* and *function call-graph profiling*. Instrumentation is also used in several other important program analysis tool such as *program tracing* (5) and *memory trace generation for cache simulation*. Tools like Intel Thread Profiler (6) extend performance profiling even to multithreaded applications.

   Apart from manual optimizations based on profiling, many compilers, such as GNU gcc (7), Microsoft's Visual C++ (8) and Intel C++ and Fortran compilers (9), can automatically use profiling data to

[1] Basic blocks are well-known abstract program elements. A basic block is defined as the maximum sequence of program statements that do not contain any control flow. For detailed definition of basic blocks please consult Ref. 1.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

optimize applications. This method is usually known as *profile guided optimization*. There are certain performance events, such as cache miss rate and branch prediction, which are difficult to track through static analysis. Instrumentation is also used to dynamically optimize programs by analyzing such events (10,11).

2. **Programming error detection and debugging.** Instrumentation is used heavily in many program error detection—especially memory access error detection—tools. Memory access errors (e.g., out-of-bound accesses from statically or dynamically allocated arrays, memory leaks, etc.) are the most common sources of program malfunctions or performance degradations. Several tools—such as IBM Rational Purify (12), Valgrind (13), and Insure++ (14)—use instrumentation for detecting memory-access errors. For example, IBM Rational Purify automatically modifies the object code of a program by inserting instrumentation code before every memory access instruction (i.e., load or store) and every invocation of dynamic memory allocation/deallocation routines (e.g., malloc and free). When the program is executed, the added instructions keep track of the memories allocated/deallocated during execution and signal error when access violations occur. The results of memory error detection process can also be used to eliminate bugs from the program. Other tools such as Intel Thread Checker (15) address issues in multithreaded programming (e.g., detection of race conditions).

3. **Virtualization.** Virtualization is a technique that emulates or simulates applications, operating systems (OSs), or whole platforms on a host environment (i.e., a single physical computer running a specific operating system). The emulation engine is usually called a *Virtual Machine* (VM). Virtual machines are frequently used for porting and testing of software on new or unsupported hardware/OS, or for migrating to a new hardware/OS. Another common usage of virtualization is to facilitate implementation of easily portable and interoperable languages [such as C# (16) or Java (17)], and efficient execution engines for scripting languages [such as Python (18) and Tcl (19)]. For example, programs written in Java are translated by the Java compiler to a platform-independent *bytecode* that, in turn, is executed by a platform specific implementation of the Java Virtual Machine (JVM) (17).

   Another application of virtualization is in building *Instruction-Set Simulators*[2] (ISSs) (20) that can imitate the behavior of Instruction Set Architectures (ISAs) other than that of the host machine. Apart from allowing programmers to debug, test, and optimize their applications on different ISAs, ISSs can also be used to evaluate the hardware performance while designing new processor architectures, or embedded Systems-on-Chip (SoCs).

   Instrumentation techniques are used in many abovementioned virtualization platforms. Tools such as VMWare (21), Virtual PC (VPC) (22), and PinOS (23) use a technique called *Dynamic Binary Instrumentation* (DBI) to emulate the behavior of a *guest OS* on the host computer. These tools have varying purposes—the most prominent being porting, testing, and migration to unsupported OSs. For a more-detailed discussion on virtualization, the interested reader may consult Ref. 24. Other tools, such as the novel *Virtual Co-Processor* (VCP) (25) use instrumentation to facilitate extremely quick ISA simulation and debugging for embedded system programmers. Tools such as Ref. 26 use instrumentation for evaluation of SoC performance in the virtualization environment described in Ref. 27.

4. **Software quality assurance and testing.** Instrumentation is often helpful in many tasks related to software quality assurance and testing. The uses of instrumentation in memory error detection has already been illustrated. Many memory errors—specially memory leaks—do not directly exhibit themselves as bugs but degrade program performance in the long run. Therefore, eliminating them is often a requirement for writing high-quality software.

   Another usage of instrumentation is in *code coverage* analysis. A piece of software is said to have, say 90% code coverage, if 90% of all *Lines-Of-Code* (LOC) are executed at least once for a set of given test data. A high percentage of code coverage usually indicates a highly tested software, whereas a low code coverage percentage indicates that either the software has many unreachable sections of code (and therefore is in need of cleanup), or the test suite is inadequate. Code coverage detection tools, such as Insure++ (14), Quantify (28), and gcov (29), usually insert instrumentation code at the end of each basic block to test whether that basic block has been executed at least once.

One characteristic of instrumentation is its *intrusiveness* (i.e., the instrumentation code almost always modifies the exact program behavior). For example, added code might increase the execution time of the program or might affect the cache behavior by changing the exact memory locations accessed. Such intrusive behavior might not be acceptable in many cases, especially for performance analysis, program error detection, and debugging.

Classification of Instrumentation Techniques

Traditionally, applications are written in human readable high-level languages (such as C, C++, FORTRAN, and

[2] Many of todays ISSs are built using a technique called binary translation, which dynamically translates one Instruction Set Architecture to another during program execution. Because, binary translation is not really instrumentation, it is kept out of discussion in this article.

Pascal), which are automatically translated to binary executables by the compiler tool chain. This binary executable is normally executed on a host machine. Instrumentation techniques are usually classified based on how and when the instrumentation code is added inside a program in this compilation-execution process. Tools that add instrumentation code before execution are called *static instrumenters*, whereas those modifying a program during execution are known as *dynamic instrumenters*. Some examples of prominent static and dynamic instrumentation techniques are provided in Fig. 1 along with pointers to the sections and subsections where they are discussed in more detail.

Many modern high-level languages such as Java and C# are often compiled to machine-independent intermediate formats that, in turn, are executed through interpretive or *Just-In-Time* (JIT) compilation techniques. The .NET framework (30) from Microsoft (Redmond, WA) extends this concept by allowing several different languages to be compiled to a single intermediate format and runs it on a VM called *Common Language Runtime (CLR)*(31). For the sake of brevity, these intermediate formats will be referred to as byte codes. For such languages and platforms, static instrumenters can only instrument the byte codes of corresponding applications, because no executables are available.

Some tools exist that support both static and dynamic instrumentation. Two examples of such tools are Insure++ (14) and Vulcan (10). Insure++ is a runtime memory analysis and error-detection tool for C and C++ which can perform instrumentation at three abstraction levels (1) source code instrumentation, (2) binary instrumentation at link time, and (3) dynamic instrumentation based on the tool Chaperon (part of Insure++ suite). Vulcan is an executable editing framework for instrumenting programs that are composed of components in IA-32, IA-64, and Microsoft Intermediate Language (MSIL) binaries. Vulcan supports both static and dynamic instrumentation, as well as facilities to instrument distributed components. However, it should be noted that tools that support both static and dynamic instrumentation are usually rare.

STATIC INSTRUMENTATION

As has been mentioned earlier, static instrumentation techniques generally insert instrumentation code inside a program *statically* i.e. during of after compilation *but definitely* prior to execution. Compiling the source code of a program to the linked binary executable generally involves three steps (as shown in Fig. 1):

1. **Compilation.** In this step, the source code written in a high-level programming language (such as C, C++, Java, or Pascal) is translated to the assembly language representation for a target machine.
2. **Assembling.** The assembly language representation of the program is converted to binary object code in this step. For languages like C# or Java, this means translation into some form of bytecode.
3. **Linking.** In this step, a set of separately compiled and assembled binary object files are linked together to produce the target executable. For languages like C# and Java, linking can mean merging of several bytecode files into one single bytecode that can be executed on a VM.

Instrumentation code can be inserted during each of the above three steps. It is also possible to instrument the source code before it is handed over to the compiler *(source-to-source instrumentation)*, or the linked executable produced by the compiler tool chain *(binary instrumentation / rewriting)*. In the following subsections, many such static instrumentation techniques are discussed in detail with a special focus on their relative merits and demerits. The instrumentation techniques have been categorized depending on the step in the compilation process (or, before and after it) where instrumentation code is inserted.

Source-to-Source Instrumentation

Source-to-source transformations can insert instrumentation code directly inside a program's text. Usually, such instrumentation strategies are applied to measure some abstract source-level behavior of a program, rather than testing, debugging on a target machine. The goal of such instrumentation can vary widely—from measuring potential parallelism in scientific/engineering programs (32) to evaluating high-level algorithmic complexity for multimedia and signal processing algorithms (33) and performance estimation during embedded SoC design (26). Naturally, the program instrumentation techniques also vary a lot depending on the final goal. For example, Ref. 32 directly rewrites source code of FORTRAN programs to measure parallelism, Ref. 33 translates C programs to C++ programs and uses overloaded operators to collect execution statistics, whereas Ref. 26 lowers standard ANSI-C code to a *Intermediate Representation* (IR) for instrumentation and then writes back the instrumented IR as low-level C code. Although useful in niche application areas (such as high-performance computing and embedded systems design), source-to-source instrumenters are not widely popular because of the *slow speed of instrumented programs* compared with other forms of static instrumentation, inability to track *library functions* and requirement of *reinstrumentation before compilation* each time a program's source is modified.

One source-to-source instrumentation framework, which is not bound to niche application areas and consequently can find wide acceptance, is CCured (34). CCured has been invented to detect memory access violations in C applications. It analyzes a program and inserts the smallest number of runtime checks needed to detect memory access errors. It claims to be an order of magnitude faster than another popular memory access detection tool purify (12).

Instrumentation During Compilation

During compilation, a compiler can introduce instrumentation code inside a program as it is compiled. Most common examples of such profilers are the UNIX prof and the GNU gprof (2) profilers. For example, the gprof profiler is tightly bound to the *gcc compiler tool chain*, which inserts a call to a monitoring routine at the prolog of each function being compiled. When the instrumented binary executes, the monitoring routine collects execution statistics and dumps it into a file. The self- and cumulative execution times of different functions, as well as the dynamic call graph of the program, are later reconstructed by an analysis program from the dumped information.

The advantages of compiler-based instrumentation are twofold. Firstly, the instrumenter can use the extensive program analysis done by the compiler to insert the instrumentation code intelligently, which reduce the overhead of profiling/tracing/measurement. Second, the instrumentation code can be made to report measurement statistics in human-readable terms such as procedure names, variable names, file names and line numbers by using the database of syntactic and semantic structures constructed by the compiler.

However, several drawbacks of compiler based instrumentation are outlined below:

1. Compiler based instrumentation techniques are not easily extensible. Because most compilers are extremely complex pieces of software, adding new instrumentation functionalities is very difficult.
2. A program may be built from source code written in different languages (which, in turn, might be compiled by different compilers) and precompiled libraries. Compiler-based instrumentation cannot be used in such cases, because each compiler might use a different instrumentation strategy, and the libraries might be compiled without using any instrumentation.
3. Compiler-based instrumentation requires a re-compilation of source files. This is often time consuming and annoying for a programmer who intends to quickly analyze or debug an application.

Instrumentation During Assembling

A compiler generates assembly code for a target machine, which is handed over to an assembler for producing the binary object code. One possible point for instrumentation is to rewrite the assembly code before passing it to the assembler. Two examples of such instrumentation systems are presented in Refs. 5 and 35. In contrast to compiler-based instrumentation, instrumenting the assembly code has the advantage that it can be extended easily to incorporate new functionalities. Still, assembly instrumentation is not very popular, because it suffers from other disadvantages similar to compiler based instrumentation (e.g., tracking library function calls and need to re-assemble before debugging and analysis).

Instrumentation of Object Code Before Linking

Many drawbacks of compiler-based and assembler-level instrumentation strategies can be overcome if instrumentation is performed on the assembled object code. This process of object code modification is called *Object Code Insertion* (OCI). One prominent user of this technique is the software testing and quality assurance tool IBM Rational Purify (12). Purify reads object files generated by existing compilers and adds instructions to track memory leaks and access errors without changing the symbol table or the program semantics. The major advantages of OCI techniques over compiler-based or assembly-level instrumentation are as follows:

1. OCI does not require recompilation of high-level language programs to object code level. Consequently, OCI is much faster than compiler-based instrumentation.
2. Several different languages can be supported easily at the object code level. For example, one major difference between object codes generated from C and C++ is that C++ objects contain *mangled names*. An OCI instrumenter for C object codes can be used easily for C++ objects with the *assistance of a demangler*.
3. OCI works well with all kinds of objects, which includes the ones derived from hand optimized assembly code, as well as precompiled libraries.

Link-Time and Post-Linking Executable Editing

One of the most common forms of static software instrumentation is *executable editing*.[3] Executable editing can be carried out during linking the different components (i.e., object modules and static libraries) of a program or by directly modifying the linked binary executable. Like object code instrumentation, executable editing eliminates most disadvantages of compiler-based and assembly-level instrumentation. Executable editors can be used to instrument programs without recompiling the sources, track statically linked library functions, and handle executables built using a collection of different source languages.

Information about the entire application, which includes the relocation information, is available during (or after) linking an executable. The executable editors usually use this global information for efficiently instrumenting binaries, which is impossible for compiler-based, assembly-level, and even object code-level instrumenters. Such global information is used by many binary tools not only to instrument but also to *optimize programs* (36). However, the focus of this section will be confined to instrumentation techniques based on binary tools.

One of the earliest examples of executable editors is the MIPS profiling and tracing tool Pixie (3), which instrumented fully linked executables. Following Pixie, several binary tools, such as QP, QPT (4), and Epoxie (37) appeared. The major problem with these tools were that they were designed to perform only one single type of instrumentation, typically program tracing and basic block counting. It was difficult to extend or alter the functionalities of these tools. Naturally, these fixed-functionality tools were followed by many *executable editing frameworks* that facilitated the construction of *customized program instrumentation and analysis tools*. The genesis and evolution of these frameworks are discussed in the next few subsections.

It is to be mentioned that several bytecode instrumentation tools also exist for languages like Java or C#. One example is the *Java Runtime Analysis Toolkit* (JRat) (38), which can keep track of timing statistics, function tracing, and so on. JRat currently allows five different kinds of Java application instrumentation, one of which is bytecode instrumentation.

Executable Editing Frameworks. Executable editing frameworks were first conceived as tool-construction systems that could be used to build a variety of instrumentation programs. They are built on the observation that several apparently different tasks such as basic block counting, cache simulation, memory access error detection, and program tracing can be performed by inserting instrumentation code at a few selected points in a program. Such selected insertion points may include, but are not limited to, the beginning and the end of a basic block, prologue and epilogue of a function, and before and after an instruction. An executable editing framework usually provides a common infrastructure that facilitates injection of *user-defined routines* inside a program's executable at some such *selected insertion points*.

To understand the philosophy of executable editing frameworks, a simple program analysis tool, which counts the number of times each conditional branch in the program is taken (39), can be considered. The building of such a program analysis tool can be divided into two phases:

1. **Instrumentation phase**. The instrumenter needs to examine each instruction of the edited executable and test whether this instruction is a conditional branch. If the instruction in question is indeed a conditional branch, then the instrumenter needs to insert a function call that increments a counter.
2. **Analysis phase**. The analysis phase is activated when the instrumented binary executes. The function calls, inserted during the instrumentation phase, increment required counters and finally, dumps the collected statistics into a file before the program exits.

The major hurdle in constructing the above analysis tool is to build a program representation that can be traversed one instruction at a time, examined to detect conditional branches, and modified by inserting instrumentation code. It is relatively simple to write the instrumentation and analysis routines that insert and collect the branch profiling data. This is the general case for many program analysis tools. The philosophy of executable editing frameworks is to let the user write the instrumentation and analysis routines, while a convenient, intuitive and modifiable representation of the program binary is supplied by the framework itself. This work flow reflected is in the Fig. 2 where the binary executable program (or, a prelinking object file) is translated to an internal representation inside the editing framework. A set of *custom instrumentation routines* can traverse and modify this representation using an API, which is also provided by the editing framework. The final instrumented binary may contain *custom analysis routines* inserted through instrumentation.

Figure 2. General work flow of executable editing frameworks.

[3] Executable editing is also known by a variety of names, such as rewriting an executable file, and binary rewriting. Tools that perform executable editing are known as *binary tools or executable editors*. These terms will be used interchangeably during the rest of this article.

As an example, ATOM (39) can be considered as one of the first executable editing frameworks. The program representation used by ATOM was based on OM (40)—a link-time code optimization framework. OM modeled a program as a sequence of procedures. Each procedure consisted of a sequence of basic blocks, and each basic block, in turn, consisted of a sequence of instructions. Instructions were modeled using a simple *Register Transfer Level* (RTL) syntax which was machine independent and generic enough for a variety of RISC machines. The custom instrumentation routines were combined with OM to build custom instrumenters. During linking, the object modules and static libraries could be supplied to such a custom instrumenter that would first build up a symbolic representation of the whole program through OM. The custom instrumentation routines then interfaced with the symbolic representation to traverse and insert analysis code in the program.

Another instrumentation framework built on ATOM-like philosophy was EEL (41), which also constructed a program representation and provided means for user-defined routines to traverse and modify it. The major difference was that whereas ATOM was a link-time instrumentation system EEL worked on linked binary executables. However, the interfaces of EEL were lower level and more detailed than those of ATOM. The added details provided more control over the instrumentation process while complicating the writing of user routines.

One major innovation of EEL was that it provided ways to retarget the analysis tools for processing binaries of different target machines. This retargeting was done by providing a concise description of the target instruction set that helped EEL tools to parse binary instruction codings and understand the syntax and semantics of different machine instructions, typically jump, branch, and memory access instructions.

Following the footsteps of ATOM and EEL, several binary instrumentation frameworks, such as Etch, BIT, and Vulcan appeared. Etch (42) was designed to tackle Win32 binaries on x86 machines, whereas *Vulcan* has been designed to tackle components available in IA-32, IA-64, and MSIL binaries in Win32 environment.

Vulcan (10) deserves a special mentioning because, to the best of our knowledge, it is the only framework that not only permits both static and dynamic instrumentation/modification of binaries on a single machine, but also provides tools for dynamic modification of binaries that run on remote machines. It is a framework that has been specially designed to modify/analyze/instrument applications whose components might be distributed over several machines in a networked environment. For such applications, it is important that tasks like code generation or optimization are delayed until execution time, which is what Vulcan facilitates.

With the increasing popularity of languages like Java and C# and platforms like .NET, which support interoperable software development by compiling source code to some kind of intermediate bytecode, the number of frameworks targeting some form of bytecode instrumentation and manipulation has been also increasing. One of the first Java bytecode instrumentation frameworks is BIT (43). Two other important Java bytecode manipulation frameworks are JOIE (44) and BCEL (45) (BCEL is now part of the Apache project). All of them provide APIs for manipulation of Java bytecodes. Other similar instrumentation frameworks include SERP (46) and Javassist (47).

Several frameworks also exist for instrumentation of .NET bytecode. One of them is AbstractIL (48) from Microsoft, which provides methods to access .NET binaries in a convenient format which can be analyzed, transformed or instrumented. RAIL (49) is another framework, which claims to be a general purpose instrumentation library for .NET platform.

DYNAMIC INSTRUMENTATION

Historically, static instrumentation techniques appeared first; so far, they have been mainly used in program analysis, debugging, testing, and code-coverage tools. However, they suffer from some major limitations, which are sketched below:

1. Static instrumentation techniques modify the software executable. Running an extra tool for instrumentation before executing the code is often not convenient for programmers.
2. Static instrumentation can only cover code that is statically linked. It is not possible to track execution of dynamically linked code, shared libraries, or dynamically generated code through static instrumentation. This issue is the most severe with static instrumentation, because most executables nowadays contain a large section of code in dynamically linked libraries.
3. Static binary instrumentation is often difficult for binary formats that allow mixing of code and data, rather than separating them in well-defined sections (e.g., Win32 binaries).

These limitations have forced the development of dynamic instrumenters that perform instrumentation at runtime (i.e., when the program is executing). Unlike static instrumenters, dynamic instrumenters can only work on compiled executable binaries (or, bytecodes). Therefore, dynamic instrumentation is also called *Dynamic Binary Instrumentation* (DBI). Unlike static instrumenters that expect the instrumented code to run directly on the host machine, DBI tools insert themselves between the original application and the host machine to supervise the execution closely (Fig. 3 highlights this difference between DBI and static instrumentation). Such close monitoring can be performed in various ways. For example, some dynamic instrumenters, such as Pin (50) and DynInst (51) use UNIX/LINUX ptrace (ptrace is part of the Linux kernel (52)) command to obtain control of an application. ptrace allows the dynamic instrumenter to monitor the execution of each instruction, and accordingly add instrumentation code. Another method for dynamic instrumentation is to use the so-called library interposers (53). For instance, in UNIX systems, the LDPRELOAD environment variable forces the dynamic loader to load a shared library in an application's address space. This shared library can contain

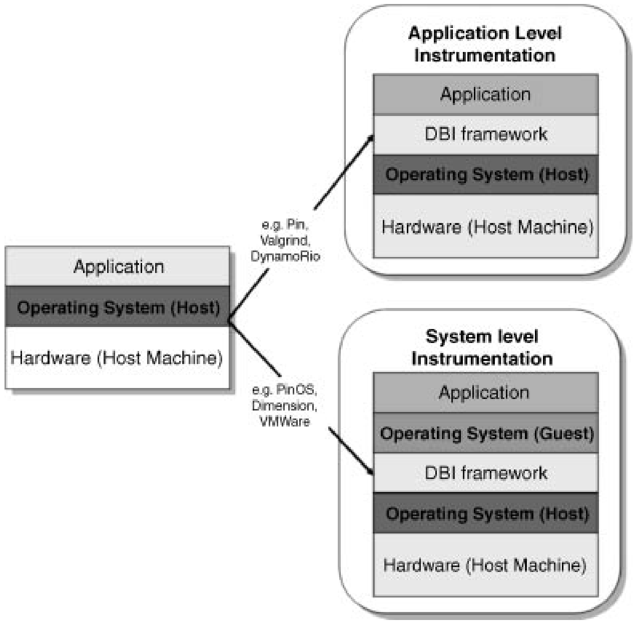

Figure 3. Overview of dynamic instrumentation techniques.

functions to monitor execution of the application and perform instrumentation. One user of this technique is DynamoRio (54).

The most important advantage of dynamic instrumentation is that any piece of code executed can be tracked and analyzed. Through dynamic techniques it is possible to instrument not only statically linked libraries and object files, but dynamically generated or linked code and shared libraries, too. Additionally, dynamic instrumenters do not need to parse through a program binary to detect code and data segments and build a complete program representation before instrumentation. Moreover, indirect branches are especially difficult to handle through static instrumentation. As the targets of indirect branches cannot be resolved at compile time, a static instrumenter must conservatively assume that each instruction is a potential branch target. Therefore, each instruction has to be instrumented, even for simple basic block counting. Through dynamic instrumentation, such cases can be easily handled. From a programmer's perspective, dynamic instrumentation is extremely convenient for debugging, because no extra pass for instrumentation is necessary.

Although dynamic instrumentation is advantageous in many ways, it is not without its limitations. The overall execution time of an application can be affected greatly if dynamic instrumentation is used on it in runtime. Therefore, both static and dynamic instrumentation frameworks suffer from intrusiveness, as they alter the timing of software execution. Additionally, dynamic instrumenters are rather difficult to implement compared with static ones.

Unlike static instrumenters, DBI frameworks cannot be categorized on the basis of the step (in the compilation process) where instrumentation code is added. Instead, the DBI frameworks are classified based on the *techniques* used for instrumentation. Figure 3 shows a possible classification of DBI tools based on those *techniques*. DBI techniques can be applied on application level for the use of profiling, performance measurement, and memory error detection. Several DBI tools, such as Pin (50), Valgrind (13) and DynamoRio (54), are used mostly (but not exclusively) for this purpose. Some other DBI tools can be applied on the system level. Examples of such tools are VMWare (21), Dimension (55), and PinOS (23). These tools mostly exploit instrumentation for running a virtual guest OS on top of a host OS and can even keep track of the OS kernel and its performance characteristics. Such a technique is typically referred to as virtualization and is discussed in depth in Ref. 24.

Based on the underlying techniques of instrumentation, all DBI tools can be classified under two major categories. The first one is called *probe-based* DBI. In this approach, code snippets, which are known as *trampolines*, are inserted in an application during its execution. Examples for such probe-based instrumentation frameworks are DynInst (51), DTrace (56), and Vulcan (10). The second technique is known as *dynamic binary transformation*. This technique can be subdivided into three main approaches—namely, *copy* & *annotate, copy* & *modify* and *Just-In-Time*(JIT)*-compilation* based approaches.

The *copy* & *annotate* approach copies code that is about to be executed, inserts the instrumentation code into this copy, and executes this annotated code. Example frameworks that use this techniques include PIN (50), Nirvana (57), and Dimension (55). A very similar binary transformation approach is *copy* & *modify*. However, the use cases of these two techniques differ significantly. Whereas *copy* & *annotate* tools are mostly used for profiling, error detection and debugging, *copy* & *modify* tools are mostly used for virtualization [VMWare (21) and Virtual PC (22)].

The second binary transformation approach is known as *Just-In-Time-compilation* based approach [e.g., Valgrind (58)]. Such DBI frameworks intercept a program element [usually a basic block (1)] that is about to be executed, and recompiles the application code JIT to insert instrumentation code. All binary transformation techniques are typically considered to be costly in terms of execution time. Therefore, these frameworks incorporate caching strategies to improve performance of DBI engines.

In the following subsections, the focus will be on dynamic instrumentation techniques and not on the instrumentation tools themselves. For example, the dynamic instrumentation tools Memcheck (13) and Cachegrind (13) target different problems in software development, nevertheless both are based on the underlying Valgrind (13) framework. So Valgrind, rather than Memcheck or Cachegrind, will be discussed in detail.

Probe-Based Approaches

Probe-based approaches dynamically analyze executing applications to identify *instrumentation points* that are, typically, either function boundaries, or the start/end of basic blocks. The instrumentation framework then inserts *probes* into the executing code at suitable instrumentation points. A probe usually overwrites the instruction at the corresponding instrumentation point, and adds a jump to a code segment usually called a *trampoline*. The overwritten instruction is usually relocated inside the trampoline. The

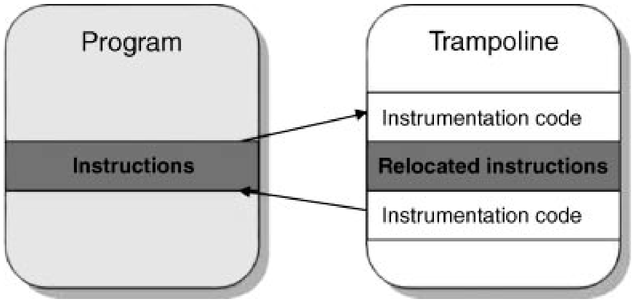

Figure 4. Probe-based instrumentation.

trampoline also contains additional instrumentation code that might increment a counter, a timer or do something else depending on the instrumentation objective. Figure 4 depicts the principle of probe-based dynamic instrumentation. It is to be noted that trampolines themselves can be complex and make calls to other trampolines. For the sake of simplicity, this information is omitted from the figure.

Examples of well-known probe-based instrumentation frameworks are DTrace (56), ParaDyn (59), which is based on DynInst (51), as well as Vulcan (10). Despite several advantages, probe-based instrumentation frameworks have been mostly replaced over time by binary transformation techniques because of the following disadvantages.

1. Trampolines are implemented using one or more levels of branches. This can have significant performance penalties.
2. In probe-based instrumentation, the instructions from the original code are overwritten and/or relocated by the jumps to the trampolines. Adding such jump instructions requires relocation of all other instructions after the overwritten instruction. Additionally, all jump targets, whether direct or indirect, have to be updated as the intended jump target might have been relocated. Such update can only be handled by a dynamic relinking and update step, which is, in principle, feasible, but rather difficult to implement in practice. Consequently, the execution of such code loses transparency, and the implementation task becomes extremely challenging.

Binary Transformation

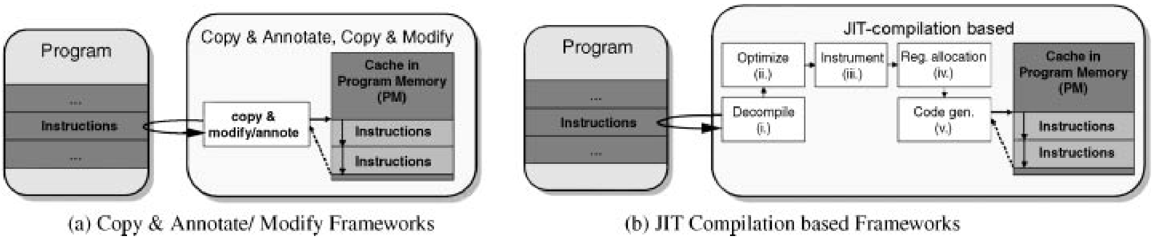
Figure 5 illustrates the common philosophy behind the binary transformation frameworks. As can be observed from the figure, in contrast to the probe-based frameworks, which insert instrumentation code in the original program text. A binary transformation tool copies the original code and generates a completely new set of instructions from it. The new piece of code may contain instrumentation code added inside it. The behavior of the original code, however, is preserved as far as possible. Usually, the copied code is put into a software cache inside the program memory for future execution to the same section of the application.

Binary transformation frameworks/tools such as the Pin (23, 50) and VMW are (21) make use of the *copy* & *annotate* / *modify* approach, whereas Valgrind (58) relies on the JIT-compilation based approach. *Copy* & *annotate* / *modify* frameworks are typically, but not necessarily, used for performance measurements and error detection. JIT-compilation based approaches are rather often used for more fine-grained software instrumentation.

Advantages of binary transformation compared to probe-based approaches are:

1. The original application is never executed in such frameworks and no code modifications are applied to the original application's code. Therefore separation of the instrumented and original code can be done safely (e.g., Pin separates both into two different threads). Moreover, there is no need for code relocation which makes the implementation simpler.
2. Optimized caching strategies of the copied code can improve performance of the instrumentation framework. Even jumps and branches can be removed dynamically by flattening the cached application's instructions.
3. Instrumentation can be incorporated at the very start of the application's code and not only after calling the entry point (usually the main function) of the application. For example, Valgrind can even monitor the loading process of an application and accordingly detect errors there.
4. Self-modifying and referential code can be better supported through binary transformation. For example, Valgrind supports the Ada programing language, which particularly uses self-modifying code (58).

Copy and Annotate/Modify Frameworks. The *copy* & *annotate* and *copy* & *modify* approaches both come under the category of binary transformation frameworks and are closely related from technical point of view. Whereas *copy* &



(a) Copy & Annotate/ Modify Frameworks (b) JIT Compilation based Frameworks

Figure 5. Binary transformation frameworks.

annotate frameworks, like Pin, focus on performance measurements as well as on error detection, the main purpose of *copy* & *modify* frameworks lies on virtualization, like VMWare (21) and VirtualPC (22).

Figure 5(a) depicts the basic principle of such DBI frameworks. The first step is the fetching of a piece of code from the application's text (which is characteristic of all binary transformation approaches), and a transformation process that directly inserts extra code into original text according to the objectives of instrumentation. The transformation process is typically very simple within *copy* & *annotate*/*modify* tools—it does not contain any transformations to and from an intermediate representation (which is characteristic of the JIT-compilation based tools). The resulting instructions are then executed on the host machine, and the procedure is repeated from the beginning.

JIT-Compilation-Based Frameworks. Just-in-time compiled DBI frameworks are more suitable for fine-grained instrumentation of executables. The key idea of such frameworks is to decompile and then to re-compile the binary code dynamically. Examples for such JIT-based instrumentation frameworks are Valgrind (58), Strata (60), DynamoRio (54), and Diota (61).

To understand the philosophy of JIT-based instrumentation frameworks, Valgrind can be considered as an example. Valgrind is an open-source framework that is used in many large projects [e.g. the Linux Desktop Environment KDE (62) and Firefox (63)]. Valgrind is the underlying infrastructure or core of a collection of assorted tools. Other softwares, like Memcheck (13) or Cachegrind (13), can build on this core framework to accomplish specific tasks by performing appropriate types of instrumentation.

Like other binary transformation frameworks, Valgrind first copies a set of instructions from the executable binary. The next step is to generate a new set of instructions that contain instrumentation code. Instead of directly inserting instrumentation code in the copied instructions as within the *copy* & *annotate*/*modify* technique, Valgrind follows a complex process as outlined below and in Fig. 5(b):

1. *Decompilation.* The IA-32 binary code of the application is dynamically disassembled into an intermediate representation named UCode.
2. *Optimization.* In this step, redundancy introduced by the previous phase is removed to improve execution of the instrumented code.
3. *Instrumentation.* Appropriate instrumentation code can be inserted by a tool in this step. This exactly is the phase when tools like Memcheck or Cachegrind interact with the Valgrind core framework to instrument the intermediate UCode.
4. *Register allocation.* Here registers are allocated for the virtual registers of the intermediate UCode.
5. *Code generation.* Finally, instrumented IA-32 code is generated from the register-allocated UCode. The generated code is then executed.

As is clear from this example, insertion of instrumentation by a JIT-compilation based approach introduces a lot of execution overhead. Consequently, most JIT-based tools are much slower than their *copy* & *annotate*/*modify* counterparts, which use direct techniques for instrumentation. For example, in Valgrind, the slowdown factor ranges between 20 and 50 (13) times of the original execution depending on the instrumentation used. This result is 4 times slower than Pin and 4.4 times slower than DynamoRio (58). Another problem of JIT based DBIs is that the recompilation process completely erases all links to the original code.

The advantage of JIT-based approaches is that they can go beyond performance analysis and simple OS virtualization. For example, JIT approaches can be used to emulate a completely different ISA on the host machine. This approach will be difficult to accomplish through *copy* & *annotate*/*modify* DBI frameworks, however, it is possible in principle.

SUMMARY

Software instrumentation is a technique that is widely applied in program analysis, debugging, performance optimization, and virtualization. The instrumentation techniques can be classified into static and dynamic software instrumentation. Historically, static approaches appeared first. They have been, and still are, used in the fields of performance analysis, error detection, and software quality assurance and testing. Dynamic approaches can be used for all of these, but additionally, they are used in several virtualization environments.

Static instrumentation frameworks/tools can be classified into five groups according to the compilation step in which instrumentation code is added. These are source-to-source instrumentation, instrumentation during compilation, instrumentation of the assembly, instrumentation of the object code before linking and finally, link-time and post-link instrumentation. Static instrumentation techniques suffer from the problem that dynamically generated or linked code cannot be tracked using them. Moreover, static instrumentation often involves an extra pass over the application, which adds instrumentation code. This code is often inconvenient for many programmers. Despite of these limitations, static approaches are often simple to implement and still find widespread usage in many profiling, program analysis, error detection, and testing tools.

In contrast to static instrumentation, which has to be applied before execution of the application, techniques based on dynamic instrumentation can be applied at runtime. They can track any piece of executed code, which includes shared and dynamically linked libraries and dynamically generated code. Moreover, they can be used directly on a compiled binary without any extra pass through a special tool. Two major approaches are used for dynamic instrumentation: probe-based approaches and binary transformation. Binary transformation approaches can be subclassified into three different techniques, which are copy & annotate, copy & modify, and JIT-compilation based. Copy & annotate and JIT-compilation based-approaches target primarily performance measurement and error detection, whereas copy & modify frameworks and tools are targeting the field of virtualization.

SOFTWARE MODULE RISK ANALYSIS

INTRODUCTION

The practical goal of a software development team is to deliver the product within the allotted time and budget. The team strives to achieve the best possible software quality within the given resources. Assessing software module risk is generally a precursor to a software quality enhancement initiative. To improve software quality, development teams apply various techniques such as reengineering, extra reviews, and additional testing. Analyzing the risk associated with modules for a given system often involves *software quality estimation* and then applying quality improvement techniques to the modules that need it the most.

In software engineering practice, assessing the risk of a software module is often attained by either classifying it into risk-based classes, such as *fault-prone* (*fp*) or *not fault-prone* (*nfp*), or by predicting the number of *software faults* expected. In addition, a software module's risk can be assessed by obtaining a relative risk-based ordering of all software modules. The software attribute that represents software quality, i.e., risk-based class, number of faults, or another factor, is referred to as *software quality data*. Although other software quality models exist, we focus primarily on software quality classification, software fault prediction, and software module-order models. These models are more widely used in software engineering practice.

Software measurements play a vital role in developing software quality estimation models (1), because of the software engineering assumption that software metrics reflect the quality of a software product. A software metric is an attribute that quantifies or qualifies a certain aspect of the software module or program. For example, "lines of code" can represent the size of a program. Several types of software metrics exist in the literature (2) ranging from very basic attributes to more complex attributes. The use of specific software metrics for software quality estimation depends on the system under evaluation and other practical considerations.

The output of software quality estimation models are predictions that the development team can use to identify high-risk or low-quality modules in the software system. The need for identifying such modules is primarily from economic and practical needs. An ideal software development situation would be that all modules are targeted for inspection and quality improvement to maximize software reliability. However, in practice, a software development team generally has limited and finite resources allocated for quality improvement. Software quality estimation models provide practical assistance to the development team by isolating high-risk software modules for a targeted and cost-effective use of project resources.

We present three types of software quality estimation models, i.e., software quality classification, software fault prediction, and module-order modeling, all built using a case study of software measurement data from a large telecommunications system. A software quality classification model predicts the class membership of modules into predefined quality-based classes (3). A software fault prediction model predicts the number of faults expected in the modules (4). A module-order model predicts the relative risk-based ordering of the software modules (5). Our aim is to provide the reader with sufficient information of research on software module risk analysis, so as to promote further software quality and/or interdisciplinary research.

SOFTWARE QUALITY ESTIMATION MODELS

Software development is a human-intensive endeavor, and software quality is invariably affected by many factors that vary among development organizations. To achieve useful accuracy, software quality models must be built for each specific development environment. In addition, each software project team must decide on which software measurements are to be collected and recorded for software quality estimation. Software measurements have been used as quality predictors in software development. However, there is yet no consensus as to what software metrics are preferable for quality estimation.

Most literature on software metrics is typically aimed at demonstrating the efficacy of individual metrics. However, this does not directly relate to building useful software quality models. Our previous experience with software measurement data from industrial projects has indicated that a software quality model based on only one software metric does not have useful accuracy and robustness. A simple metric, such as lines of code, is not sufficient by itself. A more complex metric, such as McCabe's cyclomatic complexity (2), is also not enough by itself. A better approach is to employ multiple software metrics to build a software quality model instead of only one metric.

A given software development organization is often equipped with data collection tools, such as a software metric-analyzer tool. Hence, the relative cost of collecting many software metrics, instead of just a few, is not a practical problem. To determine software metrics that are better predictors of quality for a given system, a data mining approach should be taken instead of an arbitrary- or heuristic-based selection approach. Pragmatic considerations usually determine the set of available software metrics. We do not advocate the universal use of a given set of software metrics; instead, we prefer a data mining approach to selecting software metrics that are good quality predictors for the given software system.

To build a useful software quality estimation model, the following modeling steps are followed:

- Analysis of a previous system release or similar project, for which software quality data is known. Software measurement data are collected for this project.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

- The known software metrics and software quality data are used to build a software quality model. The model is then used to predict the quality of modules in the current project, for which software quality data are not known. We shall focus our discussion to three types software quality estimation models: software fault prediction, software quality classification, and software module-order modeling.
- The obtained predictions are used as a guide to allow a targeted software quality improvement initiative.

A software fault prediction model tries to find the relationship between the given set of software measurements of the modules and the number of faults expected in each module. A software fault is a defect in an executable product that causes a software failure. Faults are a result of mistakes or omissions made by the developers. A software quality classification model tries to find the relationship between the given set of software measurements of the modules and their membership into predetermined risk-based classes, such as *fp* and *nfp*. An advantage of a fault prediction model is that it allows the development team to observe the quality of modules in a relative sense. However, a development team may only be interested in knowing which modules should be targeted for quality improvement, regardless of their relative quality—a classification model provides such a software quality model.

A classification model, however, does not provide the relative risk of the modules classified as *fp*, which makes it difficult to initiate software quality improvement toward the most high-risk modules. In addition, a fault prediction model may predict well for low-risk modules but predict poorly for high-risk modules. These disadvantages are overcome by a module-order model, in which the relative risk-based order of the software modules is predicted. More specifically, the output of such a model is a ranking of the modules according to a risk factor, such as number of faults expected. Such a model is attractive to the software quality assurance team because it provides valuable guidance for quality improvement without quantifying the quality of individual program modules. To obtain a cost-effective software quality improvement, the available resources can be applied to the modules starting from the most-risky and selecting additional modules according to the quality-based ranking of program modules until the available resources are exhausted.

A given software development team may choose to select any one of the three software quality models based on their organizational preference, expertise with the modeling approach, and available resources for carrying out the software quality modeling and analysis process. The performance of software quality models is often measured by their prediction accuracy. The prediction of a software quality classification model is often measured by its misclassification error rates—the lower the error rates, the better the model. In a two-group (*fp* and *nfp*) classification model, two types of errors can occur, Type I and Type II. A Type I error occurs when a *nfp* module is predicted as *fp*, whereas a Type II error occurs when a *fp* module is predicted as *nfp*. A Type II error is more costly than a Type I error, because it implies a lost opportunity to fix a fault before system operations. In contrast, a Type I error implies unnecessary inspection of a good quality module. In our studies (6), we have observed an inverse relationship between the Type I and Type II error rates—as one increases, the other decreases. Hence, the selection of the final model requires the knowledge of a preferred balance between the two error rates.

The prediction of a fault prediction model can be measured by the average absolute error (AAE) or the average relative error (ARE). The relative importance of these two performance measures is out of scope for this article and is an open research issue. The AAE and ARE performance measures are computed as follows:

$$\mathrm{AAE} = \frac{1}{n}\sum_{i=1}^{n} |y_i - \hat{y}_i| \tag{1}$$

$$\mathrm{ARE} = \frac{1}{n}\sum_{i=1}^{n} \left|\frac{y_i - \hat{y}_i}{y_i + 1}\right| \tag{2}$$

where y_i is the actual number of faults in a module, $\hat{y}_i$ is the predicted number of faults in a module, and n is the number of modules in the target dataset. The denominator in ARE has a one added to avoid division by zero, because a software module could have zero faults associated with it. Our studies evaluate fault prediction models using both AAE and ARE.

In our study, the prediction of a module-order model is measured by evaluating, for a given cutoff percentage of modules, how accurately the model accounts for the actual number of faults for that cutoff point. A cutoff point reflects the percentage of modules that the software development team will choose to apply software quality improvement techniques. Subsequently, different projects will choose different cutoff points according to their quality improvement requirements. The precise evaluation procedure for a module-order model is discussed in more detail in the next section.

MODELING TECHNIQUES

In the literature one can find various techniques and methods for building software quality estimation models. Although most techniques are suited either for quality classification or fault prediction, not many can address both problems. Some techniques used for software quality classification include discriminant analysis (7), logistic regression (8,9), decision trees (6,10), artificial neural networks (11,12), genetic programming (13), belief networks (14), fuzzy logic (10), and case-based reasoning (15). Some techniques used for software fault prediction include multiple linear regression (16), artificial neural networks (16), case-based reasoning (17), and regression trees (18).

In this study, we present the logistic regression technique for building software quality classification models and the multiple linear regression technique for software fault prediction. These methods are commonly used in classification and regression problems, especially in the software quality engineering field. A good comparative study that compares seven software quality classification methods is presented in Ref. (3). A similar comparative study that compares five software fault prediction methods is presented in Ref. (16).

Logistic Regression

Logistic regression is a statistical modeling technique in which the dependent variable has only two possible values and the independent variables may be categorical, discrete, or continuous (8). In the context of classification with logistic regression, we designate a module being *fp* as an "event" (19). Therefore, if p is the probability of an event, i.e., a module is *fp*, $(\frac{p}{1-p})$ is the odds of an event. We denote x_j as the jth independent variable. A logistic regression model has the following form:

$$\log_e\left(\frac{p}{1-p}\right) = \beta_0 + \beta_1 x_1 + \ldots + \beta_j x_j + \ldots + \beta_m x_m \quad (3)$$

where m represents the number of independent variables and $\beta_0, \ldots, \beta_m$ are model coefficients.

In software engineering, most software metrics have a monotonic relationship with faults that are inherent in the underlying processes. In practice, not all independent variables may contribute to the logistic regression model. To exclude insignificant variables, the stepwise logistic regression method for *model selection* was adopted (19). The significance tests for each variable are based on the chi-squared statistic. We compute the maximum likelihood estimates of the parameters of the model, b_j, using the iteratively reweighted least-squares algorithm (20), where b_j is the estimated value of β_j. The estimated logistic regression model takes the following form:

$$\log_e\left(\frac{\hat{p}}{1-\hat{p}}\right) = b_0 + b_1 x_1 + \ldots + b_j x_j + \ldots + b_m x_m \quad (4)$$

To classify program modules as either *fp* or *nfp* with the logistic regression model, $(\frac{\hat{p}}{1-\hat{p}})$ is computed using the above equation. A module x_i's class, *Class*($\mathbf{x}_i$), is assigned as *nfp* if $(\frac{1-\hat{p}}{\hat{p}}) > \zeta$ and *fp*, otherwise. The term ζ is a modeling parameter that can be empirically varied to obtain the preferred classification model (19). The desired balance between the error rates is project dependent and is largely influenced by the software quality improvement needs of the development team and the disparity between the respective costs of misclassifications.

Multiple Linear Regression

The multiple linear regression technique provides a statistical means of estimating or predicting a dependent variable as a function of known independent variables. The model is in the form of an equation where the response or dependent variable is expressed in terms of predictors or independent variables. The general form of a multiple linear regression (MLR) model can be given by

$$\hat{y} = a_0 + a_1 x_1 + \ldots + a_m x_m \quad (5)$$

$$y = a_0 + a_1 x_1 + \ldots + a_m x_m + e \quad (6)$$

where $x_1, \ldots, x_m$ are the m independent variables' values, $a_0, \ldots, a_m$ are the parameters to be estimated, $\hat{y}$ is the dependent variable to be predicted, y is the actual value of the dependent variable, and $e = y - \hat{y}$ is the error in prediction.

The data available are initially subject to statistical analysis, with the aim to remove any correlation existing between independent variables and to remove insignificant independent variables, not accounting for the dependent variable. The process of determining the variables that are significant is known as *model selection*. Several methods of model selection exist. They are forward elimination, stepwise selection, and backward elimination (20). Here, stepwise regression is used.

Stepwise regression selects an optimal set of independent variables for the model. In this process, variables are either added or deleted from the regression model at each step of the model building process. Once the model is selected, the parameters $a_0, \ldots, a_m$ are then estimated using the *least-squares* method. The values of the parameters are selected such that they minimize $\sum_{i=1}^{N} e_i^2$, where N is the number of observations in the *fit* dataset.

Module-Order Modeling

A module-order model (MOM) can be defined as a software metrics-based quality estimation model, which is used to predict the prioritized rank-order of modules according to a predetermined software quality factor. The choice of the quality factor is dependent on the project management team; however, it should be a good representation of the actual quality of the module. A good example would be the number of faults (as defined by the project) expected in a software module during system test or operations. A MOM predicts the relative quality of each program module, especially those that are the most faulty.

A MOM comprises the following three components: (*1*) an underlying software quality prediction model; (*2*) a ranking of modules according to the quality factor predicted by the underlying model; and (*3*) a procedure for evaluating the accuracy and effectiveness of the predicted ranking. In the context of a MOM, a software metrics-based underlying software quality prediction model may be considered as a function of a vector of software measurements $\mathbf{x}_i$, predicting a quality factor F_i, for module i; i.e., $F_i = f(\mathbf{x}_i)$. Generally speaking, any prediction technique may be selected as an underlying quality prediction model. We use the prediction obtained by the multiple linear regression technique.

When obtaining the quality-based rankings of software modules, the following notations are used. Let $\hat{F}(\mathrm{x}_i)$ be an estimate of F_i by the underlying prediction model $\hat{f}(\mathrm{x}_i)$. R_i is the perfect ranking of the observation i according to F_i, whereas $\hat{R}(\mathrm{x}_i)$ is the same ranking but according to $\hat{F}(\mathrm{x}_i)$. In module-order modeling, the emphasis is on whether a module falls above a certain cutoff percentile that indicates the proportion of modules that are to be targeted for reliability enhancements. All modules that fall above the cutoff percentile will be subjected to quality improvement. According to the allocated software quality improvement resources, the project management team will select a certain cutoff percentile and apply quality enhancement processes to all modules that fall within that cutoff value.

Once the quality-based rankings are determined, the following steps illustrate the evaluation procedure for a module-order model (5). Given a model and a test dataset with software modules indexed by i:

1. Management will choose to enhance modules in a priority-based order, beginning with the most faulty. However, the rank of the last module that will be enhanced is uncertain at the time of modeling. Determine a range of percentiles that covers management's options for the last module (from the rank order), based on the schedule and resources allocated for a software quality improvement. Choose a set of representative cutoff percentiles c from that range.
2. For each cutoff percentage value of interest c, define the number of faults accounted for by the modules above the percentage c. This process is done for both the perfect and the predicted ranking of the modules: $G(c)$ is the number of faults accounted for by the modules that are ranked (perfect ranking) above the percentile c, and $\hat{G}(c)$ is the number of faults accounted for by the modules that are predicted as falling above the percentile c.

$$G(c) = \sum_{i:R \geq c} F_i \tag{7}$$

$$\hat{G}(c) = \sum_{i:\hat{R}(\mathbf{X}_i) \geq c} F_i \tag{8}$$

3. Calculate the percentage of faults accounted for by each ranking, namely, $\frac{G(c)}{G_{tot}}$ and $\frac{\hat{G}(c)}{G_{tot}}$, where G_{tot} is the total number of actual faults of all program modules in the given dataset.
4. Calculate the performance of the module-order model $\phi(c) = \frac{\hat{G}(c)}{G(c)}$, which indicates how closely the faults accounted for by the model ranking match those of the perfect module ranking. In the context of accuracy of a MOM at a given c value, the performance of the model, i.e., $\phi(c)$, should be as close to 1 (or 100%) as possible. After evaluating the accuracy and robustness of a MOM, it is ready for use on a current similar project or subsequent release. Determine the predicted ranking, by ordering modules in the current dataset according to $\hat{F}(\mathbf{x}_i)$.

In practice, a manager is interested in the accuracy of a MOM only at the preferred cutoff percentile value. As all modules that fall above the preferred cutoff point get the same reliability enhancement treatment, the distance of the predicted rank-order from the actual is not an appropriate measure of model accuracy. We are therefore not interested in the accuracy of the rank-order within the enhanced group, which consists of modules that are subjected to quality improvements. However, we do want $\phi(c)$ to be close to 100% for the c of interest.

EMPIRICAL CASE STUDY

System Description

The case study data were collected over two successive releases, from a very large legacy telecommunications system, abbreviated as LLTS. The software system is an embedded-computer application that included finite-state machines. Using the procedural development paradigm, the software was written in a high-level language and was maintained by professional programmers in a large organization. The releases considered in our study are labeled as Release 1 and Release 2 and do not represent the first two chronological releases of the system.

A software module was considered as a set of related source-code files. Faults attributed to a software module were recorded only if their discovery resulted in changes to the source code of the respective module. Software fault data were collected at the module level by the problem reporting system and comprised post-release faults discovered by customers during system operations. A problem reporting system is an information system for managing software faults from initial discovery through distribution of fixes. Preventing the occurrence of software faults after deployment was a high priority for the developers, because visits to customer sites involved extensive consumption of monetary and other resources.

Configuration management data analysis identified software modules that were unchanged from the prior release. A configuration management system is an information system for managing multiple versions of artifacts produced by software development processes. Fault data collected from the problem reporting system was tabulated into problem reports, and anomalies were resolved. Because of the nature of the system being modeled, i.e., a high-assurance system, the modules associated with post-release faults were very few as compared with modules with no faults. Two clusters of modules were identified: unchanged and updated. The updated modules comprised those that were either new or had at least one update to their source code since the prior release. Among the unchanged modules, almost all (over 99%) of them had no faults and, therefore, were not considered for modeling purposes.

We selected updated modules with no missing data in the relevant variables. These updated modules had several million lines of code, with a few thousand of these modules in each system release. The number of updated modules (that remained after unchanged modules or those with missing data were removed) that were considered for the two releases are 3649 for Release 1 and 3981 for Release 2. In the case of the software quality classification study, a module was considered as *nfp* if it had no post-release faults and *fp* otherwise. The proportion of modules with no faults among the updated modules of Release 1 was $\pi_G = 0.937$, and the proportion with at least one fault was $\pi_R = 0.063$. Such a small set of *fp* modules is often difficult for a software quality modeling technique to identify.

The set of available software metrics is usually determined by pragmatic considerations. A data mining approach is preferred in exploiting software metrics

Table 1. LLTS **Software Product Metrics**

Symbol	Description
	Call Graph Metrics
CALUNQ	Number of distinct procedure calls to others.
CAL2	Number of second and following calls to others. *CAL2* = *CAL* − *CALUNQ* where *CAL* is the total number of calls.
	Control Flow Graph Metrics
CNDNOT	Number of arcs that are not conditional arcs.
IFTH	Number of non-loop conditional arcs, i.e., if–then constructs.
LOP	Number of loop constructs.
CNDSPNSM	Total span of branches of conditional arcs. The unit of measure is arcs.
CNDSPNMX	Maximum span of branches of conditional arcs.
CTRNSTMX	Maximum control structure nesting.
KNT	Number of knots. A "knot" in a control flow graph is where arcs cross due to a violation of structured programming principles.
NDSINT	Number of internal nodes (i.e., not an entry, exit, or pending node).
NDSENT	Number of entry nodes.
NDSEXT	Number of exit nodes.
NDSPND	Number of pending nodes, i.e., dead code segments.
LGPATH	Base 2 logarithm of the number of independent paths.
	Statement Metrics
FILINCUQ	Number of distinct include files.
LOC	Number of lines of code.
STMCTL	Number of control statements.
STMDEC	Number of declarative statements.
STMEXE	Number of executable statements.
VARGLBUS	Number of global variables used.
VARSPNSM	Total span of variables.
VARSPNMX	Maximum span of variables.
VARUSDUQ	Number of distinct variables used.
VARUSD2	Number of second and following uses of variables. *VARUSD2* = *VARUSD* − *VARUSDUQ*, where *VARUSD* is the total number of variable uses.

data, by which a broad set of metrics are analyzed rather than limiting data collection according to a predetermined set of research questions. Data collection for this case study involved extracting source code from the configuration management system. The available data collection tools determined the number and selection of the software metrics. Software measurements were recorded using the EMERALD (Enhanced Measurement for Early Risk Assessment of Latent Defects) software metrics analysis tool, which includes software-measurement facilities and software quality models. Another project might collect and consider a different set of software metrics for modeling purposes (21–23).

Preliminary data analysis selected metrics that were appropriate for our modeling purposes. Another software project may consider (depending on availability) a different set of software metrics as more appropriate. Software metrics collected included 24 product metrics, 14 process metrics, and 4 execution metrics. The 14 process metrics were not used in our empirical evaluation, because this study is concerned with the software quality estimation of program modules after the coding (implementation) phase and before system tests. Therefore, the case study consists of 28 independent variables (Tables 1 and 2) that were used to predict the respective dependent variable: *Class* (*fp* or *nfp*) for software quality classification, and *Faults* for software fault prediction. The predicted number of faults are used to rank the modules for building the module-order model.

The software product metrics in Table 1 are based on call graph, control flow graph, and statement metrics. An example of call graph metrics is the number of distinct procedure calls. A module's control flow graph consists of nodes and arcs depicting the flow of control of the program. Statement metrics are measurements of the program statements without implying the meaning or logistics of the statements. The problem reporting system maintained records on past problems. The proportion of installations that had a module, *USAGE*, was approximated by deployment data on a prior system release. Execution times in Table 2 were measured in a laboratory setting with different simulated workloads.

It should be noted that software quality estimation models based on source code metrics that are available

Table 2. LLTS **Software Execution Metrics**

Symbol	Description
USAGE	Deployment percentage of the module.
RESCPU	Execution time (microseconds) of an average transaction on a system serving consumers.
BUSCPU	Execution time (microseconds) of an average transaction on a system serving businesses.
TANCPU	Execution time (microseconds) of an average transaction on a tandem system.

relatively later (such as software product metrics) in the software development process may have some drawbacks. For example, it may be difficult to relate the model with software engineering issues related to the requirements and specifications development phase. In addition, some early software design quality issues may not be completely reflected by the model. The ideal scenario would be to evaluate software quality in a progressive manner as the project develops, using techniques suited for the given development phase. However, limited software project funds often restrict implementing such an ideal scenario.

Software Quality Classification Model

The logistic regression model formed after the stepwise logistic regression procedure for identifying significant independent variables (at an $\alpha = 0.15$ significance level) for the LLTS case study is shown below:

$$\begin{aligned}\log\left(\frac{\hat{p}}{1-\hat{p}}\right) \\ &= -6.0473 + 0.0327\,\mathit{FILINCUQ} + 1.9610\,\mathit{USAGE} \\ &\quad + 0.0230\,\mathit{LGPATH} + 0.0145\,\mathit{LOP} \\ &\quad + 0.0002\,\mathit{VARSPNMX} - 0.0032\,\mathit{STMCTL} \\ &\quad + 0.0079\,\mathit{NDSPND} + 0.0031\,\mathit{IFTH} \qquad (9)\end{aligned}$$

where $\hat{p}$ is the estimated value of p, and the respective software metrics are described in Tables 1 and 2. This model was built using the Release 1 software modules as a training dataset. The modules of Release 2 were used as a test dataset to evaluate the prediction accuracy of the model.

In our case study, we varied the value of the parameter ζ to obtain the preferred balance between the error rates. The misclassification rates for the logistic regression models based on the different values of ζ are presented in Table 3. Other values for ζ were also considered; however, we have presented a representative set in the table. An inverse relationship between the Type I and Type II error rates is observed. A very high value of ζ yielded a very low Type II error and a very high Type I error. On the other hand, a very low value of ζ yielded a very high Type II error and a very low Type I error. For example, when ζ = 50, the corresponding fitted (Release 1) model yielded a Type I error rate of 67% and a Type II error rate of 3.5%. Moreover, when ζ = 1, the corresponding model yielded a Type I error rate of 0.4% and a Type II error rate of 91.7%.

In our previous studies with high assurance systems such as the legacy telecommunication system presented, a preferred balance of equality between the Type I and Type II error rates and Type II being as low as possible was chosen as the model selection criterion. Such a model selection criterion is representative of a software project that has very few *fp* modules in comparison with the *nfp* modules, and when the cost of misclassifying a *fp* module is much greater than the cost of misclassifying a *nfp* module. In addition, such a model selection strategy provides a practical software quality classification. If a model with the lowest Type II error rate is selected as the final model, it will have a very high Type I error rate. This implies that a large number of modules will be predicted as *fp*, with many of them actually being *nfp*. Such a model is not practical for cost-effective software quality improvement.

Therefore, based on our model-selection strategy, the preferred balance was obtained when ζ = 16. We observe that for ζ = 16 the two error rates are approximately equal, with the Type II error rate being low. The performance of this model for the test dataset, i.e., Release 2, is fairly reasonable and is not too overfitted. An overfitted model is one that performs very well on the fit dataset but performs very poorly on the test dataset. We observe that, for Release 2, the model with ζ = 16 maintains the preferred balance between the two error rates reasonably well.

Table 3. Logistic Regression Classification Models

	Release 1		Release 2	
ζ	Type I	Type II	Type I	Type II
50	67.00 %	3.50 %	64.79 %	4.23 %
30	49.80 %	8.70 %	46.70 %	11.64 %
25	42.90 %	13.50 %	39.90 %	14.81 %
20	34.90 %	19.70 %	31.59 %	21.69 %
18	31.00 %	21.00 %	28.11 %	24.87 %
16	**27.00 %**	**24.90 %**	**25.00 %**	**29.60 %**
10	15.50 %	38.90 %	14.61 %	41.80 %
5	6.20 %	60.30 %	6.20 %	67.20 %
1	0.40 %	91.70 %	0.40 %	91.53 %
0.067	0.00 %	100.00 %	0.00 %	100.00 %

Software Fault Prediction Model

The multiple linear regression technique with stepwise regression selected seven software metrics at a significance level of α = 0.05. A significance level represents the statistical degree of importance for the independent variables. The selected metrics are *FILINCUQ*, *CNDNOT*, *NDSENT*, *NDSEXT*, *NDSPND*, *NDSINT*, and *STMDEC*. The model parameters were estimated, and the following model was obtained:

$$\begin{aligned}\mathit{Faults} &= 0.0143\mathit{FILINCUQ} - 0.0035\mathit{CNDNOT} \\ &\quad + 0.0238\mathit{NDSENT} - 0.009\mathit{NDSEXT} \\ &\quad + 0.017\mathit{NDSPND} + 0.0066\mathit{NDSINT} \\ &\quad - 0.0031\mathit{STMDEC}\end{aligned}$$

The values of average absolute and average relative errors obtained from the model are presented in Table 4. The table also shows the standard deviation of the two error measures. We observe that, with respect to AAE, the performance of the model for the test dataset is better than the

Table 4. Fault Prediction Model Performance

Dataset	AAE	SDAE	ARE	SDRE
Release 1	1.007	1.534	0.550	0.545
Release 2	0.890	1.091	0.571	0.610

fit dataset, which is generally not expected. The trained model has an AAE of about 1 fault, with its predictive performance of AAE = 0.890. With respect to the ARE performance measure, the trained model has an error rate of 0.55. The performance of the model for the test dataset is very similar with ARE = 0.571. When considering both performance measures, we note that the multiple linear regression model does not show overfitting tendencies.

A comparison of the software metrics used by the classification and fault prediction model reveals that the *FILINCUQ* and *NDSPND* metrics are common to the two models. This finding may suggest that these two metrics are useful (among others) software quality predictors for the legacy telecommunications system considered in this study. The problem of feature selection or attribute selection is very important in software quality estimation, because it could reduce data collection efforts and improve the robustness of the software quality models.

Software Module-Order Model

The software fault prediction obtained by the multiple linear regression model is used as the underlying prediction model for the module-order model. More specifically, for the given dataset, the modules are ranked according to their predicted number of faults, starting with the highest. The results of the model are summarized in Table 5, which evaluates the model at different cutoff values, i.e., c values. We note that, for Release 1, 100 % of software faults are accounted for at c = 0.50; i.e., $\frac{G(c)}{G_{tot}} = 1.000$. Similarly, for Release 2, 100 % of software faults are accounted for at c = 0.60.

The fourth and seventh columns in the table represent the performance $\phi(c)$ of the module-order model for the Release 1 and Release 2 datasets, respectively. We observe that $\phi(c)$ generally increases with a decrease in c, which is expected because as c is decreased more modules are subjected to inspection and hence more software faults will be accounted for. The performance of the model is generally lower for the test dataset than the fit dataset, which suggests that the module-order model may be prone to some overfitting. However, it should be noted that the ranking of the model is obtained by the predictions of the underlying multiple-linear regression model. This finding suggests that the efficiency of the underlying prediction model is likely to affect the performance of the subsequent module-order model.

Table 5. Module-Order Model Based on Multiple Linear Regression

	Release 1			Release 2		
c	$\frac{G(c)}{G_{tot}}$	$\frac{\hat{G}(c)}{G_{tot}}$	$\phi(c)$	$\frac{G(c)}{G_{tot}}$	$\frac{\hat{G}(c)}{G_{tot}}$	$\phi(c)$
0.95	0.381	0.239	0.627	0.368	0.204	0.554
0.90	0.541	0.361	0.667	0.539	0.330	0.613
0.85	0.645	0.458	0.709	0.671	0.421	0.628
0.80	0.743	0.522	0.703	0.748	0.489	0.654
0.75	0.794	0.577	0.726	0.814	0.539	0.662

0.65	0.891	0.670	0.752	0.946	0.632	0.668
0.60	0.940	0.706	0.751	1.000	0.672	0.672
0.55	0.988	0.737	0.746	1.000	0.709	0.709
0.50	1.000	0.771	0.771	1.000	0.740	0.740

THREATS TO VALIDITY

Controlled experiments to evaluate the usefulness of empirical models are not practical because of the many human factors that affect software quality. Hence, we adopted a case study approach to demonstrate the usefulness of the software quality estimation models in a real-world setting. To be credible, the software engineering community demands that the subject of an empirical study be a system with the following characteristics (24). The subject of an empirical case study must be developed

- By a group and not by an individual
- By professionals and not by students
- In an industry/government organization and not in a laboratory
- As large as industry projects and not a toy problem

We note that our case study fulfills all of the above criteria through collaborative arrangements with the development organization.

CONCLUSION

The task of delivering a software product with good quality is daunting, especially in the presence of limited budget and time constraints. Software development teams apply various techniques to improve software quality, so as to maximize software quality within the given project resources. Software quality estimation models predict the quality of software modules can be used to provide a targeted software quality improvement initiative.

A software quality classification model predicts the class membership of modules into risk-based classes, such as fault-prone and not fault-prone. A software fault prediction model estimates the number of faults in a software module. A software module-order model predicts the relative risk-based order of the modules. These software quality models are built using software measurements and quality data obtained from a previous system release or similar project. The trained models are then used to predict the software quality of the modules currently under development. These software quality models have successfully been used in software engineering practice toward software quality improvement of real-world projects.

This article presents the useful principles of building software quality classification, software fault prediction, and software module-order models. The logistic regression technique was used to build the classification model, whereas the fault prediction model was built by using the multiple linear regression technique. The module-order model was obtained by ranking the modules according to the predictions of the fault prediction model. A case study of software measurement data obtained from a telecommunications system was used to build the respective models. Several other software systems have also been explored in other related studies, and have demonstrated the effectiveness of software quality estimation models toward cost-effective software quality improvement.

Some modeling tools that can be used for building software quality models include SAS (www.sas.com), S-Plus (www.mathworks.com), CART (www.salford-systems.com), MATLAB (www.mathsoft.com), SMART (www.cse.fau.edu/esel), IBM Intelligent Data Miner (www.ibm.com), and WEKA (25). Not all tools have a wide selection of modeling techniques. For example, CART predominantly implements a decision- and regression-tree-based modeling approach. In contrast, WEKA provides a collection of modeling techniques, such as C4.5 decision tree and instance-based learning.

ACKNOWLEDGMENTS

We express our gratitude to Dr. Kehan Gao for her patient reviews of the manuscript. In addition, we thank the various current and previous members of the Empirical Software Engineering Laboratory, Florida Atlantic University, for their assistance with empirical and modeling analysis.

SOFTWARE PERFORMANCE EVALUATION

INTRODUCTION

Performance and quality of service (QoS) aspects of modern software systems are crucially important for their successful adoption in the industry. Most generally, the *performance* of a software system indicates the degree to which the system meets its objectives for timeliness and the efficiency with which it achieves this. Timeliness is normally measured in terms of meeting certain response time or throughput requirements and scalability goals. Response time refers to the time required to respond to a user request, for example a Web service call or a database transaction, and throughput refers to the number of requests or jobs processed per unit of time. Scalability, on the other hand, is understood as the ability of the system to continue to meet its objectives for response time and throughput as the demand for the services it provides increases and resources (typically hardware) are added.

Numerous studies, for example, exist in the areas of e-business, manufacturing, telecommunications, military, health care, and transportation that have shown that a failure to meet the performance requirements can lead to serious financial losses, loss of customers and reputation, and in some cases even to loss of human lives. To avoid the pitfalls of inadequate QoS, it is important to evaluate the expected performance characteristics of systems during all phases of their lifecycle. The methods used to do this are part of the discipline called *software performance engineering* (SPE) (1,2). Software performance engineering helps to estimate the level of performance a system can achieve and provides recommendations to realize the optimal performance level (3).

However, as systems grow in size and complexity, estimating their performance becomes a more and more challenging task. Modern software systems are often composed of multiple components deployed in highly distributed and heterogeneous environments. Figure 1 shows a typical architecture of a multitiered distributed component-based system (4). The application logic is partitioned into components distributed over physical tiers. Three tiers exist: presentation tier, business logic tier, and data tier. The presentation tier includes Web servers hosting Web components that implement the presentation logic of the application. The business logic tier includes a cluster of application servers hosting business logic components that implement the business logic of the application. Middleware platforms such as Java EE (5), Microsoft .NET (6), or CORBA (7) are often used in this tier to simplify application development by leveraging some common services typically used in enterprise applications. The data tier includes database servers and legacy systems that provide data management services. The inherent complexity of such architectures makes it difficult to manage their end-to-end performance and scalability. To avoid performance problems, it is essential that systems are subjected to rigorous performance evaluation during the various stages of their lifecycle. At every stage, performance evaluation is conducted with a specific set of goals and constraints. The goals can be classified in the following categories, some of which partially overlap:

Platform selection: Determine which hardware and software platforms would provide the best scalability and cost/performance ratio. Software platforms include operating systems, middleware, database management systems, and so on. Hardware platforms include the type of servers, disk subsystems, load balancers, communication networks, and so on.

Platform validation: Validate a selected combination of platforms to ensure that taken together they provide adequate performance and scalability.

Evaluation of design alternatives: Evaluate the relative performance and scalability of alternative system designs and architectures.

Performance prediction: Predict the performance of the system for a given workload and configuration scenario.

Performance tuning: Analyze the effect of various deployment settings and tuning parameters on the system performance and find their optimal values.

Performance optimization: Find the components with the largest effect on performance and study the performance gains from optimizing them.

Scalability and bottleneck analysis: Study the performance of the system as the load increases and more hardware is added. Find which system components are most utilized and investigate whether they are potential bottlenecks.

Sizing and capacity planning: Determine the amount of hardware that would be needed to guarantee certain performance levels.

Two broad approaches help conduct performance evaluation of software systems: *performance measurement* and *performance modeling*. In the first approach, load testing tools and benchmarks are used to generate artificial workloads on the system and to measure its performance. In the second approach, performance models are built and then used to analyze the performance and scalability characteristics of the system. In both cases, it is necessary to characterize the workload of the system under study before performance evaluation can be conducted. The *workload* can be defined as the set of all inputs that the system receives from its environment during a period of time (3).

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

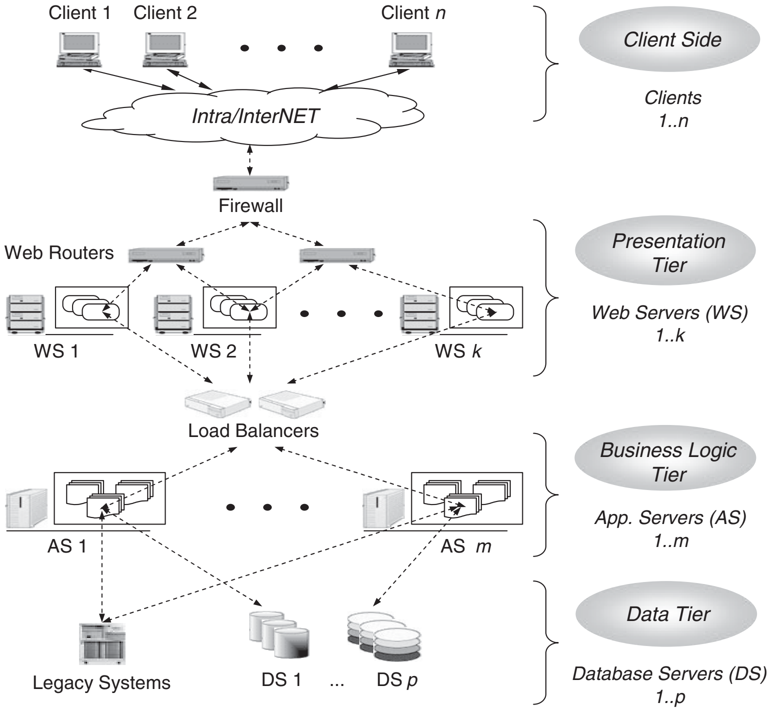

Figure 1. A multitiered distributed component-based system.

In performance evaluation studies normally workload models are used that are representations of the real system workloads.

WORKLOAD MODELS

A *workload model* is a representation that captures the main aspects of the real workload that have effect on the performance measures of interest. We distinguish between *executable* and *nonexecutable* models. Executable models are programs that mimic real workloads and can be used to evaluate the system performance in a controlled environment. For example, an executable model could be a set of benchmark programs that emulate real users sending requests to the system. Nonexecutable models, on the other hand, are abstract workload descriptions normally used as input to analytical or simulation models of the system. For example, a nonexecutable model could be a set of parameter values that describe the types of requests processed by the system and their load intensities. Workload models are aimed to be as compact as possible and at the same time representative of the real workloads under study.

As shown in Fig. 2, workload models can be classified into two major categories: *natural models* and *artificial models* (3). Natural models are constructed from real workloads of the system under study or from execution traces of real workloads. In the former case, they are called *natural benchmarks,* and in the latter case they are called *workload traces*. A natural benchmark is a set of programs extracted from the real workload such that they represent the major characteristics of the latter. A workload trace is a chronological sequence of records describing specific events that were observed during execution of the real workload. For example, in the three-tier environment described earlier, the logs collected by the servers at each tier (Web servers, application servers and database servers) can be used as workload traces. Although traces usually exhibit good representativeness, they have the drawback that they normally consist of huge amounts of data and do not provide a compact representation of the workload.

Unlike natural models, artificial workload models are not constructed using basic components of real workloads as building blocks, however, they try to mimic the real workloads. Artificial models can be classified into *synthetic benchmarks, application benchmarks*, and *abstract*

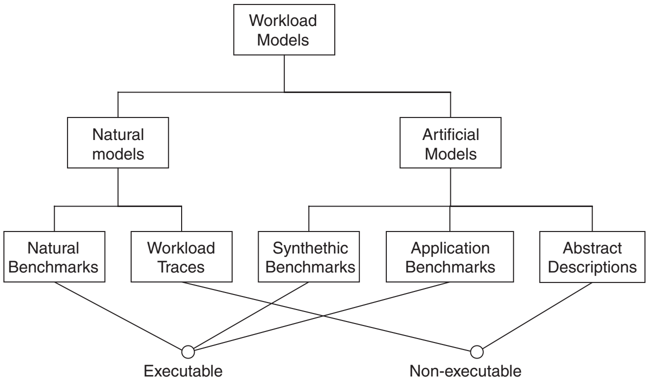

Figure 2. Taxonomy of workload models.

workload descriptions. Synthetic benchmarks are artificial programs carefully chosen to match the relative mix of operations observed in some class of applications. They usually do no real, useful work. In contrast, application benchmarks are complete real-life applications. They are normally designed specifically to be representative of a given class of applications. Finally, abstract workload descriptions are nonexecutable models composed of a set of parameter values that characterize the workload in terms of the load it places on the system components. Such models are typically used in conjunction with analytical or simulation models of the system. Depending on the type of workload, different parameters may be used, such as transaction/request types, times between successive request arrivals (interarrival times), transaction execution rates, transaction service times at system resources, and so on. As an example, an e-commerce workload can be described by specifying the types of requests processed by the system (e.g., place order, change order, cancel order), the rates at which requests arrive, and the amount of resources used when processing requests, that is, the time spent receiving service at the various system resources such as central processing units (CPUs), input–output (I/O) devices, and networks. For additional examples and details on executable and nonexecutable workload models, the reader is referred to Refs. 8 and 9, as well as 3 and 10, respectively.

PERFORMANCE MEASUREMENT

The measurement approach to software performance evaluation is typically applied in three contexts:

– *Platform benchmarking:* Measure the performance and scalability of alternative platforms on which a system can be built and/or deployed.

– *Application profiling:* Measure and profile the performance of application components during the various stages of the development cycle.

– *System load testing:* Measure the end-to-end system performance under load in the later stages of development when a running implementation or a prototype is available for testing.

In all three cases, executable workload models are used. In this section, we briefly discuss the above three contexts in which performance measurements are done. A more detailed introduction to performance measurement techniques can be found in Refs. 1, 8, 9, 11 and 12. The *Proceedings of the Annual Conference of the Computer Measurement Group* (CMG) are an excellent source of recent publications on performance measurement tools, methodologies, and concepts.

Platform Benchmarking

While benchmarking efforts have traditionally been focused on hardware performance, over the past 15 years, benchmarks have increasingly been used to evaluate the performance and scalability of end-to-end systems including both the hardware and *software* platforms used to build them (9). Thus, the scope of benchmarking efforts has expanded to include software products like Web servers, application servers, database management systems, message-oriented middleware, and virtual machine monitors. Building on scalable and efficient platforms is crucial to achieving good performance and scalability. Therefore, it is essential that platforms are validated to ensure that they provide adequate level of performance and scalability before they are used to build real applications. Where alternative platforms are available, benchmark results can be used for performance comparisons to help select the platform that provides the best cost/performance ratio. Two major benchmark standardization bodies exist, the Standard Performance Evaluation Corporation (SPEC) (13) and the Transaction Processing Performance Council (TPC) (14). Many standard benchmarks have appeared in the last decade that provide means to measure the performance and scalability of software platforms. For example, SPECjAppServer2004 and TPC-App for application servers, SPECjbb2005 for server-side Java, TPC-W and SPECweb2005 for Web servers, TPC-C, TPC-E and TPC-H for database management systems, and SPECjms2007 for message-oriented middleware. Benchmarks such as these are called *application benchmarks* because they are designed to be representative of a given class of real-world applications.

Although the main purpose of application benchmarks is to measure the performance and scalability of alternative platforms on which a system can be built, they can also be used to study the effect of platform configuration settings and tuning parameters on the overall system performance (9,15,16). Thus, benchmarking not only helps to select platforms and validate their performance and scalability, but also helps to tune and optimize the selected platforms for optimal performance. The *Proceedings of the Annual SPEC Benchmark Workshops* are an excellent source on the latest developments in benchmarking methodologies and tools (17).

Application Profiling

Application profiling is conducted iteratively during the system development cycle to evaluate the performance of components as they are designed and implemented. Design and implementation decisions taken at the early stages of system development are likely to have a strong impact on the overall system performance (1). Moreover, problems caused by poor decisions taken early in the development cycle are usually most expensive and time-consuming to correct. Therefore, it is important that, as components are designed and implemented, their performance is measured and profiled to ensure that they do not have any internal bottlenecks or processing inefficiencies. Software profilers are normally used for this purpose.

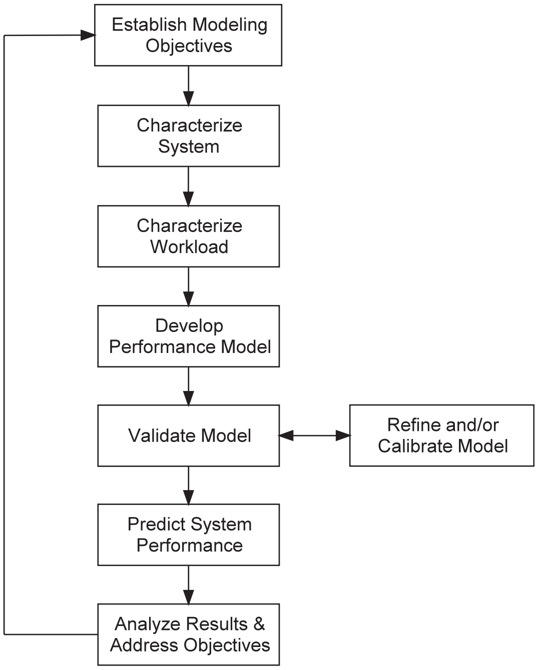
Software profilers are performance measurement tools that help to gain a comprehensive understanding of the execution-time behavior of software components. They typically provide information such as the fraction of time spent in specific states (e.g., executing different subroutines, blocking on I/O, running operating system kernel code) and the flow of control during program execution. Two general techniques are normally used to obtain such information, *statistical sampling* and *code instrumentation* (11,12). The statistical sampling approach is based on interrupting the program execution periodically and recording the execution state. The code instrumentation approach, on the other hand, is based on modifying the program code to record state information whenever a specified set of events of interest occur. Statistical sampling is usually much less intrusive; however, it only provides statistical summary of the times spent in different states and cannot provide any information on how the various states were reached (e.g., call graphs). Code instrumentation, on the other hand, is normally more intrusive; however, it allows the profiler to precisely record all the events of interest as well as the call sequences that show the flow of control during program execution. For example, in CPU time profiling, statistical sampling may reveal the relative percentage of time spent in frequently-called methods, whereas code instrumentation can report the exact number of times each method is invoked and the calling sequence that led to the method invocation.

System Load Testing

Load testing is typically done in the later stages of system development when a running implementation or a prototype of the system is available for testing. Load-testing tools are used to generate synthetic workloads and measure the system performance under load. Sophisticated load-testing tools can emulate hundreds of thousands of "virtual users" that mimic real users interacting with the system. While tests are run, system components are monitored and performance metrics (e.g., response time, throughput and utilization) are measured. Results obtained in this way can be used to identify and isolate system bottlenecks, fine-tune system components, and measure the end-to-end system scalability (18). Unfortunately, this approach has several drawbacks. First of all, it is not applicable in the early stages of system development when the system is not available for testing. Second, it is extremely expensive and time-consuming because it requires setting up a production-like testing environment, configuring load testing tools, and conducting the tests. Finally, testing results normally cannot be reused for other applications.

PERFORMANCE MODELING

The performance modeling approach to software performance evaluation is based on using mathematical or simulation models to predict the system performance under load. Models represent the way system resources are used by the workload and capture the main factors that determine the system behavior under load (10). This approach is normally much cheaper than load testing and has the advantage that it can be applied in the early stages of system development before the system is available for testing. A number of different methods and techniques have been proposed in the literature for modeling software systems and predicting their performance under load. Most of them, however, are based on the same general methodology that proceeds through the steps depicted in Fig. 3 (1, 3, 19–21).



Establish Modeling Objectives
Characterize System
Characterize Workload
Develop Performance Model
Validate Model
Refine and/or Calibrate Model
Predict System Performance
Analyze Results & Address Objectives

Figure 3. Performance modeling process.

First, the goals and objectives of the modeling study are specified. After this, the system is described in detail in terms of its hardware and software architecture. The aim is to obtain an in-depth understanding of the system architecture and its components. Next, the workload of the system is characterized and a workload model is built. The workload model is used as a basis to develop a performance model. Before the model can be used for performance prediction, it has to be validated. This is done by comparing performance metrics predicted by the model with measurements on the real system. If the predicted values do not match the measured values within an acceptable level of accuracy, then the model must be refined and/or calibrated. Finally, the validated performance model is used to predict the system performance for the deployment configurations and workload scenarios of interest. The model predictions are analyzed and used to address the goals set in the beginning of the modeling study. We now take a closer look at the major steps of the modeling process.

Workload Characterization

Workload characterization is the process of describing the workload of the system in a qualitative and quantitative manner (20). The result of workload characterization is a nonexecutable workload model that can be used as input to performance models. Workload characterization usually involves the following activities (1, 22):

- The basic components of the workload are identified.
- Basic components are partitioned into workload classes.
- The system components/resources used by each workload class are identified.

- The inter-component interactions and processing steps are described.
- Service demands and workload intensities are quantified.

In the following, we discuss each of these activities in turn.

The Basic Components of the Workload are Identified. *Basic component* refers to a generic unit of work that arrives at the system from an external source (19). Some examples include HTTP requests, remote procedure calls, Web service invocations, database transactions, interactive commands, and batch jobs. Basic components could be composed of multiple processing tasks, for example client sessions that comprise multiple requests to the system or nested transactions (open or closed). The choice of basic components and the decision how granular they are defined depend on the nature of the services provided by the system and on the modeling objectives. Because, in almost all cases, basic components can be considered as some kind of requests or transactions processed by the system, they are often referred to as *requests* or *transactions*[1].

Basic Components are Partitioned into Workload Classes. To improve the representativeness of the workload model, the basic components are partitioned into classes (called *workload classes)* that have similar characteristics. The partitioning can be done based on different criteria, depending on the type of system modeled and the goals of the modeling effort (19, 23). The basic components should be partitioned in such a way that each workload class is as homogeneous as possible in terms of the load it places on the system and its resources.

The System Components and Resources Used by Each Workload Class are Identified. For example, an online request to place an order might require using a Web server, application server, and backend database server. For each server, the concrete hardware and software resources used must be identified. It is distinguished between active and passive resources (10). An *active resource* is a resource that delivers a certain service to transactions at a finite speed (e.g., CPU or disk drive). In contrast, a *passive resource* is needed for the execution of a transaction, but it is not characterized by a speed of service delivery (e.g., thread, database connection or main memory).

The Intercomponent Interactions and Processing Steps are Described. The aim of this step is to describe the processing steps, the inter-component interactions, and the flow of control for each workload class. Also for each processing step, the hardware and software resources used are specified. Different notations may be exploited for this purpose, for example client/server interaction diagrams (20), execution graphs (1), communication-processing delay diagrams (19), as well as conventional UML sequence and activity diagrams (24).

Service Demands and Workload Intensities are Quantified. The goal is to quantify the load placed by the workload components on the system. *Service-demand parameters* specify the average total amount of service time required by each workload class at each resource. Most techniques for obtaining service-demand parameters involve running the system or components thereof and taking measurements. Some techniques are also available that can be used to estimate service-demand parameters in the early stages of system development before the system is available for testing (25). *Workload-intensity parameters* provide for each workload class a measure of the number of units of work (i.e., requests or transactions), that contend for system resources. Depending on the way workload intensity is specified, it is distinguished between open and closed classes. For open classes, workload intensity is specified as an arrival rate, whereas for closed classes it is specified as average number of requests served concurrently in the system.

The product of the workload characterization steps described above (i.e., the workload model) is sometimes referred to as *software execution model* because it represents the key facets of software execution behavior (1).

Performance Models

A performance model is an abstract representation of the system that relates the workload parameters with the system configuration and captures the main factors that determine the system performance. Performance models can be used to understand the behavior of the system and predict its performance under load. Figure 4 shows the major types of performance models that are available in the literature for modeling computer systems. Note that this model classification is not clear cut because some model types partially overlap. Performance models can be grouped into two main categories: *simulation models* and *analytical models*. One of the greatest challenges in building a good model is to find the right level of detail. A general rule of thumb is: “Make the model as simple as possible, but not simpler!” Including too much detail might render the model intractable, on the other hand, making it too simple might render it unrepresentative.

Simulation Models. Simulation models are software programs that mimic the behavior of a system as requests arrive and get processed at the various system resources. Such models are normally stochastic because they have one or more random variables as input (e.g., the request interarrival times). The structure of a simulation program is based on the states of the simulated system and events that cause the system state to change. When implemented, simulation programs count events and record the duration of time spent in different states. Based on these data, performance metrics of interest (e.g., the average time a request takes to complete or the average system throughput) can be estimated at the end of the simulation run. Estimates

[1] The term transaction here is used loosely to refer to any unit of work or processing task executed in the system.

are provided in the form of confidence intervals. A confidence interval is a range with a given probability that the estimated performance metric lies within this range. The main advantage of simulation models is that they are very general and can be made as accurate as desired. However, this accuracy comes at the cost of the time taken to develop and run the models. Usually, many long runs are required to obtain estimates of needed performance measures with reasonable confidence levels.

Several approaches to developing a simulation model (22) exist. The most time-consuming approach is to use a general purpose programming language such as C++ or Java, possibly augmented by simulation libraries (e.g., CSIM or SimPack). Another approach is to use a specialized simulation language such as GPSS/H, Simscript II.5, or MODSIM III. Finally, some simulation packages support graphical languages for defining simulation models (e.g., Arena, Extend, SES/workbench). A comprehensive treatment of simulation techniques can be found in Refs. 26 and 27.

Analytical Models. Analytical models are based on mathematical laws and computational algorithms used to derive performance metrics from model parameters. Analytical models are usually less expensive to build and more efficient to analyze compared with simulation models. However, because they are defined at a higher level of abstraction, they are normally less detailed and accurate. Moreover, for models to be mathematically tractable, usually many simplifying assumptions need to be made impairing the model representativeness.

Queueing networks and generalized stochastic Petri nets are perhaps the two most popular types of models used in practice. Queueing networks provide a very powerful mechanism for modeling hardware contention (contention for CPU time, disk access, and other hardware resources) and scheduling strategies. A number of efficient analysis methods have been developed for a class of queueing networks called *product-form queueing networks*, which enable models of realistic size and complexity to be analyzed (28). The downside of queueing networks is that they are not expressive enough to model software contention accurately (contention for processes, threads, database connections, and other software resources), as well as blocking, simultaneous resource possession, asynchronous processing, and synchronization aspects. Even though extensions of queueing networks, such as *extended queueing networks* (29) and *layered queueing networks* (also called stochastic rendezvous networks) (30–32), provide some support for modeling software contention and synchronization aspects, they are often restrictive and inaccurate.

In contrast to queueing networks, generalized stochastic Petri net models easily can express software contention, simultaneous resource possession, asynchronous processing, and synchronization aspects. Their major disadvantage, however, is that they do not provide any means for direct representation of scheduling strategies. The attempts to eliminate this disadvantage have led to the emergence of *queueing Petri nets* (33–35), which combine the modeling power and expressiveness of queueing networks and stochastic Petri nets. Queueing Petri nets enable the integration of hardware and software aspects of system behavior in the same model (36, 37). A major hurdle to the practical use of queueing Petri nets, however, is that their analysis suffers from the state space explosion problem limiting the size of the models that can be solved. Currently, the only way to circumvent this problem is by using simulation for model analysis (38).

Details of the various types of analytical models shown in Fig. 4 are beyond the scope of this article. The following books can be used as reference for additional information (3, 12, 28, 35, 39–42). The *Proceedings of the ACM SIGMETRICS Conferences* and the *Performance Evaluation Journal* report recent research results in performance modeling and evaluation. Further relevant information can be found in the *Proceedings of the International Conference on Quantitative Evaluation of SysTems (QEST)*, the *Proceedings of the Annual Meeting of the IEEE International Symposium on Modeling, Analysis, and Simulation of Computer and Telecommunication Systems* (MASCOTS), the *Proceedings of the International Conference on Performance Evaluation Methodologies and Tools*, (VALUETOOLS) and the *Proceedings of the ACM International Workshop on Software and Performance* (WOSP).

Model Validation and Calibration

Before a model can be used for performance prediction, it has to be validated. We assume that the system modeled or a prototype of it is available for testing. The model is said to be *valid* if the performance metrics (e.g., response time, throughput, and resource utilization) predicted by the model match the measurements on the real system within a certain acceptable margin of error (3). As a rule of thumb, errors within 10% for utilization and throughput, and

within 20% for response time are considered acceptable (10). Model validation is normally conducted by comparing performance metrics predicted by the model with measurements on the real system. This testing is performed for several different scenarios varying the model input parameters. If the predicted values do not match the measured values within an acceptable level of accuracy, then the model must be refined. Otherwise, the model is deemed valid and can be used for performance prediction. The validation and refinement process is illustrated in Fig. 5. It is important that the model predictions are verified for several scenarios under different transaction mixes and workload intensities before the model is deemed valid. The model refinement process usually involves the following activities:

- The model input parameters are verified.
- Assumptions and simplifications made when building the model are revisited.
- The system is monitored under load to ensure that all critical aspects of its behavior are captured by the model.
- It is considered to increase the level of detail at which the system is modeled.

If after refining the model, predicted metrics still do not match the measurements on the real system within an acceptable level of accuracy, then the model has to be calibrated. *Model calibration* is the process of changing the model to force it to match the actual system (43). This is achieved by changing the values of some model input or output parameters. The parameters may be increased or decreased by an absolute or percentage amount. Normally, input parameters are changed (e.g., service demands); however, in certain cases, also output parameters might be changed. If an output parameter is altered when calibrating the baseline model, then it must be altered in the same manner whenever the model is used for performance prediction. After the model is calibrated, the validation procedure must be repeated to make sure that the calibrated model now accurately reflects the real system and workload. For a detailed discussion of model calibration techniques, the reader is referred to Refs. 10 and 44.

The extent to which a model can be validated quantitatively as described above depends on the availability of an implementation of the system components. In the initial phases of system development when no implementation is available, model validation would be limited to revisiting the assumptions made when building the model. If a system or a prototype with a similar architecture to the one modeled is available, then it could be used to provide some rough measurement data for quantitative validation.

Software Performance Engineering

Over the last 15 years, a number of approaches have been proposed for integrating performance evaluation and prediction techniques into the software engineering process. Efforts were initiated with Smith's seminal work pioneered under SPE (45). Since then many meta-models for describing performance-related aspects (46) have been developed by the SPE community, the most prominent being the UML SPT profile and its successor the UML MARTE profile, both of which are extensions of UML as the de facto standard modeling language for software architectures. Other proposed meta-models include SPE-MM (47), CSM (48), and KLAPER (49). The common goal of these efforts is to enable the automated transformation of design-oriented software models into analysis-oriented performance models, which make it possible to predict the system performance. A recent servey of model-based performance prediction techniques was published in Ref. 50. Many techniques that use a range of different performance models have been proposed including standard queueing networks (3, 25, 47, 51), extended queueing networks (49, 52, 53), layered queueing networks (48), stochastic Petri nets (54, 55), and queueing Petri nets (4, 21). In recent years, with the increasing adoption of component-based software engineering, the performance evaluation community has focused on adapting and extending conventional SPE techniques to support component-based systems. For a recent survey of performance prediction methodologies and tools for component-based systems, refer to Ref. 56.

OPERATIONAL ANALYSIS

An alternative approach to performance evaluation known as *operational analysis* is based on a set of basic invariant relationships between performance quantities (57). These relationships, which are commonly known as *operational laws*, can be considered as consistency requirements for the values of performance quantities measured in any particular experiment. We briefly present the most important operational laws. Consider a system made up of K resources (e.g., servers, processors, disk drives, network links). The system processes transactions requested by clients. It is assumed that during the processing of a transaction, multiple resources can be used and at each point in time the transaction is either being served at a resource or waiting for a resource to become available. A resource might be used multiple times during a transaction, and each time a request is sent to the resource, we will refer to this as the transaction *visiting* the resource. The following notation will be used:

V_i the average number of times resource i is visited during the processing of a transaction.

S_i the average service time of a transaction at resource i per visit to the resource.

D_i the average total service time of a transaction at resource i.

U_i the utilization of resource i (i.e., the fraction of time the resource is busy serving requests).

X_i the throughtput of resource i (i.e., the number of service completions per unit time).

X_0 the system throughput (i.e., the number of transactions processed per unit time).

R the average transaction response time (i.e., the average time it takes to process a transaction including both the waiting and service time in the system).

N the average number of active transactions in the system, either waiting for service or being served.

If we observe the system for a finite amount of time T, assuming that the system is in steady state, then the following relationships can be shown to hold:

Utilization Law:

$$U_i = X_i \times S_i$$

Forced Flow Law:

$$X_i = X_0 \times V_i$$

Service Demand Law:

$$D_i = U_i / X_0$$

Little's Law:

$$N = X_0 \times R$$

The last of the above relationships, Little's Law, is one of the most important and fundamental laws in queueing theory. It can also be extended to higher moments (58). If we assume that transactions are started by a fixed set of M clients and that the average time a client waits after completing a transaction before starting the next transaction (the client think time) is Z, then using Little's Law, the following relationship can be easily shown to hold:

Interactive Response Time Law:

$$R = \frac{M}{X_0} - Z$$

Although operational analysis is not as powerful as queueing theoretic methods for performance analysis, it has the advantage that it can be applied under much more general conditions because it does not require the strong assumptions typically made in stochastic modeling. For a more detailed introduction to operational analysis, the reader is referred to Refs. 3, 10, and 22.

SUMMARY

In this article, an overview of the major methods and techniques for software performance evaluation was presented. First, the different types of workload models that are typically used in performance evaluation studies were considered. Next, an overview of common tools and techniques for performance measurement, including platform benchmarking, application profiling, and system load testing, was given. Then, the most common methods for workload characterization and performance modeling of software systems were surveyed. The major types of performance models used in practice were considered and their advantages and disadvantages were discussed. An outline of the approaches to integrating model-based performance analysis into the software engineering process was presented. Finally, operational analysis was introduced briefly as an alternative to queueing theoretic methods.

SOFTWARE PRODUCT CERTIFICATION

INTRODUCTION

Here, we examine the process and challenges of certifying software-intensive systems. We will first review the interpretation of the term, *certification*. We then review different types of certification processes, and discuss challenges to forming software certification procedures. And finally, we discuss a strategy for gaining the maximum benefit from performing certification by formulating the correct procedures that are needed to roll out a certification plan by recommending appropriate guidelines to those developers whose products will be judged.

DIFFERENT TYPES OF CERTIFICATION (WHO, WHAT, WHY?)

Software certification is simply the process of generating a *certificate* that supports claims such as (1) the software was developed in a certain manner, (2) the software will exhibit some set of desirable run-time characteristics (also termed attributes), (3) the software version is the authentic one, or (4) the software has some other static characteristic embedded into it (for example, there are no faults of type *X*). The reason for having certificates in the first place is to be able to make predictions about how successfully the software will operate over time. Missions, environments, hardware, threats, personnel, and many other factors change during the software's lifetime, and the purpose for creating certificates is to reduce the uncertainty as to what impact all of these changes will have on the software.

So, for example, the certificate could simply state that a particular type of testing was applied and to what degree of thoroughness that testing was performed. A certificate can state that the software should be successfully composed with any other software component that contains a certain set of predefined characteristics. Or a certificate can state that the software will never fail more than once in 10,000 hours. Furthermore, any certificate created for (2) must have very specific assumptions about the environment, mission, and threat space that the software will experience during operational deployment. Thus, a *certificate* is simply the end product of this accreditation process.

Note that the information content in a certificate must be carefully written. Failure to remove ambiguities or inconsistencies in certificates essentially renders them as dangerous. For example, if a certificate that is based on test results only claims that, for 10 distinct test cases that were used, the output from the software was always a positive integer, that should not be interpreted as a guarantee that all other test cases not tried, the output will always be a positive integer. Therefore, key facet to software certification is to not over claim aspects of how the software will behave in the future. And without a proper scoping of the bounds of the claims in the certificate, the certificate will be flawed.

Two key questions that arise before certification occurs are as follows: (1) *Who* does the certification? and (2) *what* is being certified?

Let's first turn to the question of who performs the certification. The process of creating a certificate is typically performed by one of three parties: (1) either by the vendor of the software, (2) by a user, or (3) by an independent *third party* that is performing the service independent of the vendor or users. These key approaches roll a certification process out after the appropriate *standards* (i.e., criteria for certificate judgment and scope) are formed. Note, however, that first-party certification is always viewed suspiciously, and second-party certification adds an additional burden on the user of the software that may be a burden for which the user cannot perform. Therefor, third-party certification is generally viewed as preferable.

Numerous examples of third-party certification occur in industries such as electronics (e.g., Underwriters Laboratory), aviation [e.g., DERs (designated engineering representatives)], and, consumer products (e.g., *Consumer Reports* magazine). In industrial applications, organizations such as TUV dominate the market for the assessment of programmable controllers used in the process industry, and they are also active in railways and nuclear power plant assessments. In aviation, DERs are employee representatives of the company building the aircraft or components who have sworn their allegiance to a regulatory organization such as the FAA or CAA. And in terms of consumer products, a plethora of consumer advocate organizations do everything from rate the safety of toys for children to rating the quality of automobiles.

Many quality-of-service (QOS) attributes of software can be certified: reliability, safety, security, performance, etc. In this effort, we are focusing on two attributes: interoperability and safety.

Certification approaches are not a totally new idea. For example, The Open Group certifies that Linux implementations are indeed Linux and that X-windows conforms to their standards. Other examples are protocol testing by telecoms laboratories and compiler testing to demonstrate conformance with a language definition. (The rather misnamed Ada validation suite tests for certain functional aspects of the compiler but not for all required QOS attributes such as *reliability*.) However, the uniqueness of this effort stems from the following hypothesis: it is better to certify products that have negative safety consequences if they fail than to only certify how those products were developed.

We begin from the premise that interoperability can only be successfully achieved if the following characteristics are considered: (1) composability, (2) predictability, (3) attribute measurement, (4) QoS attribute trade-off analysis (economic and technical), (5) fault tolerance and

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

non-interference analysis, (6) requirements traceability, (7) access to prequalified components, and finally, (8) precise bounding of the software's mission, environment, and threat space. If we have access to information concerning these 8 considerations, we contend that a plausible and scientifically sound approach to software certification can be formulated. Furthermore, information concerning human factors must be included in the definition concerning the assumed, target environment.

This discussion then brings us to the issue concerning the difference between an (1) original certification, (2) decertification, (3) miscertification, and (4) recertification. As mentioned, the original certification is based on specific assumptions about the environment, mission, and threat space that the software will encounter during operational usage. In most systems over time, these assumptions will change more quickly than the code itself can be modified.

Therefore, some events require that an existing certificate (or parts of it) be nullified. This process is a decertification. To ensure that the software can handle changing assumptions, additional certification activities will be required. This process is a recertification, and it need not necessarily be a complete start from scratch effort, provided that assurances included in the original certificate still hold. And a miscertification is simply the problem of creating the wrong certificate or no certificate at all (when one should have been created). Miscertifications are of grave concern, and the goodness of the certification process and how well it is adhered to in order to avoid this event are of much importance.

Before leaving the topic of miscertifications, we must stress that, ultimately, any certification program must ensure *fairness*. Vendors of products generally view regulation and certification suspiciously, where vendor A believes that vendor B got a better deal when going through the process. All steps must be considered to ensure that a fair hearing of all evidence occurs. This process does not mean that mistakes will not be made, but if a certification program is perceived as a coin toss, where the outcomes made are lacking repeatable, scientific, and statistical processes, the certification program will ultimately die.

Certificates are typically done as a follow-up check to ensure that certain processes were followed during development; these "process certificates" are the first type of certification that will be discussed here. The second type of software certification often mentioned refers to the licensing of software engineering professionals; this is still referred to as software certification but should more appropriately be referred to as "professional licensing." And the third and most important but most difficult claim that a certificate can make is the determination of how the software will behave in use. This process is referred to as "product certification," and that is our focus here.

Note that the three key messages that a certificate can convey are not necessarily the same:

1. Compliance with standards *vs*.
2. Fitness for purpose *vs*.
3. Compliance with the requirements.

Compliance with the standards simply means that the standards that were required during development were indeed followed, but that does not mean that the product itself is fit for the purpose that the user needed for it to be, and that does not necessarily mean that the software complies with the requirements.

The key difference between (2) and (3) is that those two are only equivalent if the requirements accurately and completely defined what the user needed the software to do, and thus, it is possible that the software meets the requirements but does not perform as the user needs. Note that (1) deals with process certification and that (2) and (3) deal with product certification.

The beauty of having a certificate with correct information is that it allows for a common language (a.k.a., mutual recognition agreements that support *interoperability*) that can be employed to discuss relatively abstract notions. As we know, software is somewhat amorphous in that, unlike a hardware entity, it is hard to get an understanding about the QoS properties of entities that are so abstract.

So from that standpoint, certification standards can be beneficial. One classic example is the recent adoption by many nations of the Common Criteria, which is simply a process certificate that defines various security levels and the processes that must be employed to demonstrate those levels. And furthermore, some accreditation agencies (e.g., NIST) now certify third-party companies that actually perform the work and generate the certificates.

But with the exception of a few other process certificates (e.g., IEC 61508 and RTCA DO-178B), not many organizations perform third-party certifications that are product-focused. In fact, organizations such as Microsoft and Netscape have been accused of violating user privacy, by spying on their users during product usage and sending information back to the companies that allow those companies to not only collect accurate *operational profiles* (operational profiles are part of what we consider as the environment) but also to perform a "quasi" first-person product certification.

Note that software certification is similar to Independent Verification and Validation (IV&V), a technique that has long been used in the NASA and DoD communities, and so we now should explain how those two term relate. To begin, Barry Boehm defines *validation* as making sure that you are building the right product, and *verification* involves assuring that you build the product right (i.e., correctly). And although these terms may seem confusing, they are both closely related.

Furthermore, little "i" Validation and Verification (V&V) is simply performing first-person V&V on a system, and big "I" V&V requires independence, from either a second party or third party (third party is typically preferred). How IV&V relates to certification is as follows: They are the same, provided that the type of certification being performed is either a process certification or product certification. However, one caveat here: Certification typically results in a certificate, and IV&V does not necessarily result in a certificate.

BENEFITS AND THREATS

The development, deployment, and integration of systems developed and perhaps certified to a wide range of military standards is an inescapable part of the problem of interest here. There are, however, benefits and threats from attempting this, as follows.

Potential Benefits

- Certification can influence the vendor space from which the DoD acquires components. That is to say that a certification program can force a minimum set of requirements that all software should satisfy. This processs has the potential to raise the general level of dependability or to reduce costs to the users.
- Certification as a basis for gaining assurance over time, as a form of trend analysis that shows that a system is improving during development or maturing during usage.
- Risk transfer from the user or vendor to the certification authority.
- Guarantees of some minimum level of behavior (both functional and nonfunctional) for products. Note that nonfunctional behaviors generally include safety, security, availability, performance, fault tolerance, maintainability, survivability, and sustainability. And also note that *quantitative* and *qualitative metrics* such as mean-time-to-failure, mean-time-to-repair, mean-time-to-hazard, up-time, and performance can all be collected as part of the evidence needed to create a software certificate.

Potential Threats

- Adding unnecessary costs and delays to projects
- Giving unwarranted confidence in system behavior as a result of miscertification
- Preventing flexibility, innovation, and interoperability, as certificates can be quite narrowly defined
- Reducing the ability of user to undertake an examination of a product (why bother if organization XYZ has already done it?)

Although it is unclear as to what the current world market is in software certification, we can look at the recent NIST report that said that, in the United States alone, the United States lost around $60B as a result of inadequate software testing in 2001. Had the United States had access to a certification organization such as Underwriter's Laboratory to provide independent assessments on the quality of the software before its release, it is not surprising to assume that that number could have been decreased.

Note that there are two differing "political" camps on the ethics of having certification processes: there are those that believe any "bar" that people are forced to cross is better than no bar at all. And there are those that believe that any bar lulls those that produce products into a false sense of security: So long as they do "just enough" to cross the bar, then they have done enough to satisfy minimum industry standards. In practice, any certification approach will have an impact on the market and the behavior of suppliers, and so the issues are not solely technical, and any strategy must be cognizant of the perhaps subtle interplay of technical, social, and market forces.

The future systems are likely to be heterogeneous, dynamic coalitions of systems of systems (SoS), and as such, they will have been built and assessed to a wide variety of differing standards and guidelines. Our main recommendations are that the certification of SoS should be based around the concept of interoperability cases, generalizing the current requirement for safety and reliability cases. Examples of "reliability cases" can be found in British Def Stan 00-42 Part 3, which deals with system reliability and maintainability; Part 2 of that standard deals specifically with building software reliability cases. Safety cases are required in the British military's Def Stan 00-55 and more recently in the United Kingdom's CAA Safety Regulation of air traffic management systems and its proposals[1].

Ultimately, all certificates are not warranties or guarantees but evidence, arguments, and claims. Thus, all information to support creation of a certificate should be based on a *claims-arguments-evidence*[2] framework with the following components:

1. A goal-based view of that expresses certification requirements in terms of a set of claims about the system and its QoS attributes
2. Evidence that support the claims
3. An explicit set of argument that provides a link from the evidence to the claims
4. For critical systems, the underlying assumptions and concepts used to support and formulate the goals and claims should be described in terms of a series of models (e.g., at system, architecture, design, and implementation levels)

Such a framework should provide a technical basis that allows for interworking of standards such as IEC 61508 , UL 1998, and DO178[3] IEC 61508 is process and system safety focused, UL 1998 is component safety and product oriented, and DO178B is system and reliability focused. Thus, harmonizing three such standards into a single approach can only be accomplished using an approach such as the claims-evidence-arguments perspective because standard is attempting to convey a different definition for what is or is not trustworthy.

Although this goal-based approach moves from safety to other dependability areas (e.g., to interoperability), it needs

[1] CAP670 SW01, "*Requirements for Software Safety Assurance in Safety Related ATS Equipment*."

[2] An introduction to safety cases on which these idea are built can be found at http://www.adelard.com/ that hosts the guidance for the IEE Functional Safety portal on this topic.

[3] Need a cross-reference and consistency with the standards section of the report.

supporting technical work and the development of a body of practice. Although there is considerable experience with this approach for safety applications worldwide, it may be new to some organizations, and the deployment of the approach could be facilitated by:

1. Guidance on strategies and arguments for demonstrating claims and on how claims might be derived, including guidance on what are useful certifiable and measurable properties.
2. Guidance on how evidence is generated by validation and vertifcation techniques. This is not found in any existing standards, and we have begun to elaborate on how evidence is generated throughout the lifecycle. It should be noted that it is extremely difficult to provide high-fidelity certificates for highly critical systems. To obtain substantially improved mean-time-to-failure measures (beyond those of commercial software), one order of magnitude in fault density reduction is generally required.
3. Guidance on pragmatics such as feasibility, scalability, and tool support.
4. Guidance on the relationship to (and the interface with) frequently used standards.

CONCLUSIONS

Disparate forms of certification exist, and they vary widely in their objectives, the level of detail information they provide, and their ability to effectively reduce project and system risk.

Certification is an attempt to transfer a product's risk to the certifier, but in most safety situations, the user of the system remains responsible for the product's safety. However, in other situations, the risk transfer can be real, thus making it highly attractive to the user. However, for software, the fear of liability that stems from potentially miscertifying software has prevented much commercial interest in creating laboratories such as UL.

All military organzations, both in the United States and abroad, should encourage certification as a tool for supporting interoperability and hence confidence that their systems are behaving as anticipated. Process certification should not be totally dismissed and can support confidence in the evidence collected (and normally be a prerequisite to baseline standards such as ISO9001), but the overall emphasis of certification should be on the product. We propose that a claim-argument-evidence-based approach should be adopted as best practice.

At this stage, we are cautious about recommending the actual arrangements for rolling out a certification program, and whether self-certification, second-party, or independent certification is optimal. For critical systems, third party is generally regarded as best practice. And for less critical systems, the benefits of independent oversight should be assessed, and only those activities that add value to prejects should be identified.

SOFTWARE QUALITY CLASSIFICATION MODELS

INTRODUCTION

Software quality is an important attribute for the successful operation of high-assurance systems. Many measures of quality exist, fault content being the most common. An ideal system will have no faults, but given the current state-of–the-art of software engineering, no large system can be guaranteed to be fault-free, and the goal is to minimize the presence of faults in the delivered product. Toward this objective, a variety of tools and techniques are employed throughout the development lifecycle. Among these, testing is considered to be the most effective technique. Because testing resources are limited and expensive, it is highly desirable to identify and target potentially fault-prone components early for efficient allocation of testing and other quality assurance efforts, where the term "fault-prone" is application-dependent, which requires objective and dependable models that relate component metrics to fault-proneness. Such models can be used to classify components into two classes, fault-prone or not fault-prone. However, the software development process is not understood well enough to derive theory-based models. Therefore, such models are mostly obtained from experimental or historical data using one of many available techniques after an empirical modeling process. The conjecture is that new components that are similar to the old ones likely are to have equivalent fault-proneness.

Formally, this modeling activity can be described as developing an input–output mapping pattern on the basis of limited evidence about its nature. The evidence available is a set of labeled data about n components, denoted as

$$D = \{(\mathbf{x}_i, y_i) : x_i \in R^d, y_i \in R, i = 1, 2, \ldots, \mathrm{n}\} \tag{1}$$

Here, $\boldsymbol{x}_i$ are the component metrics and y_i are the class labels. This article addresses various issues that occur during the model development and evaluation process.

Classification models are employed in many disciplines (e.g., astronomy, medicine, computer science, social sciences, and engineering). A vast body of literature exists that deals with the development of such models using techniques from statistics, machine learning, neural networks, and so on. In software engineering, the component classification problem has been addressed using techniques such as principal component analysis, logistic regression, neural networks, classification trees, and case-based reasoning. Some of the reported studies provide a comparative assessment of various classification techniques to gain insight into their applicability and predictive performance in varying software development environments.

The remainder of this article is organized as follows. A brief technical description of some component classification techniques is presented, as is an overview of selected representative studies. A generic model development and evaluation process is then presented, which includes a description of several important issues that occur during this process. The radial basis function (RBF) model, a recent technique used for software component classification, is also described. A case study is presented to illustrate the modeling process using RBF and NASA software data. Some concluding remarks are presented to finalize the article.

CLASSIFICATION TECHNIQUES

This section provides a brief description of some commonly used techniques reported in the literature for software classification applications. Details about their theoretical underpinnings and model fitting algorithms can be found in Han and Kamber (1) and in Hastie et al. (2).

Logistic Regression

Logistic regression is used to determine the posterior probability of a class as a linear function of predictor variables. In the simple case of two classes, the probability, p, of a component being fault-prone in terms of metrics $x_1, x_2, \ldots, x_d$ is given by

$$\log\left(\frac{p}{1-p}\right) = \beta_o + \sum_{i=1}^{d} \beta_i x_i \tag{2}$$

The parameters β's are usually obtained by the maximum likelihood estimation method. Let the class of a component be y_i, $y_i = 0$ or 1, where 0 is not fault-prone and 1 is fault-prone, and suppose there are n components in the dataset. Then treating y_i's as n independent Bernoulli trials, with success probability p, the likelihood function is obtained from Equation (2) based on the data from Equation (1). The function is then solved using the Newton Raphson algorithm. The metrics values of a new component are then used to determine its class using the fitted model obtained from Equation (2).

Classification Trees

Tree-based classification models partition the metrics space according to some specified criterion. The model is represented graphically as a spanning tree that is traversed according to component metrics and their values. The leaf nodes represent component classes. The tree is generated recursively in a top-down fashion using one of many algorithms. Quinlan's (3) in a popular algorithm that starts with a single node (root node) that represents the metric that best discriminates between component classes

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

using an entropy-based criterion. Subtrees are then generated recursively using the remaining metrics.

Principal Component Analysis

In most practical applications, the metric values are correlated so that the resulting models are hard to interpret and are not stable. Principal component analysis (PCA) is a statistical technique that generates new metrics, called the principal components, that are weighted sums of the original metrics. These metrics are orthogonal to each other, but not independent. Generally, small number of principal components can capture the effect of all the metrics. A classification model is developed in terms of these principal components, which leads to a reduction in the dimensionality of the model, a desirable feature of a classifier. However, all the metrics values of a new component are still needed to determine its class.

Case-Based Reasoning

This technique generates classification models based on previous similar cases in the database, called the case base. The similarity of a component in terms of its metrics is determined by a specified distance measure. The rationale behind this technique is that components that are similar to each other are likely to have a similar fault-proneness property. Many issues need to be resolved while designing a case-based classifier, such as choice of distance measure, number of neighbors to use for determining fault-proneness, and weights to assign to the component metrics.

Neural Networks

A neural network consists of one input, one output, and one or more hidden layers, each responsible for data processing. The component metrics are presented to the input layer. Their weighted values are processed by the nodes (neurons) in the first hidden layer according to a specified activation function, weights, and bias values. The outputs are then presented to the next layer for processing. This process continues until the output layer evaluates the component class. The architecture and other parameter values of the network are determined by using one of many algorithms, such as the popular back-propagation algorithm. During training, the discrepancy between the network generated and the true output values is back-propagated through the network to update the weight and bias parameters. The training process is repeated for a specified number of iterations or when a desired accuracy is achieved.

SOFTWARE CLASSIFICATION STUDIES

Several classification models have been developed and are employed in software engineering applications. Many studies during the past 15 years have described the results of classification investigations using domain-specific data from specific development environments and one or more classification techniques. As a result, it is not practical to draw general inferences about the relative merits of various techniques. Yet, they provide insights into their applicability and use for different environments and applications. Some selected representative studies are summarized below. The objective here is to provide a perspective on the state of research and of practice rather than a complete literature review.

An empirical comparison of several classification techniques was reported in Lanubile and Visaggio (4) based on small business applications written by students. They considered discriminant analysis, PCA, logistic regression, classification trees, and so on. Their results indicated that no model was able to discriminate effectively between fault-prone and non-fault-prone components. Denaro et al. (5) applied logistic regression and cross validation by using many metrics combinations from systems produced in industrial environments. Their results are optimistic but cautionary about the cost-effectiveness and practical applicability of such models. Briand et al. (6) studied subsets of metrics, called optimized set reduction, to characterize objects. These subsets form patterns that are used to classify new objects. Tree-based models were presented by Khoshgoftaar and Seliya in Ref. 7. Classification trees were used by Selby and Porter (8) to analyze fault-proneness of components from several NASA software systems. Fenton and Neil (9) provided a critical evaluation of many defect detection models. They suggested the use of Bayesian belief networks for improved performance.

Case-based reasoning classification models were compared by El Eman et al. (10). They evaluated many combinations of the parameters that need to be specified for such models. The data source was a large real-time system, written by professional programmers in a commercial environment. They found that the classification performance was not sensitive to the choice of parameters.

Khoshgoftaar and Seliya (11) give the results of a comparative assessment of logistic regression, case-based reasoning, classification trees, and so on by using data from four releases of a large telecommunication system. They also presented tree-based methods in Ref. 7. They found that the predictive performance of the techniques was significantly different across releases. This observation is consistent with some other studies, indicating that prediction of fault-proneness is influenced by system and data characteristics.

Various studies have investigated the fault-proneness issue for classes in object-oriented development based on class metrics. A study by Basili et al. (12) compared the relative predictive performance of design-based object-oriented metrics. Recently, Zhou et al. (13) reported that design metrics were able to predict low severity faults better than high severity ones in fault-prone classes. Nagappan et al. (14) studied post-release defects in some Microsoft systems and their statistical correlation to complexity metrics. They employed principal component regression to predict the likelihood of defects in the field for new entities. They also noted that the predictors from one project can be useful for similar new projects.

Ma et al. (15) analyzed fault data from five NASA projects for software quality prediction. They employed balanced random forests, classification trees, k-nearest neighbors, and several other machine learning and statistical techniques to compare performance using six measures, including accuracy.

Neural network-based classification models have also been employed by many authors [e.g., Zhang and Tsai (16)]. Two recent studies using radial basis functions, a special type of neural network, are reported by Goel and Shin (17) as well as Shin and Goel (18).

MODEL DEVELOPMENT PROCESS

Classification model development can be seen as an iterative multistep process as shown in Fig. 1. Most techniques follow such a process even though they differ in implementation details. The modeling process requires a thorough understanding of the data, the techniques, and the application environment. The first step involves the selection of metrics data to be used and the undertaking of data preprocessing. In the second step, statistical or other algorithms are used to determine parameters and to evaluate model performance. Multiple candidate models are usually considered. The third step involves model selection and its assessment. Some pertinent issues that occur during the modeling process are briefly described below. Details can be found in Goel and Shin (19), Han and Kamber (1), and Hastie et al. (2).

Data Selection and Preprocessing

Selection of data to be used for modeling is a nontrivial task that requires an understanding of the development environment and the application domain. Using too many or too few metrics is undesirable. Sometimes data about many metrics are available, but all may not be necessary, which can happen when some metrics have interdependencies or when some are irrelevant. Subset selection techniques can be used to reduce the number of metrics for modeling. Preprocessing of data (e.g., data cleansing, normalization, grouping, and transformation) are undertaken at this stage.

Model Fitting and Evaluation

Often, multiple algorithms are available for determining model parameters. Efficiency and accuracy considerations generally dictate the choice of the algorithm to use. The performance of the model is evaluated using criteria such as Type I and Type II errors, overall classification accuracy, and so on. Several models are generally considered and their performance measures are evaluated. A commonly used approach is to divide the data into three groups called training, validation, and test data. Training data is used to fit candidate models. Their performance is evaluated on the validation data and generally the model with the lowest validation error is preferred. Some other common approaches are cross-validation, leave-one-out, and bootstrap (2). If the models are not good, different datasets or modeling techniques are selected.

Model Selection and Assessment

In this step, a preferred model is determined, based on several considerations. In addition to the error measures, model complexity is also an important issue. Generally, a parsimonious model is preferred. Yet, too simple a model may not fit the data well, whereas a complex model may fit it too well and will fail to produce good results on new components. This phenomenon is well known as the underfitting-overfitting or bias-variance dilemma. Sensitivity analyses are performed to evaluate multiple models. The adequacy of the model from its use and applicability perspectives is assessed at this stage. Issues such as comprehensibility and reasonableness are also considered. An appropriate model is then selected based on the above considerations. The performance of the selected model on the test data is used as a measure of its predictive accuracy and usually is considered to be an important criterion to evaluate the usefulness and applicability of a model. If no model is satisfactory or alternate models are desired, the iterative process is repeated.

RADIAL BASIS FUNCTION MODEL

This section presents a recently introduced new technique (17,18) for software quality evaluation using radial basis functions (RBF), a class of advanced mathematical models for function approximation or classification. They have been employed in a wide variety of disciplines, from signal processing to medical diagnosis. The RBF is a nonlinear model that consists of two mappings. In the first, inputs are transformed nonlinearly by the basis functions; in the second, the transformed outputs are weighted linearly to produce the output. Formally, for a mapping $f : R^d \rightarrow R$, the RBF network model can be described as

$$\mathrm{f}(\mathbf{x}) = \sum_{\mathrm{j}=1}^{\mathrm{m}} \mathrm{w_j} \varphi_{\mathrm{j}}(\mathbf{x}) = \sum_{\mathrm{j}=1}^{\mathrm{m}} \mathrm{w_j} \varphi(\|\mathbf{x} - \mu_{\mathrm{j}}\|/\sigma_{\mathrm{j}}) \tag{3}$$

where $\mathbf{x} \in \mathrm{R^d}$ is the input vector and m is the number of basis functions. Also, $\mu_\mathrm{j} \in \mathrm{R^d}$ is the jth basis function center, σ_j's are basis function widths, w_j's are weights, and $\| \cdot \|$ denotes the Euclidean distance. The basis functions $\phi(\cdot)$ here play the role of transfer functions in traditional neural networks, except for the unique feature that their responses to the input vectors are monotonically decreasing or increasing with distance from the centers, and hence the name. In practice, the Gaussian is the most popular basis function because it has attractive mathematical properties of universal and best approximation and its hill-like shape is easy to control with the parameter σ. The mathematical form of the mapping in Equation (3) for the Gaussian case becomes

$$\mathrm{f}(\mathbf{x}) = \sum_{\mathrm{j}=1}^{\mathrm{m}} \mathrm{w_j} \exp(-\|\mathbf{x} - \mu_\mathrm{j}\|^2/2\sigma_\mathrm{j}^2) \qquad (4)$$

A diagrammatic representation showing the details of the above mappings is given in Fig. 2. Here, the input layer takes the metrics data **X** to be used for classification modeling. The hidden layer performs the nonlinear transformations on these data via the *m* basis functions. The output layer produces the classification results y by the weighted responses from the basis functions.

The RBF model is defined completely by the parameter set $P = (m, \sigma, \mu, w)$. Therefore, the RBF design problem is to determine its three m parameters, namely, *m* centers, *m* widths, and *m* weights. Many algorithms have been proposed in the literature to determine these parameters. In a new algorithm, called the SG (Shin–Goel) algorithm, the modeling problem is formulated as follows (17,18,20). First, the algorithm selects the number of basis functions for a given global σ that satisfies a specified measure of model complexity, called representational capability. For a selected (*m*,σ) pair, the corresponding centers are determined next. Finally, the linear parameters *w* are determined by the pseudo-inverse method. This algorithm is purely algebraic and employs only matrix computations. In particular, it avoids random iterations and leads to a consistent and reproducible design.

ILLUSTRATIVE EXAMPLE

Data from selected NASA software systems, SEL (21), are used in this section to illustrate the classification model development, evaluation, and selection process. The database contains project and product measure from space-related systems and has been used in many other studies [e.g., Selby and Porter (8), Selby (22), and Shin and Goel (18)]. The RBF model and the SG algorithm described above are employed for developing the classification models in this example.

Data Selection and Preprocessing

The database contains values of several metrics and the number of faults for each component in the form of Equation (1). Only three metrics, the design metrics, are used in this simple example. These metrics are listed in Table 1 along with two statistics, the average and the standard deviation. A module is defined to be fault-prone if the number of defects exceeds five. The design metrics become available early in the software development lifecycle and, therefore, classifiers based on these can be used for early identification of potential fault-prone components. However, as mentioned earlier, metrics selection is an important issue but is not discussed further in this example.

Next, the three metrics were normalized to be in the range [0,1] as follows.

$$Normalized\,Value = \left(\frac{Original\,value - Minimum\,value}{Maximum\,value - Minimum\,value}\right)$$

For model development, evaluation, and selection, half of the components were randomly selected to form the training set. The other half were randomly divided into two equal sets to form the validation and test sets.

Model Fitting and Evaluation

The algorithm described in the previous section was used to develop RBF classifiers. Six fitted models and their classification errors on the training, validation, and test sets are listed in Table 2. It is noted that the training error tends to decrease with increasing model complexity (m) but not monotonically. Because of noise in real-world data, the training error can sometimes increase with m, as is the case here. However, the trend will show decreasing training error as m increases, and the value eventually will become very small when the model complexity gets very high. The validation and test errors first decrease with m

Table 1. List of Metrics

Variable	Description	Average	Standard Devidation
X_1	Function calls from this component	9.51	11.94
X_2	Function calls to this component	3.91	8.45
X_3	Input/Output parameters	27.78	23.37

Table 2. RBF Models and Classification Errors

			Classification Error (%)		
Model	σ	Complexity (m)	Training	Validation	Test
A	0.2	21	23.86	24.62	26.62
B	0.4	10	23.37	24.62	25.13
C	0.6	7	23.12	24.12	25.63
D	0.8	4	23.62	25.63	26.13
E	1.0	4	23.87	26.13	26.13
F	1.2	4	23.62	26.13	26.63

and then increase. Again, the values are not likely to follow a monotonic pattern for data from actual systems, although the trend will be as mentioned above . Plots of these errors versus m and σ as well as versus m are shown in Figs. 3 and 4, respectively. These plots provide useful insight into the behavior of training, validation, and test errors, even for this limited set of data and models.

Model Selection and Assessment

In practice, the model with the smallest validation error is selected from the candidate models. From the data in Table 2 and the plots in Figs. 3 and 4, model C would seem to be the preferred choice. However, other models may also be acceptable, depending on the application. When evaluated on test data, the classification error of this model is 25.63%. This indicates that if model C is used to determine the fault-proneness of new, yet unseen, components, it is likely to make about 25.63% erroneous classifications. From the software engineering perspective, this value is respectable and the model could be considered to be satisfactory.

Sensitive Analysis

The above classifiers were obtained from the design metrics only. To evaluate the effect of metrics selection, classifiers were also developed based on three coding metrics (size, comment lines, and number of decisions) as well as for all six metrics. The test errors for these cases were 24.92% and 23.86%, respectively. From a software engineering viewpoint, they are all satisfactory values. Other error measures could be used for model evaluation and selection, as well as different sensitivity analyses could also be pursued. Such choices depend on the software development and application environment.

CONCLUDING REMARKS

This article discusses the importance of classification models for early identification of fault-prone software components to increase testing efficiency and effectiveness. Some commonly used modeling techniques and selected classification studies are summarized. A generic modeling process is presented and some issues that develop during this process are highlighted. A recently introduced classification technique based on radial basis functions is described. A case study is discussed to illustrate the model development, evaluation, and selection process. In conclusion, it should be noted that modeling from data is a difficult problem, which is especially true in software engineering applications.

SOFTWARE QUALITY MODELING AS A RELIABILITY TOOL

INTRODUCTION

Software engineering practitioners agree that a software quality- and reliability-centric focus is ideal for most software project development efforts. A specific definition of software quality, however, is often a point of debate because "software quality" encompasses many different attributes of software with varying relative importance (1). For example, one may argue that conformance to requirements and specifications must govern software quality, whereas another may argue that ease of maintenance, low complexity, and good documentation are equally, if not more, important. Although software quality can often have a qualitative or subjective evaluation, software reliability is typically measured using objective criteria. In essence, software reliability is one of the multiple software quality factors, such as understandability, maintainability, usability, and testability.

The general aim of software quality and reliability methods is to obtain a defect-free, dependable, and functional software system. This article provides a brief overview of software quality and reliability tools[1] and presents a detailed case study on software quality modeling by using decision tree models. Software quality is the burden of all stakeholders involved in the project, including management, developers, and customers. Hutton (2) defines "must haves" for a successful outcome of a software quality improvement initiative, which include (*1*) a compelling reason for change, (*2*) suitable sponsors, (*3*) an informed commitment of sponsors, and (*4*) a change agent or "champion." Having effective software quality tools has been the subject of core software engineering research and practice, and suggested standards such as CMMI (3,4) and ISO 9001 (5) explicitly state requirements that must be met for a high quality software product. Some commonly used software quality improvement methods include formal inspections, walkthroughs, defect tracking, software measurement-based analysis, and testing (1,6). The advent and acceptance of agile software engineering has introduced new issues in software quality engineering, some of which are aptly discussed by Ming et al. (7) and Mnkandla et al. (8).

Software reliability engineering has been introduced with various models and tools over the last two decades (9–11). The growth of software reliability engineering research is about 35% per year (12), attributed largely to technical conferences and journals dedicated to this maturing field. Operational profiles and their use for software reliability and testing was introduced initially by Musa (12). Different types of software reliability models are options depending on available project data and the development phase. A good overview of different types of software reliability models is provided by Asad et al. (9), in which the authors lay out a logical approach to selecting a specific software reliability model among the over-thirty models surveyed. The different models were classified based on early prediction models, software reliability growth models, input domain-based models, architecture-based models, and hybrid reliability models. The selection criteria used by Asad et al. [9] included attributes such as required model input, required user output, structure and nature of project, data validity, and the development and testing processes. The popularity of object-oriented development and increasing use of service-oriented architectures has fueled research in reliability analysis exhaustive literature review is out of scope for this article. based on software architecture. A recent study provides good insight into the state of the art of software architecture-based reliability analysis (10).

Our research focus has included software quality models as effective tools for targeted and resource-aware software quality improvement. A software quality estimation model is typically trained with known software measurement and defect data of a previously developed system release or similar project (13–16). The model then is applied to predict unknown defect data of program modules currently under development. Based on such a quantitative analysis, software quality modeling can generally be achieved by two commonly used approaches: software defect prediction and software quality classification. The former involves estimating the expected number of defects in the software, whereas the latter involves grouping similar program modules based on their expected quality, for example, fault-prone (*fp*) or not-fault prone (*nfp*). We focus on the software quality classification models because they are more appealing from a practical point of view. In addition to software quality modeling, classification models have been studied for other software engineering problems, such as requirements engineering (17) and component-based software engineering (18). Although different methods have been investigated for software quality classification, decision trees models have gained popularity among practitioners because of their comprehensible model structure, ease in model interpretation, and quick rule extraction for database retrievals (19–23).

The empirical case study presented compares five decision tree methods for software quality modeling, and they include, Classification and Regression Trees (*CART*)(21), *S-PLUS* (*SPL*), Sprint-Sliq (*SPT*) (22), C4.5 (23), and Treedisc (*TD*) (24). The software measurement and defect data is obtained from multiple releases of a very large telecommunications software system (21). The different models are evaluated for decision tree structure, model complexity, and software quality prediction performance. In addition, the decision trees are evaluated for their expected costs of misclassification at different cost ratios. A relative ranking of the five models is obtained based on statistical testing using ANOVA models and

[1] As exhaustive literature review is outside the scope of this article.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

multiple- pairwise hypothesis testing. It is shown that with respect to expected costs of misclassification, the *CART* model yielded better results at lower cost ratios, where as the *SPT* model yielded better results at higher cost ratios.

The remainder of this article summarizes the decision tree models investigated in our study and details our empirical case study, including software system description, modeling approach, and empirical results. Finally, we summarize our work and include some directions for future work.

DECISION TREE-BASED CLASSIFICATION MODELS

The *Classification and Regression Trees* (*CART*) (25) system is a widely used decision tree model with many applications to data mining and data preprocessing. The algorithm searches for questions that split tree nodes into relatively homogeneous child nodes, such as a high-(or low-)-risk group. The nodes become more homogeneous as the tree evolves, identifying important segments. The initial tree is grown to the maximum possible size and then is pruned backward using cross validation and cost complexity. Certain model parameters, such as number of observations in leaf nodes and depth of tree, can be controlled to yield different models (21).

The *SPL* system combines an intuitive graphical user interface with an extensive data analysis environment for advanced data mining, including regression tree models (26). At the core of the *SPL* system is *S,* the language designed specifically for data visualization and exploration, statistical modeling, and programming with data. Limited to processing only numerical data, the regression tree is constructed by recursive binary partitioning of the training data. A generalized classification rule is used to label each leaf node after the regression tree is built. Model parameters, such as minimum node size and minimum node deviance, can be controlled to obtain the desired pruned tree (20).

The *C4.5* learner is an inductive supervised learning system, which employs decision trees to represent a quality model (27). It consists of four principal programs: decision tree generator, production rule generator, decision tree interpreter, and production rule interpreter. In contrast to *CART* and *SPL*, the *C4.5* classifier can entertain non-numeric data types during modeling and provide a non binary partitioning of data at decision nodes. Tree pruning can be controlled by modeling parameters, including minimum node size and pruning percentage (23).

The *TD* algorithm is an SAS macro implementation of the modified chi-square automatic interaction detection algorithm (19). A predictor variable is selected to be the variable that is most significantly associated with the dependent variable according to a chi-squared test of independence in the contingency table. The algorithm requires special preprocessing of the data sets and is suitable for ordinal predictors with many categories. A decision tree is built by recursively partitioning the data set until a stopping criterion is satisfied, such as minimum node size and p-value.

The *SPT* algorithm the (scalable parallelizable induction of decision trees-supervised learning in quest algorithm also known as the *sprint-Sliq* algorithm) can be used to build classification trees that can analyze both numeric and categorical attributes (28,29). As a modified version of the *CART*, it uses a pruning technique based on the minimum description length principle. The IBM Intelligent Data Miner that implements the *SPT* algorithm, was used in our study (22). The *Gini* index is the default for evaluating goodness-of-fit of possible splits at a decision node.

EMPIRICAL CASE STUDY

Software System and Measurements

The case study data was collected from a very large legacy-embedded telecommunications system (abbreviated as LLTS) over four successive releases. Using the procedural development paradigm, the software was written in a high-level language similar to Pascal and was maintained by professional programmers in a large organization. A software module was considered as a set of related source-code files. Fault data was collected at the module level by the problem reporting system and consisted of post release faults discovered by customers during system operations. Faults were recorded only if their discovery resulted in changes to the source code of the respective module. Preventing discovery of faults after deployment was a high priority for the developers because visits to customer sites involved extensive consumption of monetary and other resources.

Configuration management data analysis identified software modules that were unchanged from the prior release. Fault data collected from the problem reporting system were tabulated into problem reports, and anomalies were resolved. Because of the nature of the system being modeled, for example, a high-assurance system, the number of modules associated with post release faults were very few compared with modules with no faults. Two clusters of modules were identified: unchanged and updated. The updated modules consisted of those that were either new or had at least one update to their source code since the prior release. Among the unchanged modules, almost all of them had no faults and, therefore, were not considered for modeling purposes.

We selected updated modules with no missing data in relevant variables. These updated modules had several million lines of code, with a few thousand of these modules in each system release. The number of updated modules (that remained after unchanged modules or those with missing data were removed) that were considered for each of the four releases are: 3649 for Release 1, 3981 for Release 2, 3541 for Release 3, and 3978 for Release 4. A module was considered as *nfp* (non fault-prone) if it had no post release faults and *fp* (fault-prone)otherwise.

The proportions of modules with no faults among the updated modules of Release 1, Release 2, Release 3, and Release 4 were respectively 93.7%, 95.3%, 98.7%, and 97.7%. The corresponding proportions of modules with one or more faults were 6.3%, 3.9%, 1.0%, and 2.1%. The number of modules with no faults generally increased over successive releases, as is expected for a legacy system in an environment similar to LLTS. This increase is because the development process for such a high-assurance software system generally tends to improve with time. However, for another system, other factors such as new development staff or changes in system functionality could increase the number of faults and introduce additional *fp* modules. Software quality models for LLTS were trained with Release 1 program modules, whereas the latter three releases were used as test data for model evaluation.

Software data collection for LLTS involved recording measurements using the EMERALD software metrics analysis tool (21). Preliminary analysis selected metrics appropriate for our modeling purposes and included 24 product metrics, 14 process metrics, and 4 execution metrics. The process metrics were not used in this study because we focus on software quality modeling and prediction after the coding (implementation) phase and before system tests. The case study, hence, consists of 28 independent variables that are used to predict a program module as *fp* or *nfp*. In Table 1, the top 24 attributes are product metrics based on call graph, control flow graph, and statement metrics, whereas the bottom four attributes are execution metrics. The *USAGE* metric was approximated by deployment data on a previous system release, whereas execution times were measured in a laboratory setting with different simulated workloads.

Modeling and Evaluation

The decision tree models are trained using a common model building and selection process. The Release 1 program modules are used as training data, whereas the Release 2 data set is used for model selection. For each decision tree method, different models are built by varying the respective model parameters. In the case of *CART*, model selection was based on 10-fold cross validation with Release 1. However, a close inspection of the different *CART* models indicated that the same model would be selected if Release 2 was used for model selection. This situation alleviates any threat to empirical validity from a non uniform model-selection process. We note that cross validation was not explicitly available for the other four decision tree classifiers. A generalized classification rule is used with all five methods for classifying modules as *fp* or *nfp*(19–22).

A Type I error occurs when a *nfp* module is misclassified as *fp,* whereas a Type II error occurs when a *fp* module is misclassified as *nfp*. Although it is beneficial to detect, before operations, as many *fp* modules as possible, the usefulness of a software quality classification model is affected by its Type I error rate. A model with a very low Type II error rate and a very high Type I error rate is not practical because given the large number of modules predicted as *fp* (many of them are actually *nfp*), deploying the limited quality improvement resources will pose a difficulty. The model-selection strategy of our study consists of finding the preferred balance of equality between the two error rates, with Type II being as low as possible. Such a strategy was used based upon the recommendation of the software quality engineers and the project management team of the system being modeled. A different application

Table 1. Software Metrics

Symbol	Description
CALUNQ	Number of distinct procedure calls to others.
CAL2	Number of second and following calls to others
CNDNOT	Number of arcs that are not conditional arcs
IFTH	Number of non loop conditional arcs, i.e., if–then constructs
LOP	Number of loop constructs
CNDSPNSM	Total span of branches of conditional arcs. The unit of measure is arcs
CNDSPNMX	Maximum span of branches of conditional arcs
CTRNSTMX	Maximum control structure nesting
KNT	Number of knots, which is where arcs cross because of a violation of structured programming principles
NDSINT	Number of internal nodes, i.e., not an entry, exit, or pending node
NDSENT	Number of entry nodes
NDSEXT	Number of exit nodes
NDSPND	Number of pending nodes, i.e., dead code segments
LGPATH	Logarithm (base two) of the number of independent paths
FILINCUQ	Number of distinct include files
LOC	Number of lines of code
STMCTL	Number of control statements
STMDEC	Number of declarative statements
STMEXE	Number of executable statements
VARGLBUS	Number of global variables used
VARSPNSM	Total span of variables
VARSPNMX	Maximum span of variables
VARUSDUQ	Number of distinct variables used
VARUSD2	Number of second and following uses of variables
USAGE	Deployment percentage of the module
RESCPU	Time of an average transaction on a system serving consumers
BUSCPU	Time of an average transaction on a system serving businesses
TANCPU	Time of an average transaction on a tandem system

may consider another preferred balance between the error rates.

The cost of a Type I misclassification, C_I, is the effort wasted (ineffective reviews) on an *nfp* module, and the cost of a Type II misclassification, C_{II}, is the lost opportunity to correct faults early for an *fp* module. The disparate costs of misclassifying an *fp* and *nfp* module poses a problem in evaluating competing software quality models. Hence, a unified cost metric, normalized expected cost of misclassification (NECM), is proposed and used in our case study (30). The NECM metric is a function of the two error rates, the prior probabilities of the two groups, and the cost ratio $\frac{C_{II}}{C_I}$. The cost ratio used during modeling depends on the project type and application domain, for example, a mission-critical software will have a higher C_{II} compared with an in-house business application. Moreover, the actual cost ratio for a project cannot be determined until after development and deployment. Hence, for a given application domain, one may consider a range of cost ratios that include representative and basic values. We compute the NECM values for our case study system at different cost ratios. If π_{fp} is the prior probability of *fp* modules, π_{nfp} is the prior probability of *nfp* modules, $Pr(fp|nfp))$ is the proportion of *nfp* classified as *fp*, and $Pr(nfp|fp)$ is the proportion of *fp* classified as *nfp*, then NECM is given by $Pr(fp|nfp)\pi_{nfp} + \frac{C_{II}}{C_I} Pr(nfp|fp)\pi_{fp}$.

In a comparative study such as ours, it is important to know whether performance differences between models are statistically significant. We use the two-way ANOVA (analysis of variance) randomized complete block experimental design with five factor treatments (i.e., decision tree classifiers) and three blocks (i.e., Release 2, 3, and 4 test data sets) (31). We are interested in observing if the different tree models and the different system releases are significantly different from their respective counterparts. The response variable is the NECM metric of the five decision trees computed for the three test data releases at a given cost ratio. The p-values obtained by the ANOVA design models indicate the significance of the differences among the five models and among the three test data sets. Multiple-pairwise comparison methods facilitate more detailed insight into the differences of means and provide a statistical technique for comparing two methods at a time. We use the Bonferroni's multiple-pairwise comparison equation (32) in conjunction with hypothesis testing using the p-vsdue approach. For two competing models A and B, the null (H_o) and alternate (H_A) hypotheses for the multiple-pairwise comparison are $H_0 : NECM_A \geq NECM_B$ and $H_A : NECM_A < NECM_B$.

Results and Discussion

The five decision tree models are compared with respect to their *complexity, robustness*, and *prediction* performances. For a given tree model, the number of leaf nodes (*TN*) and the number of unique software attributes used (*IVUT*) express the model's complexity. Robustness is evaluated in terms of model stability, for example, how consistently the preferred balance (between Type I and Type II error rates) of equality is maintained across the different releases. A robust model is important because the software quality assurance team typically prefers a "no surprise" software reliability engineering policy. Classification performance is evaluated in terms of misclassification error rates and NECM values. In our study, we consider a large range of cost ratios, for example, $\frac{C_{II}}{C_I} = \{1, 2, 3, 4, 5, 10, 15, 20, 25, 50, 100, 200, 350, 500\}$,to compute NECM values. However, for a high-assurance system such as LLTS, a range of 20 to 100 is most practical and likely.

Given the limited space considerations, we graphically illustrate only two of the five decision trees, for example, *CART* (Fig. 1) and *SPT* (Fig. 2). The other three models are presented in our respective prior works (19,20,23). The *CART* model ($TN = 3; IVUT = 2$) depicted lowest complexity, whereas the *SPT* model ($TN = 15; IVUT = 11$) showed highest complexity. Both models selected FILINCUQ, the number of unique include files, as the most important (i.e., root node) software attribute for LLTS. The five models would be ranked in descending order as *CART*, *SPL*, *TD*, *C4.5*, and *SPT* if based solely on model complexity. In our study, we observed that *TN* and *IVUT* were generally proportional, for example, a larger tree used more unique software attributes.

The misclassification error rates and normalized expected costs of misclassification for the five models are shown in Tables 2 and 3, respectively. The error rates are typical for the given system. The *NECM* values are only shown for cost ratios 1, 2, 5, 10, 25, 50, and 100, again because of limited space considerations. The *SPT* and *TD* models provide the best consistency in the preferred balance between the Type I and Type II error rates, whereas the *CART* model yielded the poorest consistency in the preferred balance. The average balance across Releases 2, 3, and 4 for *SPT*, *TD*, and *CART* are 2.84%,

	2	0.311	0.326	0.370	0.443	0.663	1.030	1.763
CART	3	0.293	0.303	0.331	0.378	0.518	0.753	1.222
	4	0.348	0.363	0.406	0.478	0.693	1.053	1.772
	2	0.252	0.268	0.318	0.402	0.652	1.068	1.902
SPL	3	0.263	0.277	0.317	0.384	0.585	0.920	1.591
	4	0.316	0.329	0.371	0.439	0.644	0.987	1.672
	2	0.253	0.272	0.327	0.418	0.693	1.152	2.068
TD	3	0.287	0.303	0.351	0.432	0.673	1.075	1.879
	4	0.283	0.301	0.354	0.443	0.711	1.156	2.046
	2	0.233	0.252	0.307	0.398	0.673	1.132	2.048
C4.5	3	0.252	0.265	0.305	0.372	0.573	0.908	1.578
	4	0.311	0.329	0.383	0.472	0.739	1.184	2.074

2.49% and 12.21%, respectively. These values were computed by averaging the absolute differences between the Type I and Type II error rates of a given model across the three test data sets. For *SPT*, this average is computed as $\{|24.47 - 26.84| + |25.38 - 20.83| + |28.48 - 26.88|\}/3 = 2.84$. In terms of model robustness, the five models would be ranked in descending order as *TD*, *SPT*, C4.5, *SPL*, and *CART*.

A graphical illustration of the influence of cost ratios on the significance of the differences between the methods is shown in Fig. 3. The figure plots *p*-values against the different cost ratios. The details of our ANOVA models, including degrees of freedom, mean squares, sums of squares, and *F* statistic, are not shown to maintain simplicity. The ANOVA models revealed that for all cost ratios considered, the system releases are significantly different (at $\alpha = 0.05$) from each other. In addition, the five decision tree methods were significantly different (at $\alpha = 0.10$) from each other for most cost ratios, except 10 (*p*-value = 0.3070), 15 (*p*-value = 0.3640), 20 (*p*-value = 0.2520), and 25 (*p*-value = 0.1570). The spike in the middle portion of the curve (Fig. 3) indicates poor significance of the difference in NECM values of the tree models.

In our multiple-pairwise comparisons, each tree model is compared with the other four models using a one-tailed pairwise comparison. For example, *CART* is compared with *SPL*, *SPT*, *TD*, and *C4.5* individually. Thus, for each pair of methods A and B, we have two comparisons: *"Is A better than B?"* and *"Is B better than A?"*. The *p*-values computed from the multiple-pairwise comparisons for the limited set of cost ratios is shown in Table 4. The table can be viewed as a matrix, for example, each pair of methods forms a comparison; methods in the second column are compared with the methods listed in the headings of the tables. Methods are not compared to themselves, and this situation is indicated by a "*" in the table. Because five methods comparise our comparative study, 20 comparisons exist for each cost ratio.

To infer the performance rank order of the methods, we present the details only for cost ratio 2. The following steps break down the inference process of how the rank order for the five models is obtained.

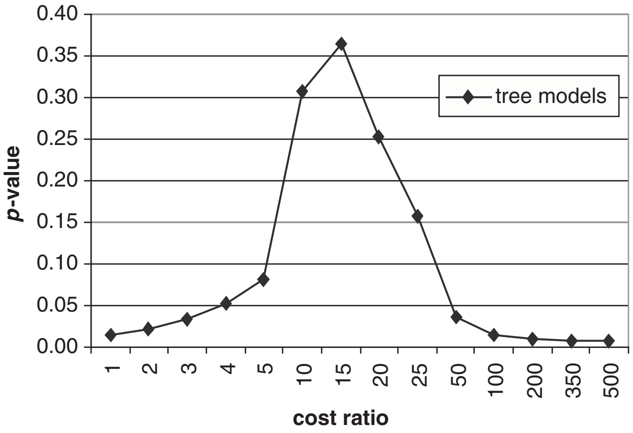

Figure 3. *p*-values.

1. From comparisons *SPT* vs. *CART* ($p = 0.0062$), *CART* vs. *SPT* ($p = 1.0000$), *SPT* vs. *SPL* ($p = 0.5347$), *SPL* vs. *SPT* ($p = 1.0000$), *SPT* vs. *TD* ($p = 0.5115$), *TD* vs. *SPT* ($p = 1.0000$), *SPT* vs. *C4.5* ($p = 1.0000$), and *C4.5* vs. *SPT* ($p = 1.0000$), we observe that *SPT* is better than all methods except *C4.5*. Therefore, *SPT* will be ranked either first or second.
2. From comparisons *C4.5* vs. *CART* ($p = 0.0118$), *CART* vs. *C4.5* ($p = 1.0000$), *C4.5* vs. *SPL* ($p = 0.9749$), *SPL* vs. *C4.5* ($p = 1.0000$), *C4.5* vs. *TD* ($p = 0.9383$), *TD* vs. *C4.5* ($p = 1.0000$), *C4.5* vs. SPT ($p = 1.0000$), and *SPT* vs. *C4.5* ($p = 1.0000$), we observe that *C4.5* is better than all the methods except *SPT*. Therefore, *C4.5* will be ranked either first or second.

   Given the intermediate results from Steps 1 and 2, we can conclude that the first two in the rank order are *SPT* and *C4.5*
3. From comparisons *TD* versus *SPL* ($p = 1.0000$) and *SPL* versus *TD* ($p = 1.0000$), we conclude that *SPL* and *TD* are similar to each other. However, looking at comparisons *SPT* versus *SPL* ($p = 0.5347$), *SPT*

versus *TD* ($p = 0.5115$), *C4.5* versus *SPL* ($p = 0.9749$), and *C4.5* versus *TD* ($p = 0.9383$), we observe that *SPL* performs relatively better than *TD* when both are compared against *SPT* and *C4.5*. Hence, *SPL* will be placed before *TD*.

4. Based on comparisons *SPL* versus *CART* ($p = 0.0348$), *CART* versus *SPL* ($p = 1.0000$), *TD* versus *CART* ($p = 0.0365$), and *CART* versus *TD* ($p = 1.0000$), *SPL* and *TD* are both better than *CART*.

   Given the intermediate results from Steps 3 and 4, we can conclude the following partial rank order: *SPL*, *TD*, and *CART*.
5. Combining the partial rank order deduction in Step 4 with the knowledge of the first two (deduction of Step 2) in the rank order, the final order for cost ratio 2 is *SPT*, *C4.5*, *SPL*, *TD*, and *CART*.

The rank orders for different cost ratios are shown in Table 5, where the notation $\geq$ signifies that the method on the left side is either better than or similar to the method on right side. At lower cost ratios ($\frac{C_{II}}{C_I} \leq 15$), *SPT* performs the best, whereas *CART* performs the worst. For cost ratio 20, *SPL* performs the best, whereas *TD* performs the worst. For cost ratios between 25 and 500, *CART* performs the best, whereas *TD* performs the worst. The *SPT* model is more robust to changes in the cost ratios. Thus, based on the performance order presented in Table 5, we conclude that for lower cost ratios *SPT* should be preferred, whereas for higher cost ratios *CART* should be preferred.

In empirical software engineering, threats to internal validity are unaccounted influences that may affect case study results. To be credible, the subject of an empirical study must be a system that is (33): (*1*) developed by a group rather than an individual, (*2*) developed by professionals rather than students, (*3*) developed in an industrial environment rather than an artificial setting, and (*4*) large enough to be comparable to real industry projects. The software system investigated in this study meets all these requirements. In the context of this study, poor estimates can be caused by a wide variety of factors, including measurement errors while recording software metrics, errors in model selection, and the presence of outliers and noise in the training data. Measurement errors are inherent to the data collection effort. A common model-building and model-selection approach has been adopted, and the statistical analysis was performed by only one skilled person to keep modeling errors to a minimum. Threats to external validity are conditions that limit generalization of case study results. As our results are based on analysis of the LLTS data set, another system may yield different conclusions. However, the comparative modeling approach would be the same.

Table 5. Performance Order of Tree Models

$\frac{C_{II}}{C_I}$	Performance Order
1	$SPT \geq C4.5 \geq TD \geq SPL \geq CART$
2	$SPT \geq C4.5 \geq SPL \geq TD \geq CART$
5	$SPT \geq C4.5 \geq SPL \geq TD \geq CART$
10	$SPT \geq SPL \geq C4.5 \geq TD \geq CART$
25	$CART \geq SPL \geq SPT \geq C4.5 \geq TD$
50	$CART \geq SPL \geq SPT \geq C4.5 \geq TD$
100	$CART \geq SPL \geq SPT \geq C4.5 \geq TD$

CONCLUSION

An important requirement for a high-quality and dependable software product is the availability and application of effective tools for software quality and reliability improvement. In this article, software quality estimation models have been used to provide insight into the reliability of software systems and, thereby, control the software development process to minimize software failures. Many software applications involve the use of software in safety-critical situations, which warrant the need to develop and quantify effective measures and models of software quality. The timely prediction of faulty components, before their operations, can enable software quality assurance teams to target enhancement efforts only to the needed areas.

Tree-based classification modeling is a simple yet efficient technique that facilitates such a prediction. We compared existing tree-based classification techniques with respect to their performance accuracy, model structure, and model complexity. The modeling methods we compared are *CART*, *S-PLUS*, *Sprint-Sliq*, *C4-5*, and *Treedisc*. These methods were used to build software quality models that predict program modules as either *fp* or *nfp*. The case study used data collected over four successive releases of a very large telecommunications system. A common model building, selection, and evaluation process is used for all the decision tree classifiers. A two-way ANOVA randomized block experimental design analysis examines (*1*) whether the decision trees perform significantly differently than each other and (*2*) whether the different system releases were different from each other.

We observe that in the context of classification accuracy, obtained preferred balance, and model stability, the *Sprint-Sliq* classification model is generally a better method as compared with the other four decision tree models. However, with respect to model interpretation and model complexity, *CART* and *S-PLUS* are generally better methods. We note that results of this study may not be applicable to another software system because the models were built using software metrics and defect data of the LLTS software. However, the modeling and evaluation process generally remain unchanged when applied for software quality modeling of another system. Hence, future work may include investigating a similar comparative study with software metrics data from another software system.

SOFTWARE SAFETY

INTRODUCTION

Safety is a property of a system such that it will provide hazard-free operation and, thus, will not endanger human life, jeopardize property, nor harm the environment. Alternatively, safety relates to those activities that seek either to minimize or to eliminate hazardous conditions that can cause bodily injury (1). *Merriam-Webster* (2) defines safety as "the condition of being safe from undergoing or causing hurt, injury, or loss." Leveson (3) states: "Safety is freedom from accidents or losses." Safety is a relative term as it depends on the perspective of an individual of what is risky; some would pass on a rock climbing or parachute jumping opportunity. Additionally, as a the state of a system changes in time, its level of safety also may change: Consider the airplane in a hangar and one cruising at 30,000 feet.

In addition, to provide desired functionality, performance, and quality of service, system designers strive to prevent *accidents, mishaps,* and *incidents*. An accident is defined by safety engineers as "an unwanted and unexpected release of energy" (4). This incomplete definition is expanded: A mishap is defined as "... an unplanned event or series of events resulting in death, injury, occupational illness, damage to or loss of equipment or property, or damage to the environment" (5). An incident is an event that involves no loss but a potential for loss under a different circumstance. All three terms exemplify a *safety violation*. With more systems relying on software, spectacular mishaps (e.g., accidents of Ariane-5, Therac-25 radiation therapy machines, the Mars Climate Orbiter mission, the Patriot Missile problem, the London Ambulance Service failure, the Osprey crash, etc.) have been attributed to software (6,7).

For modern software-intensive systems, safety-critical software functions are those that directly or indirectly can cause or allow a hazardous system state to exist, which in turn, may lead to a safety violation. However, software is unique: it is an abstract concept similar to music. Software is represented by a set of computer instructions like music is represented by a set of notes on a music sheet. By itself, software can do nothing and therefore, obviously, it is not hazardous. Similar to music, which must be played on an instrument, software must be executed on hardware in order to do anything useful. And if the hardware is part of a system that can lead to injury, death, destruction, loss of property, or damage to the environment, then system safety, including software safety, is paramount. Such systems will be called *safety-critical*. With more of our ubiquitous technology being controlled by software, a significant portion of the risk we face is in the hands of software engineers.

Software is considered safety-critical if it meets one of the three following criteria (8):

1. Resides in a safety-critical system, as determined by the system hazard analysis, AND (at least one of the following):
   a. causes or contributes to an identified hazard
   b. provides control or mitigation for identified hazards
   c. controls safety-critical functions
   d. processes safety-critical commands or data
   e. detects and reports, or takes corrective action, if the system reaches a specific hazardous state
   f. mitigates damage if a hazard occurs
   g. shares the processor with safety-critical software
2. Processes data or analyzes trends that lead directly to the safety decisions of the operator
3. Provides full or partial verification or validation of safety-critical systems, including hardware or software subsystems

Modem microprocessors and their flexible software have replaced the physical constraints of the electromechanical components of earlier systems. The real-time nature of modern application adds an additional layer of complexity and indeterminism (9,10). Adding functionality is an attractive proposition, and the design may expand beyond capabilities of the developers to properly analyze it. Because of software flexibility, the number of interactions increases to the point that they cannot be properly understood or planned. Inability to consider all possible system states or operator actions increases the likelihood for system mishaps. Additionally, computers introduce failure modes that cannot be handled easily by traditional hardware-based methods (e.g., redundancy), where the failures or random nature are caused by individual components rather than by systemic interactions between multiple components (11).

FAULTS AND FAILURES

Nothing is perfect, and thus mistakes are expected to be made by people in all phases of system development: specification, design, coding, manufacturing, and so forth. A mistake can cause a fault, which may be a defect within the hardware or a software bug introduced by the developer. Another source of fault can be a component or a tool deficiency. External disturbance also may trigger a fault by changing the system operating conditions.

IEEE standards define a *fault* as "an incorrect step, process, or data definition in a computer program" (12). A system or a component is said to have *failure* if it cannot perform its required functions within specified performance requirements. A symptom of the failure is observable as the system "incorrect" behavior at the system boundary, which represents an external view of the system not meeting the requirements.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

Software professionals use the term *error* to designate the result of a fault that leads to failure—resulting not only from the fault but also from the current system state and possibly a combination of events. However, the error often is understood as a defect, bug, or flaw in a program. The term *software anomalies* have been used (13) classifying the items that are missing *(omission errors)* and items that are incorrect *(commission errors)*. Therefore, differentiating between faults and errors is extremely difficult. For fault-tolerant systems, it is essential to define faults and failures. Other terms like error, defect, or bug can be only a source of confusion. Thus, it is recommended to substitute the term *fault* anywhere *error* or a similar term is used.

All faults are internal and may lay *dormant,* either being *latent* (not discovered) or *detected*. Alternatively, faults can be *active*, propagating other faults but still latent or resulting in failures observable outside the system boundary. Thus, a fault can lead to other faults or to a failure or to neither. Effectively, fault and failure are equivalent, except the boundary of the relevant system or subsystem is different: A failure of a subsystem may be considered a fault in the parent system.

There are numerous reasons for system faults to occur. Hardware may exhibit faults because of component defects and external disturbances like electromagnetic interference, radiation, temperature, pressure, and a physical damage. Operator mistakes constitute yet another reason for faults to occur. The reasons attributed mostly to software are:

- Specification mistakes in a form of wrong software requirements, incorrect algorithms, bad architectural decisions, ill-selected hardware platform, flawed tools, etc.
- Implementation mistakes, including poor design, sloppy construction, inadequate testing, wrong component selection, misunderstanding system software and low-level interfaces, faulty interfaces, imperfect tools, coding defects, etc.

Faults can be categorized considering their *nature, duration,* and *extent*. The *nature of fault* can be *random* or *systematic*. Random faults typically are limited to hardware, because of the wear-out of a component or a loose interconnect. Systematic faults can occur both in hardware and software because of mistakes in specification, design, and implementation (coding and manufacturing) (4).

The *duration of a fault* can be categorized as *permanent* or *intermittent*. A permanent fault remains until a corrective action is taken. The typical systemic causes of software permanent faults include mistakes in specification (incorrectness, ambiguity, inconsistency, and incompleteness), conceptual or architectural error in design, logical errors in algorithmic calculations, coding issues like improper parameter passing, location of synchronization constructs, instruction side-effect, stack problems (in terms of overflow, underflow, and memory leak), incorrect initialization of variables, range excess, and so forth. Another category of fault duration is the intermittent or transient fault, which tends to appear and then disappear after a short time. It may appear once more at a later time when appropriate conditions occur again. Typical causes of software intermittent faults are because of real-time conditions, concurrency, and resource contention (e.g., deadlock, live-lock, and priority inversion). However, the resulting failure may persist even though the fault seemingly disappeared. The *extent of a fault* can be either *localized*, for example, limited to one software module by means of partitioning and protection to prevent fault propagation, or *global*, with system-wide effects.

Techniques for fault management include requirement definition methodologies, architectural and design solutions, testing strategies, and use of mathematical formalism in the system requirements and design.

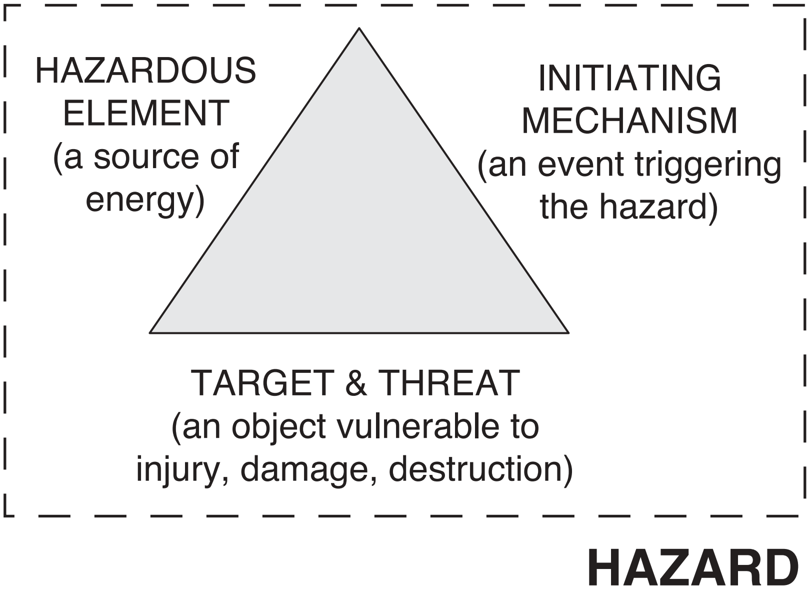
HAZARDS ANALYSIS

A *hazard* is a situation in which a potential source exists for danger or harm to people or the environment (14). Risk of human life, destruction of environment, and financial loss are the primary considerations in safety assessment. The issue is the gravity of a mishap, for example, the consequence of the operation rather than the actual operation outcome: Risk is evaluated as a combination of the *likelihood* of a mishap and the *severity* of the mishap consequences. A hazard is a set of conditions, or a state, that could lead to a mishap, given the right environmental trigger or set of events. A mishap (or even worse, an accident) is the actual realization of the negative potential inherent in a hazard. As presented in Fig. 1, three components of a “hazard triangle” must exist for a hazard to occur: hazardous element, initiating mechanism, and target and threat (15).

Often hazards and the related mishaps can result from a mismatch between a model of the process used to create the software and the actual physical process the software is controlling. The mismatch may be caused by an incorrect or incomplete software model of the process or by lack of accurate information about the system state. One goal of the software safety analysis then is to verify that the model (representing the requirements) specifies sufficiently safe behavior in all circumstances (16). The specification is analyzed with respect to known hazards by using the state machine concept and searching. Safety analyses often need to consider what can be termed as a negative property (i.e., “bad things do not happen”), as opposed to functional requirements defined in terms of positive properties (i.e., “good things do happen”) (17).

Some accidents could have been avoided by considering potential hazards. Building safe systems requires performing detailed analysis of the software with respect to system hazards. Specific hazards must be identified early in the development lifecycle, safety-critical requirements must be identified, and the likelihood and the criticality of a potential resulting accident need to be assessed. Special precautions need to be taken, and the resulting software should be designed in such a way that these potential hazards can either be avoided or controlled and that the risks associated with these hazards can be mitigated.

A variety of system-level hardware mechanisms, external to the computer, can be used to handle hazardous



HAZARDOUS ELEMENT (a source of energy)
INITIATING MECHANISM (an event triggering the hazard)
TARGET & THREAT (an object vulnerable to injury, damage, destruction)
HAZARD

Figure 1. Hazard triangle.

conditions. They often have an equivalent representation in software. Requiring depressing the brake pedal before turning the ignition key limits a sequence of events that might permit a little child to start an engine, this example illustrates *interlock*. In software, interlocks are implemented by designing the execution of specific code elements in a sequence (using synchronization mechanisms, for example, semaphores) or by inhibiting execution until certain conditions are met. To prevent the system from entering into an unsafe state (or someone from entering a dangerous area), *lockouts* are used. In software, lockouts are techniques to control access to safety-critical code or data, implemented by a variety of access-right mechanisms (e.g., monitors and safety kernels). To enforce continuation in a safe state, *lockins* are used, for example, rejecting an input that would transition the system to an unsafe state (3).

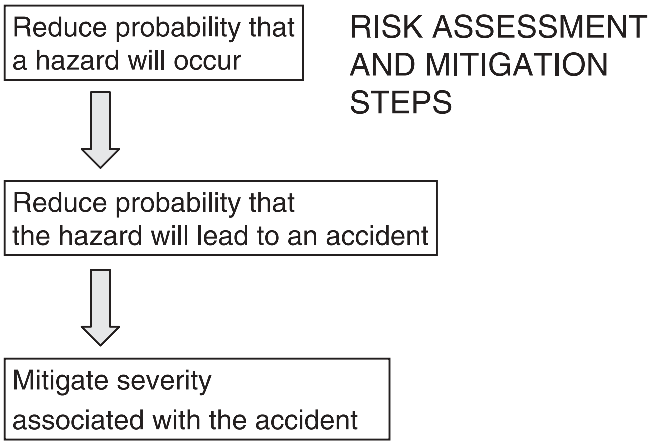
A variety of techniques have been applied successfully to software modules and to components used to analyze the software behavior and its impact on the overall system operations. Analysis can be *static* in the early development phase, focusing on prevention, and *dynamic*, requiring actual execution of the program. Another categorization is between *functional* (including traditional testing, formal inspections, Cleanroom, and code/scenario analysis) and *logical* (including special cases of testing: boundary, fault injection, and structural) (18).

Of particular value to software safety have been well-established techniques common to both system and hardware: Fault Tree Analysis (FTA), Event Tree Analysis (ETA), Failure Modes and Effects Analysis (FMEA), Failure Modes, Effects and Criticality Analysis (FMECA), Markov Chains (MKV), Bayesian Belief Networks (BBN), Petri Nets (PN), Hazard and Operability Analysis (HAZOP), Cause Consequence Analysis (CCA), Operational/Support Hazard Analysis (OSHA), and Sneak Circuit Analysis (SCA) (15).

RISK ANALYSIS

The reality is that hazards do exist. The related risks need to be assessed and mitigated by considering three steps of building from a hazard to a mishap as presented in Fig. 2.

When building safety-critical software, the developers need to ensure an acceptable level of risk. At each of the three steps, the objective is to eliminate the risks where possible and to reduce the risks that are unavoidable. The criterion for risk acceptance is based on the decision of whether the risk is "As Low As Reasonably Practicable" (ALARP). The approach is to identify clearly two distinct and separated regions: acceptable and unacceptable regions of risk. Between these two regions, a gray area exists where the risk is tolerable only if further reduction is impractical or the cost of reduction is disproportional to the gained improvement (4).



RISK ASSESSMENT AND MITIGATION STEPS
Reduce probability that a hazard will occur
Reduce probability that the hazard will lead to an accident
Mitigate severity associated with the accident

Figure 2. Progression from hazard to mishap.

Table 1. Risk categorization

	AVIATION: RTCA DO-178B	MILITARY: Mil Std 882D
Severity	• Catastrophic—prevents flight continuation • Hazardous—large reduction of flight safery and possible accident • Major—significant safety reduction of flight safely and possible injuries • Minor—slight reduction of flight safety and discomfort • No effect—no influence on safety	• Catastrophic—deaths, total disability, \$1M loss, irreversible environmental damage • Critical—pennanent multiple injuries resulting in partial disability, \$200K loss, reversible environmental damage • Marginal—injury or illness, \$10K loss, environmental damage easy to mitigate • Negligible—minor injury or illness, \$2K loss, minimal environmental damage
Likelihood	• Probable (frequent and reasonably probable): l0^{-4}–10^{0} • Improbable (remote and extremely remote): 10^{-9}–10^{-5} • Extremely improbable: $< 10^{-9}$	• Frequent—likely to occur often; $\sim 10^{-1}$ • Probable—fikely to occur several times: 10^{-2}—10^{-1} • Occasiional—likely to occur some times: 10^{-3}—10^{-2} • Remote—unlikely but possible to occur: 10^{-6}—10^{-3} • Improbable—extremely unlikely to occur: $< 10^{-6}$

Risk is a measure associated with hazard, representing the relative importance of the hazard and defining a possibility of something undesirable to occur. Risk is a composite of the probability and the severity of a mishap. Typically, the risk is expressed as a combination of likelihood (frequency) and severity (consequence).

Table 1 presents an example of risk categorization for civil aviation, according to the Radio Telecommunication Committee for Aviation DO-178B (19), and for military applications, following Department of Defense MIL STD 882D (5).

Considering the categorization of the likelihood and severity, the overall mishap risk can be classified using a risk assessment matrix in the order of decreasing risks level (e.g., letters A to D, Roman numerals I to IV, High to Low). Software may be categorized regarding its impact on the system operation. Table 2 shows an example of such categorization based on MIL STD 882C (20).

Using the defined software control category and the related system hazard criticality, a hazard criticality matrix can be built to identify the hazard risk index. This system-level assessment allows the software developers to apply varying levels of rigor and managerial approval.

THE NATURE OF SOFTWARE

Software does not degrade or change over time. Software does not fail by itself, and it always works the same way. Unlike when manufacturing physical entities, software can

Table 2. Mil Std 882C software control categories

MilStd 882C Software Control Categories	Description
I	Software exercises autonomous control over potentially hazardous hardware systems, subsystems, or components without the possibility of intervention to preclude the occurrence of a hazard. Failure of the software or a failure to prevent an event leads directly to a hazard's occurrence.
IIa	Software exercises control over potentially hazardous hardware systems, subsystems, or components allowing time for intervention by independent safety systems to mitigate the hazard. However, these systems by themselves are not considered adequate.
IIb	Software item displays information requiring immediate operator action to mitigate a hazard. Software failures ill allow or fail to prevent the hazard's occurrence.
IIIa	Software item issues commands over potentially hazardous hardware systems, subsystems, or components requiring human action to complete the control function. There are several, redundant, independent safety measures for each hazardous event.
IIIb	Software generates information of a safety-critical nature used to make safety-critical decisions. There are several, redundant, independent safety measures for each Hazardous event.
IV	Software does not control safety-critical hardware systems, subsystems, or components and does not provide safety-critical information.

be duplicated bit by bit without any variations. It seems to be easy to modify and change. However, physical change of a line of code may wreck havoc in the logical structure of the program. Leveson writes: "...while natural constraints enforce discipline on the design, construction, and modification of a physical machine, these constraints do not exist for software" (3). The unique and typically complex nature of software, combined with its tremendous flexibility, makes it difficult to analyze all the possible ways software performs (or occasionally fails to perform) the desired function. Despite recent progress in component-based design, software is not standardized to the extent that hardware is. Software may break immediately after installation, because of environmental or usage conditions not considered by the developers. It may fail intermittently, because of sporadic environmental conditions related to the timing sequence of external events. It may perform reliably until a certain unexpected combination of events or user inputs. It may work well for years until specific operating conditions change. Hardware fails because of physical stress, time, wearing out, and environmental factors. In contrast, software fails by human error during requirements, design, code, test, or maintenance. Factors affecting software failure rate, and thus software reliability, include complexity, methodologies and tools, process, schedule, and computing platforms (21).

The advantages of software, because of its flexibility, easy upgrade, high level of sophistication, and added functionality, outweigh potential risk associated with the software use in safety-critical systems. Software-controlled devices can collect information, interpret information, perform diagnostics, or present elegant interfaces to the user, typically at a more acceptable cost than can their hardware counterparts.

According to Brooks (22), the "essential" properties of software represent inherently its nature. To build safe software, these properties need to be considered and dealt with:

- *Complexity:* Computer programs have an extremely large number of execution paths and binary data that can create a number of combinations exceeding the number of hardware states in most complex integrated circuits.
- *Error Sensitivity:* Small errors may have a huge impact on the output; for example, flipping one bit totally may change the outcome of computations, resulting in a catastrophic failure.
- *Difficulty with Testing:* Exhaustive testing is not achievable for a program exceeding a few hundreds lines of code; it is particularly difficult in reactive systems, where sporadic external events may have impact on execution flow.
- *Correlated Failures:* Most failures in software do not result from wear-out but rather from developer-inserted defects; redundant systems may duplicate the original error, whereas the alternative designs may introduce new defects.
- *Lack of Professional Standards:* Anyone writing computer code can be called a "software engineer," and no objective way exists to argue with that, given the increasing dependency on software, the idea of licensing software engineers is ever more attractive.

Software is just another system component. The defects in software can cause hazardous events in the hardware it is controlling. A close collaboration between the system, safety, and software engineers is essential to identify potential causes of hazards. Software must be evaluated for its contribution to the safety of the system during the concept and planning phases and before its development or acquisition.

There are two aspects to be considered for software in safety-related systems. The first aspect is to design software in such a way to help mitigate the known hazards to the system. The second aspect is to construct the software in such way that it will not contribute to additional hazards because of undesired or incorrect operation.

SAFETY: TERMS AND CONCEPTS

The term *software safety,* or better *software system safety,* relates to the features and procedures (18) that ensure that the software is designed so that (a) the system performs predictably under normal and abnormal conditions and (b) the likelihood of unplanned events is minimized; their consequences are controlled and contained. The discipline of software safety is the systematic approach to identifying, analyzing, and tracking software mitigation and control of hazards and hazardous functions to ensure safe enough (ALARP) software operation within a system.

Software safety is an integral component of the system development. A software specification inaccuracy, design defect, or the lack of appropriate safety-critical requirements can contribute to a system failure or unsafe human decision. To achieve an acceptable level of safety for software used in critical applications, software safety methodology must be used not only in the requirements definition and the conceptual design, but also throughout the development and operational lifecycle of the system.

Despite visible progress since Leveson (3) made these observations in the early 1990s, often only marginal or superficial connection exists between software engineers and system/safety engineers. The former treat the computer as a stimulus–response subsystem and do not consider the system hazards or effects of software on system safety. The latter often ignore software and treat the computer as a black box, not giving consideration to hazards that it can mitigate or introduce.

Safety engineers identify different modes of safe operation of a *fault-tolerant system*. A *fail-safe system* is one that in case of failure will revert to a non operating state that will cause no mishap. A *fail-operate system* is a system that will continue to operate and will remain in a safe, possibly degraded state (23). The assessment of the system hazards and risk is the base for determination of what mode of fault-tolerant system will be necessary.

The *Software System Safety Handbook*(24) defines fundamental goals for software to ensure system safety. They are adapted here as “the ten commandments” of software safety:

1. Identify, evaluate, and eliminate hazards associated with the system and its software and reduce the risk to an acceptable level throughout the lifecycle.
2. Design safety into the software in a timely, cost-effective manner.
3. Address failure modes in the design of the software, including hardware, software, human, and system.
4. Minimize the number and complexity of safety-critical interfaces.
5. Minimize the number and complexity of safety-critical computer software components.
6. Apply sound human engineering principles to the design of the software user interface to minimize the probability of human error.
7. Minimize reliance on administrative procedures for hazard control.
8. Use sound software engineering practices and documentation in the development of the software.
9. Address safety issues as part of the software testing effort at all levels of testing.
10. Design software for ease of maintenance and modification or enhancement.

RELIABILITY VERSUS SAFETY

One important characteristic of a system is reliability. A widely accepted definition of reliability is the probability that the system will perform its function at a given time (25,26). Software reliability is the probability of failure-free software operation for a specified period of time in a specified environment. To assess reliability, developers and analysts take a bottom-up approach, placing the focus on the sources of the failures. In contrast, safety is a top-down paradigm, concentrating on system hazards, for example, on how the system contributes to endangering people; destruction of the system; and its environment (3). Because both reliability and safety assessment practices use the same methods and tools, they often are misconstrued as equivalent. Reliability engineering can complement safety. However, even a highly reliable system may be unsafe and, conversely, an unreliable (or simply not working) system may be perfectly safe. To make the point, consider a loaded unsecured gun in the hand of a child (reliable but not safe) and an aircraft with a non working engine sitting in a hangar (not reliable but safe). In fact, accidents may happen without evident system failure. Most accidents result from a combination of procedural or operator mistakes, environmental events, and system faults. A safety analysis considers the possibility of reaching a hazardous state when components operate without evident failure, concentrating on the interaction between the components in various states and environmental conditions.

According to Leveson (11), with respect to the requirements, the produced software may be reliable and correct, but still unsafe when:

- The software correctly implements its requirements, but the specified behavior is unsafe from a system perspective.
- The requirements do not specify a particular behavior required for the safety of the system.
- The software has unintended (and unsafe) behavior beyond what is specified in the requirements.

Nearly all software-related accidents can be traced either to (a) incomplete or incorrect assumptions about the operation of the system or the operations required from the computer, or to (b) environmental conditions or system states remaining unhandled. Failure of the software may cause a situation that leads to the system getting out of control and endangering or harming the operator and/or public. The complexity and apparent “easy” modifiability of software is the major obstacle to achieving system safety.

SOFTWARE FAULT TOLERANCE

The handling of software faults takes place in the context of overall system fault tolerance (23,27–29). Because software faults are expected to exist, they need to be managed. Fault management (in the form of avoidance, removal, evasion, and tolerance) depends on the phase of the project. In the development phase the concept of *fault avoidance* is applied, for example, the reduction of faults through carefully selected design and implementation methodologies, the adherence to a rigorous development process, verification, and validation (including testing, inspections, and application of formal methods). Another complementary approach is *fault removal*, which is based on identification and removal of faults found through testing. In the operational phase, *fault evasion* is based on the detection and mitigation of fault effects before they occur.

The ability of a system or component to continue normal operation regardless of presence of hardware or software faults is known *as fault tolerance*. The objective of fault tolerance is to design a system in such a way that faults do not result in a system failure and a related safety violation. Fault-tolerant systems have an ability to continue with normal operation even though a fault has occurred. Fault tolerance evidently improves reliability, availability, and safety.

Fault-tolerant software is capable of mitigating the impact of errors before they cause the failure of the system. In software-intensive systems, the issue is to handle requirements and design deficiencies where most of software faults reside. The fault-tolerance process consists of four stages:

- *Detection*—identification of the problem, for example the erroneous state.
- *Diagnosis*—evaluation of the potential damage and determination of the causes.
- *Containment*—prevention of the damage propagation to other system modules.
- *Recovery*—replacement of the erroneous system state with a correct state to continue operation.

A fault detection mechanism is based on checking the functionality of the components. The specific techniques for detecting data inconsistency include parity, checksum, residue, and cyclic code. Built-in testing (BIT) either in a form of predefined pattern generators to check the output against expected result or in a form of progress monitoring watchdogs/timeouts to detect illegal sequences, deadlock, or system inactivity are other popular techniques. Use of predefined reference devices to monitor correctness of the input or a device self-test at startup is often used in embedded dependable systems. At the system level, two basic fault detection mechanisms are the *acceptance test* (with either a known value or by comparison) and *voting* (30). The quality of such decision elements (adjudicators) is vital to the dependability of a system.

Recovery can be executed either *backward or forward*. In backward recovery, upon detection of error, the system is rolled back to the previously saved checkpoint, which is an error-free known state. Backward recovery typically is an application-independent scheme that can be used as long as the previous error-free state is known. However, the scheme may require that the system stops its operation in the process of recovery. Another disadvantage is that significant resources may be required to save the checkpoints periodically and to roll back when the error is detected. In more complex systems, a domino effect may occur when interacting processes are not properly synchronized. One process rolls back to a checkpoint, which causes the interacting process to roll back, which in turn may cause the first process to roll back further, and so forth. In contrast, the forward recovery is based on either a transition to a predefined state from which the system operation can be continued or a compensation for the detected discrepancy from the desired value. Forward recovery is application-specific and requires knowledge of the system state. Typically, the forward recovery scheme is faster because it does not require time-consuming rollback (31).

Software fault-tolerance techniques allow a system to tolerate software faults that may remain after system delivery. Software fault-tolerance techniques are based on the concepts of diversity in three areas: *design, data*, and *temporal*. Diversity introduces overhead that requires additional resources in terms of time, space, or both. The techniques depend on the type of computing software environment, A common misconception exists that the system must be redundant to be safe. A simplex system is one that does not employ redundancy and still can be fail-safe (but not necessary fail-operate). Redundant systems, with more than one computer, are employed in situations that require high dependability to ensure operation in presence of failure (23). In either case, a system may have one or more versions of the software. In a single version software environment, the techniques are limited to monitoring, assuring atomicity of operations, verifying decisions, and handling exceptions. Multiple version software environments, with independently developed software versions, provide for more assurance and complete recovery. The techniques used include (a) *recovery blocks* where the critical block of execution is checked for acceptance and, in case of failing the acceptance test, an alternate version is executed sequentially, (b) *N-version programming* where separate, independently developed software versions are operating in parallel on redundant computer resources and the output is decided based on the voting or based on the application-specific acceptance test, and (c) *N-self-checking programming* where the outputs from each concurrently operating component are compared and accepted only when they agree. Multiple data representation environments use diverse representation of input data. Example techniques are (a) *retry blocks* where an acceptance test is used to determine if the retry should be activated, and (b) *N-copy programming* using two or more copies of the program and an appropriate data re-expression algorithm (31). For more detailed description, see the article Fault Tolerant Software.

SOFTWARE SAFETY IMPLEMENTATION

Application of coding standards and the need to create readable, easy-to-maintain code often contradicts smart programming focused on reducing the execution time or/and saving memory. Safety-critical software often implements defensive programming guards against run-time errors. Each module has an initial code segment, which checks assumptions and data validity before the algorithm execution. For object-oriented programming, a class should be instantiated only one time as an object declared outside the block with a static lifetime. Using pointers is prohibited explicitly in much safety-critical application code. Also, to avoid potential memory leaks a dynamic allocation and de-allocation of memory should be avoided. Use of software-based checksums (e.g., cyclic redundancy check) also is recommended.

Evaluation and assessment of software safety is a rather difficult proposition. The approaches include safety requirement coverage, checklists, meeting specific process objectives, and so forth (32–34). Formal methods, based on discrete mathematics, provide a rigorous mechanism for describing both system and software during the development lifecycle. This description can be analyzed to verify the system behavior. The methods can prove certain properties of the system (safety, liveness, and reachability) and demonstrate that the computer program transfers its pre-conditions into desired post-conditions. In highly dependable applications, the use of formal methods has been encouraged and occasionally mandated (35–37).

A popular approach is to annotate a program with specification constructs to support formal verification. A proof of correctness is a formal verification approach based on enforcing a strict subset of the programming language thus applicable to the new development of safety- and mission-critical software rather than on trying to improve the quality of legacy code. The goal of another formal verification approach is the detection of a substantial proportion of defects rather than proving program correctness. Both approaches have been developing a variety of tools supporting formal analysis. Some of these tools forgo completeness and soundness of a new language in order to be more useful on un annotated or lightly-annotated legacy code.

Language Subsets

Programming languages need to be tailored before they can be used in safety-critical software. This tailoring is done by identifying a subset of the language that excludes certain features that are hard to use and verify (38).

An example of a formal verification approach that focuses on providing proof of correctness is SPARK Ada (39), a commercially-supported notation that has been used to develop some sizeable critical systems. SPARK uses an ordinary Ada 95 compiler. However, SPARK is more than an Ada subset because of the addition of annotations and the availability of the SPARK examiner tool that checks for adherence to the subset. The annotations provide design information about the usage of variables that would not be present in conventional Ada code. SPARK is really a design tool using the concept of correctness by construction (40).

The Motor Industry Software Reliability Association (MISRA) has developed coding guidelines for the C programming language intended to improve intelligibility of the programs and the predictability of the code behavior for safety-critical applications (41). A major difference from SPARK Ada is that no specific tool is associated with the guidelines. However, the industry has developed a variety of tools that check for the selected subset. The MISRA guidelines are formulated as set of rules based on two principles: (a) promotion of a common programming style and (b) avoidance of language features that are suspected to lead to program failure (with or without appropriate failure data). The first principle is supporting code maintainability; the second is related more to the actual hazards originating from the coding practices, and these rules can be the base for the selection of a safe language subset to prevent the occurrence of common mode failures. For example, the C language has a rich set of operators that can be combined without multiple levels of tedious parentheses. Unfortunately, problems are reported with the precedence of the default operators and the side effects, which can be avoided by adhering to specific rules. Some development groups in other industries have adopted the MISRA C guidelines, which can be enforced by performing static code analysis on application source code. However, MISRA-C rules and the related static checking do not guarantee predictable execution, for example, an array index range only can be checked dynamically (42).

The Ravenscar profile was established as a model for building safe and reliable real-time systems. The profile was defined in 1997 at an Ada 95 workshop convening at the village of Ravenscar in northern England (43). The workshop defined a set of tasking features compatible with a realistic size of application but defined to be implemented efficiently and be reasonably easy to certify. Such a safe Ada 95 subset includes tasking that is restricted by preventing local declaration of tasks, dynamic allocation of tasks, and asynchronous transfer of control. Memory allocation is allowed only once at program elaboration time. Deallocation is disallowed, simplifying run-time system. Task rendezvous is not allowed, and tasks can communicate only via protected objects. The tasks are dispatched in FIFO manner, with a ceiling-locking protocol priority. A single global handler handles all exceptions. The restrictions support a deterministic model of computation required for safety critical applications, which could be certifiable to the highest integrity levels.

Java has not been considered a suitable programming language for safety-critical applications because of its automatic garbage collection, complex object-oriented programming features, and inadequate support for real-time multi threading. The Real-Time Specification for Java has introduced features that help in the real-time domain. However, the complex programming model and the resulting supporting real-time virtual machine complexity prevent confident use of Java in high-integrity systems. The proposed Ravenscar-Java profile (44) concentrates on reliability, robustness, traceability, and maintainability, with an objective to ensure predictability in three areas: memory use, timing, and control and data flows. The profile allows for concurrent execution of schedulable objects (threads and event handlers) based on pre emptive priority-based scheduling. Schedulable objects have to be either periodic or sporadic with minimum inter-arrival times, and the priority ceiling protocol is required to be implemented in the runtime system. This profile facilitates the use of off line schedulability analysis, which is associated with fixed priority scheduling (for example, deadline- or rate-monotonic analysis)

Partitioning and Firewalls

For highly critical applications in regulated industries, depending on the criticality of the application as defined by system safety assessment, object code analysis on the target level often is required. To reduce potential errors, the development methodology calls for *independence* and *diversity*. For independence, it is understood that the verification/validation is performed by an independent entity. Depending on the criticality of the module, it can be a different organization, a different unit within the same company, or a different person not previously engaged in the development. Diversity in development of the same module, independently by two or more teams, is a mechanism to reduce the likelihood of similar human mistakes. Despite wide use in highly critical applications (nuclear, aviation, and space), the approach has been considered controversial, because common specification defects or the selection of the same approach in a difficult part of the implementation by the teams may compromise the diversity concept (45).

Certainly, the additional safety code required for checking, monitoring, redundancy, voting, and acceptance tests adds complexity to the software and thus inherently increases the safety risk. Rigorous software verification by means of testing, analysis, and inspection always is required (46). The recommended option to reduce the impact of potential safety violations and fault propagations includes the use of firewalls for safety-critical modules. Such firewalls can be accomplished by placing the source in separate translation units (separate files) and declaring all external functions and data inside the module as static (private in C++), with the only not-static functions being external ports (public in C++).

Partitioning is a fundamental concept used to implement differing levels of protection in systems combining both critical and non critical software. Partitions are used in fault-tolerant systems that require high availability, redundancy, or dynamic re-configuration (47). Traditionally, partitioning has been implemented via memory address space to ensure that the non critical and critical codes do not use the same physical resources. A microprocessor supervisor/ user mode can be a vehicle to implement such partition. The increasing demands on reliability and dynamic reconfiguration require the use of an explicit *spatial firewall* often implemented as a memory management unit. Additionally, a *temporal firewall* implemented by the run-time executive may be used. Such a solution may include fixed time-slice round-robin scheduling of all partitions or implementation of a partition priority scheme such that the critical partition gets as much CPU time as it needs.

Some modern real-time operating systems (RTOS) support partitioning adhering to standards such as the ARINC 653 Application Executive (APEX) for integrated modular avionics (48). The partitioned system executive consists of two major parts: (a) the operating system kernel that controls the scheduling of and the communications between the partitions that are resident on that processor and (b) the partition operating system that supports the internal scheduling of each of the partition threads and the mechanism to detect and respond to error situations within the application partition.

Safety Kernels

The software in safety-related systems must have certain behavioral properties to be considered safe. These properties can be expressed as predicates that the software must maintain with respect to its inputs, outputs, and states. Showing that the software for a particular system satisfies a given set of predicates is a verification problem, which typically is carried out via combination of analyses, tests, and inspections. More formal analysis for code of a significant size is difficult and expensive. One useful strategy is to design the software so that the most rigorous analysis can be applied to a relatively small portion of the entire software, with conventional methods applied to the remainder of the software.

Safety kernels are small, relatively simple units, which ensure desired particular behavior for the overall system without making any assumptions about the proper functioning of the remaining software. Kernels have a successful history in operating systems as a means of protecting access to computing resources and in security applications as a means of preventing unauthorized information flow. Because of the small size of the kernel, it can be thoroughly tested, analyzed, and verified. To enforce safety, two conditions must hold: (a) All predicates describing safe operation at the system level must be under the kernel control, and (b) an arbitrary behavior external to the kernel cannot impact the predicates (17).

SAFETY IN THE LIFECYCLE

Successful software safety can be implemented only as part of an overall system safety program. A continuous coordination and open communication between systems engineers, system safety personnel, software developers, software assurance personnel, and project management is the key to success. The critical steps to achieve software safety is first to perform rigorous safety analysis of the system, identifying the role and impact of software on safety. The identification of hazards and failure modes attributed to software allows developers to trace the safety requirement to software components and to appropriate testing procedures.

For software developers building safety-critical systems, an ideal and practically impossible objective to realize is to develop complete and correct requirements, a defect-free design, and a fault-free software implementation. Thus, the accepted feasible approach is to develop fault-tolerant designs, which will detect and compensate for software faults while the system is operating.

Depending on their placement in the system development lifecycle, the hazard analyses may have variety of forms (15):

- Preliminary Hazard List (PHL), to identify potential hazards/mishaps in the conceptual phase of developing a system
- Preliminary Hazard Analysis (PHA), to analyze the hazards and establish the initial system safety requirements
- Subsystem Hazard Analysis (SSHA), concentrating on the system components to identify hazards causal factors, effects, risks, and mitigation measures
- System Hazard Analysis (SHA), focusing on integration to ensure that overall system risk is known and accepted
- Operating/Support Hazard Analysis (OSHA), with a focal point on the procedures and human interface to assess the safety of operations
- Safety Requirements/Criteria Analysis (SRCA), to ensure that all identified hazards match their respective safety requirements and that they can be validated

IEC 61508 standard (49) identifies two types of safety requirements: safety function requirements and safety integrity requirements. The *safety function requirements* define the input/output sequences that perform the safety-critical operation. For example, a boiler could have a pressure sensor (input) that can reach a maximum value (algorithm) before the gas is shut off (output) to the burner. The *safety integrity requirements* define diagnostics and fail-safe mechanisms used to ensure that failures of the system are detected and that the system goes to a safe state if it is not capable of performing a safety function. Examples of integrity elements in the boiler would be a current-range diagnostic on the pressure sensor or a watchdog timer. If either of these elements detected a failure, they could force the system to a safe state.

The *Software System Safety Handbook* (24) divides safety requirements into two categories: generic and specific. The *generic software safety requirements* are domain independent and are applicable to common safety problems.

Generic requirements address such issues as the need for detection, isolation, and recovery from any failure of a safety-critical software function, checking the prerequisite conditions, status, and handling of software inhibits by the modules and assuring return to safe state/mode; they also use self-tests, unused code, configuration, fault containment, exception handling, error propagation, and so forth. The complete list of generic software safety requirements can be found in the Appendix E of the *Handbook* (50). The *specific, software safety requirements* include application-specific, system-unique constraints that can be identified in three ways (50):

(a) Top-down analysis of system requirements to identify system hazards and to specify which system functions are safety-critical. The entire safety organization participates in the mapping of these requirements to the software.

(b) Preliminary hazard analysis considers whether system hazards are mapped to the software. Software hazard-control features are identified and specified as requirements.

(c) Bottom-up analysis (e.g., flow diagrams, failure modes, effect analyses, fault trees) where the design solutions are analyzed and new hazard causes can be identified.

STANDARDS AND CERTIFICATION

A safety standard is a systematic approach to assure safety that is codified by a regulatory authority organization. The purpose of such a standard is to improve the safety of a critical system, to specify minimum standards of design and development techniques within the relevant industry, to encourage a structure of professional responsibility, to promote uniformity of approach between different teams and industries, as well as to provide legal basis in the case of a dispute.

Certification (or approval) is a process of getting a formal approval from a statutory authority (government or industry) to use the product. Depending on the determined system safety integrity level, an independent verification and validation (IV&V) effort may be required to get the system certified (from another developer, department, organization, or governmental agency). Collection of appropriate supporting evidence, particularly safety-related, in a format defined by standards and guidelines is the basis for the certification. Certification indicates a conformance to standards or guidelines and can be applied to individuals, organizations, tools, methods, systems, or products.

In other terms, certification is a legal recognition by the authority that an entity (product, service, organization, or person) complies with the applicable requirements. The objective of certification is to improve safety of the product by (51):

- enforcing minimum safety standards,
- increasing the awareness of safety,
- improving organizational structure, and
- encouraging professional responsibility.

The developer needs, therefore, to prepare and present the safety case that proves adherence to standards, which typically is a huge investment of time and resources.

Table 3 represents selected standards used in the development of safety-critical systems. The focus is on the standards directly related to the systems with significant software components.

The Functional Safety: The Safety Related Systems IEC61508 standard (49) was issued by the International Electrotechnical Commission in 1995. This standard is accepted in Europe as a generic standard for the functional safety of a programmable electronic system with a focus on product functionality in terms of the entire system, not only the software. Part 3 of the document (IEC 61508-03) is dedicated to software safety. Meeting the requirements of IEC 61508 for software development involves a systematic process, which emphasizes requirements traceability, criticality analysis, and validation.

Three major guidelines for ensuring safety of software intensive systems are: RTCA DO-178B (aviation), NASA-STD-8719.13A (aerospace), and MIL STD 882C/D (military).

Aviation

In 1980, the Radio Technical Commission for Aeronautics, now RTCA, Inc., convened a special committee to establish guidelines for developing airborne systems. After two revisions, DO-178B was published in 1989 (19). The FAA Advisory Circular AC20-115B mandates use of DO-178B for the development of software in airborne systems. The FAA Order 8110.49 compiles a variety of guidelines related to the use of software in airborne systems (52). Chapter 10 of the *FAA System Safety Handbook* (53) addresses issues of software in airborne system development.

DO-178B addresses the issue of lack of software visibility at the system level by describing ihe system aspect of software development, software lifecycle, planning, development, verification, configuration management, quality assurance, certification, required data, and additional considerations. The document amplifies the notion that safety assessment is a hierarchical process including functional hazard analysis on the aircraft and at the system level, common cause analysis, preliminary system safety assessment, and system safety assessment (SSA). The SSA documentation includes a system description, event probabilities, and classification and analyses of failure conditions. DO-178B defines safety and reliability categories for airborne equipment (catastrophic 10^{-9}, hazardous 10^{-7}, major 10^{-5}, minor 10^{-3}, and no effect) and their relation to the development assurance levels from the highest A to the lowest E. The main element of DO-178B are ten tables of objectives related to lifecycle processes described in the guide. Each table includes entries for an objective (identifier, description, and document section reference), applicability by software level, required artifacts, and control category. The objectives can be satisfied either with or without independence, conditional on the assurance level. The focus is on the lifecycle transition criteria and traceability.

Table 3. Selected safety/software standards

Domain	Standards/Guidelines	Organizations Involved
Aerospace	• RTCA/DO-178B • NASA-STD-8719.13A • NASA GB-1740.13-96 • ECSS-Q-80A	• FAA : Federal Aviation Administration, • NASA : National Aeronautic and Space Agency • EUROCAE : European Organisation for Civil Aviation Equipment • RTCA : Radio Telecommunication Committee for Aviation • ESA - European Space Agency
Military	• MIL-STD-882C/D • DEF STAN 00-55	• DoD : Department of Defense • MoD: Ministry of Defence
Nuclear	• EC 60880 Ed. 2,2006 • AECL CE-1001 rev 2 • IEC 62138, 2004	• CANDU : Canada Deuterium Uranium
Transportation	• EN 50128 • IEC 62279, 2002 • MISRA Guidelines	• MISRA : Motor Industry Software Reliability Association
Biomedical	• IEC 601-1-4 (1996-06) • ANSI/AAMI SW68 • ANSIUL1998 • AAMI TIR32:2004	• FDA : Food and Drug Administration
Generic	• IEC 61508-3, 1998 • IEC 61511-1,2003 • AS 61508.3,1999 • IEEE 1228-1994	• IEC - International Electrotechnical Commission • IEEE - Institute of Electrical and Electronic Engineers • ANSI - American National Standards Institute • CENE - Comité Européen de Normalisation Electrotechnique

Software development processes artifacts defined in the DO-178B include the plan for software aspect of certification (PSAC), development, verification, configuration management and quality assurance plans, design and code standards, requirements and design specification data, source and executable code, verification procedures and test cases and their results, life cycle configuration index, problem reports, configuration management and quality assurance records, and the software accomplishment summary (SAS). The PSAC and SAS are obligatory, whereas others need to be either submitted to the certifying authority for review or made available when requested, depending on the assessed criticality of the system.

Aerospace

The *NASA Software Safety Guidebook* NASA-STD-8719.13A (54) replaces the older NSS1740.13. The standard defines whether the software is safety-critical and describes the activities necessary to ensure that safety is designed into the software. This standard also specifies the software safety requirements, activities, data, and documentation necessary for the acquisition or development of software in a safety-critical system. The standard describes the general purpose of a safety process and the minimal requirements for a safety process (as a list of "shall" statements for specific stages of the software lifecycle) with an emphasis on IV&V.

For a software quality analysis process, the following activities are prescribed:

- Evaluation of standards and procedures
- Audits of management, engineering, and assurance processes
- Reviews of project documentation
- Monitoring of formal inspections and reviews
- Monitoring/witnessing of formal acceptance-level software testing

For software quality engineering process, the following activities are recommended:

- Analysis, identification, and detailed definition of quality requirements
- Evaluations of standards, design, and code
- Collection and analysis of metric data pertaining to quality requirements

Military

System Safety Program Requirements MIL-STD-882C was released in 1993 (20) and the updated version Standard Practice for System Safety MIL-STD-882D in 2000 (5). The standard focus is on the entire system rather than on the software specific components. In version 882C entire sections are dedicated to the software safety, and the appendix identifies specific tasks associated with management and engineering. In contrast, version 882D mentions software only three times, and the specific tasks are not described clearly. The standard identifies acronyms and definitions, general requirements (approach, hazards and risks mitigation, and hazard reduction), and the detailed requirements—delegated to appendix as guidelines. The main objective of the standard is to reduce or eliminate hazards via the following mitigation measures:

- Hazard elimination through design selection
- Incorporation of safety devices (with periodic functional checks of the devices)
- Use of warning devices to detect the hazard condition and to produce warning signals
- Development of operating procedures and training for personnel
- Reduction of risk to acceptable level
- Performing verification and risk assessment review
- Tracking hazards

The STD-882D defines hazard severity categories (I–IV: catastrophic, critical, marginal, and negligible) and probability levels (A–E: frequent, probable, occasional, remote, and improbable). It also provides the related definition of risk levels (high, serious, medium, and low), their impact, approaches, and mitigation measures, as well as the system safety design order of precedence (i.e., the order to be followed for satisfying system safety requirements and reducing risks). The standard also provides the definition of system safety planning (objective, organization, milestones, reporting, approach, and methodology), safety performance requirements (quantitative and standards), and safety design requirements.

SOFTWARE SECURITY

Software security is a branch of computer security that addresses enforcement of secure behavior of development and operation of software systems. As shown in Fig. 1, computer security consists of four layers: crypto, protocols, systems and languages, and applications (1). Although the crypto and protocol layers often involve software and operating systems and programming languages are in essence software, software security is primarily concerned with security issues at the application layer. It is built upon the crypto, protocols, and systems and languages layers. The goal is to prevent, detect, and recover from software attacks that violate application-specific security requirements with respect to confidentiality, integrity, and availability (CIA). Confidentiality, integrity and availability refer to the concealment, trustworthiness, and desired use of information and resources (2).

Software security has been a major source of cyber security risks for many reasons. First, many attacks against a company's network come at the application layer. They bypass the traditional security mechanisms at the crypto, protocols, and systems layers (e.g., firewall and intrusion detection, to name a few). However, protection of software applications is in general beyond the capabilities of these mechanisms because they lack knowledge of application semantics. For example, a firewall cannot distinguish between the traffic of an attempted attack and the traffic of legitimate use of an application through the open ports. Second, software security is often added as an afterthought near the end of software development. It is well-known that "penetrate-and-patch" is a common yet dumb practice for software security. Although secure coding is important, software security requires a lot more beyond coding. For example, a large portion of the security flaws uncovered during Microsoft's "security push" in 2002 were closely related to design-level problems (3). Principled use of assurance techniques is yet seldom adopted throughout software development processes (4). Last, a lack of well-trained workforce exists for secure software development. Software security has not gained much attention until recently.

It is well accepted that software security should be addressed throughout software development processes. The rest of this article discusses software security from the software engineering perspective. It serves as an overview of secure software engineering.

THE ADVERSARY'S PERSPECTIVE OF SOFTWARE SECURITY

As mentioned before, the goal of software security is to prevent, detect, and recover from software attacks. Attacks are misuses and anomalies of the intended system functionality. They violate the security goals of information, resources, and services. Consider a web-based shopping cart application. One of its intended functions is to allow customers to purchase goods online. A potential misuse of this intended function is that the customers may purchase goods at reduced prices by unexpected modification to the price data. This misuse violates integrity of the price data. The adversary's perspective of software security refers to the idea that thinks of software security from the standpoint of how an adversary would attack or exploit a software application. A software application should be considered insecure until demonstrated to be resistant to all potential attacks. Strictly speaking, no software is absolutely secure. We refer to the potential attacks as security threats.

As shown in Fig. 2, the adversary's perspective of software security advocates that security threats should be identified according to the security objectives imposed on the intended functions, services, and related information and resources. The information and resources that a software system must protect from attacks are called assets. They are potential targets of attacks. The security threats then suggest what, where, and how security features for threat mitigation should be applied. Thus, the intended functions and threat mitigations together form a system that is secured from the identified security threats. The adversary perspective of software security can be applied throughout the software development processes, which include from requirements analysis, design, implementation, testing, and deployment.

Amplification of Vulnerabilities in Software Development Processes

Security threats are caused by security vulnerabilities in software artifacts (e.g., design and code). A vulnerability is a security flaw that represents a valid way for an adversary to realize one or more threats. An unfortunate fact is that more vulnerabilities and hence more security threats may emerge when the development moves from one phase to the next (e.g., from design to implementation). We call this phenomenon amplification of vulnerabilities in software development processes, as shown in Fig. 3 where each shaded circle represents a vulnerability. On one hand, one vulnerability in the artifact of an earlier software development phase can result in multiple vulnerabilities in a later development phase. For example, a missing or incomplete security requirement can lead to several vulnerabilities in the design and code. On the other hand, design and implementation may introduce new security holes that are specific to the design and implementation choices. For example, the design of a web-based shopping cart application that relies on client-side input validation may leave a vulnerability that can be exploited to purchase goods at modified and reduced prices. Using C as the implementation language may result in C-specific buffer overflow vulnerabilities. Amplification of security

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

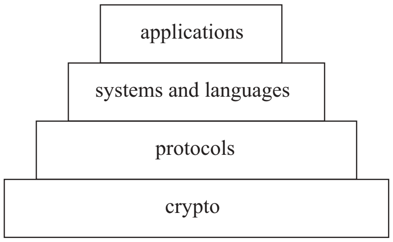

Figure 1. Layers of computer security (1).

vulnerabilities requires that threat modeling, risk assessment, threat mitigation, and risk control should be conducted in each development phase. The earlier the vulnerabilities are found, the cheaper the cost to fix them.

Threat Modeling

To better understand security requirements and solutions, it is important to identify, specify, evaluate, prioritize, and mitigate security threats. Threat modeling is the process of producing a simplified, abstract description of how an adversary would perform potential attacks or pose security threats to the system. It can be conducted at various levels of abstraction and granularity or in various software development phases—requirements, design, implementation, and even testing.

Several notations have been proposed for threat modeling, such as misuse cases (based on use case modeling), threat trees (a variation of fault trees for safety analysis), threat nets (based on Petri nets), anti-goals (based on goal-oriented requirements analysis), and threat traces (based on sequence diagrams or activity diagrams). Among these notations, threat trees and misuse cases have been widely applied. Threat trees [or attack trees (6)] represent security threats in a tree structure, with the goal as the root node and different ways of achieving that goal as leaf nodes. Figure 4 shows a sample threat tree. The goal of the threat is to obtain another person's username and password. To achieve this goal, the adversary must obtain a valid username AND a valid password for the username. To obtain a valid username, the adversary can either use an error string from the login page to determine username validity OR trick a user to disclose her username. Similarly, to obtain a valid password of the username, the adversary can either use the login page to guess the password by brute force OR trick the user to disclose her password. In general, AND nodes represent different steps toward achieving the same goal, whereas OR nodes are alternatives. A threat tree implies attack paths through which the threat can be accomplished. Each attack path is a route from a leaf to the root, inclusive of AND nodes. For example, the threat in Fig. 4 has four attack paths. It is also possible to compose threat trees. A threat tree can represent a node in another threat tree. In addition, threat trees can be documented in a textual form. Figure 5 shows the textual description of the threat tree in Fig. 4. Threat trees are simple and easy to understand. For rigorous modeling, however, formal methods such as Petri net can be applied (5).

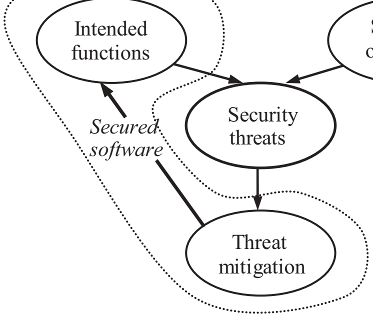

Figure 2. The adversary's perspective of software security (5).

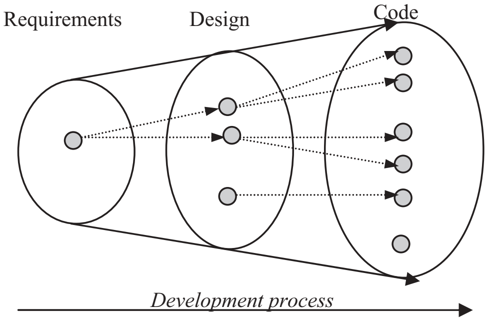

Figure 3. Amplification of security vulnerabilities in software development processes.

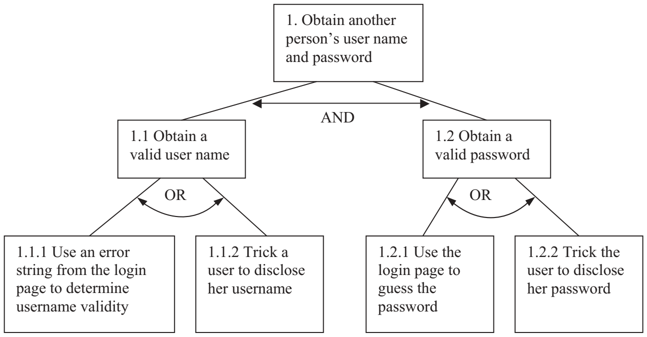
From the adversary's perspective of software security shown in Fig. 2, threat modeling should not be independent of system modeling. System modeling should deal with both intended functions and threat mitigations (security requirements or mechanisms). A threat makes no sense if it is irrelevant to the intended functions. For example, the node 1.1.1 in Fig. 4 indicates that the system offers a login page. Threat modeling and system modeling may exploit different modeling notations. For example, the Microsoft's threat modeling approach (7,8) uses data flow diagrams for system modeling and threat trees for threat modeling, Xu and Nygard's approach (5) uses Petri nets as a unified formalism for system modeling and threat modeling.

To select appropriate notations for threat modeling and system modeling, the following issues should be taken into consideration:

- The notations for threat modeling and system modeling must be able to express the desired level of abstraction. Security threats make sense only when they are defined with respect to the intended functions at the same level of abstraction. For example, misuse cases are suitable for capturing security threats at the requirements phase because they are based on the use case modeling approach to requirements analysis. However, they are probably inappropriate for modeling threats at the level of detailed design.
- The notation for system modeling must be able to capture the information, resources, and services that



1. Obtain another person's user name and password
AND
1.1 Obtain a valid user name
1.2 Obtain a valid password
OR
OR
1.1.1 Use an error string from the login page to determine username validity
1.1.2 Trick a user to disclose her username
1.2.1 Use the login page to guess the password
1.2.2 Trick the user to disclose her password

Figure 4. A sample threat tree.

should be protected but can be threatened. A threat is meaningless unless it involves some asset or target that is of interest to the adversary.

- The notation for threat modeling must be able to capture the interaction between the threat model and the system model. A threat is meaningless unless it involves some way through which the adversary can interact with the system. In other words, threat models must be traceable—it can be determined which part of the intended functionality is relevant to a given threat and which part of the system mitigates the threat if the threat is claimed to be mitigated.

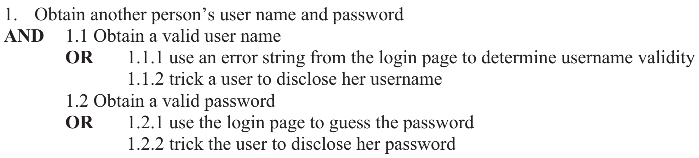
Threat identification is often a challenging task before threat modeling can be done. In general, we can identify security threats in terms of security objectives (e.g., CIA), threat catalogs, and threat elements (assets of interest to the adversary and way of interaction with the system).

- Identifying threats with respect to security objectives. We can check each intended function and related information and resources to see if it can be misused to violate confidentiality, integrity, or availability. For example, purchasing goods online is an intended function in a shopping cart application. To elicit security threats, we can ask such questions: Could the adversary purchase goods without payment or at reduced price? Could the adversary put the system out of service?
- Identifying threats using threat catalogs or checklists. We can use a security catalog (a list of threat types) to elicit security threats. For example, Shirey (14) categorizes security threats as disclosure (unauthorized access to assets and services), deception (acceptance of false data), disruption (interruption or prevention of correct operation), and usurpation (unauthorized control of some part of a system). Howard and LeBlanc's STRIDE catalog (7) includes spoofing (an impersonation of one entity by another), tampering (unauthorized change of data), repudiation (a false denial that an entity sent or created something), information disclosure (unauthorized access to information or exposure of protected data), denial of service (a long-term inhibition of service), and elevation of privilege (access to assets with a higher security context than intended). Different threat catalogs can be overlapping. For example, spoofing is a form of both deception and usurpation; tempering is a form of deception, disruption, and usurpation; repudiation is a form of deception; and denial of service is a form of usurpation.
- Identifying threats in terms of assets and system interactions.
  A meaningful threat must involve assets of interest to the adversary and a way of interacting with the system. We can identify threats by inspecting whether the information and resources (e.g., patient information) and the user interface (e.g., input of user name and password) can be misused or exploited.

Assessment of Security Risks

Security threats are unwanted risks that have negative consequences. After security threats have been identified and specified, we can evaluate their risks quantitatively and decide how to control the risks. As security threats are ubiquitous, the quantitative evaluation helps prioritize the threats. With limited budget and resources, for example, we can choose to mitigate the threats that are of highest risks.

Risk exposure is a traditional approach to quantifying the effects of risks. The risk exposure of a threat is the multiplication of the risk impact (i.e., the loss associated with the threat) by the risk probability (i.e., the likelihood that the event will occur). Consider the disclosure of patient information as an example. If the likelihood of this threat is 0.4 and the loss caused by such an attack is $100,000, then the risk exposure of the threat is $40,000. Although threat mitigation reduces security risks, it may not be possible or practical to completely remove the risks. In particular, a threat mitigation technique, (e.g., SSL) may have its own



```
1.   Obtain another person's user name and password
AND     1.1 Obtain a valid user name
        OR       1.1.1 use an error string from the login page to determine username validity
                 1.1.2 trick a user to disclose her username
        1.2 Obtain a valid password
        OR       1.2.1 use the login page to guess the password
                 1.2.2 trick the user to disclose her password
```

Figure 5. The textual description of a threat tree.

Table 1. An Example of DREAD Risk Rating

Threat Description	Attacker Manipulates Patient Information
Threat target	Patient data
Threat category	Tempering with data and potentially information disclosure
Risk	Damage potential: 10 Reproducibility: 7 Exploitability: 8 Affected users: 10 Discoverability: 10 Overall: 9
Comments	This threat concerns accessing the patient information as it travels across the network.

threats. We must take into account the cost of threat mitigation and the security risks after the mitigation. To do so, we can measure the risk leverage of threat mitigation. It is the difference in risk exposure divided by the cost of mitigating the threat. Formally, risk leverage is equal to (risk exposure before mitigation-risk exposure after mitigation)/ cost of mitigation.

If the leverage value of the threat mitigation technique is not high enough to justify the action, then we can look for other mitigation techniques.

Microsoft's DREAD is another way to evaluate the risks of security threats. For each threat, the damage potential, reproducibility, exploitability, affected users, and discoverability are rated on a scale of one to ten. The bigger the rating, the greater the risk the threat poses to the system. The overall risk is determined by averaging the five ratings. As an example, Table 1 shows the DREAD ratings of threat "attacker manipulates patient information."

Threat Mitigation

Different strategies are used for dealing with the risks of security threats. Primary examples include (*1*) assuming the risks without taking any action, (*2*) avoiding the risks by changing functional or performance requirements such that the threats no long exist, and (*3*) adopting security requirements or techniques to mitigate the threats. To reduce the threat of spoofing, for example, we can add an authentication requirement. To meet this requirement, several security techniques are available, such as digest, Kerberos, and passport. To mitigate the threats of tempering with data, we may choose from authorization, message authentication codes, digital signatures, and temper-resistant protocols, e.g., SSL/TLS. A partial list of mitigation requirements and techniques for the STRIDE threats can be found in (7). In addition, security design patterns can also serve as general mitigation techniques.

A mitigation requirement or technique may countermeasure multiple threats. For example, authentication is useful for mitigating both spoofing and denial of service. One threat (e.g., information disclosure) may entail multiple mitigation techniques. When a mitigation requirement or technique is applied, the threat model and system model should be updated to reflect the decision. This model will improve the traceability of threats and mitigations within a development phase and across different development phases.

Appropriate applications of mitigation techniques can significantly reduce the risks of security threats. it does not mean that the software will be absolutely secure. Security threats are ubiquitous. Even if it is possible to identify all threats, mitigation of all threats is in general beyond the availability of required resources. Moreover, mitigation requirements and techniques are subject to their own threats. It is not realistic to expect the prevention of all potential attacks, although the process of threat modeling, risk assessment, and threat mitigation within a development phase is often repetitive. The process would stop when, for the limited resources available, the level of security has become acceptable, and the unmitigated threats are believed to be sufficiently expensive for an adversary to accomplish. Prevention of attacks is critical, but it is not the only goal of software security. Security-intensive software should also address issues that pentain to the detection of and recovery from attacks. Auditing such as logging and monitoring is a common approach to this end. Auditing is also critical to forensics, the goal of which is to investigate when and how an attack has happened and who is responsible.

REQUIREMENTS ANALYSIS OF SECURE SOFTWARE

The requirements analysis process for building a software system aims at capturing precisely what to build. The requirements of a software system include functional requirements, nonfunctional requirements, design constraints, and process constraints (9):

- A functional requirement describes required behavior in terms of required activities, such as reactions to inputs.
- A nonfunctional requirement, or quality requirement, describes some quality characteristic that the software solution must possess, such as fast response and ease of use.
- A design constraint is a design decision, such as choice of platform or interface components, that has already been made and that restricts the set of solutions.

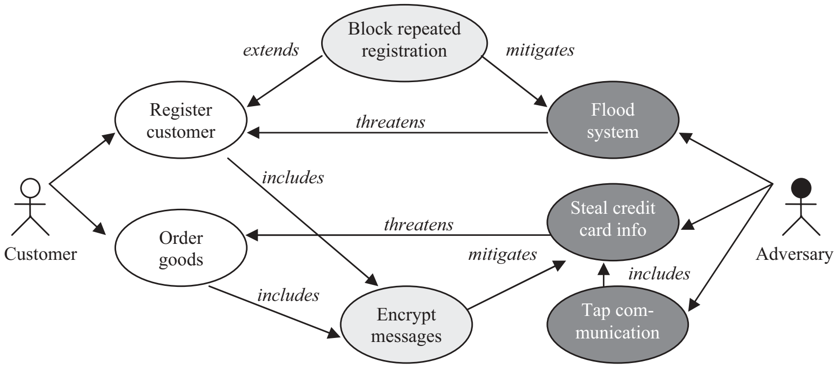


Figure 6. A use/misuse/mitigation use case diagram.

- A process constraint is a restriction on the techniques or resources that can be used to build the system.

In general, security requirements are nonfunctional requirements. However, they can entail functional requirements and additional constraints on the development process. For example, user registration can be considered as a functional requirement that is raised by the need of authentication. Security requirements are not independent of functional requirements, design constraints, or process constraints. Security requirements analysis should therefore be an integral part of the requirements analysis process. Modeling notations for security requirements are usually extensions to those for functional requirements. For example, the misuse case approach (10–15) is based on the use case approach, the anti-goal approach (16) is based on the goal-oriented requirements analysis, and the abuse frame approach (17) extends the problem frames.

Misuse Cases

The misuse case approach centers a round an interactive modeling of use cases, misuse cases, and mitigation use cases. From the adversary's perspective, use cases, misuse cases, and mitigation use cases (or security use cases) describe the intended behaviors (i.e., functional requirements), security threats, and security mitigations (i.e., security requirements), respectively. In the interactive modeling, we first identify use cases; each use case defines the interaction between an external actor (role played by a person or thing) and the system to accomplish a goal. Then, we identify potential misuse cases with respect to the use cases; each misuse case defines the interaction between an adversary (or mis-actor) and the system to accomplish the goal of attacking the system by exploiting the use cases. For example, "Steal credit card information" is a misuse case that threatens the use case "Order goods" in an online shopping application. Finally, mitigation use cases are suggested as countermeasures of the misuse cases. Each mitigation use case defines the requirement for mitigating the misuse cases. For example, "Encrypt messages" is a mitigation use case for the misuse case "Steal credit card information." The interactive modeling is often iterative, starting with a small set of use cases and dealing with more use cases in the next iteration. As mitigations are subject to misuses, misuses of mitigation use cases should also be examined in each cycle.

Use/misuse case diagrams and textual descriptions are often used to document use cases, misuse cases, and mitigation use cases and the relationships among them. Figure 6 shows some use cases ("Register customer" and "Order goods"), misuse cases ("Flood system", "Steal credit card information", "Tap communication"), and mitigation use cases ("Block repeated registration," "Encrypt messages") in an online shopping application. As in the traditional use case approach, "includes," "extends," and "generalization" can be used to label the relationships between misuse cases. For example, "Steal credit card information" includes "Tap communication." These relationships may also exist between mitigation use cases and regular use cases. "threatens" can be used to label the link from a misuse case to the corresponding use case(s), and "mitigates" to depict the relationship between a mitigation use case and the corresponding misuse case.

A use/misuse/mitigation use case diagram provides a high-level view of the intended functions and security requirements. To better understand the system, however, many details need to be described. In Fig. 6, for example, "Steal credit card information" is a misuse case with regard to the use case "Order goods." It makes no sense unless the use case requires the customer to provide credit card information. To complement a use/misuse/mitigation use case diagram, textual descriptions are often used to capture the detailed use cases, misuse cases, and mitigation use cases. A use case template in the traditional use case approach, although no standard, exists usually includes case number, case name, goal, actors, preconditions, main flow of events, alternative flows, related business logic, and postconditions. This template can be used as a basis for describing use cases, misuse cases, and mitigation use cases. To keep track of the relationships between use cases, misuse cases, and mitigation use cases, we can add a new entry for enumerating misuse cases and mitigation use cases to the template for use cases and mitigation use cases. Table 2 shows the textual description of the use case UC 11 "Order goods." In Step 6 of the main flow of events, the customer submits credit card information. This is where

Table 2. Textual Description of the Use Case "Order Goods"

Case Number	UC11
Case name	Order goods
Goal	To order goods from the system
Actors	Customer, system
Preconditions	1. The customer is registered. 2. The customer has logged on to the system.
Main flow of events	1. The customer enters order goods section. 2. The system displays the customer's account detail. 3. For each product that the customer wishes to order, the customer enters its identity. 4. The customer provides delivery details. 5. The system calculates and displays the price of the goods ordered. 6. The customer submits credit card information. 7. The system confirms the result of transaction. 8. The system collects the detail of the order. 9. The system processes the order.
Postconditions	1. The order and its detail are entered in the system and the order is processed.
Misuse cases and mitigation cases	MC10 Steal credit card info (Step 6 in the main flow of events) SC5 Encrypt messages

the use case is threatened by the misuse case MC 10 "Steal credit card information." Therefore, the last entry of the table lists the misuse case (MC10) and the corresponding mitigation use case (SC 5).

Anti-Goals

The anti-goal approach (16) is based on the goal-oriented requirements analysis, in which goals prescribe intended behaviors. Goals may refer to the intended services (functional goals) or to quality of service (nonfunctional goals). They are organized in AND/OR refinement-abstraction hierarchies in which higher-level goals are strategic and coarse grained, whereas lower-level goals are technical and fine grained. AND-refinement links relate a goal to a set of subgoals whereas OR-refinement links may relate a goal to a set of alternative refinements. Goal refinement ends when every subgoal is realizable. A requirement is a terminal goal under responsibility of an agent (active component such as a human and device).

To produce requirements for more robust systems, obstacle analysis (18) takes a pessimistic view at the goals. It tries to identify and resolve as many ways of obstructing the goals as possible. An obstacle to some goal is a condition that prevents the goal from being achieved. In the context of security, threats are obstacles or anti-goals intentionally set up by attackers. Threat trees are built systematically through anti-goal refinement until leaf nodes are either software vulnerabilities or anti-requirements. New security requirements are then obtained as countermeasures by application of threat resolution operators to the specification of the anti-requirements and vulnerabilities.

SECURE SOFTWARE DESIGN

Secure software design is a process of transforming the software security problem into a solution. It must meet the security requirements and avoid potential vulnerabilities caused by the design decisions.

Principles of Secure Design

In addition to the principles of traditional software design, such as abstraction and modularization, the design of secure software should also follow the general principles for security design. Six principles of secure software design are discussed below. Although they all originate from the general design principles of computer and information security (19), the discussion below places an emphasis on software applications. When these principles are applied to a specific application, they may need to be scoped and revisited to resolve potential conflicts. More design principles can be found in Refs. 20–22.

Least Privilege. The principle of least privilege states that a subject (user or software component) should be given only those privileges necessary to complete a task. If a subject does not need access to an object to perform its task, then it should not be granted that access privilege. If a subject needs extra privileges required of a specific action, then the extra privileges should be relinquished immediately on completion of the action. For example, if a web server is only responsible for serving marketing pages, then it should only be given access to the exact set of files it serves to its clients.

Simplicity. The principle of simplicity is also known as the principle of economy of mechanism. It states that security design should be as simple as possible. Complex design is more difficult to understand, test, and maintain. It is likely to have more possibilities for errors. For example, the UNIX sendmail utility that routes mail from a sender to a recipient is a complicated program with many security holes. Complex design often makes assumptions about the system and environment. Security problems may develop when these assumptions are made incorrectly. To achieve simplicity and reduce the number of security holes, a secure design should try to localize security checks. For example, choke points and aspect-orientation can serve this purpose. A choke point is a centralized component through which all control must pass. Aspect-orientation can modularize security concerns into separate components.

Secure Defaults. The principle of secure defaults states that a user or software component should be denied access to an object unless it is given explicit access to that object or the access request is found to be consistent with security policy. When the software is designed, it should, by default, be optimized for security wherever possible. The principle of secure defaults is of particular importance for software deployment—the initial configuration should not turn on every possible feature and make every service available to the user by default.

Secure Failure. The principle of secure failure states that a failure or exception in a function or mechanism should not lead to violation of security policy. When the failure or exception occurs, the software should be kept in a state that denies rather than grants access. When a user or software component has access to an object but cannot complete its task, it should still ensure some level of security. It should undo the changes that it had made in the secure state of the system before it terminates. It should not report error messages that reveal useful information to malicious users. For example, a basic trick of Structured Quens Language (SQL) injection attacks is to first determine the names of data fields in a database by exploiting the error messages for maliciously crafted SQL queries. Some SQL servers by default include the names of data fields in the error messages.

Defense in Depth. The principle of defense in depth states that a secure design should manage security risk with diverse or hierarchical strategies rather than rely on any one defense. As mentioned before, mitigation techniques or secure mechanisms cannot prevent all potential attacks because they are subject to their own threats. To protect sensitive information on a server, for example, one can integrate a hierarchy of defense strategies, such as a firewall, authentication, encrypted storage, and encrypted messages. The defense in depth would significantly increase the difficulty and costs of a full breach. This defense also contributes to secure failure—the software can continue securely even when one strategy has failed. As mitigation techniques are not perfect, a secure design should also consider mechanisms that help to detect and recover from attacks.

Usability. The principle of usability states that security mechanisms should not make the software more difficult to use than if the security mechanisms were not present. The extra burden on users added by the security mechanisms should be minimal and reasonable. From the usability study of a program for sending and receiving encrypted email, Whitten and Tygar (23) observed that most users were not able to successfully send or receive encrypted e-mail, even though the user interface seemed "reasonable." According to Whitten and Tygar, secure software is usable if the users: "(1) are reliably made aware of the security tasks they need to perform; (2) are able to figure out how to successfully perform those tasks; (3) don't make dangerous errors; and (4) are sufficiently comfortable with the interface to continue using it."

Security Design Patterns

As many security problems are shared by various distributed applications, security design patterns can provide reusable security solutions from application to application. A security design pattern is a generic, well-understood solution to a recurring security problem. For example, passwords are a widely accepted approach to remote user authentication. To mitigate the common threat of password cracking via brute force (e.g., guessing), one can block repeated password attempts through the security pattern "account lockout." This pattern imposes on a limit on the number of incorrect password attempts. More patterns can be found in Refs. 26 and 27.

Beyond design patterns, security patterns can also be used to improve the development process of secure software. For example, the Security Patterns Repository (Version 1.0) (24) describes 13 patterns (called procedural patterns) that often impact the organization or management of a software development project.

SECURE CODING

Secure design does not automatically guarantee a secure implementation. Secure coding must not only correctly implement all security policies and mechanisms (e.g., authentication and authorization) of a secure design, but also it must avoid potential implementation-level vulnerabilities caused by the chosen programming languages, compilers, tools (e.g., database systems and commercial software packages), and platforms (e.g., operating systems). Relatively more work has occurred on secure coding than any other aspects of secure software development. A great variety of implementation-level vulnerabilities and countermeasures has been identified. A root cause for most vulnerabilities is inadequate validation of inputs from users and software components (of course, adequate input validation is not as easy as one might think). This section introduces a few of the most common problems (buffer overflow, format string, SQL injection, and cross-site scripting). Some good practices of secure coding are also suggested. For further reading, we refer the reader to Refs. 3, 7, 21, 22, 27 and 28.

Buffer Overflow

Buffer overflow has been and likely continues to remain the principal method for remotely injecting malicious code into target software. A buffer overflow, or buffer overrun, is an anomalous condition in which a program attempts to store data beyond the boundaries of a buffer (e.g., stack and heap) because of insufficient bounds checking. For example, it can happen if a string of characters is copied from one buffer to another when the length of the string is greater than the size of the target buffer. As a consequence, adjacent memory is overwritten by the extra code and data that may cause a program to crash or produce incorrect results. In particular, the extra code and data can be injected maliciously to make the program operate in an unintended way.

The techniques to exploit buffer overflow fall into two categories: stack overflow and heap overflow. An exploit of stack overflow attempts to manipulate a program by (*1*) overwriting a local variable that is near the buffer in memory on the stack to change the behavior of the program, (*2*) overwriting the return address in a stack frame, or (*3*) overwriting a function pointer or exception handler, which is subsequently executed. An exploit of heap overflow attempts to corrupt a heap to cause the program to overwrite the internal structures such as linked list pointers. A heap is an area of memory that is dynamically allocated by a program at run-time. The canonical heap overflow technique overwrites dynamic memory allocation linkage and uses the resulting pointer exchange to overwrite a function pointer.

Various techniques exist for detecting or preventing buffer overflows with various tradeoffs (http://en.wikipedia.org/wiki/Buffer_overflow):

- Choosing a type-safe programming language can avoid many buffer overflow problems. It requires a careful consideration of tradeoff between safety and performance costs. Among the most popular languages, C and C++ provide no built-in protection against accessing or overwriting data in any part of memory. The Java and .NET bytecode environments are relatively safer.
- Correct use of safe libraries of an unsafe language can prevent most buffer overflow vulnerabilities. For example, strings and arrays are the two main building-block data types in C and C++ in which buffer overflows commonly occur. When C/C++ is chosen for the implementation, safe library implementations for these datatypes should be used.
- Stack-smashing protection can detect the most common buffer overflows by checking that the stack has not been altered when a function returns. If it has been altered, then the program exits with a segmentation fault.
- Executable space protection can prevent execution of code on the stack or the heap. Any attempt to execute that code will cause an exception.
- Address space layout randomization randomizes the virtual memory addresses at which functions and variables can be found. This method can make exploits of buffer overflows more difficult, but not impossible.
- Deep packet inspection attempts to block packets which have the signature of a known attack or have a long series of no-operation instructions.

Format String

The format string problem stems from the use of unfiltered user input as the format string parameter in certain C/C++ functions that perform formatting, such as printf(). A malicious user may use the %s and %x format tokens to print data from the stack or possibly other locations in memory or use the %n format token to write data or code to the memory. This error would lead to the same problems as buffer overflows: crashing the program or executing the maliciously injected code. Format string vulnerabilities develop because C/C++'s argument passing conventions are not type safe. Many compilers can check format strings and report warnings for dangerous or suspect formats.

SQL Injection

SQL is a standard programming language for retrieving information from and updating a database. SQL injection is a technique that injects SQL statements into an input (e.g., user-supplied identity and password in a web page) for malicious purposes (e.g., obtaining other users' passwords and unauthorized access to a database). It exploits security vulnerability in the database layer of an application.

Primary forms of SQL injection vulnerabilities (http://en.wikipedia.org/wiki/SQL_injection) are as follows:

- Incorrectly filtered escape characters. User input is passed into a SQL statement without being filtered for escape characters. It may allow for potential manipulation of the statements performed on the database by the end user.
- Incorrect type handling: SQL injection may occur when a user supplied field is not strongly typed or is not checked for type constraints.
- Vulnerabilities inside the database server, such as MySQL server's real_escape_chars() functions.

Techniques for avoiding SQL injection include:

- Input sanitization. User inputs are sanitized to ensure that they contain no dangerous code.
- Security privileges. Setting security privileges on the database to the least required. For example, the delete rights to a database for end users are seldom required.
- Disabling literals. SQL injection can be avoided if the database engine supports a feature called disabling literals, where text and number literals are not allowed as part of SQL statements.

Cross-Site Scripting

Cross-site scripting (XSS) is a technique that injects code (e.g., HTML code and client-side scripts) into the web pages viewed by other users. An XSS vulnerability can be exploited to bypass access controls and produce phishing attacks and browser exploits.

Three forms of XSS vulnerabilities exist (http://en.wikipedia.org/wiki/Cross-site_scripting):

- Vulnerability in a client-side script. For example, if a piece of JavaScript accesses a URL request parameter and uses this information to write some HTML to its own page, and it this information is not encoded using HTML entities, then an XSS hole will likely be present, because this written data will be reinterpreted by browsers as HTML that could include additional client-side script.
- Non-persistent or reflected vulnerability. It occurs when data provided by a web client is used immediately by server-side scripts to generate a page of results for that user. If user-supplied data is not validated but included in the resulting page without HTML encoding, this will allow client-side code to be injected into the dynamic page.
- Stored or persistent or second-order vulnerability (also referred to as HTML injection) can occur when data provided to a web application by a user is first stored persistently on the server (in a database, file system, or other location), and it is later displayed to users in a web page without being encoded using HTML entities.

Techniques for avoiding XSS exploits, among others, include encoding of all user-supplied HTML special characters so as to prevent them from being interpreted as HTML and input validation of all potentially malicious data sources.

Good Secure Coding Practices

The principles of secure design in previous section also apply to detailed code design. Besides these principles, the Top 10 Secure Coding Practices by Robert Seacord's (https://www.securecoding.cert.org/) include the following:

- Validate input:

  Validate input from all untrusted data sources. Proper input validation can avoid most implementation-level vulnerabilities. Be suspicious of most external data sources, including command line arguments, network interfaces, environmental variables, and user-controlled files.

- Heed compiler warnings:

  Compile code using the highest warning level available for the compiler and eliminate warnings by modifying the code.

- Sanitize data sent to other systems:

  Sanitize all data passed to complex subsystems such as command shells, relational databases, and commercial off-the-shelf components. Attackers may invoke unused functionality in these components through the use of SQL, command, or other injection attacks. It is not necessarily an input validation problem because the complex subsystem being invoked does not understand the context in which the call is made. Because the calling process understands the context, it is responsible for sanitizing the data before invoking the subsystem.

- Adopt a secure coding standard:

  Develop and/or apply a secure coding standard for the chosen language and platform. The CERT Secure Coding Standards for C and C++ can be found at https://www.securecoding.cert.org/.

VALIDATION AND VERIFICATION FOR SECURITY ASSURANCE

Security assurance provides justification that security mechanisms, as implemented and operated, meet security requirements through assurance evidence and approvals based on evidence (2). Many problem sources exist in the development of secure software, such as omissions and mistakes in requirements specifications, design flaws, and implementation errors. Assurance addresses each of these problem sources. For instance, design assurance is the evidence establishing that a design is sufficient to meet the requirements of the security policy. In the following, we discuss several common approaches to security assurance. It should be noticed, however, that no silver bullet exists for security assurance. Various techniques are often used throughout software development to improve the level of assurance.

Review for Security

Review is a common practice of software development. Review of specification, design, and code can identify and eradicate many problems at various development phases, such as omissions and inconsistency in requirements specification, flaws in design, and programming errors (e.g., format string and buffer overflow vulnerabilities). Review practices include formal inspections and lightweight reviews. A formal inspection involves a careful and detailed process with multiple participants and multiple phases. A lightweight review requires less overhead than formal inspections. Review approaches include over-the-shoulder (one developer looks over the author's shoulder as the latter walks through the documentation or code), pair programming, email pass-around, and tool-assisted review (e.g., anonymous CVS allows groups of individuals to collaboratively review code).

Assurance Arguments and Formal Methods

Assurance arguments fall into two main categories: property-based and threat-based arguments. A property-based argument is a statement about a security property or constraint [e.g., if a user is authorized by the given security policy to perform operations on a resource, then the system must grant the access request (29)]. A threat-based argument is a statement about whether a threat exists (e.g., an adversary can intercept payment information). Property-based and threat-based arguments imply different strategies for proof or disproof. To verify a property-based argument, one can check to observe whether the specification or code *always* satisfies the property or constraint. To verify a threat-based argument, one can check to observe whether a chance *exists* for the threat to be realized according the specification or code. However, both approaches can take advantage of formal methods for specifying and reasoning about software security. Formal methods are mathematical tools for rigorous specification and (partially) automated verification. In the property-based approach, properties are often formalized as logical formulas and then proved via either theorem-proving or model-checking. In the threat-based approach, security can be assured through refutation. A threat-driven security design (5), for example, is said to be secured from the anticipated security threats under two conditions: (*1*) It is possible for the security threats to occur in the intended functions alone—the functions are insecure and the security threats are identified correctly; and (*2*) the security threats will never take place after the security features are applied—they are indeed absent from the security design unless the security features themselves are compromised. As a matter of fact, this style of refutation for assurance can be applied to threat modeling, no matter whether the modeling notation is formal (5) or informal (12,30).

Static Code Analysis for Security

Static code analysis is the analysis of source code or a compiled form of the program (e.g., object code or byte code) that is performed without actually executing the code (31). Often supported by automated tools, static analysis can help to identify and eradicate many coding problems, including security vulnerabilities, before a program is released. The basic idea of static analysis is to look for a predefined set of patterns or rules in the code that indicate possible security vulnerabilities. As the results of static analysis are not perfect, they require additional evaluation. For example, a static analysis tool can produce false negatives or false positives (32). False negatives mean that the program contains vulnerabilities that the tool does not report, whereas false positives refer to reported vulnerabilities that the program does not contain. False negatives are very dangerous because they lead to a false sense of security.

Static analysis tools often take advantage of compiler technology. For example, some tools are based on lexical analysis. They preprocess and tokenize source files and then match the resulting token stream against a library of vulnerable constructs such as gets(&buf) in the C language. Annotations can be used to help the analysis. For example, CQual (33) requires a C programmer to annotate a few variables as either tainted or untainted and then uses type inference rules to propagate the qualifiers. Once the qualifiers are propagated, type checking can reveal format string vulnerabilities in the C program. Splint (33) allows developers to add annotations for finding abstraction violations, unannounced modifications to global variables, and possible use-before-initialization errors. Computer-aided verification techniques have also been applied to static analysis. The Eau Claire tool (31) uses a theorem-prover to create a general specification-checking framework for C programs. It can help find common security problems like buffer overflows, file access race conditions, and format string bugs. MOPS (35) takes a model-checking approach to look for violations of temporal safety properties. Developers can model their own safety properties, and some have used the tool to check for privilege management errors, incorrect construction of chroot jails, file access race conditions, and ill-conceived temporary file schemes.

Software Testing for Security

Different from static code analysis for security, software testing for security is the process of executing a program with the intent of finding vulnerabilities. Software testing exercises a program with not only positive test cases for verifying that the system does what it is supposed to do (e.g., access is granted to authenticated and authorized users), but also negative or dirty test cases for verifying that the system does not do what it is not supposed to do (e.g., access is not granted to unauthorized users). Although both positive and negative tests are required of testing of any software, testing for security must pay more attention to negative tests because by nature they verify whether the system can be misused. This finding indicates that security testing is hard because too many possible negative tests can occur. It needs to test the "presence of an intelligent adversary bent on breaking the system"(36), which is the major difference between software security and software safety.

Security testing of software applications is different from network and system testing for security, such as network scanning, vulnerability scanning, password cracking, log reviews, file integrity checkers, virus detectors, and war driving for identifying unauthorized modems or wireless access points. When feasible, however, it can extend or take advantage of existing system security testing techniques, particularly penetration testing. A penetration test is a traditional method of evaluating the security of a computer system or network by simulating an attack by an adversary, known as a cracker. This testing is conducted from the position of a potential attacker and can involve active exploitation of security vulnerabilities. The underlying idea is aligned with the adversary's perspective of software security and applicable to security testing of software applications. Specifically, one can derive security tests as attack attempts from threat models (e.g., threat trees, threat nets, misuse cases) and threat mitigations. Then the code is exercised with the derived tests to determine whether the software is free from the attacks. This strategy is an example of black-box testing, which views the software under test as a black box without knowledge of internal workings of the code. As security threats are pervasive and software testing is highly labor-intensive, security testing should be based on risk assessment and threat prioritization (called risk-based testing),

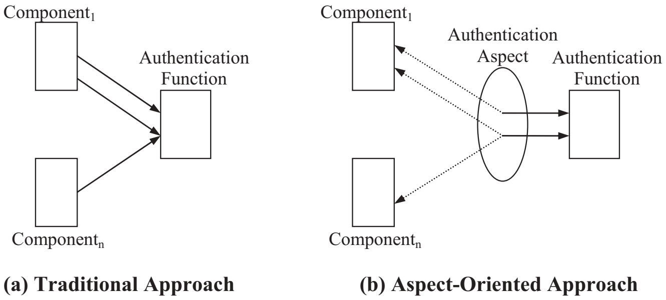

Figure 7. Tradition approach versus aspect-oriented approach.

which is usually an integral part of the threat modeling process. Black-box testing closely simulates the actions of an actual cracker and tests whether security mechanisms are properly implemented. It is yet weak at detecting the attacks that require some implementation-level knowledge of the software. At the other end, white-box testing takes advantage of the knowledge of the internal workings from the source code. It is often very effective in finding programming errors. According to the amplification phenomenon of vulnerabilities in software development processes, all different types of vulnerabilities (e.g., omissions in specification, flaws in design, and implementation specific faults) might accumulate in the code. To detect and reduce these vulnerabilities, various testing strategies are often required.

ADVANCED TOPICS: ASPECT-ORIENTED DEVELOPMENT OF SECURE SOFTWARE

Separation of concern is one important software engineering principle. Aspect-oriented programming (AOP) (37) is a new paradigm for separating concerns that crosscut multiple system components. The representative AOP language is AspectJ, which is an extension to the Java programming language. AOP modularizes crosscutting concerns into aspects with the advice invoked at the specified points of program execution. An aspect-oriented program consists of base components (or classes) and aspects that can be woven into an executable whole. The base classes in an aspect-oriented program can also be executed independently. This model allows for incremental or separate development of aspects. An aspect is an encapsulated entity of inter-type declarations, pointcuts, and advice. Inter-type declarations introduce new members such as instance variables and methods to the base classes. A pointcut is a collection of join points, and each join point is a well-defined point (e.g. method-call) in the flow of a program execution. A piece of advice for a pointcut defines additional code to be executed at each of the join points picked out by the pointcut. Originated from AOP, aspect-oriented software development (AOSD) aims to deal with crosscutting concerns at different development phases, (e.g., requirements analysis, architectural design, and detailed component design).

Security is in natural a crosscutting concern that involves many components of a software application. For example, authentication is often required of many system components in an online shopping application. With a traditional approach, each of the places that require authentication would first need to call an authentication method, as shown in Fig. 7(a). With the aspect-oriented approach, however, the authentication concern is separated from these components and modularized into an authentication aspect, as shown in Fig. 7(b). These components, when first developed, are not concerned about authentication. The authentication aspect will collect all places that are required of authentication (i.e., join points) and define what authentication method is applied (i.e., advice). In the traditional approach, security concerns are scattered across many components. This approach may require frequent, close interaction between nonsecurity and security personnel on the development team. Generally speaking, this method would make the development of secure software ineffective and inefficient because of the common shortage of security experts available. AOSD also fits in the adversary's perspective of software security—both security threats and threat mitigations have a nature of crosscutting. Notice that AOSD itself is not a security feature. It can help to address software security issues primarily because it caters for the principle of simplicity through improved modularization.

Aspect-Oriented Security Requirements

Aspect-orientation offers a better way to structure security threats and mitigation requirements. In the misuse case approach, one can easily identify these issues: (*1*) a single misuse case can threaten a use case at different steps of its main or alternate flows of events, (*2*) a single misuse case can threaten multiple use cases, and (*3*) a single step in the main or alternate flows of events of a use case can be threatened by multiple misuse cases. For example, step 6 "the customer submits credit card information" in the main flow of events of the use case "Order goods" in Table 2 is subject to such threats as block system, replay of message, modification of messages, and tap communication. The same issues exist for mitigation use cases. As such, the relationships among use cases, misuse cases, and mitigation use cases can be very complex. If a single use/misuse case diagram is used to depict all use cases, misuse cases, mitigation use cases, and their relationships, then the diagram likely becomes unreadable.

In the aspect-oriented misuse case approach developed by Xu et al.(38), misuse cases are called threat aspects, whereas mitigation use cases are called mitigation aspects. A point in a use case section (e.g., step 6 in the main flow of events of use case “Order goods”) can be referenced as a join point. If a join point is a point at which a security threat can happen, then it is called a threat point (a point of vulnerability). The various join points that are threatened by a particular threat are grouped together in a pointcut. That is, a threat pointcut is a collection of join points that are vulnerable to a common threat. Thus, each threat aspect consists of a group of pointcuts and their advice (how the threats can happen at corresponding threat points). After crosscutting threats are specified, one can identify the requirements for mitigating the threats. A mitigation aspect consists of mitigation pointcuts and advice. Each mitigation pointcut includes one or more threat pointcuts, which means that a mitigation can apply to one or more threats. A piece of mitigation advice contains the mitigation logic required to countermeasure the identified threats. Therefore, each mitigation aspect indicates a security concern. The above aspect-oriented organization can help different stakeholders understand requirements specifications by better clarifying the following questions: (*1*) For a given use case, what are the identified misuse cases and mitigation use cases? (*2*) For a given misuse case, what use cases does it threaten and what mitigation use cases are identified? (*3*) For a mitigation use case, to what use cases and misuse cases does it apply?

Aspect orientation can also be integrated into other approaches to security requirements analysis. Based on the notion of problem frames for elicitation of functional requirements, for example, Haley et al.(39) have developed away to derive security requirements from crosscutting threat descriptions.

Aspect-Oriented Design for Security

Aspect orientation can contribute to the principle of simplicity for secure design by separating crosscutting security policies and mechanisms from functional components. For example, enforcing access control policies in a secure design may spread the access control concern across many design modules. The interference of the access control concern with other application behavior can make it difficult to understand, analyze, and evolve the access control concern (40). Using an aspect-oriented modeling approach to addressing the pervasive access control concern of an application, one can localize the access control concern in an aspect. Aspect orientation also fits in the adversary’s perspective of secure software design. One can first identify security threats with respect to the components of intended functions and then specify mitigation mechanisms as aspects (5).

AOP for Security

An obvious application of AOP to security is separation of crosscutting security code from functional code for better modularization (41). Another application is to improve the security of legacy applications. According to Viega et al. (42), a large portion of commercial applications have significant security problems that are present in the design phase and persist through to implementation. Penetrate-and-patch is the traditional approach to resolving security problems—after vulnerabilities are revealed, the source code is modified, and then the revised version is compiled and released. With AOP, however, some security problems of a legacy application can be addressed without direct modification to the legacy code. To this end, aspects can be used to insert code before or after points of interest or replace the code at the points of interest. Sample scenarios are replacing insecure function calls with secure replacements, performing error-checking on security-critical calls, and logging data that are relevant to security.

AOP also offers a potential for better reuse of security solutions. Various core security requirements are common to many distributed software applications. Although these applications can follow security design patterns for respective security requirements, the implementation of the security patterns often vary from application to application. With AOP, a security design pattern can be realized as an abstract aspect that encodes the security solution in advice. When an application adopts a security design pattern, it only needs to extend the abstract aspect of the pattern and provide concrete pointcuts. The concrete pointcuts collect the points of program execution at which the security solution should be applied.

SOFTWARE TESTING: TESTING NEW SOFTWARE PARADIGMS AND NEW ARTIFACTS

INTRODUCTION TO THE ARTICLE

The purpose of software testing is to *improve the quality* of the software product by detecting and removing as many failures as possible, so to increase the developer confidence in the proper functioning of the software. For this purpose, software testing is not meant to be an exhaustive technique for software verification and validation. It can show that software defects are present, while not being able to show their absence (1).

Software testing is centered on the concept of selecting *some* (fault enabling) inputs from a possibly infinite input domain, to perform system runs driven by such inputs, and to compare the expected results with the real ones. If expected and observed behaviors differ, then a failure is manifested because of a system fault that needs to be fixed. A successful test is the one that uncovers undiscovered errors.

By taking a look at the evolution of software testing in the past decades, we can recognize that two (among the others) can be considered the main sources of advances in software testing: *(1)* testing techniques have been applied over new software development paradigms, languages, and applications, and (*2*) testing techniques have been applied over new artifacts (other than the source code).

This article presents current testing techniques along those two directions.

Testing New Software Paradigms

Over the course of the past 50 years, the way software has been produced is changed greatly. We have moved from procedural code, toward object-oriented systems, to component-based development (as pictorically described in Fig. 1); from thousands to millions of lines of code with real-time, reliability, safety, and performance requirements. Software testing has had to change accordingly. Traditional techniques, adopted for testing procedural code, had to be extended for testing object-oriented (OO) software: inheritance, polymorphism, dynamic binding, and other OO characteristics required new testing features. With the introduction of component-based systems, component-based testing has been introduced for testing the components in isolation or the assembly.

Testing New Artifacts

In traditional approaches to software testing, specific methodologies are used to select test cases based on the source code of the program to be tested (2). The main practical drawback related to (purely) source code testing is that because the code is produced at the latest step in the software production process, testing activities are left to the end of the software lifecycle. In consequence, schedule slippage, time-to-market pressures, and cost-constraints result in neglected testing.

Nowadays, source code is no longer the single source for selecting test cases, and we can apply testing techniques all along the development process, by basing test selection on different pre-code artifacts (3); the test selection phase can be based on system specifications (formally or informally defined), on architectural high-level design, or on component-based or object-oriented specifications.

All these testing techniques deserve consideration. Recent studies have shown that different test selection techniques target different classes of faults (e.g., Ref. 4), and that the combined use of diverse techniques is always more effective than concentrating the effort on only one technique (even though proved to be the most efficacious) (5).

This Article

The goal of this article is to provide a view on software testing techniques from this specific perspective, as graphically described in Fig. 2. It discusses code-based testing with a specific focus on testing object-oriented software. It covers component-based testing and distinguishing between component-testing and component-based testing. It analyzes specification-based testing (with particular attention to formal testing, model-based testing, and software-architecture-based testing).

This article provides the most comprehensive treatment of the testing subject from the specific perspective presented above, which describes the state of the art and provides references for further readings and expected directions for future work. As the article is oriented to a wide audience of readers, a glossary of testing terms has been provided in Appendix A to facilitate the reading to inexperienced readers. As the study is limited in size, references are provided to those best sources an interested reader may refer to for detailing the concepts outlined in this work. The focus has also been oriented to mature research, to practices of current use, and to current trends, while limiting the discussion on the latest speculative research that, although promising, might never work out. Moreover, this article focuses on systematic testing techniques, while not considering purely experience-driven, not repeatable, testing techniques.

The remaining sections are structured according to the following template: problem statement, information on the main achievements, links to tool support, and references to further readings.

Further Readings

M.J. Harrold's (6) ICSE 2000 Future of Software Engineering track paper on software testing provides a clear and wide roadmap on fundamental research topics to be further investigated to obtain practical testing methods, tools, and processes to develop high-quality software. A. Bertolino's (7) ICSE 2007 Future of Software Engineering track paper

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

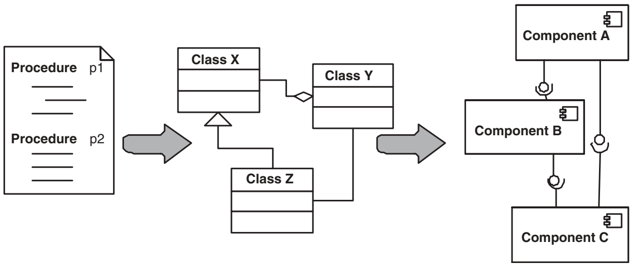

Figure 1. From procedural programming to component-based development.

on software testing provides a roadmap that structures and classifies software testing into three main aspects: achievements (where we are today), dreams (where researchers would like to go), and challenges (as a way to move from achievements to dreams). M. Pezzé and M. Young (8) authored a recent book on Software Testing and Analysis, which covers both the basic concepts and techniques, testing methods, and processes. *ISSTA* (9), *ICST* (10) and *TESTCOM* (11) are among the main conferences on software testing.

CODE-BASED TESTING: TESTING THE SOURCE CODE

Problem Statement

Code-based testing (also known as structural testing or white box testing) assumes visibility into internal data and structures of the system implementation. Test cases are selected according to the structure of the program and executed to exercise program statements.

The code structure is (typically) represented through a *graph:* Traditional white box analysis techniques use a control flow or data flow graph representation of a program. In *control flow* graphs, nodes correspond to sequentially executed statements whereas edges represent the flow of control between statements. A *data flow* graph extends the content of a control flow graph by adding information on variables accessed and modified by program statements.

Achievements

The *test selection* phase in code-based testing consists of selecting the minimum number of test cases that cover as much as possible of the flow graph. Designers have been applying white box techniques for a long time, and several coverage criteria are available today. Some criteria are based on the control flow, whereas others are based on the data flow.

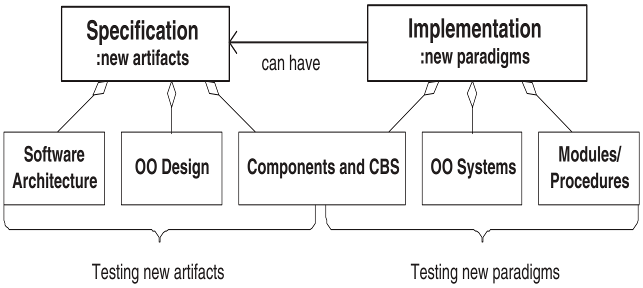

Figure 2. Testing new software paradigms and new artifacts.

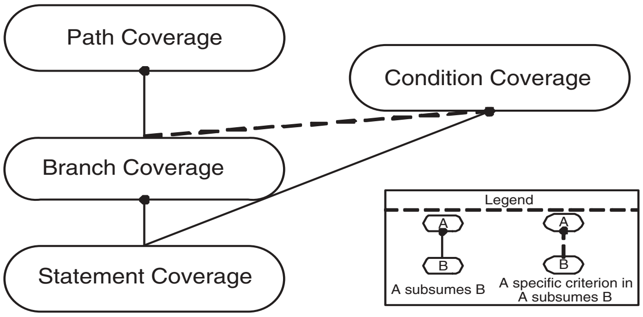

Figure 3. *Subsume* relationship among the analyzed coverage criteria.

Statement Coverage. This criterion reports whether *each executable statement* is encountered. This coverage selects a test set T such that, by executing a program P for each test in T, each elementary statement of P (i.e., each node in the graph) is executed at least once. The chief characteristic of this measure is that it provides the weakest coverage: If compared with other coverage criteria (see Fig. 3), then statement coverage is subsumed by any of the structural coverage criteria.

Branch Coverage. This criterion measures the coverage of *all blocks* and *case statements* that affect the control flow. Boolean expressions are evaluated for both true and false conditions. This criterion selects a test set T such that, by executing P for each test in T, each of P's control flow graph is traversed at least once (i.e., each branch of the control flow graph has to be executed by at least one test case). This measure has the advantage of simplicity, but it may ignore branches within Boolean expressions (see condition coverage below), or relevant combinations of branches (considered in path-based criteria).

Condition Coverage. This criterion measures the *subexpressions* independently of each other, allowing for a better analysis of the control flow. It forces the exploration of possible conditions of a boolean expression in a branch, which covers *different combinations of the individual conditions* in a compound boolean expression. This coverage criterion selects a test set T such that, for each test in T, each edge of P's control flow is traversed at least once and all possible values of the constituents of compound conditions are exercised at least once. Many variations of the condition coverage criterion exist (see Ref. 8 chapter 12 for a detailed explanation). Here, it is worth mentioning the modified condition/decision coverage (MCDC), which is required by many certification agencies: It enhances the condition/ decision coverage criterion requiring that each condition independently affecting the outcome of the corresponding decision has to be tested (12). MCDC is an attractive compromise between number of required test cases and thoroughness of the test, since with a complexity of $n+1$[1] (in

[1] $n+1$ test cases for a decision with n inputs

the best case), it achieves many of the benefits of the multiple-condition testing, which has a complexity of 2^n.

Path Coverage. It measures the coverage of all paths. Path coverage is similar to condition/decision coverage, but it handles multiple sequential decisions. As the number of paths soon becomes unfeasible, several variations of this criterion are considered to limit the number of loops. This technique selects a test set T such that, executing P for each test in T, all paths that lead from the initial to the final node of the P's control flow graph are traversed at least once.

Data-Flow Coverage. *Data-flow testing* (13–15) offers a family of criteria for unit testing of programs represented as *data-flow graphs*. It improves control-flow testing by identifying how the execution of a certain statement can affect the system computation. Data flow testing criteria pair *variable definitions* with *uses,* which ensures that each computed value is actually used, and thus selecting from among many execution paths a set that is more likely to propagate the result of erroneous computation to the point of an observable failure (8). Many coverage criteria are based on data flow, the most important being: *all DU pairs* adequacy criterion (it requires each DU pair to be exercised in at least one program execution), *all DU paths* adequacy criterion (extends the all DU pairs criterion by requiring each simple DU path to be traversed at least once) and *all definitions* adequacy criterion (which requires pairing each definition with at least one use).

Let P be the following program:

```
function P return INTEGER
begin
    X, Y:INTEGER;
    READ(X); READ(Y);
    while (X > 10) loop
        X := X - 10;
        exit when X = 10;
    end loop;
    if (Y < 20 and then X mod 2 = 0) then
        Y := Y + 20;
    else
        Y := Y - 20;
    end if;
    return 2 * X + Y ;
end P;
```

The corresponding control flow graph is shown in Fig. 4.

Some structural tests follow:

All-statement coverage: Inputs: (x = 20, y =10) and (x = 20, y = 30), where (x = 20, y = 10) covers nodes <1,2,3,4,5,6,8,9>, and (x = 20, y = 30) covers nodes <1,2,3,4,5,7,9>.

All-branches coverage: Inputs: (x = 20, y = 10), (x = 15, y = 30), and (x = 20, y = 15) where (x = 20, y = 10) covers nodes <1,2,3,4,5,6,8,9> and braches in <2T,4T,5T,6T>, (x = 15, y = 30) covers nodes <1,2,3,4,2,5,7,9> and braches in <2T,4F,2F,5F>, and (x = 20, y = 15) covers nodes <1,2,3,4,5,6,7,9> and braches in <2T,4T,5T,6F>.

It is important to remark that a 100% coverage is typically unfeasible because it may require the execution of unreachable code (referred as "infeasibility" problem).

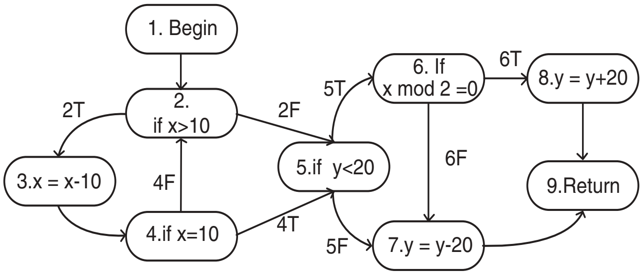

Figure 4. The control flow graph of the P program above.

Many other coverage criteria are used in practice. For more details, please refer to Refs. 16–19. How coverage criteria have been adapted to concurrent programs may be found in Ref. 20. An analysis of coverage criteria costs may be found in Ref. 21. A comparison of structural testing criteria can be found in Ref. 8.

Tool Support

As far as concerns tool support, the Open Source Testing Tools (22) website presents a list of open source testing tools (for white-box testing), whereas the Software QA Testing and Test Tool Resources (23) website presents a list of software quality-assurance and testing tools.

Further Readings

M. Pezzé and M. Young (8) authored a chapter (ch.12), entitled "Structural Testing," which presents the various structural testing techniques with examples. Chapter 13, which is entitled "Data Flow Testing," presents theory and examples on data flow testing.

Testing Object-Oriented Software: Testing the Source Code

Problem Statement. Testing OO software resembles testing procedural software, in which the focus moves from unit, to integration and system testing, and regression testing (24). However, OO software has some specific characteristics that make testing OO software diverse from other testing strategies and requires specialized techniques. In particular, as remarked in Ref. 25 and thoroughly discussed in Refs. 8 and 26, the unique facets of testing OO software are that each method must be tested in the context of its class and inherited features; objects are stateful and need to be tested in the different states; and encapsulation, dynamic binding, inheritance, and exceptions make the system behavior unpredictable so that an apparently harmless modification may affect different portions of the program.

Achievements. In code-based testing of OO software,[2] new criteria are introduced (extending the classic statements, branches, conditions, and decisions coverage) to cope with state-dependent behavior.

[2] Although this section will focus on structural testing of OO software, model-base testing techniques will be described in the Specification-Based Testing Section.

When considering *unit testing of OO code,* a unit is the class, and unit testing aims at testing the functions that belong to a class. As noticed in Ref. 8, although an individual method might be considered as a unit, testing a single method can become unpractical, because methods (in a class) interact by modifying object states and affect other methods' behavior. For this reason, unit testing of OO software is usually referred as *intraclass testing*. When performing intraclass testing of the source code, a graph model [typically, a control flow graph (CFG)] is built for each method, and CFGs of the various methods in a class are joined together to specify intraclass method calls. This joined graph is usually referred to as a class control flow graph (CCFG) (27). CCFGs are then used to compute def-use pairs, by first annotating the CCFG with definitions and uses and then traversing it to compute all pairs.

When different classes are integrated, *inter-class testing* checks interactions among objects of different classes. Souter and Pollock (28) define a *contextual def-use pair (d, u)* of a variable *o* to be used in interclass testing. Buy, et al. (29) combine dataflow analysis with symbolic execution and automatic deduction to generate test cases that satisfy data flow criteria. In Refs. 30 and 31, it is recognized that a representation based on simple CFGs is inadequate for interclass testing of Java programs. To handle all Java language constructs and features adequately (such as inheritance, polymorphism and dynamic binding, and exception handling), a Java interclass graph (JIG) representation is provided. A JIG extends the CFG to handle variable and object type information, internal or external methods, interprocedural interactions through calls to internal or external methods from internal methods, interprocedural interactions through calls to internal methods from external methods, and exception handling. The JIG is used in Refs. 30 and 31 for regression testing of Java programs.

Data flow testing criteria for computing definitions and uses of object attributes have been proposed in the context of unit and integration testing of OO software (as discussed in Ref. 26).

Tool Support. As far as tool support for testing object-oriented code, a recent study on tool support for white-box testing of OO software seems to be missing. Other than the popular JUnit unit testing framework for Java code (32), many other tools (typically, for structural intra class testing of Java or C++ programs) can be found in References 33–36.

Further Readings. D.C. Kung, et al. (37) authored a book that initially identifies difficulties and challenges in testing object-oriented software, then focuses on unit, integration, regression, and object state testing. J.D. McGregor and D.A. Sykes (24) cover the entire process in testing OO software, focusing on the what, why, how, who, and when. This text specifically focuses on testing classes, testing interactions, class hierarchies, and distributed objects. M. Pezzé and M. Young (8), chapter 15, entitled "Testing Object-Oriented Software" focuses on interclass and intraclass testing. It also focuses on testing in case of polymorphism, dynamic binding, inheritance, genericity, and exceptions. In L. Mariani and M. Pezzé (26), both specification-based and structural-based approaches for intra-class and inter-class testing of OO software are discussed.

COMPONENT-BASED TESTING

Roughly speaking, a component-based software system is an assembly of reusable components that are designed to meet the quality attributes identified during the architecting phase (38), whereas a component is defined as "a unit of composition with contractually specified interfaces and explicit context dependencies only" (39). Components are specified, designed, and implemented with the intention to be reused, and they are assembled in various contexts to produce a multitude of software systems. The main peculiarities in component-based software development are that components can be white-box or black-box (e.g., if components are off-the-shelf, their implementation is not accessible), they can be produced in house or bought from external vendors, they can be written in different programming languages and run in different execution environments, a detailed specification may exist or not.

Problem Statement

Component-based testing consists of two main tasks: testing the individual components (i.e., component testing), and testing the component-based systems built by assembling components.

In *component testing,* the goal is to detect software errors and to validate the quality of the software components considered as the smallest test unit (40). Testing of components becomes extremely important for the success of the entire component-based system (CBS) because the quality of the entire system is strongly affected by the quality of each single component. In *testing component-based systems,* instead, the main goal is to test the assembly of heterogeneous components, possibly written in different programming languages, distributed across the network and executed in various platforms.

Although many issues are specific to component testing and testing component-based software (see Ref. 41 chapters 2.3 and 4.2, and Ref. 42) two issues can be considered the most relevant, which are common to both aspects of component-based testing:

– *Availability of information about components:* The basic ingredient of any testing strategy is the availability of information/representation that describes relevant aspects of the component to be tested. Although in traditional software development processes the organization has a full control on the system under development (from requirements down to implementation), in component-based development the source code is in the general case not available. In the specific context of commercial-off-the shelf (COTS) components, components are retrieved from the market and come to the users without the source code. This lack of information poses particularly difficult questions to the final user for what concerns testing.

- *Presence of different stakeholders:* Different stakeholders take place in the development of a component-based system, which belongs to even unrelated organizations. Each of these stakeholders has to define and follow a specific testing process while pursuing, in general, different objectives. In this article we mainly differentiate between two main roles: the *component developer* (who implements software components to be easily and widely reused) and the *component user* (who integrates the component in a final system).

  The *component developer* starts the development of a component having in mind possible reuse scenarios that will make the component worthy to be bought by a possible user. In general, the process adopted will follow a "traditional" approach, and the testing process will not show major novelties.

  The *component user* is the developer of a complex system that decided to manage the complexity by reusing existing components. In case of COTS components, the unavailability of the source code makes all the traditional code-based techniques not applicable. Moreover, the scarcity of information makes also black-box approaches more difficult to apply.

Therefore, developers and users of components are completely different actors from a testing point of view, in which the former has complete view of the component internal details but little information on the final deployment environment, and the latter has little information on the inner parts of the component but a precise understanding of the final deployment environment.

In summary, component-based testing strongly relies on the information available to any possible stakeholder interested in carrying on a testing campaign on a software component or a set of them. At the same time, it is necessary to understand how the available information can be fruitfully used for testing purposes.

Achievements

In the following part of this section, existing component-based testing approaches are classified according to two main criteria: *who defines the test to be executed,* and *which information are sued to define the test cases.* Alternative classifications can be found in Refs. 41,43,44 and 45.

Following the proposed classification, three main classes have been identified:

- Developer-defined test cases;
- Developer-defined component models suitable for analysis and testing derivation by the user;
- User-defined test cases.

In developer-defined test cases, test cases are defined by the developers and provided as they are to the component user, who can just run them (i.e., the user has no control on the test selection phase).

Built in test (BIT) approaches and *testable architectures-based CB testing* are typical examples of approaches in this category. Built in testing is a generic approach to testing where the component is augmented with executable test cases that are built into the component, together with its normal functions. BIT requires component developers to embed tests in software component implementation to support self-testing. By running the embedded test cases, the component user can thus validate in the final environment the hypotheses made by the component developer. Several techniques have implemented this philosophy. Edwards (46) has proposed a framework to provide BIT wrappers for component testing, using the specification language RESOLVE as an example. Wang et al. (47) make use of the BIT for enhancing component-based software maintainability. They build tests in component source code as extra member functions. Other BIT techniques are used in Refs. 48 and 49. More details on BIT approaches can be found in Refs. 41 and 43.

The *testable architectures-based CB testing* approach can be recognized as a special case of BIT in which component developers equip the component with a specific testable architecture that allows the component user to execute the test cases easily. The test information is appended by the developer in the form of specifications, instead of enclosing them in the component itself. One of the most known approaches is the one presented by Momotko and Zalewska (50) which propose a testable architecture based on the Component+ built in testing (C+ BIT) technology for testing component interactions with the environment at run-time.

In *developer-defined component models suitable for analysis and testing derivation by the user,* the component developer provides users with (behavioral) models to use for test case selection. All forms of additional information appended to the software component (either by the developer, the user, or a third-party tester, so as to simplify software testing) can be regarded as forms of *meta-data.*

Wu et al. (51) define a test model called component interaction graph (CIG) for integration testing. As a first step, test elements are identified to build a CIG, and test cases are generated for each test element in the CIG. Another interesting approach, likewise relying on the definition of a particular framework for component testing, has been proposed by Atkinson and Gross (52). The framework is not intended for the execution of generic test cases, but rather focuses on providing the component user with specific test cases derived from contract specifications.

In *user-defined test cases*, the user has full control on the test selection phase. Three main approaches can be assigned to this class: *interface probing* (53), in which the component user derives a set of test cases, executes the component in accordance with them, and analyzes the outputs produced; the *component deployment testing (CDT) approach* where Bertolino and Polini (54) propose an integration testing framework for easing the execution of test cases derived from user architectural specifications; the *Behavior Capture and Test Framework* proposed by Mariani and Pezzé (55) in which the saving and monitoring of test results in one environment can be useful for evaluating component behavior in another environment.

Further Readings

M.J. Harrold et al.'s (42) paper focuses on issues and challenges in analysis and testing of CBS, from both the component developer and component user perspectives. J. Z. Gao, et al. (41) published a complete book on component testing and testing component-based systems and quality assurance. S. Beydeda and V. Gruhn (56) provide a collection of papers that cover the topics of built-in testing, metadata, software product line, testability, and integration testing. M. Jaffar-ur Rehman et al. (43) published a recent survey on issues and solutions in component-based testing.

SPECIFICATION-BASED TESTING

A software specification describes the expected behavior and characteristics of a software product as outlined by Poston (57).

In *specification-based testing* (also called functional testing or black box testing), the internal structure and behavior of the program is not known (i.e., the program is considered as a black box, because we cannot observe what internally happens). What is assumed to have is a *model of the system under test* and the objective is to analyze whether the system behaves correctly with respect to the specifications, that is, to find discrepancies between the actual behavior of the implemented system's functions and the desired behavior, as described in the functional specifications. Test sets are derived from the system specification, and the test selection phase can start even before the code is available (although test execution still needs the existence of the system implementation).

Manifold are the motivations for making use of a specification-based testing approach. (*1*) Code unavailability: If source code is not available (not yet developed or not publicly released), then test cases can be produced out of a specification. (*2*) *Scalability:* Even if source code is available, it becomes rapidly unfeasible to provide complete coverage of complex systems. Being specifications more abstract than source code, specification-based testing is certainly more scalable. (*3*) *Accuracy:* specification-based testing complements code-based testing techniques; although source code testing is typically structural and at a syntactic level (i.e., source code structure coverage), specification-based testing is more functional and at a semantic level (i.e., system functions coverage). (*4*) *Effectiveness:* A specification-based testing plan can start before the code is available, which avoids having to leave the testing activities to the end of the software lifecycle, when schedule slippage, time-to-market pressures, and cost-constraints may result in neglected testing.

The rest of this section will cover the topics of *model-based testing based on formal specifications* (when the model is generated from *a formal specification* or the formal specification itself is used as the test input), and *model-based testing based on diagrammatic specifications* (which refers to UML-based testing and testing based on models designed through *diagrammatic tools).* Next, this article presents existing work on software architecture-based testing (to be considered as a form of specification-based testing).

Model-Based Testing Based on Formal Specifications

Problem Statement. A formal specification can be regarded as "the expression in some formal language and at some level of abstraction, of a collection of properties some system should satisfy" (58). A formal specification language consists of a clearly defined syntax (the notation), fully specified semantics (the specifiable objects), and some satisfied relation (the semantics associated to the syntax). Although a formal specification can be of difficult use (if compared with informal specifications), it has precise, unambiguous semantics, which enables mathematical precision of the analysis of systems and the reasoning about them (59). Moreover, a specification written in a formal language can be processed by automated tools, and formal specification-based testing guarantees higher accuracy, objectivity, and repeatability than ad-hoc test derivation from informal specifications.

Achievements. Testing from formal specifications has received much attention in the last decades. The first approaches for specification-based testing were proposed in the 1980s. Since then, many specification-based testing approaches have been proposed, based on formal languages such as Z, VDM, CSP, CCS, LOTOS, SDL, and Petri Nets (60). More recently, conformance testing approaches based on Labeled Transition Systems or Finite State Automata (or their variations) have been proposed (61–63). Here, we restrict our attention to test selection and execution from such formal specifications, for which a mature theory of conformance testing now exists, together with automated tool support.

The aim of a formal conformance testing framework is to define a *conformance relation* between the implementation under test *IUT* and the (formal) specification *S*. Such a relation precisely establishes when *IUT* is a correct implementation of *S* and is based on the *test hypothesis,* that is, the *IUT* can be modeled by a formal object *MOD,* such that all the observations that we can make on the *IUT* and on *MOD* (along the executions of all defined test cases) cannot be distinguished (64). In such a way, we can formally define an "implementation relation" *(imp)* that correlates *S* with *MOD*. *IUT* conforms to *S* iff *MOD* is *imp*-correct with respect to *S*.

Figure 5. graphically summarizes how a conformance testing framework works.

In Tretmans' approach (62,65), both the specification *S* and the model *MOD* of the implementation *I* are expressed

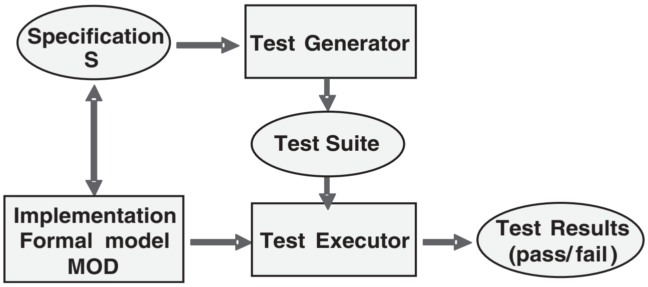

Figure 5. The conformance testing framework.

using input/output transition systems (IOTSs), which is an extension of the classic LTS model, in which the set of actions are partitioned into the input actions and the output actions. The implementation relation *imp* used is of the form **ioco**, that is a relation holding when *MOD* can never produce an output that could not have been produced by *S* after the same sequence of actions, or *trace*(66).

Similar derivations are obtained by von Bochmann et al. (63) who use finite state machines to derive the system specification, its implementation and "conformance relations" (equivalence, quasi-equivalence, reduction) to generate test sequences. Fernandez et al. (67), use IOLTS in their approach for an automatic, on-the-fly generation of test cases.

Tools. TorX, TGV, and TVEDA are well-known tools for automating the test selection and execution process in formal testing.

TorX (68) allows an on-the-fly test generation and execution (i.e., test derivation and test execution occur simultaneously). The input language is LOTOS or Promela, and the test selection can be random or manual. In TGV (61) the tester can use his/her knowledge of the implementation under test and of the context to guide the test selection through the notion of a *test purpose* (61,66) (which permits to focus on testing relevant interactions, while hiding the others). The TGV input languages are LOTOS or SDL, and test cases are derived in TTCN (69). TVEDA (70) derives TTCN tests from SDL specifications.

Differently from TGV and TVEDA, TorX allows test derivation and execution in an integrated manner.

Further Readings. *C. Jard and T. Jeron* (71) provide one of the most recent papers on TGV; it describes the tool and the theory behind it. Reference (72) points to the TGV website. *J. Tretmans* (59) covers the theory behind conformance testing in an easy-to-understand and complete way.

Model-Based Testing Based on Diagrammatic Specifications

Problem Statement. A model-based testing approach accepts two main inputs, a model of the software under test and a set of test generation directives (which guide the test cases selection), and outputs a test specification (which includes a set of stimuli the tester should introduce in the system together with expected responses) (73). This section will focus on model-based specifications in the Unified Modeling Language (UML) (74).

Achievements. Binder surveys how each and every UML diagram could be tested (Reference 25, ch. 8). Although UML structural diagrams are usually employed for testing design consistency (gray-box testing), behavioral diagrams are used for functional testing, precisely, interaction diagrams for integration testing (interactions among objects), and state diagrams for functional testing of objects.

This section will focus especially on a representative subset of (mostly academic) scenario-based and state-based testing approaches. Figure 6 [taken from Navlasky (75)]

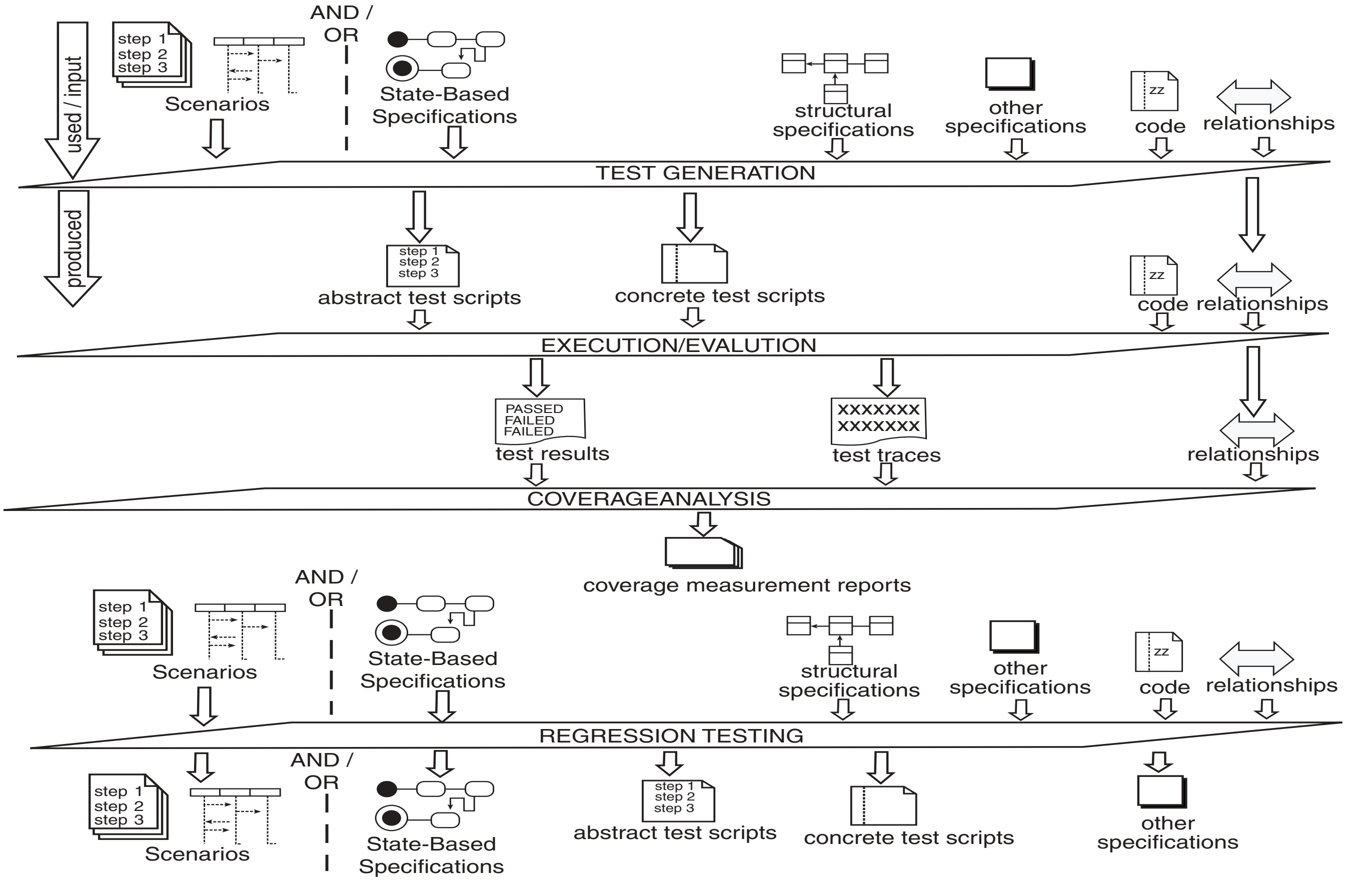

Figure 6. Steps in model-based testing.

summarizes the test generation, test execution and evaluation, coverage analysis, and regression testing activities implemented by automated model-based testing approaches.

The *test selection* activity receives models as input and produces test scripts as output. The inputs are textual or graphical scenarios, state-based, or other specifications (structural specifications, such as class or component diagrams and activity diagrams). Sometimes, the code itself becomes an input of the test generation activity. The outputs are *test scripts* (sometimes referred to as test sequences), and comprise the following: a set of steps to be followed when testing a program, as well as input and output values. Test scripts are either abstract or concrete. Abstract test scripts describe the steps a tester should follow when using the system, the inputs to provide, and the outputs to expect. Concrete test scripts can be compiled and automatically executed. They consist of calls to methods in the code, the inputs to provide, and the outputs to expect. The evaluation is either made manually by the tester or automatically by an oracle.

The *test execution and result evaluation* activity receives as input abstract or concrete test scripts outputted by the test generation activity. Test execution runs test scripts over the source code. The observed behaviors are evaluated against expected results, as expressed by the specification models.

Coverage analysis can be automatically performed to evaluate how much of the code has been covered. *Regression testing* can be applied to re-test changed models.

In the study conducted in Ref. 75 and summarized in Ref. 76, 11 automated model-based testing approaches were evaluated. Six of them are based on scenarios, two on state-based models, two on both scenarios and state machines, and one on scenarios or state machines. Figure 7 summarizes the input artifacts used by the 11 surveyed model-based testing techniques.

By taking a look at other surveys on the topic, Utting et al. (77) place model-based testing approaches into a seven-dimension orthogonal taxonomy. The dimensions characterize the approaches with regard to the nature of the model used (e.g., what is modeled, notation used), to the nature of the test generation techniques used (e.g., test selection coverage) and to the nature of the test execution (e.g. on-line, or off-line).

In their work, Prasanna et al. (78) survey test case generation approaches. They classify these approaches into two categories: specification-based approaches and model-based approaches.

	UCSC-System	SeDiTeC	SCENTOR	COW-SUITE	SOOTF	TOTEM	AGEDIS	UML Test	UMLAUT	TESTOR	AsmL
Scenario-based	x	x	x	x	x	x			x	x	x
State Machine							x	x	x	x	x
Structural spec.		x		x		x	x		x		
Other specifications	x	x	x	x	x	x	x		x	x	x
Code	x	x	x		x						

Figure 7. The main artifacts used in model-based testing.

Tools. Hartman (73) presents a survey on model-based test generation tools. He distinguishes between test generators and model-based input generators. He also distinguishes between test generators and test automation framework, where the automation framework executes the test sequences without human supervision. The objective of Hartman's survey is to place the AGEDIS (79) project and tool in relation to other tools. He groups the tools into academic and commercial and succinctly describes each of them. It is therefore a good reference to a list of tool supported approaches.

In their book chapter (80), Belinfante et al. provide an in-depth evaluation of test case generation tools. The book, however, is on model-based testing for reactive systems, where models are described in their majority with formal specification languages.

Further Readings. R. V. Binder (25) mostly describes model-based test design techniques (based on combinational models, state machines and the UML) for OO systems and test design patterns. M. Broy et al. (81) provide a collection of papers presented at the 2004 Dagstuhl seminar on "Model-Based Testing of Reactive Systems." It covers testing of finite state machines, testing of labeled transition systems, model-based test case generation, tools and case studies, standardized test notation, and execution architectures. L. Mariani and M. Pezzé (26) discuss both specification-based and structural-based approaches for intra-class and inter-class testing of OO software. The Model Based Testing Forum (82) is a useful forum on model-based testing.

Software Architecture-based Testing

A software architecture (SA) is the first design artifact that can be produced during the software development. It breaks down the system into several cooperating elements (components, connectors, data elements). Although components represent the core artifacts, a software architecture consists in the study of how such components can be integrated in order to satisfy desired functional and non functional requirements.

According to Stafford and Bosch (38), software architecture represents an integral part of any component-based software system; software architecture and components are two sides of the same coin. A component-based design can be (*1*) component-driven, if existing components are integrated via a component framework, according to a certain architecture; or (*2*) architecture-driven, if components are produced or acquired in order to satisfy architectural requirements.

Problem Statement. A growing interest in software architectures characterizes the last decade. Although most initial effort has been on how to specify an architecture, how to select the right architecture has become one of the most relevant challenges in recent days. In particular, the importance of the role of SA in testing and analysis is becoming evident (83).

When referring to software architecture and testing, we need to distinguish between SA-based testing and testing

SAs. In *SA-based testing*, the goal is to use the SA specification as a reference model to extract suitable test classes for the higher levels of testing and to refine them into concrete tests at the code level (84). In *testing SA,* instead, the main goal consists in assessing the SA quality with respect to expected requirements it shall meet.

Two major issues are to be solved in architecture-based testing: *traceability* and *test execution*.

Traceability consists of "relating the abstract values of the specification to the concrete values of the implementation" (85). Because test cases are selected from the (intentionally abstract) architectural model, they have to be refined into more concrete test sequences to execute these tests on the code. Similar problems can be found in specification-based testing (previously discussed), but they are typically solved by making use of detailed and lower-level specifications.

Test execution entails forcing the implementation under test (IUT) to execute the specific sequence of events that has been selected. However, a problem develops with concurrent programs that, starting from the same input, may exercise different sequences of interactions (among several concurrent processes) and produce different results. This problem has already been analyzed in the literature, and nondeterministic and deterministic-testing (86) approaches have been proposed.

Achievements. Several authors have advocated the use of architectural models to drive testing, and in particular to select relevant behaviors of interactions between system components based on the early SA specification. In Ref. 87, the authors analyze the advantages in using SA-level testing for reuse of tests and to test extra-functional properties. In Ref. 88, the authors define six architecture-based testing criteria, which adapt specification-based approaches. Those two papers represent the fist attempts in software testing based on an architectural specification.

In Ref. 89, the authors present an architecture-based integration testing approach that takes into consideration architecture testability, simulation, and slicing. In Ref. 90, Harrold presents an approach for effective software architecture regression testing, and in Ref. 6 she also discusses the use of software architecture for testing. In Ref. 91, Rosenblum adapts his strategy for component-based systems testing to SAs. The testing approach is based on architectural models, which could be simulated or executed or used to guide integration or regression testing of the implemented system. The author also shows how formal models of test adequacy can be used in conjunction with architectural models to guide testing.

In Ref. 92 the authors propose a technique to test data flow and control flow properties at the architectural level. Six architecture relations among architecture units are defined and then used to define architecture testing paths. Five architecture-level testing criteria are proposed. However, to the best of our knowledge, the approach in Ref. 84 is still the only comprehensive attempt to tackle the whole cycle of SA-based testing.

Reference 93 presents a framework for SA-based regression testing, coping with two main types of evolution: architectural evolution and code evolution.

Figure 8 shows a synthetic table of SA-based testing techniques, pointing out the specific goals of each given paper/approach.

Further Readings. H. Muccini, et al. (84) present a comprehensive attempt to tackle the whole cycle of SA-based testing. H. Muccini et al. (93) propose an approach for SA-based regression testing.

ONGOING RESEARCH IN SOFTWARE TESTING

Although previous sections have discussed consolidated testing techniques based on different development paradigms and based on different precode artifacts, this section introduces some ongoing research that, while not consolidated, is being used in academic and practical domains and are being considered key technologies. We here focus on testing service-oriented applications, on the UML testing profile, and on product line testing.

Testing Service-Based Applications

Service oriented computing aims to provide the basis for building software by assembling independent, loosely coupled services. Services are understood as autonomous, platform-independent computational entities that can be described, published, categorized, discovered, and dynamically assembled for developing massively distributed, interoperable, evolvable systems and applications. These characteristics pushed service-oriented computing toward its present widespread success, which is demonstrated by the industrial investments on this technology.

Problem Statement. Web services represent a concrete instantiation of the service oriented paradigm, where web services are distributed and integrated via Web standards. Because web services are considered a key technology in software production today, how to test them is becoming a relevant task in many industrial organizations.

The main issues and challenges related to testing web services resemble those related to component-based testing (as already analyzed previously and remarked in Ref. 95), with some extensions as in the following:

- *Lack of control:* As in component-based development, services can be produced by different stakeholders. However, although component-based applications can be produced by a single organization by integrating reusable components, service oriented systems are never under the full control of a single organization.
- *Different Stakeholders:* Although two main stakeholders are involved in component-based testing, five main actors might be concerned with testing of services: service developers, service providers, service integrators, third-party certification authorities, and final users. Each can thus require specific testing techniques, which are related to the level of knowledge/control they do have on the service and on the testing purpose.
- *Different stages:* A web service can be tested at three different stages: before deployment, at registration time, and at execution time.

  A service can be tested *before its deployment* by using off-line testing. At this time, the service developer or provider tests the service by simulating possible usage scenarios. Successively, at *registration time*, the test can be executed in a real execution environment to provide more realistic results. The discovery and directory services can then be reinforced with testing functionalities. Eventually, at *execution time*, the system can be monitored so as to discover run-time service failures.
- *Different ways of integrating services:* Services can be composed by following two complementary views: orchestration and choreography. In the orchestration, an orchestrator defines the interaction order among components. A choreography, instead, specifies the interaction among all the services that take place in the system. Different interaction primitives and languages are used by the two views, which impose clear distinctions among choreography-based and orchestration-based testing (96).

Achievements. Many approaches have been proposed so far for testing web services.

The survey study in Ref. 97 takes into consideration 12 web services testing frameworks and classify them according to many parameters, the most relevant being the following: the testing web service architecture, the stakeholders involved in the testing activity, the web services specification languages, and the testing strategies. The table in Fig. 9 summarizes the survey main results.

In Reference 95 , a comparison among three web services testing tools (Parasoft SOATest, Mindreef SOAPScope, and PushToTest TestMaker) is reported according to the following (main) parameters: support for functional testing; support for custom scripting, type of licence, and type of interface; support for simulation and recording; and support for extra-functional testing.

MDA-Based Testing: The UML Testing Profile

Problem Statement. With the widespread adoption of software models and model-based testing techniques, new challenges arise. A multitude of different model-based testing approaches are available today (as outlined previously), each one focusing on different UML models, different level of abstractions, and different test selection/execution/coverage criteria. As soon as a model evolves, related models and the test themselves shall evolve to keep the specification and test specification consistent. Explicit support for models' alignment is rarely available. Moreover, it is not uncommon during evolution that only the low-level design and implementation are changed to meet tight deadlines, while the model specification is not updated to track the changes being made to the implementation (99). As soon as the specification "drifts" out of conformance with the implementation, it is no longer representative of the expected behavior.

Explicit relationships need to be devised between specifications and their implementations (sometimes called mapping), and between specifications and test results (sometimes called traces) (as initially discussed in Ref. 85).

Achievements. To handle such problems and to bridge the gap between models and implementation, in 2001 the object management group (OMG) has released the UML testing profile request for proposal. As a result, the UML testing profile (UTP) (100) has become an official OMG standard since late 2005, with the main goal of allowing a conformance testing activity to take place in parallel with the system development. The main objectives of the UTP are to provide an ontology of testing-related artifacts needed for testing purposes and to model transformation algorithms to move toward different models. The UTP implements the MDA philosophy by providing a common framework for system development and testing. The UTP profile extends the UML 2.0 meta-model to introduce test-specific concepts. The analogy to MDA has been illustrated in Fig. 10. The PIT is the platform independent test, which is generated through model-to-model transformation techniques from the platform independent model (PIM). Following the MDA philosophy, as the PIM is transformed into a platform specific model (PSM), the PIT is transformed into a platform specific test (PST), i.e., a test executable on the PSM. Although vertical transformations permit to move from the PIT, to the PST and test code, horizontal transformations permit to move back and forth from development to testing.

The main goals and principles of UTP are:

- **To interweave software development and testing**. The main principle implemented in the UTP is that software testing needs to be carried out during the entire software development, and it should be connected as much as possible with the system development models. The UTP thus provides a unique notation based on the UML to be used by both software developers and software testers, and it provides the ability to move from the modeling domain to the testing one.
- **Conformance Testing**. The UTP has been proposed to provide an answer to the need of solid conformance testing, certification, and branding.
- **Structure + behavior Modelling**. The UTP takes into consideration both structural and behavioral diagrams. Structural diagrams are used to specify the testing components. Behavioral diagrams are used for specifying test cases and for identifying the test cases execution order.
- **Black-box testing**. UTP focuses on black-box conformance testing. For this reason, the profile itself does not consider any information on the internal structure of the system under test.

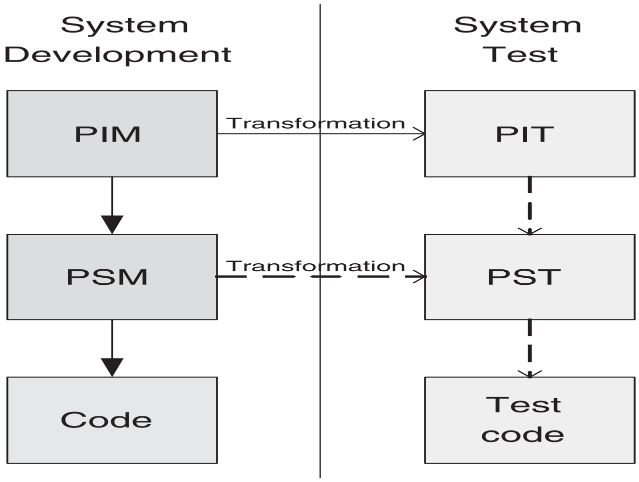

Figure 10. The UTP contextualization in MDA.

The UTP contributes to the aforementioned goals in two different ways; it provides an *ontology of model-based testing concepts* to produce a testing model, and it describes some *transformation rules* for moving from development models (PIM and PSM) to testing models (PIT and PST). The ontology of concepts has been categorized into four conceptual packages: test architecture, test behavior, test data, and time. Each package has a specific goal and contains meta-classes that identify the UTP ontology. Each package is described in detail in Ref. 100.

Further Readings. The UML Testing Profile (100) provides the OMG official specification for the UML Testing Profile, v 1.0. von P. Baker and colleagues (101) authored the first book on the UML Testing Profile. Z. Ru Dai et al. (102,104) present three papers on the UTP and its relation with TTCN-3.

Testing Software Product Lines

Software product lines (SPLs) represent a more strategic approach to reuse, where components and other assets are identified in relation with specific application domains, architectures, and scopes (opposed to software reuse schemes which try to create assets as general as possible). Quoting Clements and Northrop (105), “a software product line is a set of software-intensive systems sharing a common managed set of features that satisfy the specific needs of a particular market segment or mission and that are developed from a common set of core assets in a prescribed way.” The idea behind a system–family approach is to build a new system or application from a common set of assets (e.g., component, known requirements or design elements, models, artifacts) in the same domain.

The main concepts that characterize an SPL are those of:

- *Domain-specific core assets:* Instead of creating libraries of general purpose components, hoping they will be used in future development, SPLs make a predictive analysis of such artifacts that may be reused in the development of a specific domain-related product (106).
- *Commonality and variability:* Commonality defines what different products have in common and guides the production of domain-specific core assets. Variability is the ability to change or customize a software system (107) (i.e., to distinguish one product from another in the SPL), and it requires to delay design decisions such that many decisions are left open until a certain product is selected out of the product line. A variation point identifies one or more locations at which the variation will occur.
- *Domain engineering and application engineering:* Taking a look at an SPL software process, two main phases are always contemplated: domain engineering and application engineering. In the former phase, commonality and variability of the entire family are analyzed, whereas during application engineering an individual application, member of the SPL, is selected.

When testing an SPL, traditional testing techniques have to be adapted so as to take into consideration the SPL peculiarities described above. The main challenge is in investigating *how the entire SPL can be used to generate testing information automatically that may be effectively reused to test each derivable product*, as discovered in Ref. 108.

Further Readings. J.D. McGregor (109) provides principles and techniques in testing software product lines. A. Tevanlinna et al. (110) describe the state-of-the art of product family testing techniques.

FUTURE DIRECTIONS IN SOFTWARE TESTING

Harrold (6) and Bertolino (7) in their ICSE 2000 and ICSE 2007 (respectively) Future of Software Engineering (FOSE) papers on software testing, highlight several working directions and challenges in software testing. While sharing most of them, I would like to briefly discuss here those areas I personally believe will be of major relevance in next generation software testing techniques.

Testing Evolving at Run-Time Software

An increasingly important requirement for software-intensive systems is the ability of changing over time, because of the need to add/remove new features dynamically, the need to provide a more dependable system, or the need to protect the system from run-time incoming attacks or deficiencies. This newly acquired level of dynamicity, while enhancing the flexibility of a software system that can become self-adaptable, imposes new degrees of complexity when certain qualities of the system must be guaranteed. Continuously evolving systems become difficult to be analyzed with techniques used over traditionally static systems. In the context of such highly dynamic systems, the focus moves from validating the static configuration to validating the changing over-time design. Thus, whereas in traditional static systems the verification can be done once before system deployment, for dynamic architectures the validation becomes a perpetual activity to be performed during system execution. On-line testing and monitoring techniques are currently being analyzed for testing such types of software (see for example Refs. 95 and 111).

Automation in Software Testing

Practitioners regard software testing as the central means for ensuring that a system behaves as expected. The introduction of automated testing techniques has strongly facilitated the introduction of software testing into practice; automation has reduced the amount of effort spent on technical testing activities and has also increased the precision of activities, like result evaluation, often performed by humans and thus more error prone. However, testing in industrial projects can be effective only when the testing effort is “affordable”: the testing approaches should support automatic creation of test plans sooner, they should automate most testing activities, and testing and development shall proceed hand-by-hand being automated in the same development and testing framework.

As a side effect, software testing automation would also improve technology transfer of testing and analysis research. Technology transfer is fundamental for making research useful in industrial domains and for bridging the gap among academic research and industrial needs, as remarked by Boshernitsan (112) in his ISSTA 2006 invited speak. Hartman (113) describes his experience as well as the challenges and dreams in making model-based testing an industrial practice. Test automation is remarked as one of the main means to make model-based testing an industrial practice.

Integration of Testing and Analysis Techniques. Integration of analysis techniques is a topic that has recently been receiving some attention in the software engineering community (e.g., Ref. 114). This problem can be addressed from two different viewpoints: integrating analysis techniques during the development process (from requirement-based to source code analysis) and integrating different analysis techniques at the same stage in software development (e.g., design-based testing and model-checking).

Antimodel-Based Testing

Specification-based testing is certainly useful and effective; however, there can be several reasons why such an approach *cannot be applied* or is *too expensive* for deployment in a specific context. One of the main obstacles relies on the assumption that a complete and consistent model of the software system exists, whereas for certain classes of systems (e.g., component-based systems), we cannot assume a priori that a specification or the source code are available. In such cases, model-based testing is not applicable, or would be too costly.

This is the rationale for an *"antimodel-based testing approach":* whereas model-based testing starts from an a-priori established model and tries to execute some sequences derived from this model, in "antimodel based" testing the opposite direction is taken: the implementation is executed on some sample executions, and by observing the traces of execution an abstract model of the system is inferred/synthesized a posteriori.

Self-Testing

An increasingly important requirement for software systems is the ability to self-manage, (i.e., to autonomically manage themselves). According to Kephart and Chess (115), the four main autonomic areas are self-protection, self-configuration, self-optimization, and self-healing. Other colleagues describe other forms of self* -techniques, such as self-adaptivity, and self-organization. In the context of self*- systems, self-testing seems to be a natural way to move forward, in which the system has the ability to test (and repair) itself autonomically.

CONCLUDING REMARKS

This article has tried to provide an ample view on software testing from two different viewpoints: the development technology to be tested and the artifacts to be used for testing purposes. A detailed list of references on high-quality research work has been provided to help the reader acquire a more advanced knowledge on each area covered.

ACKNOWLEDGMENTS

I wish to thank the anonymous reviewers, Mauro Pezzé and Antonia Bertolino for their useful feedback on a preliminary version of this paper. I thank you Andrea Polini for his contribution and help within the component-based testing section of this article, and Damien Andrew Tamburry for is thorough proofreading.

APPENDIX A: A GLOSSARY OF SOFTWARE TESTING TERMS

This section provides an explanation of the main terms used in software testing. In order to make the explanation more practical, some of the described concepts will be applied to the *BuyOnline* fictitious web application, which allows users to register, to select products from a list, to visualize their descriptions and information, and to buy them online.

Test Case: A test case is a set of inputs, execution conditions, and a pass / fail criterion [116]. A test case thus includes not only input data but also any relevant execution conditions and procedures, and includes a way of determining whether the program has passed or failed the test on a particular execution [8].

A single test case *tc1* for the BuyOnline application might be: select product with id 563AD, put it in the chart, buy it by credit card.

Test Suite: A test suite is a collection of test cases.

Further test cases can be generated to test the BuyOnline application (by changing the selected products, by removing a product from the chart, or by changing the payment type). All together they will form a test suite for the BuyOnline system.

Test Process: The testing process consists of different activities, the most important being:

- *Test Selection: it consists in selecting a suitable and finite set of test cases from the possibly infinite set;*
- *Test Execution and Evaluation: it consists in executing the code accordingly to the selected test cases and comparing real and expected results.*

The *test selection* activity provides guidelines on how to select test cases. It is driven by a "test criterion" and has to produce "suitable" test cases:

Test Criterion: A test criterion provides the guidelines, rules, and strategy by which test cases are selected. In general, a test criterion is a means of deciding which shall be a "good" set of test cases [117] .

Suitability: A test case is suitable if it contributes to discovering as many failures as possible, according to a test criterion.

Test cases for the BuyOnline application can be selected randomly (i.e., by randomly selecting products, payments types, and functions to be run) or through a more systematic approach, like code coverage (i.e., test cases are selected so to cover all the functions, or the code statements/ branches/paths.)

The *test execution* activity consists in executing the code according to test case inputs. Typically, it describes how to bring the software system in a state so that the test input can be given.

When executing the BuyOnline application according to test case *tc1,* the user has to be registered first, then the test case inputs can be provided.

The *test oracle* evaluates whether the observed outputs comply to expected behaviors. The test oracle can be the tester herself: based on her knowledge of the expected system output, she can predict the expected behavior and thus compare the oracle with the real behavior. Otherwise, the oracle can be automatically generated e.g., from an existing specification or from a previous version of the system.

The test oracle for *tc1* may state that if product 563AD is the one selected, it is the one delivered and the credit card is charged for its correct amount.

The *test adequacy* criteria permit to judge whether the test campaign is sufficient. In general, the test adequacy should state that a test suite is adequate when it allows the identification of any failures. However, since the number of failures is not known a priori, we need to approximate the intuitive concept of adequacy. Thus, a test criterion can be used to define a stopping rule for evaluating the adequacy of the selected test suite.

The testing campaign of the BuyOnline is adequate as soon as the selected test suite covers, for example, the amount of source code defined in the test criterion.

Further Readings

A. Bertolino et al. (3) in their chapter, part of the Guide to the Software Engineering Body of Knowledge, provide a compendium and guide to the body of knowledge on software testing as developed in the past four decades.

SOFTWARE VERIFICATION AND VALIDATION

Software verification and validation are software quality assurance activities that aim to ensure that the software system is developed according to a development process and meets the customer's needs (1). In other words, verification is about "are we building the product right," and validation is about "are we building the right product" (2). Validation is divided even more into static validation and dynamic validation. Static validation checks the correctness of the software product without executing the software system or a prototype, whereas dynamic validation executes the software system or a prototype. Software testing is one form of dynamic validation.

To explain, verification is concerned about the process to produce the product. That is, are we building the product in the right way? This process includes two aspects: (1) the right process and (2) correctly following the right process. As a minimum condition, the "right process" must require that a lower level artifact satisfy the requirements stated in the higher level artifact. Unlike verification, which is concerned about the "correctness" of the process, validation is concerned about the correctness of the product. That is, are we building the correct product? We need both verification and validation because either of them alone is not sufficient. For example, an implementation may satisfy the specification, but the specification may be incorrect. Moreover, the implementation may satisfy the specification and the specification is also correct, but the code may be hard to understand, test, and maintain. Customer review and/or expert review of requirements specifications would detect the former, whereas code review and code inspection would detect the latter. Therefore, a "right" (which means "preferred") software development process should include these verification and validation activities.

In the following sections, we first provide definitions of commonly encountered verification and validation concepts, followed by verification and validation in the software lifecycle, formal verification, and software testing techniques.

DEFINITIONS

This section presents the definitions of commonly used terminologies in software verification and validation.

Bug: A defect in the program code.

Desk checking: Examination of software artifact, typically the source code, by the developer to detect bugs, anomalies, and other potential problems.

Error: An unanticipated condition that puts the system into an incorrect state.

Failure: A result produced by the software under test does not satisfy the expected outcome.

Fault: A defect in the software system.

Inspection: A step-by-step checking of the software artifact/product against a predefined list of criteria, called a *checklist*.

Peer review: Evaluating the software artifacts by peers who are required to answer a list of questions to assess the artifact and provide improvement suggestions, if any.

Regression test: Rerun some test cases to ensure that the modified software system still delivers the functionality as required.

Software attribute: Property or characteristic of software.

Software metrics: Measurements of software (attributes).

Software quality assurance: Activities to ensure that the software under development or modification will meet desired quality requirements.

Test driver: Code to invoke the component under test and to check the outcome of the component under test.

Test harness: Test driver and test stub.

Test script: Code to test functionality of software system.

Test stub: Code to replace the module or procedure that is invoked by the component under test so that the component under test can be executed.

Testing: Executing a program with the intent to uncover bugs.

Verification and validation: According to Barry Boehm, verification is "are we building the product right?" And validation is "are we building the right product?"

Walk-through: Manually reviews the software artifact by following the described logic step by step with a certain scenario of operating the system and/or on certain input data as the test case. The artifact reviewed could be requirements specifications, high-level design, detailed design and source code, and so on. The walk-through of the source code is often performed by manually executing the software with test data to simulate machine execution of the software.

VERIFICATION AND VALIDATION IN THE LIFECYCLE

This section presents verification and validation in the software lifecycle. That is, what is checked in each lifecycle phase and who performs the checking. Moreover, what techniques are used to perform the checking.

Verification and Validation for the Requirements Phase

Verification and validation in the requirements phase detects errors in the requirements specification and

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

the analysis models. The techniques used include requirements reviews, inspection, walk-through, and prototyping. Requirements reviews include customer/user reviews, technical reviews, and expert reviews.

Customer/user reviews are performed by involving the customer and/or users of the system. Customer/user reviews should examine the requirements specification and look for problems in the following areas:

1. The correspondence between requirements and the real world. That is, the requirements specification correctly describes the functional requirements of the application for which the system is to be built or extended.
2. The user interfaces, which includes the appearance, the look and feel, sequence of interaction, input/output data and formats, and the GUI implementation technologies.
3. Nonfunctional requirements. That is, whether the nonfunctional requirements, including performance requirements, security requirements, and user friendliness requirements, are stated correctly.
4. Constraints. That is, whether application-specific constraints are stated correctly. Application-specific constraints may include constraints on the operating environment, political constraints, technological constraints, and so on.

Technical review is an internal review performed by the technical team. Technical review techniques include peer review, inspection, and walk-through:

- In peer review, the requirements specification and the analysis models are reviewed by peers, who are guided by a list of review questions designed to assess qualitatively the quality of the product being reviewed. Answers to the questions by the peers may vary drastically because the answers represent the reviewer's opinion about the product under review and heavily depend on the reviewer's knowledge, experience, background, and criticality. This process is similar to the product review reports published in consumer magazines. The review reports by different writers may differ drastically. The review meeting usually runs about two hours and takes place one to two weeks after the review assignments, which allows the developer and the peers to discuss the feedback and to identify action items to address the issues.
- Inspection checks the requirements and the analysis models against a list of items that are found to be error prone or problematic (3,4). Unlike reviews, inspection looks for more specific problems and the answers can be more objective. This process is similar to car inspection in which the inspector checks the engine, brake, lights, and so on. to see whether each of them is working properly. Since it is more well defined, a computer can perform a car inspection nowadays.
- Walk-through is carried out by explaining and examining the requirements (5). In particular, the analyst who wrote the requirements specification explains each requirement to the peers who would raise questions and stimulate doubts. The analyst would answer the questions and address the doubts. In addition, each of the analysis models is examined carefully. That is, the analyst who drafted the model leads the peers through the model and provides necessary clarification while the peers may ask questions and raise doubts. This process is similar to the new car salesperson at a car dealer who demonstrates a new car to potential buyers by showing various kinds of operations of the car. The buyers usually would raise questions and concerns during the demonstration, and the salesperson would address the questions and concerns.

The above verification and validation activities should aim to reveal the following problems:

- Incompleteness, which includes
  1. Definition incompleteness; for example, some application-specific concepts are not defined.
  2. Internal incompleteness; for example, some requirement expression has an "if part" but does not have the "else part." Another example is that a decision tree or decision table has not considered all possible combinations of the conditions used to construct the decision tree or the decision table.
  3. External incompleteness; that is, cases exist in the real-world application but are not included in the requirements specification. For example, a decision table or decision tree does not include a condition that should have been included.
- Inconsistency, which includes
  1. Type inconsistency; that is, an inconsistent specification is provided of one or more data types in the requirements or analysis model.
  2. Logical inconsistency; that is, contradictory conclusions can be inferred from the specification.
  3. View inconsistency; that is, inconsistency exists between views of the system by different user groups. For example, the perception of user group A is contradictory to the perception of user group B.
- Ambiguity, which includes
  1. Ambiguity in the definition of application specific concepts.
  2. Ambiguity in the formulation of requirements.
- Redundancy, which includes
  1. Duplicate definitions of the same concept.
  2. Duplicate formulations of the same requirement or constraint.
  3. Unnecessary concepts or constraints.
- Intractability, which means the high-level requirements do not correspond to the lower level requirements. If the system is being developed using the object-oriented paradigm, then the technical review must ensure that the use cases are tractable to the requirements and vice versa. It is often facilitated by constructing a requirements–use cases tractability matrix during the analysis phase. The matrix shows which requirement is to be realized by which use cases.

The review should ensure at a minimum that each requirement is realized by some use cases and that each use case serves to realize some requirements.

- Infeasibility in terms of performance, security, and cost constraint. That is, can the development team deliver the functional capabilities as stated in the requirements specification with the expected performance and security within the cost and schedule constraints?
- Unwanted implementation details. Implementation details must not be mentioned in the requirement specification because this limits the design space. Examples include mentions of pointers, physical data structures, and use of pseudocode or programming language statements.

Expert review in the requirements phase means review of the requirements specification by domain experts, looking for

1. Incorrect or inaccurate formulation of domain-specific laws, rules, behaviors, policies, standards, and regulations.
2. Incorrect, inaccurate, inappropriate, or inconsistent use of jargons.
3. Incorrect perception of the application domain.
4. Other potential domain-specific problems or concerns.

In the requirements phase, prototyping or rapid prototyping can take many different forms. The main purpose is to construct quickly a prototype of the system and to use it to acquire customer/user feedback. That is, prototyping is used as a validation technique in the requirements phase to help ensure that the team understands whether the customer/user requirements are captured correctly.

The simplest prototype could be a set of drawings that illustrate the user interfaces of the future system. The most sophisticated prototype could be a partially implemented system that the users can experiment with to gain hands-on experience. The most commonly observed prototype is one in which the team can demonstrate the functionality and user interfaces of the system to the customer or end users. Which type of prototype to use is an application-dependent issue. For instance, applications that are concerned mostly with mission-critical operations would benefit from prototypes that demonstrate the functionality and behavior. Applications that are end user oriented would benefit from prototypes that demonstrate the user interfaces.

The requirement phase is ideal for preparing system test cases to be used to validate the system before deployment. If use cases or scenarios have been used in requirements analysis, then they can be used to prepare system test cases. First, for each use case or scenario, the user input parameters are identified. Next, the possible input values of each input parameter are determined, which can be done as follows. For each input parameter, at least three possible cases can be considered (*1*) valid value is used, (*2*) an invalid value is used, and (*3*) the input parameter is not applicable or not available. A more refined approach will consider other partitions of the input parameter according to the application at hand. In addition to equivalence partitioning, boundary values for each input parameter can also be used. A table with the columns representing the input parameters and the rows representing the test cases can then be constructed and used during the system testing phase.

Verification and Validation for the Design Phase

Verification and validation in the design phase assess the correctness, consistency, and adequacy of the design with respect to the requirements and analysis models. Verification and validation activities in the design phase use review, inspection, walk-through, formal verification, and prototyping techniques. Depending on who performs these activities, we have peer review, customer review, and expert review. Peer review, inspection, walk-through, and formal verification are performed by the development team. They are mostly verification activities, although some of them may be concerned with design validation.

Peer review, inspection, walk-through, and formal verification check the design documentation to ensure

1. Correct use of the design language, which includes:
   - The notions and notations of the design specification language are used correctly.
   - The design specification expresses clearly and correctly the design of the proposed system.
2. Adequacy. The design specification prescribes a solution that is implemented that will satisfy the requirements of the proposed system. It can be done as follows:
   - The high-level verification ensures that each requirement is realized by some modules in the design and that each module in the design is necessary for satisfying some requirements.
   - The detail-level verification aims at ensuring that the capability stated in each requirement can actually be delivered when the system is implemented according to the design specification. It can be accomplished by a design traversal to demonstrate how the requirement can be satisfied.
3. Nonredundancy, which includes:
   - The design does not include items that are not necessary for satisfying the requirements or for significantly improving design quality. (For instance, design patterns may introduce additional classes, but proper use of design patterns significantly improves design quality.)
   - The design does not contain items that are already covered by another part of the design. For instance, a rule in a decision table may already be covered by other rule(s).
4. Consistency, which includes:
   - Logical consistency. That is, the various portions of the design specification do not contain contradictory design descriptions. For example, the decision table or decision tree are commonly used in the design phase to describe a process logic for modules. A

decision table or decision tree is inconsistent if two or more rules have the same condition combination but different action sequences. When the design is represented in a modeling language such as UML, it may contain several diagrams to represent the system from different views and/or at different levels of abstraction. These diagrams must also be checked for consistency across the diagram.

- Definition-use consistency. That is, the use of a component, class, data structure, data element, or function corresponds to the respective definition and interaction sequence. For example, the invocation of a function must correspond to the definition of the function signature and return type. A commonly observed inconsistency in object interaction design or sequence diagramming is an object calling another object, but the called function is not defined.
- Design/specification consistency. That is, the design specification is consistent with the models constructed in the analysis phase.

5. Internal completeness. Checking internal completeness is to ensure that the design has covered all possible combinations of a given set of conditions. For example, if a decision table has three binary conditions, then it must contain eight independent rules to cover the eight possible combinations of the three binary conditions.
6. Design principle compliance. The design follows well-known design principles such as separation of concerns, high cohesion, and low coupling. This process can be facilitated by computing and analyzing a set of design quality metrics, such as cohesion, coupling, scope of effect, scope of control, fan-in, fan-out, class size, height of inheritance tree, and design complexity metrics. For example, the class size metric is the number of methods in a class. If the class size less the number of getters and setters is large, then the class may have been assigned too many responsibilities. It then may signify that the cohesion of the class will be low. The reviewers can then focus their effort on examining such classes.
7. Module interface. That is, communication between modules is explicit and easy to understand. Moreover, no hidden assumptions should be provided for invoking a module.

Although peer review, inspection, and walk-through are concerned mostly with design verification, customer review and prototyping are concerned mainly with design validation. They are usually performed jointly by the development team and the customer (or customer representative, including the system analyst). As a design validation activity, customer review and prototyping aim at detecting mismatches, omissions, or inconsistencies between the design and the customer's interpretation of the requirements, including

1. Mismatch between designed functionality and/or behavior and the functionality and/or behavior as expected by the customer/users.
2. Mismatch between system states, events, and cases and the actual states, events, and cases in the business domain. It includes checking of external completeness.
3. Mismatch between the system's user interface design and what is expected by the customer/users.
4. Mismatch between the system's interfaces to other systems and the required interfaces in the real world.

Another validation activity in the design phase is the preparation of functional test cases, behavioral test cases, and integration test cases. The design phase is ideal for the preparation of these test cases because all needed information is contained in the design documents. For example, if decision tables have been used in the design phase to express process logic, then each rule of the decision table is a cause–effect test case. If state machines have been used in the design phase to describe state-dependent behaviors, then the state machines can be used to derive transition sequences to test the implemented state-dependent behaviors.

Integration test cases can be derived from structured charts (also called routine diagrams) using a preorder traversal in top-down integration and postorder traversal in bottom-up integration. If the system is being developed using an object-oriented approach, then the integration test cases can be derived from sequence diagrams or collaboration diagrams, that is, deriving test cases that will exercise message passing paths according to the coverage criteria selected.

Verification and Validation for the Implementation Phase

Verification and validation for the implementation phase ensure that the source code complies with the organization's coding standards; implements the required functionality, satisfies performance, real-time, and security requirements; and properly handles exceptional situations. Desk checking, code review, inspection, and walk-through are referred commonly to as verification and static validation methods, whereas testing is referred commonly to as the dynamic validation method. All these process are used in the implementation phase.

In desk checking, the programmer checks the program written by him/her. The programmer may use a pencil, a calculator, and/or other devices. It is an informal process, and hence, the effectiveness and efficiency depends on the individual programmer. In code review, the program is reviewed by peers who are required to comment on the quality of the code and answer a set of questions. Code inspection checks the code against a list of problems or defects that are commonly found in programs. The most famous code inspection method was proposed by Fagan and is called the Fagan inspection method (3,4). In walk-through, the reviewers use test data or a specific scenario in the operation of the software and manually follow step by step the logic described in the artifact under review to understand how the system operates and then to detect errors (5). For example, when the artifact under review is a piece of source code, the reviewers manually execute the program by following the control flow between the statements and expressions in the code. Finally, testing is actually executing the program with test cases derived using ad hoc or systematic test case generation methods.

Desk checking, code review, code inspection, and walkthrough are aimed to detect problems such as follows:

1. Incorrect/inadequate implementation of functionality.
2. Mismatch of implementation and design.
3. Mismatch of module interfaces.
4. Coding standards are not followed.
5. Poor code quality as measured by various code quality metrics such as cyclomatic complexity (e.g., some companies require this to be no more than 10), information hiding, cohesion and coupling, and modularity.
6. Improper use of the programming language.
7. Incorrect/improper implementation of data structures or algorithms.
8. Errors/anomalies in the definition and use of variables such as variables or objects are defined but not used, not initialized, or not initialized correctly.
9. Infinite loop.
10. Incorrect use of logical, arithmetic, or relational operators.
11. Incorrect invocation of functions.
12. Inconsistencies caused by concurrent updates to shared variables.

Desk checking, code review, code inspection, and walkthrough are effective in detecting errors and anomalies if applied properly. In particular, ordinary testing methods may not detect problems as described by items 4–6 and 8–12. On the other hand, testing is distinct and indispensable because testing can detect performance bottlenecks and incorrect interface. These issues usually cannot be detected by the static validation methods.

Verification and Validation for Integration Phase

In the integration phase, the software modules are integrated to form a complete software system. Dynamic validation or testing is the main activity of this phase. The purpose of integration testing is to detect errors in the interfaces between the software modules. These errors include

1. Incorrect assignment of actual parameters to formal parameters.
2. Incorrect assignment of values to variables in one module and/or incorrect use of the variables in another module.
3. Incorrect interaction between modules. For example, incorrect sequence of function calls or module invocations.
4. Incorrect state behavior resulting from module interactions

Integration testing can be carried out by using one or more of the following strategies. These strategies assume that the architectural design has a tree or lattice structure with a top-level module that invokes second-level modules, which invoke third-level modules, and so on:

1. Top-down strategy. Integration testing begins with testing the interfaces between the top-level module that corresponds to the overall system and modules that are invoked by the top-level module. Lower level modules that are invoked by modules being integrated are replaced by test stubs. A test stub is a module that is constructed specifically to provide the output values as expected by the higher level module. We need to use test stubs because we have not tested the interfaces between the modules being integrated and the modules being replaced; if any of these interfaces is incorrect, then the error may propagate up and affect the integration testing result at the higher level.
2. Bottom-up strategy. Integration testing begins with testing the interfaces between the lowest level modules and their parent module and progresses up the hierarchy. A test driver is needed to invoke the parent module because the interface between the parent module and its parent module has not been tested.
3. Hybrid strategy. As the name suggests, integration testing may proceed using both of the above strategies in various combinations.
4. Criticality-based strategy. Integration testing begins with integrating critical modules of the system first as long as the modules are available. This strategy allows the critical modules to be exercised more often and hopes to detect more errors in these modules.
5. Availability-based strategy. Integration testing is carried out incrementally by adding modules that are ready to be integrated into the software system.
6. Monolithic strategy. Integration testing is performed by integrating all modules of the system at once.

Verification and Validation for System Testing

During the system testing phase, the software system is integrated with other systems and tested against the software/system requirements. System testing is usually performed in the development environment. The end product of system testing is a system that is ready for deployment and acceptance testing in the customer's target environment.

As indicated, system testing is performed against the software/system requirements, including functional and nonfunctional requirements. The objective is to ensure that the system satisfies the functional and nonfunctional requirements. In addition, the system must also satisfy the constraints stated in the requirements specification. System testing with respect to functional requirements can be carried out using one or more of the following approaches:

- Use case-based testing. As described in the section entitled "Verification and Validation for the Requirements Phase," if system use cases have been derived from the requirements, then system testing can be performed by testing that the system satisfies each use case. Please see this section for more detail.

- Random testing. Test data are selected randomly to test the system against the requirements. This process may or may not use an input data distribution profile, which can be obtained from existing or similar systems' usage log.

In addition to functional testing, performance and stress testing are also performed during the system testing phase. Performance testing includes testing the throughput and response time according to the predefined workload, and stress testing is concerned with system throughput and response time under a workload that is multiple times or even ten folds of the normal workload.

Verification and Validation for Acceptance Testing

During the acceptance testing phase, the analyst or a consultant hired by the customer will conduct or direct the testing of the system in the customer's target environment to ensure that the system operates properly in that environment. Because the difference between system testing and acceptance testing is the environment, acceptance testing can be carried out by executing a subset of the test cases used during system testing. Clearly, test cases selection should be guided by changes to environment parameters, such as system configuration, run conditions, and network configurations.

Verification and Validation for Maintenance

Once the system is installed and operational in the target environment, the maintenance phase begins. Therefore, the operation and maintenance phases are in fact one combined, indivisible phase. Because of system dynamics (6), continual changes are made to the system once it is released to field operation. Changes or enhancements performed on the system are called collectively maintenance activities, which include:

- Corrective maintenance to correct errors in the system.
- Enhancements to add additional capabilities to the system.
- Improvements to the system, including performance, response time, user friendliness, and other quality aspects.
- Migration to new hardware, new technologies, or new operating environment.
- Preventive maintenance to prepare the system for possible problems such as virus attack.

The verification and validation techniques such as review, inspection, walk-through, and testing can still be used in the maintenance phase to verify and validate the changes. However, several issues must be considered during the maintenance phase:

- Change impact analysis. Changes can affect other parts of the system, and the impact must be identified and analyzed before the changes are made. This process is described usually in the Engineering Change Proposal along with change cost and schedule and is evaluated by a Change Control Board. This topic is beyond the scope of this article and is covered by the article "Software Configuration Management."
- Review, inspection, and walk-through may be conducted for new, changed, and affected modules.
- New test cases must be designed to test the newly introduced modules.
- The changed and affected modules must be retested using existing test cases to ensure that no undesired side effect has been introduced. This process is commonly called regression testing.

FORMAL VERIFICATION

Formal verification is a means to verify a specification or a design mathematically. Two main approaches to formal verification exist.

The first approach is based on theorem-proving methods (7–9). We call this approach the proof-theoretical approach. In this approach, a system specification consists of a set of declarative statements or declarative sentences. These statements typically specify properties of real-world and/or system entities or objects, their behaviors, and their relationships. In mathematical terms, the set of statements is called a theory and is assumed to be true at all times because the statements state what are about the system. In computer science and software engineering, the statements are called nonlogical axioms because they are not logically true but assumed to be true according to laws of the real-world application. For example, "every customer has an account" and "every account is owned by a customer" cannot be proved to be true logically, but they could be true for some bank application. Formal verification in the proof-theoretical approach is to prove that desired system properties or constraints are logical consequences of the nonlogical axioms. That is, desired properties or constraints can be derived logically from the nonlogical axioms.

Consider, for example, an overly simplified formal specification of a stack:

1. Maximal size of stack.

$$\mathrm{MAX} = 2$$

2. Initial size of stack.

$$\mathrm{size(S0)} = 0$$

where S0 denotes the initial state.

3. Operation "push" (we focus only on the size but nothing else).

$$\mathrm{size(S)} = \mathrm{s}\ \&\ \mathrm{s} < \mathrm{MAX} \rightarrow \mathrm{size(push(S)} = \mathrm{s} + 1$$

(If stack size in state S is s and s is less than MAX, then stack size in the state resulting from pushing a element onto the stack is s+1.)

4. Operation "pop,"

$$\text{size(S)} = \text{s} \,\&\, \text{s} > 0 \rightarrow \text{size(pop(S))} = \text{s} - 1$$

Now suppose we want to prove the desired property stating that "there is some state in which the stack size will be MAX.-formally

5.

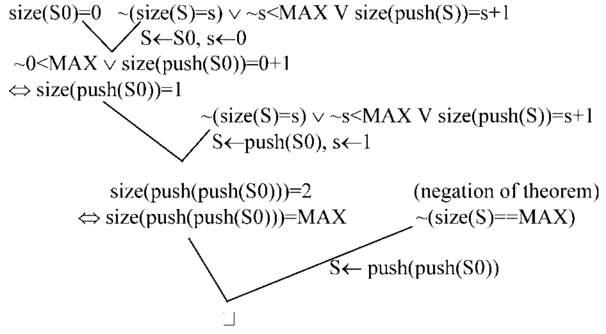
$$(\exists \text{S})\text{size(S)} = \text{MAX}$$

That is, a state S exists in which the size of the stack is MAX.

We will illustrate the proof using the resolution proof technique proposed by Robinson (10). To prove that Q is a logical consequence of P1, P2, . . ., Pn, we prove that $\sim$Q, P1, P2, . . ., Pn cannot be true at the same time, where Q, P1, P2, . . ., Pn are statements.

Aresolution proof begins with the set of statements {Q, P1, P2, . . ., Pn}, and each resolution tries to deduct a statement called resolvent from two statements using the logical inference rule "A & $(\text{A} \rightarrow \text{B}) \Rightarrow \text{B}$" or equivalently "A & $(\sim \text{A} \vee \text{B}) \Rightarrow \text{B}$." That is, from statement "A" and statement "$\sim \text{A} \vee \text{B}$," we can deduct "B." Clearly, each resolution step takes two statements and produces one new statement. If the set of statements can be deduced to produce the nil statement, denoted by "□" and representing a contradiction, then the theorem is proved. The proof of our stack example is shown in Fig. 1.

Figure 1 is a special case because it does not use the so-called "frame axiom" originally proposed by McCarthy and Hayes (11). In their effort to construct the first question answering system using logical inference, McCarthy and Hayes discovered that the specification of the effect of an operation like items 3 and 4 in the above stack specification example is not enough. The specification must also state that everything that is not changed by the operation remains true in the new state resulting from the operation. This process is commonly referred to as the "frame axiom." Fortunately, nothing is not changed by the operations push and pop; therefore, our simple example does not have to use the frame axiom.



size(S0)=0
~(size(S)=s) ∨ ~s<MAX V size(push(S))=s+1
S←S0, s←0
~0<MAX ∨ size(push(S0))=0+1
⇔ size(push(S0))=1
~(size(S)=s) ∨ ~s<MAX V size(push(S))=s+1
S←push(S0), s←1
size(push(push(S0)))=2
⇔ size(push(push(S0)))=MAX
(negation of theorem)
~(size(S)==MAX)
S← push(push(S0))
□

Figure 1. Resolution proof of the simplified stack specification.

Now suppose we want to prove another desired property that states "the size of the stack is always greater than or equal to zero." Formally

6.

$$(\forall \text{S})\text{size(S)} > \,= 0$$

The reader will soon discover that applying resolution to prove this property is extremely difficult (almost impossible). A proof technique that is commonly used to prove theorems that state properties true for all cases like this is the proof by induction technique. Using an induction proof, the property is proved for the basis case, and then it is assumed to be true for all cases up to a number k; finally, the property is proved for the k+1 case. We illustrate this in the following. We use op(S) to denote either push(S) or pop(S) and op^k(S) a sequence of k push or pop operations applied in S.

The basis step. Since size (S0) = 0 is given in item 2 in the specification, this implies size(S0)>=0. Therefore, property is true in S0.

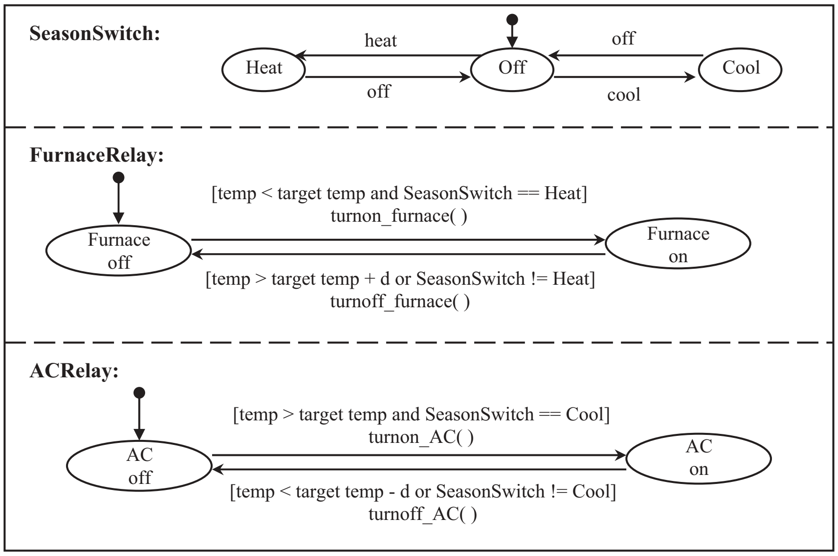
The hypothesis step. Now assume that size(op^k(S0))>=0 for all sequences of k push or pop operations applied in the initial state.

The induction step. We need to prove size(op^{k+1}(S0))>= 0. Since there are only two operations, size(op^{k+1}(S0)) can only be size(push(op^k(S0))) or size(pop(op$^{\text{k}}$(S0))). Since size(push(op^k(S0))) = size(op^k(S0))+1 according to item 3) and size(op^k(S0))>=0 from to hypothesis, size(push(-op^k(S0))) > 0, and hence size(push(op^k(S0))) >=0. Moreover, since size(op^k(S0))>=0 and pop can only be applied in state op^k(S0) if size(op^k(S0))>0. Thus, size(push (op^k(S0))) >=0. Therefore, size(op^{k+1}(S0))>=0.

A property regarding a software system that is true in all states, like the above example, is called an invariants.

The second approach is called model checking(12–15). This approach can also be called the model-theoretical approach. In this approach, the system is represented by an operational model, which typically depicts the system behavior. The commonly used operational model for model checking is a state machine consisting of vertices representing system states and directed edges representing system behaviors that cause state transitions. Each system state is specified by a logical or conditional statement. That is, the system is in that state if and only if the condition is evaluated to true using system attributes. Formal verification in the model-checking approach begins with the initial system state and generates the states by applying the operations. The desired properties or constraints are checked against each state generated, and violations are reported.

Consider a simplified thermostat example consisting of only a season switch, an AC relay and a furnace relay as



SeasonSwitch:
Heat
Off
Cool
heat
off
off
cool
FurnaceRelay:
Furnace off
Furnace on
[temp < target temp and SeasonSwitch == Heat]
turnon_furnace( )
[temp > target temp + d or SeasonSwitch != Heat]
turnoff_furnace( )
ACRelay:
AC off
AC on
[temp > target temp and SeasonSwitch == Cool]
turnon_AC( )
[temp < target temp - d or SeasonSwitch != Cool]
turnoff_AC( )

Figure 2. Thermostat specification.

shown in Fig. 2. The desired properties for the thermostat could be as follows:

C1. Not (SeasonSwitchOff and (FurnaceOn or ACOn))

C2. Not (FurnaceOn and ACOn)

C3. Not (SeasonSwitchCool and FurnaceOn)

C4. Not (SeasonSwitchHeat and ACOn)

Applying the operations of the thermostat results in the tree as shown in Fig. 3. A system state is represented by a triple (S1, S2, S3), where S1 denotes the state of the season switch, S2 denotes denotes the state of the furnace relay, and S3 denotes the state of the AC relay. The figure shows that starting in the initial state, the thermostat can enter into a state in which the season switch is at cool and the furnace and AC are both on. This state violates constraint C2 and constraint C3. In practice, model checking can be used to check not only static constraints like C1–C4 but also temporal constraints that involve sequences of states rather than a single state. This process is also true for the theorem-proving approach. Furthermore, the model checker could explore millions of state rather than only a few states as shown in Fig. 3.

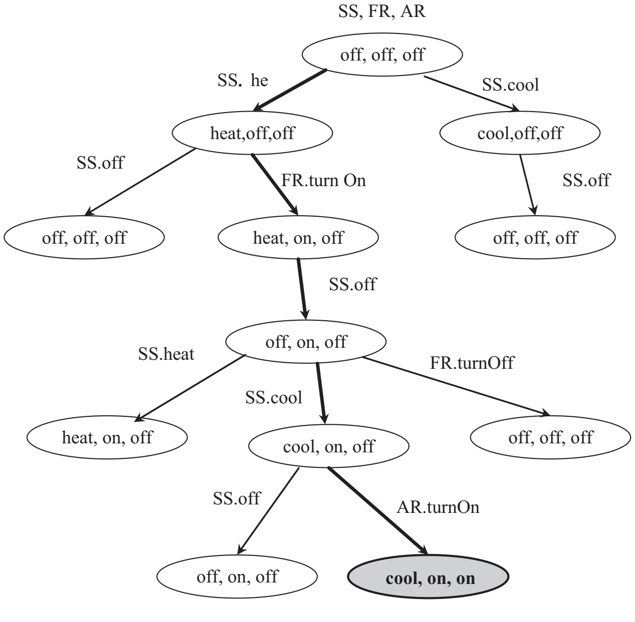


Figure 3. Partial state space of the thermostat example.

In practice, the state machine models are converted into the specification language of the model checker. Using SPIN (14), this would be the Promela language, which is a subset of the C programming language. The property to be verified is expressed as a temporal logic expression. The checker will explore the state space and verify the property.

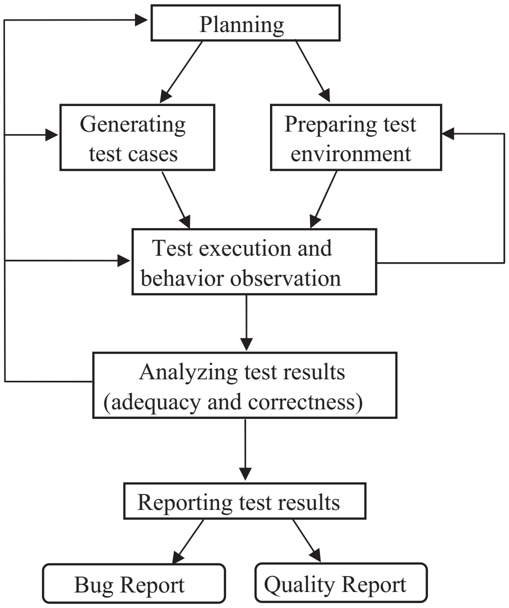
In recent years, model checking has been applied to checking code or implementation rather than to checking the specification (16–18). This process has been termed “software model checking.” In software model checking, the model is constructed from code or implementation rather than from the specification. The construction can be manual or semiautomatic.

SOFTWARE TESTING TECHNIQUES

This section gives a brief introduction to well-known software testing techniques and methods.

Software Testing Processes

Generally speaking, software testing is an iterative process that involves several technical and managerial activities. In this section, we will focus on the technical aspects. As shown in Fig. 4, the main technical activities in the software testing process include planning, generating, and selecting test cases; preparing a test environment; testing the program under test; observing its dynamic behavior; analyzing its observed behavior on each test case; reporting test results; and assessing and measuring test adequacy.



Planning
Generating test cases
Preparing test environment
Test execution and behavior observation
Analyzing test results (adequacy and correctness)
Reporting test results
Bug Report
Quality Report

Figure 4. Illustration of activities in software testing process.

In software testing practice, testers are confronted with questions like: Which test cases should be used? How to determine whether a testing is adequate? Or when can a testing process stop? These questions are known as the *test adequacy* problem (19). They are the central issues in software testing, and the most costly and difficult issues to address. A large number of test criteria have been proposed and investigated in the literature to provide guidelines to answer these questions. Some of them have been used in software testing practice and are required by software development standards. A great amount of research has been reported to assess and compare their effectiveness and efficiency.

The observation of dynamic behavior of a program under test is essential for all testing. Such observations are the basis of validating a software's correctness. The most often observed software behaviors are the input–output of the program during testing. However, in many cases, observation of the internal states, the sequences of code executed, as well as other internal execution histories are necessary to determine the correctness of the software under test. Such internal observations are often achieved by inserting additional code into the program under test, which is known as *software instrumentation*. Automated tools are available for the instrumentation of programs in various programming languages. Behavior observation can also be a very difficult task, for example, in the testing of concurrent systems because of nondeterministic behavior in testing component-based systems because of the unavailability of source code, in testing real-time systems because of their sensitiveness to timing and load, in testing systems that are history sensitive such as machine learning algorithms where the reproduction of a behavior is not always possible, in testing of service-oriented systems because of the lack of control of third-party services, and so on.

Checking the correctness of a program's output as well as other aspects of dynamic behavior is known as the test *oracle problem*. A test oracle is a piece of program that simulates the behavior of the program under test. It could be as simple as a person or a program that judges the output of the program under test according to the given input. If a formal specification of the system is available, then the output can be judged automatically, e.g., by using algebraic specifications (20–22). A recent development in the research on the metamorphic software testing method enables testers to specify relationships between outputs of a program on several of test cases and to check whether the relationships held during testing (23).

Testing methods

Testing activities, especially test case selection and generation and test adequacy assessment, can be based on various types of information available during the testing process. For example, at the requirements stage, test cases can be selected and generated according to the requirements specification. At the design stage, test cases can be generated and selected according to the architectural design and detailed design of the system. At the implementation stage, test cases are often generated according to the source code of the program. At the maintenance stage, test cases for regression testing should take into consideration the part of the system that has been modified, either the functions added or changed or the parts of the code that are modified. In general, software testing methods can be classified as follows[1].

- *Specification-based testing methods*. In a specification-based testing method, test results can be checked against the specification, and test cases can be generated and selected based on the specification of the system. For example, test cases can be generated from algebraic specifications (24), derived from specifications in Z (25, 26), or using model checkers to automatically generate test cases from state machine specifications (27, 28).
- *Model-based testing methods*. A model-based testing method selects and generates test cases based on diagrammatic models of the system, which could be a requirements model or design model of the system. For example, in traditional structured software development, test cases can be derived from data flow, state transition, and entity-relationship diagrams (29). For testing object-oriented software systems, techniques

[1] Traditionally, testing methods were classified into *white-box* and *black-box* testing. *White-box* testing was defined as testing according to the details of the program code, whereas black-box testing does not use the internal knowledge of the software. Many modern testing methods are difficult to classify either as black box or as white box. Thus, many researchers now prefer a more sophisticated classification system to better characterize testing methods.

and tools have been developed to generate test cases from various UML diagrams (30, 31) .

- *Program-based testing methods*. A program-based testing method selects and generates test cases based on the source code of the program under test. Tools and methods have been developed to generate test cases to achieve statement, branch, and basis path coverage. Another program-based testing method is the so-called *decision condition testing* method, such as the *modified condition/decision coverage* (MC/DC) criterion (32) and its variants (33), which focus on exercising the conditions in the program that determine the directions of control transfers.
- *Usage-based testing methods*. A usage-based testing method derives test cases according to the knowledge about the usage of the system. For example, a random testing method uses the knowledge about the probability distribution over the input space of the software, such as the operation profile. Another commonly used form of usage-based testing is to select test cases according to the risks associated with the functions of the software.

It has been recognized for a long time that testing should use all types of information available rather than just rely on one type of information (34). In fact, many testing methods discussed here can be used together to improve test effectiveness.

Testing Techniques

Several software testing techniques have been developed to perform various testing methods. These testing techniques can be classified as follows.

- *Functional testing techniques*. Functional testing techniques thoroughly test the functions of the software system. They start with the identification of the functions of the system under test. The identification of functions can be based on the requirements specification, the design, and/or the implementation of the system under test. For each identified function, its input and the output spaces and the function in terms of the relation between the input and the output are also identified. Test cases are generated in the function's input/output spaces according to the details of the function. The number of test cases selected for each function can also be based on the importance of the function, which often requires a careful risk analysis of the software application. Usually, functions are classified into high risk, medium risk, or low risk according to the following criteria

1. The cost and the consequences that a failure of the function may cause.
2. The frequency with which the function will be used.
3. The extent to which the whole software systems' functionality and performance depends on the function's correctness and performance.
4. The likelihood that the implementation of the function contains faults, say because of high complexity, the capability, and maturity of the developers, or any priori knowledge of the system.

A heuristic rule of functional testing is the so-called 80–20 rule, which states that *80% of test efforts and resourses should be spent on 20% of the functions of the highest risks*.

An advantage of functional testing techniques is that various testing methods can be combined. For example, functions can be identified according to the requirements specification. If additional functions are added during design, they can also be identified and added into the list of functions to be tested. An alternative approach is to identify functions according to the implementation, such as deriving from the source code. When assigning risks to the identified functions, many factors mentioned in the above criteria can be taken into consideration at the same time. Because some factors are concerned with users' requirements and some are related to the design and implementation, it naturally combines requirements-based with design and implementation-based methods. The main disadvantage is that functional testing techniques are largely manual operations, although they are applicable to almost all software applications.

- *Structural testing techniques*. Structural testing techniques regard a software system as a structure that consists of a set of elements of various types interrelated to each other through various relationships. They intend to cover the elements and their interrelationships in the structure according to certain criteria. Typical structural testing techniques include control flow testing and data flow testing techniques and various techniques developed based on them.

  Control flow testing techniques represent the structure of the program under test as a flow graph that is a directed graph where nodes represent statements and arcs represent control flows between the statements. Each flow graph must have a unique entry node where computation starts and a unique exit node where computation finishes. Every node in the flow graph must be on at least one path from the entry node to the exit node. For instance, the following program that

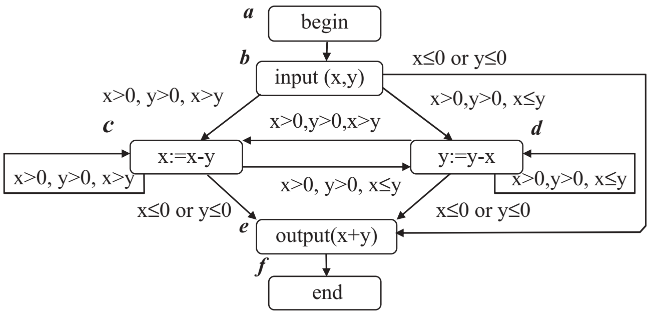


Figure 5. Flow graph of the Greatest Common Divisor program.

computes the greatest common divisor of two natural numbers using Euclid's algorithm can be represented as a flow diagram shown in Fig. 5.

```
 Procedure Greatest-Common-Divisor;
 Var x, y: integer;
 Begin
    input (x,y);
    while (x>0 and y>0) do
       if (x>y)
              then x:= x-y
              else y:= y-x
    endif
    endwhile;
    output (x+y);
end
```

As a control flow testing method, statement testing requires the test executions of the program on test cases exercise all the statements, i.e. nodes, in the flow graph. For example, paths $p = (a, b, c, d, e, f)$ in Fig. 5 cover all nodes in the flow graph; thus, the test case t_1= (x=2, y=1) that causes the path p to be executed is adequate for statement testing. Obviously, adequate statement testing may not execute all the control transfers in the program. Branch testing requires the test cases to exercise all the arcs in the flow graph, i.e. all the control flows, thus the branches, of the program. The test case t_1 is therefore inadequate for branch testing. Various path testing techniques require test executions cover various types of paths in the flow graph, such as all paths of length-N for certain fixed natural number N, all simple paths (i.e., the paths that contain no multiple occurrences of any arcs), all elementary paths (i.e., paths that contain no multiple occurrences of nodes), and so on.

Data flow testing techniques focus on how values of variables are assigned and used in a program. Each variable occurrence is therefore classified to be either a definition occurrence or a use occurrence:

– *Definition occurrence*: Where a value is assigned to the variable.

– *Use occurrence* (also called *reference occurrence*): Where the value of the variable is referred to. Use occurrences are also classified into *computation uses (c-use) and predicate uses (p-use).*

Predicate use: Where the value of a variable is used to decide whether a predicate is true for selecting an execution path.

Computation use: Where the value of a variable is used to compute a value for defining other variables or as an output value.

For example, in the assignment statement y:= x_1 − x_2, variables x_1 and x_2 have a computation use occurrence, whereas variable y has a definition occurrence. In the if-statement *if* x=0 *then goto L endif*, variable x has a predicate use occurrence. Figure 6 shows the flow graph with data flow information of the program given in Fig. 5.

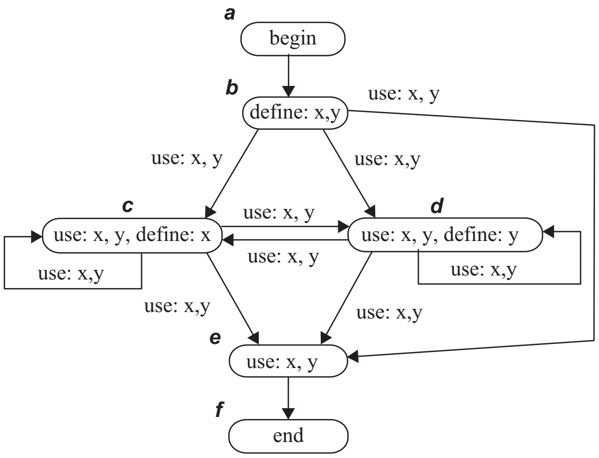

Figure 6. Flow graph with data flow information.

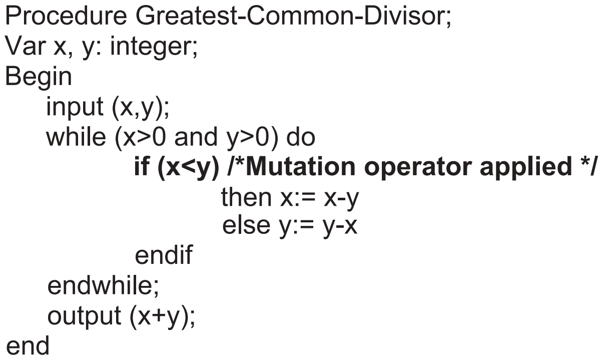
Using such data flow information, the data flow in a program can be expressed by the paths from a node where a variable x is defined to a node where the variable is used, but no other definition occurrence of the same variable x on the path (which is called the *definition-clear path of* x). Such a path is called a *definition-use association*. The principle underlying all data flow testing is that the best way to test whether an assignment to a variable is correct is to check it when its assigned value is used. Therefore, data flow test criteria are defined in the form of exercising definition-use associations or various compositions of the relation. For example, a data flow test criterion in Weyuker–Rapps–Frankl's data flowing testing techniques require testing all definition-use associations(35, 36) . Other data flow testing techniques include Laski and Korel's *definition context coverage criteria* (37), and Ntafos's *interaction chain coverage criteria* (38).

- *Fault-based testing techniques*. Fault-based testing techniques detects all faults of certain kinds in the software. For example, *mutation testing* detects all the faults that are equivalent to mutants generated by a set of mutation operators (39,40). In general, a mutation operator is a transformation that modifies the software with a single small change and preserves the software's syntax to be well formed. For example, a typical mutation operator changes a greater than symbol > in an expression to be the less than symbol <. When this mutation operator is applied to the



```
Procedure Greatest-Common-Divisor;
Var x, y: integer;
Begin
   input (x,y);
   while (x>0 and y>0) do
         if (x<y) /*Mutation operator applied */
               then x:= x-y
               else y:= y-x
         endif
   endwhile;
   output (x+y);
end
```

Figure 7. A mutant of the Greatest Common Divisor program.

Table 1. Levels of mutation analysis

Level	Goal	Method (Mutation operators)
Interface Analysis	Ensure interfaces between software components are correct and adequately tested in integration testing.	(1) Mutation operators are designed to model integration errors, (2) Tests only the connections between two modules, a pair at a time, and (3) Applies integration mutation operators only to module interfaces such as function calls, parameters, or global variables.

Language Specific Feature Analysis	Ensure language-specific features were used properly.	For example, for test of Java-specific features:
		Delete and insert *This* keyword;
		Delete and insert *Static* keyword;
		Delete member variable initialization; etc.

Polymorphism Analysis	Exercise all possible dynamic-type bindings to ensure the correctness of polymorphic behavior of object references.	Change the instantiation type of an object reference to a child or parent class; Delete, insert, or change type cast operator; Delete overloading method declarations; Change the parameters of overloading method calls.
Inheritance relationship Analysis	Ensure the inheritance relationships, including variable hiding, method overriding, uses of super, and definition of constructors, are correctly defined.	Delete or insert overriding methods and hiding variables; Change the calling position of overriding methods, Rename overriding methods; Delete and insert keyword 'Super'; Delete and insert parent constructor calls; etc.
Class Encapsulation Analysis	Ensure class declarations correctly use encapsulation facilities for various accessibility levels.	Change the access modifiers (i.e., private, protected, public, and unspecified) of the attributes and methods in class declarations.
Statement Analysis	Ensure that every branch is taken and the every statement is necessary.	Replace statement with CONTINUE; Replace logical and relational with true or false; Check labels on arithmetic IF statements for usage; Replace DO statements with FOR statements.
Predicate Analysis	Exercise predicate boundaries.	Alter predicate and DO loop limits sub-expressions by small amounts; Insert absolute value operators into predicate sub-expressions; Alter relational operators.r
Domain Analysis Coincidental Correctness Analysis	Exercise different data domains. Guard against coincidental correctness.	Change constants and sub-expressions by small amounts; Change data references and operators to other syntactically correct alternatives.

condition of the if-statement in the program given in Fig. 5, the mutant in Fig. 7 will be generated.

```
Procedure Greatest-Common-Divisor;
Var x, y: integer;
Begin
   input (x,y);
   while (x>0 and y>0) do
         if (x<y) /*Mutation operator applied*/
                  then x:= x-y
                     else y:= y-x
            endif
      endwhile;
      output (x+y);
   end
```

Each mutation operator represents a kind of error that could be made by software developers. If a test case enables the original software under test and the mutant to produce different outputs, we say that the mutant is killed by the test case or simply that the mutant is dead, which means that the modified part of the program has been executed and that the part actually affects the behavior of the system. Therefore, if the original program contains a fault at the location where the mutation operator is applied, the test case should be able to detect it. Otherwise, solely based on the test executions on the test cases, we would have no evidence to claim that the test cases are capable of differentiating the mutants from the original. In other words, if a fault exists, the test cases would not be able to detect it. Of course, there are two reasons that a mutant remains alive after testing on all test cases. First, the mutant is equivalent to the original. Thus, it cannot be killed. Second, the test cases were unable to kill it because of its inadequacy. The proportion of nonequivalent mutants that remain alive after testing, which is called *mutation score* in the software testing literature, gives a clear indication of the adequacy of the test set and serves as a test adequacy criterion.

Measuring the mutation score of a test set is, therefore, an analysis of the test adequacy. Different levels of mutation analysis can be done by applying mutation operators to the corresponding syntactical structures in the program (41–44). Table 1 summarizes the levels of mutation analysis and the methods to achieve the goals of the analysis.

Mutation testing tool such as Mothra for Fortran (42) and MuJava for Java (45) have been developed to generate automatically a large number of mutants from a program under test and to execute the program under test and the mutants and to collect the data about dead and alive mutants. Test cases can also be generated to kill a mutant (46). The equivalence of a mutant to the original is not decidable, but it can be determined automatically for a large proportion of mutants.

The idea of program mutation testing can also be extended to specification-based testing in which mutants of specifications are generated (47). A specification mutant is killed if the correctness of the output of the program under test is judged differently by the original specification.

More recently, the idea of mutation has also been applied to generate test data. A set of mutation operators designed so that when applied to a test case, they generate a set of test data that are of subtle differences from the original test case (48). This technique can be applied to test software systems whose test cases are of a complicated structure, such as modeling tools, and other test case generation techniques would have difficulties.

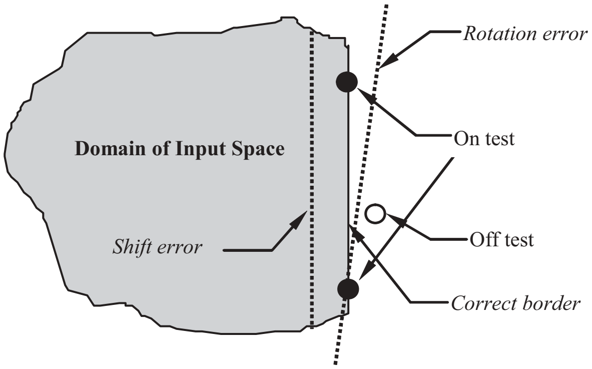


Figure 8. Illustration of boundary shift and rotation errors.

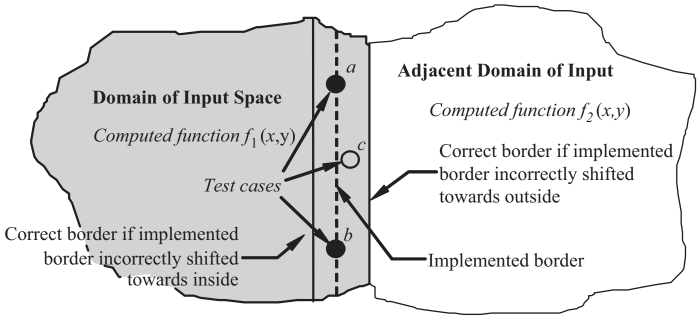
- *Error-based testing techniques*. Error-based testing techniques check all error-prone aspects of the system, where errors are mistakes made software developers. For example, test cases are often selected to test if division by zero error was processed properly by the program.

Among whether the well-established error-based testing techniques are the boundary analysis testing techniques, which select test cases on the boundary and near the boundary of an input space in order to make sure that the programmer has computed correctly the boundary, which has been recognized for a long time as error-prone. As illustrated in Fig. 8, two types of boundary errors have long been recognized as the most common programming errors. They are shift errors, in which the border of an input domain is shifted parallel to the correct border either toward the outside of the input domain or toward the outside of the domain, and rotation errors in which the border is rotated with respect to the correct border.

To detect shift errors of a border in N-dimensional input space, N test cases must be selected on the border and an additional test case must be selected nearby the border. If the input on the border belongs to the input domain, which are called on tests, the test case near the border must be selected outside the input domain, which is



a
Domain of Input Space
Computed function $f_1(x,y)$
Adjacent Domain of Input
Computed function $f_2(x,y)$
c
Correct border if implemented border incorrectly shifted towards outside
Test cases
Correct border if implemented border incorrectly shifted towards inside
b
Implemented border

Figure 9. Selection of test cases using $N \times 1$ criterion.

called off test. Otherwise, if the inputs on the border do not belong to the valid input of the domain, the test case near the border should be selected inside the input domain. In this case, the test cases on the border are off tests, whereas the test case near the border is on test. As illustrated in Fig. 9 for two-dimensional input spaces, by selecting data according to this $N \times 1$ *criterion*, all shift errors can be detected provided that the computed functions in the input domain and outside the domain are different and the border is linear, e.g., a straight line in two dimensional space (49).

However, $N \times 1$ criterion cannot guarantee the detection of rotation errors. To detect rotation errors, in addition to the selection of *N* test cases on the border, N test cases must also be selected near the border in the same way as the $N \times 1$ criterion. It is the so-called $N \times N$ criterion (50).

ACKNOWLEDGMENT

THE FINITE ELEMENT METHOD

INTRODUCTION

Finite element methods are now widely used to solve structural, fluid, and multiphysics problems numerically (1). The methods are used extensively because engineers and scientists can mathematically model and numerically solve very complex problems. The analyses in engineering are performed to assess designs, and the analyses in the various scientific fields are carried out largely to obtain insight into and ideally to predict natural phenomena. The prediction of how a design will perform and whether and how a natural phenomenon will occur is of much value: Designs can be made safer and more cost effective, while insight into and the prediction of nature can help, for example, to prevent disasters. Thus, the use of the finite element method greatly enriches our lives.

As with many other important scientific developments, it is difficult to give an exact date of the "invention" of the finite element method. Indeed, we could trace back the development of the method to the Greek philosophers and in modern times to physicists, mathematicians, and engineers (see the discussions in Refs. 2 and 3). However, the real impetus for the development of what is now referred to as the finite element method was provided by the need to analyze complex structures in aeronautical engineering and the availability of the electronic computer. Namely, when using the finite element method, large systems of algebraic equations need to be assembled and solved, and the computer provides the necessary means to accomplish this task.

The papers of Argyris and Kelsey (4) and Turner et al. (5) were seminal contributions in the 1950s. The name "finite element method" was coined by R.W. Clough in 1960 (6). The potential of the finite element method for engineering analysis was clearly foreseen, and henceforth the research on finite element methods started to accelerate in various research centers in Europe and in the United States. While significant papers and books were written in the next decade (see for example the references in Refs. 2 and 3), the development and rapidly increasing use of some computer programs clearly contributed in a major way to the acceptance and advancement of the method. Indeed, with no computer programs ever developed, the finite element method would have been a theoretical entity without much attention given to it.

The three finite element programs that had a major impact were ASKA, NASTRAN, and SAP (7–9). The NASTRAN and ASKA programs rapidly became major analysis tools in the aerospace and automotive industries. The SAP programs were largely used in civil and mechanical engineering industries and at universities. The availability and wide use of the source codes of SAP IV and NONSAP with the description of the techniques used therein, see Bathe et al. (9–12), had a seminal effect on the development of new algorithms, many finite element programs, and also finite element theory (3,13).

Today, finite element methods probably are used for the analysis of every major engineering design and probably in every branch of scientific studies. The method is now used primarily through the application of commercial finite element programs (see the section titled, "The Use of the Finite Element Method in Computer-Aided Engineering"). These programs are used on mainframes, workstations and PCs and are employed to solve very complex problems. While the finite element methods were used originally for the analysis of solids and structures, the procedures are now employed also for the analysis of multiphysics problems, including fluid flows with fluid–structure interactions (1–3).

The objective in the following sections is to briefly describe the finite element method and give some references that can be consulted for additional study. The description and references, of course, are by no means exhaustive. For the equations used, the notation of Ref. 3 is employed.

THE FORMULATION OF THE FINITE ELEMENT METHOD

Figures 1 to 3 show typical finite element meshes (or finite element assemblages) modeling some solid, structural, and fluid systems. In each case the finite elements are used to represent the volume of the system. The finite elements are connected at the nodal points located at the corners and along the sides and in the faces of the elements. However, nodal points can also be located within the volume of an element. An important feature is that the finite elements do not overlap geometrically but together fill the complete volume of the solid or fluid.

Considering the analysis of a three-dimensional solid, like the wheel in Fig. 1, the geometry and the displacements of each element (within each element including all element surfaces) are completely described by the geometric positions and displacements of the element nodal points. The element nodal coordinates prior to any displacements are known, of course, and the nodal displacements are the unknowns to be calculated. The basic step is to interpolate the element geometry and the element displacements by using the nodal values. Here the isoparametric element interpolation, a most important development due to Irons (14), is largely used. For an element with q nodal points we use

$$x = \sum_{i=1}^{q} h_i x_i;\ y = \sum_{i=1}^{q} h_i y_i;\ z = \sum_{i=1}^{q} h_i z_i$$

$$u = \sum_{i=1}^{q} h_i u_i;\ v = \sum_{i=1}^{q} h_i v_i;\ w = \sum_{i=1}^{q} h_i w_i \qquad (1)$$

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

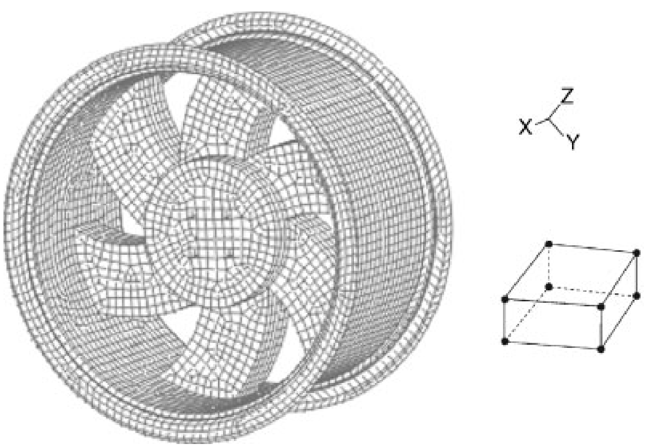

Figure 1. Finite element model of a wheel using three-dimensional brick elements, and a typical 8-node brick element (q=8).

where the h_i are the given interpolation functions, (x_i, y_i, z_i) are the known coordinates of nodal point i, and (u_i, v_i, w_i) are the unknown displacements of nodal point i. The h_i are functions of the element natural coordinates *(r, s, t)*, which relate uniquely to the global coordinates. In this assumption, the same interpolation is employed for the geometry and the displacements, and these equations are applicable to very general curved element configurations. However, in by far most analyses and certainly in nonlinear analyses, low-order linear, non-curved elements are preferred (4-node quadrilateral elements in the two-dimensional (2-D) analyses of solids, and 8-node brick elements in the three-dimensional (3-D) analyses of solids), but quadratic elements (9-node elements in 2-D analyses and 27-node elements in 3-D analyses) can be more effective (3). To obtain a more accurate solution, mostly the number of elements is simply increased; that is, the h-method is used. Alternatively, also the number and size of elements can be kept constant and the order of the geometry and displacement interpolations is increased; that is, the p-method is used. Of course, these approaches can also be combined and then an h/p-method is employed (15).

While some of the first finite elements for structural analyses were largely formulated based on physical insight and intuition, the development and use of a general theory based on the principle of virtual work (or virtual displacements) established a firm foundation and a general approach for the formulation of finite elements.

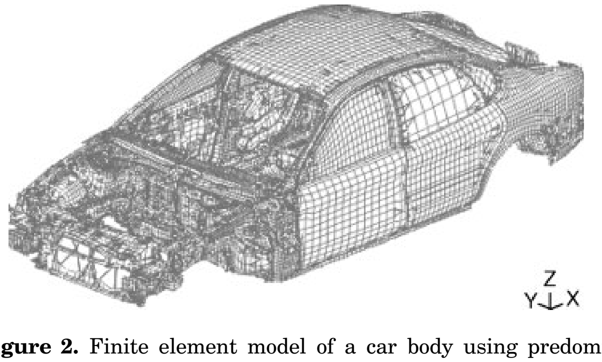

Figure 2. Finite element model of a car body using predominantly shell elements.

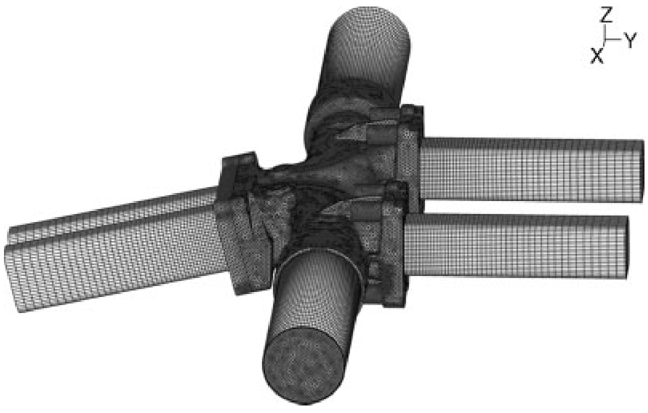

Figure 3. Finite element computational fluid dynamics (CFD) model of a manifold; FCBI elements, about 10 million equations solved in less than 1 hour on a single-processor PC.

Today, the principle of virtual displacements is the basic equation used to formulate displacement-based finite elements. Considering a general solid, this principle can be written as (3)

$$\int_V \bar{\boldsymbol{\varepsilon}}^{\mathrm{T}} \boldsymbol{\tau} dV = \int_{S_f} \bar{\mathbf{u}}^{S_f \mathrm{T}} \mathbf{f}^{S_f} dS + \int_V \bar{\mathbf{u}}^{\mathrm{T}} \mathbf{f}^{B} dV \tag{2}$$

where the unknown (real) stresses are $\boldsymbol{\tau}$, the known applied body forces are $\mathbf{f}^B$, the known applied surface tractions are $\mathbf{f}^{S_f}$, the virtual displacements are $\bar{\mathbf{u}}$, and the virtual strains that correspond to the virtual displacements are $\bar{\boldsymbol{\varepsilon}}$. Of course, the stresses need to satisfy the given stress-strain laws, and the strains (the virtual and real quantities) must satisfy the strain–displacement relationships. Also, the real displacements must satisfy the given displacement boundary conditions and the virtual displacements must be zero at the locations of the prescribed real displacements. The integrations are performed over the volume, V, and traction-loaded surface, S_f, of the solid considered.

The principle of virtual displacements, with these conditions satisfied, is totally equivalent to the differential formulation of the boundary value problem. The principle is referred to also as a variational formulation and a weak formulation (2,3).

In linear analysis, the displacements are assumed to be infinitesimally small, the material laws are assumed to be constant, and the volume and surfaces over which the integrations are performed are known and constant, that is, unaffected by the displacements. Substituting from Equation (1) into Equation (2) and invoking the principle of virtual displacements as many times as there are nodal displacement degrees of freedom, we obtain

$$\mathbf{KU} = \mathbf{R} \tag{3}$$

where $\mathbf{K}$ is the stiffness matrix, $\mathbf{U}$ is the displacement vector listing all unknown nodal point displacements (the u_i, v_i, w_i, for all nodes, i = 1, 2, ..., as applicable), and $\mathbf{R}$ is a vector of externally applied forces at the nodal-point displacement degrees of freedom. The solution of Equation (3) yields the nodal displacements for Equation (1) and hence the strains and stresses in all elements.

In dynamic analysis, the body forces include inertia and damping effects, and these can be included directly in the solution to obtain (3)

$$\mathbf{M}\ddot{\mathbf{U}} + \mathbf{C}\dot{\mathbf{U}} + \mathbf{K}\mathbf{U} = \mathbf{R} \tag{4}$$

where $\mathbf{M}$ is the mass matrix (usually a consistent mass matrix), $\mathbf{C}$ is a damping matrix (frequently the Rayleigh damping matrix is used), and $\ddot{\mathbf{U}}$, $\dot{\mathbf{U}}$ denote the nodal accelerations and velocities, respectively. In structural vibration analyses, these dynamic equilibrium equations are solved by using mode superposition or implicit direct time integration (for example, by using the popular trapezoidal rule).

However, for wave propagation analyses, the dynamic equilibrium equations solved are generally (3)

$$\mathbf{M}\ddot{\mathbf{U}} = \mathbf{R} - \mathbf{F} \tag{5}$$

where $\mathbf{F}$ represents the nodal forces that correspond to the element stresses. Usually, a lumped (diagonal) mass matrix is used.

The above equations have been written for a three-dimensional solid, but also are applicable with appropriate modifications for the analysis of two-dimensional solids. Furthermore, the equations can be extended and then also are applicable for the analysis of structures modeled by beams, plates, and shells. The extension is reached by introducing midsurfaces, displacements and rotations, and the applicable kinematic and stress assumptions. For example, in the analysis of shells, the Reissner–Mindlin kinematic assumption—that plane sections originally plane and normal to the midsurface of the shell remain plane—is introduced, and the assumption that the stress normal to that midsurface is zero is imposed. Because the pure displacement-based finite elements are not effective for thin shells (and plates and beams), that is, they ‘lock’ in bending actions (see the section below titled, “The Analysis of Shells”), mixed and hybrid formulations are used to reach more effective elements. The construction of such elements in essence is based on an extension of the principle of virtual displacements, namely the use of the Hu–Washizu variational principle (2,3). Effective structural elements can then directly be employed in Equations (3–5) together with the displacement-based solid elements (but of course $\mathbf{U}$ now also includes nodal rotations).

Considering nonlinear analysis, the nonlinear effects can arise from nonlinear material behavior, like plasticity and creep; from geometric nonlinear effects, that is, large displacements and large strains; and from contact between bodies established as a result of the displacements. In these cases, the basic principle of virtual displacements and the extensions for structural elements still are directly applicable, but the appropriate stress and strain measures need be used and the equilibrium need be considered in the deformed geometry of the bodies. For such general nonlinear analyses, the total Lagrangian (TL) and the updated Lagrangian (UL) formulations provide a fundamental basis of solution (3,16) and are widely used. In these formulations, the nonlinear material behavior is introduced to establish the stresses for “given” deformations, that is, not using a rate formulation when the constitutive relations are rate-independent (see also Ref. 17). If required, contact conditions including frictional effects are imposed as constraints on the nodal displacements and forces over the contacting surfaces. Because the large deformations and nonlinear material conditions and the solution for the actual areas of contact introduce significant nonlinearities in the governing equations, iteration for solution in general is required (see below).

Considering a dynamic solution based on implicit direct time integration, and assuming that contact conditions are not present, the incremental nonlinear analysis is accomplished by solving at discrete times Δt apart

$$\mathbf{M}\,{}^{t+\Delta t}\ddot{\mathbf{U}} + \mathbf{C}\,{}^{t+\Delta t}\dot{\mathbf{U}} + {}^{t+\Delta t}\mathbf{F} = {}^{t+\Delta t}\mathbf{R} \tag{6}$$

where the equilibrium is considered at time $t + \Delta t$, and the nodal forces ${}^{t+\Delta t}\mathbf{F}$ and ${}^{t+\Delta t}\mathbf{R}$ correspond to the internal element stresses and the externally applied loads, respectively. In static analysis, simply the inertia and damping effects are neglected and the superscript $t =$ time denotes the load level (but is also an actual physical variable when a material law is time-dependent).

Because the nodal forces highly depend on the deformations and all the considered nonlinearities need be included in calculating these forces, an iteration is necessary for the solution of Equation (6). A Newton–Raphson iteration, or variant thereof, is commonly performed, with the governing equations

$$\begin{aligned} {}^{t+\Delta t}\hat{\mathbf{K}}^{(i-1)}\Delta\mathbf{U}^{(i)} &= {}^{t+\Delta t}\hat{\mathbf{R}}^{(i-1)} - {}^{t+\Delta t}\mathbf{F}^{(i-1)} \\ {}^{t+\Delta t}\mathbf{U}^{(i)} &= {}^{t+\Delta t}\mathbf{U}^{(i-1)} + \Delta\mathbf{U}^{(i)} \end{aligned} \tag{7}$$

where ${}^{t+\Delta t}\hat{\mathbf{K}}^{(i-1)}$ is the effective tangent stiffness matrix that corresponds to the linearization of the nodal force vectors with respect to the incremental displacements $\Delta\mathbf{U}^{(i)}$. The hat in ${}^{t+\Delta t}\hat{\mathbf{K}}^{(i-1)}$ and ${}^{t+\Delta t}\hat{\mathbf{R}}^{(i-1)}$ is used to signify that also mass and damping effects are included (3). In static analysis these effects of course are neglected. The iteration is continued until appropriate convergence criteria (based on forces, displacements, or energy) are satisfied. To reach fast convergence, and quadratic convergence when near the solution, it is important to use the linearization “consistent” with the stress integration procedures and the force updating used to evaluate the right-hand side of Equation (7) (3,17,18).

If contact conditions are to be included, then for example, for normal contact the following conditions need be satisfied (3):

$$ {}^{t+\Delta t}\lambda \geq 0; \quad {}^{t+\Delta t}g \geq 0; \quad {}^{t+\Delta t}\lambda \,.\, {}^{t+\Delta t}g = 0 \tag{8}$$

where ${}^{t+\Delta t}g$ represents the gap and ${}^{t+\Delta t}\lambda$ represents the normal contact force. To reach stable and accurate solutions, appropriate interpolations of contact tractions need be used (19). Of course, with the relations in Equation (8) imposed as conditions on Equation (6), penetration is prevented at the contacting surfaces. Frictional contact conditions are similarly solved for; see Ref. 3. These conditions to enforce contact between bodies enter into the iteration for equilibrium and compatibility; that is, Equation (7) needs to be amended to enforce the contact relations.

The use of Equation (7) (in general amended for contact conditions) for dynamic analysis of course implies that a transient solution with implicit time integration is pursued. If a short time duration or wave propagation analysis is to be performed (e.g., a crash simulation in the motor car industry), then an explicit time integration frequently is more effective. In this case, Equation (5), also amended to include contact conditions, is used with the nodal vectors continuously updated for all nonlinearities, which result from large deformations, contact and nonlinear material effects in the step-by-step solution. The solution is attractive because no iteration is performed like in Equation (7); however, the disadvantage is that the time step size in the forward integration needs to be very small (because the time integration is only conditionally stable) (3).

Equations (7) and (5), as discussed above, are applicable to the nonlinear analysis of solids and structures; however, for structural elements, a mixed formulation need be used (see the section titled, “The Analysis of Shells”). Also, in material nonlinear analysis, frequently (almost) incompressible conditions are encountered, as when modeling a rubber-like material or elasto-plastic conditions. In these cases, considering a solid, it is effective to use a mixed formulation in which the unknown displacements and pressure are interpolated; that is, the u/p formulation is employed (see the section titled, “The Reliable and Effective Analysis of Solids”).

The same basic approach also can be followed to establish finite element solutions of heat transfer problems (considering solids or fluids) and of incompressible fluid flows. In these cases, the temperature and the velocities (and pressure) need to be interpolated; in essence the “principle of virtual temperatures” and the “principle of virtual velocities” are employed. These principles in concept are similar to the principle of virtual displacements and hence of course also correspond to weak formulations. A major added difficulty arises in the use of the Eulerian formulation of fluid flows because of the convective effects. A pure interpolation of velocities and temperature results in a unstable solution. This instability can be circumvented, like in finite difference solutions, by introducing some form of upwinding (see the section titled, “Finite Element Discretizations for Incompressible Fluid Flows”).

The Lagrangian formulations for the solids and structures and the Eulerian formulations for fluid flows have been fully coupled by the use of arbitrary Lagangian–Eulerian formulations, referred to as ALE formulations for fluid–structure interactions. Such formulations are now used to solve reliably very complex multiphysics problems that involve displacements of solids and structures, temperature distributions, fluid flows, electromagnetic effects, and so on (see for example Refs. 1–3, and 20).

EFFECTIVE FINITE ELEMENT PROCEDURES

The first requirement of any analysis is of course the selection of an appropriate mathematical model to represent the physical problem (3). The next requirement is to solve this model with reliable and effective numerical methods. Because the use of reliable and effective finite element methods is very important, much research effort has been expended to reach such procedures.

The Reliable and Effective Analysis of Solids

The analysis of solids is efficiently accomplished by using the pure displacement-based finite element method referred to above, unless incompressible or almost incompressible material conditions are considered, as in the analysis of rubber-like materials or in elasto-plastic response. In incompressible analysis, the pure displacement-based discretizations “lock,” and a mixed interpolation based on displacements and pressure is much more effective. However, the appropriate combination of displacement and pressure interpolations must be used.

The phenomenon of locking is of fundamental importance for the understanding of what we mean by a reliable finite element formulation. Figure 4 shows schematically the error in some norm between the finite element solution, $\mathbf{u}_h$, and the exact solution, $\mathbf{u}$, of the mathematical model to be solved, as the mesh is refined. Of course, the exact solution is in general not known, but we can think of a close approximation to the exact solution, obtained by a finite element analysis using a very fine mesh. If for almost incompressible analysis, a pure displacement-based finite element formulation is used, then the convergence curves in Figs. 4(a) and 4(b) are generally much below and above the respective curves obtained in the compressible analysis. Hence the error obtained for a given mesh depends on the bulk modulus and significantly increases as incompressible conditions are approached. Because the displacements become small measured on what they should be, the phenomenon is referred to as “locking”. Finite element discretizations that lock, like schematically referred to in Fig. 4, are not reliable because small changes in some data can cause large changes in the solution error.

Hence a reliable finite element discretization displays the following convergence behavior in the appropriate norm:

$$\|\mathbf{u} - \mathbf{u}_h\| \simeq c h^k \tag{9}$$

where c is a constant (that is, independent of the bulk modulus), h is the generic element size, and k is the order of interpolation used. To reach such finite element discretizations in almost, or fully, incompressible analysis, the use of the displacement–pressure interpolation is effective where the displacement and pressure interpolations used should satisfy two conditions (3,21–23). First, the ellipticity

Figure 4. Locking phenomenon (when using pure displacement interpolations in almost incompressible analysis).

condition must be satisfied

$$a(\mathbf{v}_h, \mathbf{v}_h) \geq \alpha \|\mathbf{v}_h\|^2 \quad \forall \mathbf{v}_h \in K_h(0) \tag{10}$$

where a (., .) is the (deviatoric strain energy) bilinear form of the problem, $K_h(0)$ represents all those finite element interpolations $\mathbf{v}_h$ over the mesh which satisfy the discretized zero divergence condition, and α is a constant greater than zero. And second, the inf-sup condition should be satisfied for any mesh, and in particular as $h \to 0$,

$$\inf_{q_h \in Q_h} \sup_{\mathbf{v}_h \in V_h} \frac{\int_{\mathrm{Vol}} q_h \mathrm{div}\, \mathbf{v}_h \, d\mathrm{Vol}}{\|\mathbf{v}_h\| \|q_h\|} \geq \beta > 0 \tag{11}$$

where, for the mesh, V_h is the space of displacement interpolations, Q_h is the space of pressure interpolation, appropriate norms are used, and β is a constant. Effective finite elements that satisfy these two conditions are given, for example, in Refs. 3 and 22. It is also possible to develop finite elements that bypass the inf-sup condition and do not lock, but these then depend on nonphysical numerical parameters (22,23).

The Analysis of Shells

The first developments of practical finite element methods were directed toward the analysis of aeronautical structures, that is, thin shell structures. Since these first developments, much further effort has been expended to reach more general, reliable, and effective shell finite element schemes. Shells are difficult to analyze because they exhibit a variety of behaviors and can be very sensitive structures, depending on the curvatures, the thickness t, the span L, the boundary conditions, and the loading applied (23). A shell may carry the loading largely by membrane stresses, largely by bending stresses, or by combined membrane and bending actions. Shells that only carry loading by membrane stresses can be efficiently analyzed by using a displacement-based formulation (referred to above); however, such formulations "lock" (like discussed above when considering incompressible analysis) when used in the analysis of shells subjected to bending. To establish generally reliable and effective shell finite elements (that can be used for any shell analysis problem), the major difficulty has been to overcome the "locking" of discretizations, which can be severe when thin shells are considered.

The principles summarized above for incompressible analysis apply, in essence, also in the analysis of plate and shell structures. The critical parameter is now the thickness to span ratio, t/L, and the relevant inf-sup expression ideally should be independent of this parameter. To obtain effective elements, the mixed interpolation of displacements and strain components has been proposed and is widely used in mixed-interpolated tensorial component (MITC) and related elements (3,23–25). The appropriate interpolations for the displacements and strains have been chosen carefully for the shell elements and are tied at specific element points. The resulting elements then only have displacements and rotations as nodal degrees of freedom, just as for the pure displacement-based elements. The effectiveness of the elements can be tested numerically to see whether the consistency, ellipticity, and inf-sup conditions (23) are satisfied. However, the inf-sup condition for plate and shell elements is much more complex to evaluate than for incompressible analysis (26), and the direct testing by solving appropriately chosen test problems is more straightforward (23,27,28). Some effective mixed-interpolated shell elements are given in Refs. 3,23 and 25.

For plates and shells, instead of imposing the Reissner–Mindlin kinematic assumption and the assumption of "zero stress normal to the midsurface," also three-dimensional solid elements without these assumptions can be used (29–31). Of course, for these elements to be effective, they also need to be formulated to avoid "locking;" that is, they also need to satisfy the conditions mentioned above and more (23).

Finite Element Discretizations for Incompressible Fluid Flows

Considering *all* fluid flow problems, in engineering practice most problems are solved by using finite volume and finite difference methods. Various CFD computer programs based on finite volume methods are in wide use for high-speed compressible and incompressible fluid flows. However, much research effort has been expended on the development of finite element methods, in particular for incompressible flows. Considering such flows and an Eulerian formulation, stable finite element procedures need to use velocity and pressure interpolations like those used in the analysis of incompressible solids (but of course velocities are interpolated instead of displacements) and also need to circumvent any instability that arises in the discretization of the convective terms. This requirement is usually achieved by using some form of upwinding (see for example Refs. 3, 32 and the references therein). However, another difficulty is that the traditional finite element formulations do not satisfy "local" mass and momentum conservation. Because numerical solutions of incompressible fluid flows in engineering practice should satisfy conservation locally, the usual finite element methods have been extended (see for example Ref. 33).

One simple approach that meets these requirements is given by the flow-condition-based interpolation (FCBI) formulation, in which finite element velocity and pressure interpolations are used to satisfy the inf-sup condition for incompressible analysis, flow-condition-dependent interpolations are used to reach stability in the convective terms, and control volumes are employed for integrations, like in finite volume methods (34). Hence stability is reached by the use of appropriate velocity and pressure interpolations, the conservation laws are satisfied locally, and, also, the given interpolations can be used to establish consistent Jacobian matrices for the Newton–Raphson type iterations to solve the governing algebraic equations (which correspond to the nodal conditions to be satisfied).

An important point is that the FCBI schemes of fluid flow solution can be used directly to solve "fully coupled" fluid flows with structural interactions (20,35). The coupling of arbitrary discretizations of structures and fluids in which the structures might undergo large deformations is achieved by satisfying the applicable fluid–structure interface force and displacement conditions (20). The complete set of interface relations is included in the governing nodal point equations to be solved. Depending on the problem and in particular the number of unknown nodal point variables, it may be most effective to solve the governing equations by using partitioning (36). However, once the iterations have converged (to a reasonable tolerance), the solution of the problem has been obtained irrespective of whether partitioning of the coefficient matrix has been used.

While the solution of fluid–structure interactions is encountered in many applications, the analysis of even more general and complex multiphysics problems including thermo-mechanical, electromagnetic, and chemical effects is also being pursued, and the same fundamental principles apply (1).

Solution of Algebraic Equations

The finite element analysis of complex systems usually requires the solution of a large number of algebraic equations; to accomplish this solution effectively is an important requirement.

Consider that no parallel processing is used. In static analysis, "direct sparse solvers" based on Gauss elimination are effective up to about one half of a million equations for three-dimensional solid models and up to about 3 million equations for shell models. The essence of these solvers is that first graph theory is used to identify an optimal sequence to eliminate variables and then the actual Gauss elimination (that is, the factorization of the stiffness matrix and solution of the unknown nodal variables) is performed.

For larger systems, iterative solvers possibly combined with a direct sparse solver become effective, and here in particular an algebraic multigrid solver is attractive. Multigrid solvers can be very efficient in the solution of structural equations but frequently are embedded in particular structural idealizations only (like for the analysis of plates). An "algebraic" multigrid solver in principle can be used for any structural idealization because it operates directly on the given coefficient matrix (37). Figure 5 shows a model solved by using an iterative scheme and gives a typical solution time.

Considering transient analysis, it is necessary to distinguish between vibration analyses and wave propagation solutions. For the linear analysis of vibration problems, mode superposition is commonly performed (3,38). In such cases, frequencies and mode shapes of the finite element models need be computed, and this is commonly achieved using the Bathe subspace iteration method or the Lanczos method (3).

For the nonlinear analysis of vibration problems, usually a step-by-step direct time integration solution is performed with an implicit integration technique, and frequently the trapezoidal rule is used (3). However, when large deformation problems and relatively long time durations are considered, the scheme in Ref. 39 can be much

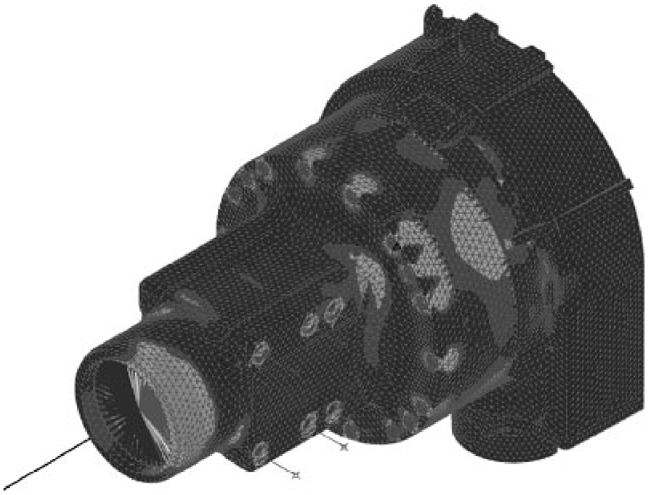

Figure 5. Model of a rear axle; about a quarter of a million elements, including contact solved in about 20 minutes on a single-processor PC.

more effective. The solution of a finite element model of one half of a million equations solved with a few hundred time steps would be considered a large problem.

Of course, the explicit solution procedures already mentioned above are used for short duration transient and wave propagation analyses (3,40).

In the simulations of fluid flows, the number of nodal unknowns usually is very large, and iterative methods need to be used for solution. Here algebraic multigrid solvers are very effective, but important requirements are that both the computation time and amount of memory used should increase about linearly with the number of nodal unknowns to be solved for. Figure 3 gives a typical solution time for a Navier–Stokes fluid flow problem. It is seen that with rather moderate hardware capabilities large systems can be solved.

Of course, these solution times are given merely to indicate some current state-of-the-art capabilities, and have been obtained using ADINA (41). Naturally, the solution times would be much smaller if parallel processing were used (and then would depend on the number of processors used, etc.) and surely will be much reduced over the years to come.

The given observations hold also of course for the solution of multiphysics problems.

MESHING

A finite element analysis of any physical problem requires that a mesh of finite elements be generated. Because the generation of finite element meshes is a fundamental step and can require significant human and computational effort, procedures have been developed and implemented that automatize the mesh generation without human intervention as much as possible.

Some basic problems in automatic mesh generation are (1) that the given geometries can be complex with very small features (small holes, chamfers, etc.) embedded in otherwise rather large geometric domains, (2) that the use of certain element types is much preferable over other element types (for example, brick elements are more effective than tetrahedral elements), (3) that graded meshes need be used for effective solutions (that is, the mesh should be finer in regions of stress concentrations and in boundary layers in fluid flows or the analysis of shells), and (4) that an anisotropic mesh may be required. In addition, any valuable mesh generation technique in a general purpose analysis environment (like used in CAE solution packages, see the section titled, “The Use of the Finite Element Method in Computer-Aided Engineering”) must be able to mesh complex and general domains.

The accuracy of the finite element analysis results, measured on the exact solution of the mathematical model, highly depends on the use of an appropriate mesh, and this holds true in particular when coarse meshes need be used to reduce the computer time employed for complex analyses. Hence, effective mesh generation procedures are most important.

Various mesh generation techniques are in use (42). Generally, these techniques can be classified into mapped meshing procedures, in which the user defines and controls the element spacings to obtain a relatively structured mesh, and free-form meshing procedures, in which the user defines the minimum and maximum sizes of elements in certain regions but mostly has little control as to what mesh is generated, and the user obtains an unstructured mesh. Of course, in each case the user also defines for what elements the mesh is to be generated. Mapped meshing techniques in general can be used only for rather regular structural and fluid domains and require some human effort to prepare the input but usually result in effective meshes, in the sense that the accuracy of solution is high for the number of elements used. The free-form meshing techniques in principle can mesh automatically any 3-D domain provided tetrahedral elements are used; however, a rather unstructured mesh that contains many elements may be reached. The challenge in the development of free-form meshing procedures has been to reach meshes that in general do not contain highly distorted elements (long, thin sliver elements must be avoided unless mesh anisotropy is needed), that do not contain too many elements, and that contain brick elements rather than tetrahedral elements. Two fundamental approaches have been pursued and refined, namely methods based on advancing front methodologies that generate elements from the boundary inwards and methods based on Delaunay triangularizations that directly mesh from coarse to fine over the complete domain. Although a large effort has already been expended on the development of effective mesh generation schemes, improvements still are much desired, for example to reach more general and effective procedures to mesh arbitrary three-dimensional geometries with brick elements.

Figure 1 shows a three-dimensional mapped mesh of brick elements, a largely structured mesh, for the analysis of a wheel, and Fig. 6 shows a three-dimensional mesh of tetrahedral elements, an unstructured mesh, for the analysis of a helmet. It is important to be able to achieve the grading in elements shown in Fig. 6 because the potential area of contact on the helmet requires a fine mesh.

Figure 7 shows another important meshing feature for finite element analysis, namely the possibility to glue in a “consistent manner” totally different meshes together (19). This feature provides flexibility in meshing different parts and allows multiscale analysis. The glueing of course is applicable in all linear and nonlinear analyses.

Because the effective meshing of complex domains still is requiring significant human and computational effort, some new discretization methods that do not require a mesh in the traditional sense have been developed (43). These techniques are referred to as meshless or meshfree methods but of course still require nodal points, with nodal point variables that are used to interpolate solid displacements, fluid velocities, temperatures, or any other continuum variable. The major difference from traditional finite element methods is that in meshfree methods, the discrete domains, over which the interpolations take place, usually overlap, whereas in the traditional finite element methods, the finite element discrete domains abut each other, and geometric overlapping is not allowed. These meshfree

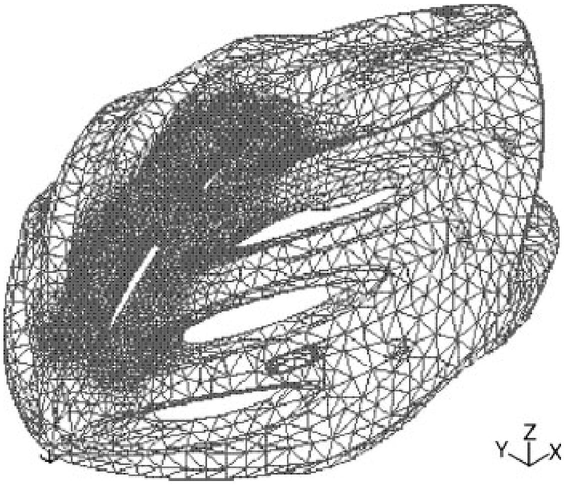

Figure 6. Model of a bicycle helmet showing mesh gradation.

methods require appropriate nodal point spacing, and the numerical integration is more expensive (43,44). However, the use of these procedures coupled with traditional finite elements shows promise in regions where either traditional finite elements are difficult to generate or such elements become highly distorted in geometric nonlinear analysis (43).

THE USE OF THE FINITE ELEMENT METHOD IN COMPUTER-AIDED ENGINEERING

The finite element method would not have become a successful tool to solve complex physical problems if the method had not been implemented in computer programs. The success of the method is clearly due to the effective implementation in computer programs and the possible wide use of these programs in many industries and research environments. Hence, reliable and effective finite element methods were needed that could be trusted to perform well in general analysis conditions as mentioned above. But also, the computer programs had to be easy to use. Indeed, the ease of use is very important for a finite element program to be used in engineering environments.

The ease of use of a finite element program is dependent on the availability of effective pre- and post-processing tools based on graphical user interfaces for input and output of data. The pre-processing embodies the use of geometries from computer-aided design (CAD) programs or the construction of geometries with CAD-like tools, and the automatic generation of elements, nodal data, boundary conditions, material data, and applied loadings. An important ingredient is the display of the geometry and constructed finite element model with the elements, nodes, and so on. The post-processing is used to list and graphically display the computed results, such as the displacements, velocities, stresses, forces, and so on. In the post-processing phase, the computed results usually are looked at first to see whether the results make sense (because, for example, by an input error, a different than intended finite element model may have been solved), and then the results are studied in depth. In particular, the results should give the answers to the questions that provided the stimulus for performing the finite element analysis in the first instance.

The use of finite element programs in computer-aided engineering (CAE) frequently requires that geometries from CAD programs need be employed. Hence, interfaces to import these geometries into the finite element pre-processing programs are important. However, frequently the computer-aided design geometry can not be used directly to generate finite element meshes and needs to be changed ("cleaned-up") to ensure well-connected domains, and by deleting unnecessary details. The effective importing of computer-aided design data is a most important step for the wide use of finite element analysis in engineering design.

As mentioned already, the purpose of a finite element analysis is to solve a mathematical model. Hence, in the post-processing phase, the user of a finite element program ideally would be able to ascertain that a sufficiently accurate solution has been obtained. This means that, ideally, a measure of the error between the computed solution and the "exact solution of the mathematical model" would be available. Because the exact solution is unknown, only estimates can be given. Some procedures for estimating the error are available (mostly in linear analysis) but need to be used with care (45,46), and in practice frequently the analysis is performed simply with a very fine mesh to ensure that a sufficiently accurate solution has been obtained. Figure 8 shows an example of error estimation. Here, the scheme proposed by Sussman and Bathe (47) is used in a linear, nonlinear, and FSI solution using ADINA.

In the first decades of finite element analysis, many finite element programs were available and used. However, the ensuing strive for improved procedures in these programs, in terms of generality, effectiveness, and ease of use, required a significant continuous development effort. The resulting competition in the field to further develop and

continuously support a finite element program reduced the number of finite element systems now widely used to only a few: MSC NASTRAN, NX NASTRAN, ANSYS, ABAQUS, ADINA, and MARC are the primary codes used for static and implicit dynamic analyses of structures, and LS-DYNA, RADIOSS, PAMCRASH are the primary codes used for explicit dynamic analyses. For multiphysics problems, notably fluid–structure interactions, primarily ADINA and ANSYS are used.

CONCLUSIONS AND KEY CHALLENGES

Since the first publications on the practical use of the finite element method, the field of finite element analysis has exploded in terms of research activities and applications. Numerous references are given on the World Wide Web. The method is now applied in practically all areas of engineering and scientific analyses. Since some time, the finite element method and related techniques frequently are simply referred to as "methods in computational fluid and solid mechanics."

With all these achievements in place and the abundant applications of computational mechanics today, it is surely of interest to ask, "What are the outstanding research and development tasks? What are the key challenges still in the field?" These questions are addressed in the prefaces of Ref. 1, see the 2003 and 2005 volumes.

Although much has been accomplished, still, many exciting research tasks exist in further developing finite element methods. These developments and the envisaged increased use of finite element methods not only will have a continuous and very beneficial impact on traditional engineering endeavors but also will lead to great benefits in other areas such as in the medical and health sciences.

Specifically, the additional developments of finite element methods should not be directed only to the more effective analysis of single media but also must focus on the solution of multiphysics problems that involve fluids, solids, their interactions, and chemical and electromagnetic effects from the molecular to the macroscopic scales, including uncertainties in the given data, and should also be directed to reach more effective algorithms for the optimization of designs.

Based on these thoughts, we can identify at least eight key challenges for research and development in finite element methods and numerical methods in general; these challenges pertain to the more automatic solution of mathematical models, to more effective and predictive numerical schemes for fluid flows, to mesh-free methods that are coupled with traditional finite element methods, to finite element methods for multiphysics problems and multiscale problems, to the more direct modeling of uncertainties in analysis data, to the analysis and optimization of complete lifecycles of designed structures and fluid systems, and finally, to providing effective education and educational tools for engineers and scientists to use the given analysis procedures in finite element programs correctly and to the full capabilities (1).

Hence, although the finite element method already is widely used, still, many exciting research and development efforts exist and will continue to exist for many years.

ABSTRACT

The objective in this article is to give an overview of finite element methods that currently are used extensively in academia and industry. The method is described in general terms, the basic formulation is presented, and some issues regarding effective finite element procedures are summarized. Various applications are given briefly to illustrate the current use of the method. Finally, the article concludes with key challenges for the additional development of the method.

UNIFIED MODELING LANGUAGE (UML)

UML is a graphically oriented computer language used to *represent* software programs and related phenomena in a manner that allows its users to focus on the essential aspects of their software without being distracted by syntactic and technology-specific details found in traditional programming languages. In effect, a UML specification of a program is an example of an engineering model, that is, a reduced representation of an existing or planned design constructed to facilitate the assessment of key characteristics of that design. Given the complexity of modern software systems, the use of models and modeling as a complexity reduction technique is both obvious and necessary.

Since its adoption as a standard technology by the Object Management Group (OMG) in 1996 (1), UML has been widely adopted by software developers and researchers and is supported by numerous tool vendors. It is also an integral part of many computer science and software engineering curricula throughout the world. It is probably the most widespread software modeling language and has served as the foundation or inspiration for numerous domain-specific modeling languages and standards.

THE HISTORY OF THE DEVELOPMENT OF UML

The idea of modeling software dates back at least as far as classic flowcharts, which were used to depict algorithmic flow in an intuitive graphical form that captured the essence of the algorithm without the encumbrance of irrelevant detail. Since those early days, many other languages were proposed for modeling software systems. In particular, during the late 1980s and early 1990s, there was an explosion of new modeling languages and notations, stimulated by the resurgence of interest in object-oriented languages and methods (2). One of the characteristics of these technologies was that software based on them typically involved complex structural relationships (often mimicking structural relationships in the physical world), which became very difficult to discern in the text-based linear forms characteristic of traditional programming languages. Unfortunately, this diversity led to major fragmentation in terms of expertise and tooling. Users who wanted to take advantage of such methods found that they were forced to make a choice that would invariably lead them into isolation and an undesirable lock-in to those tools and vendors that supported their particular selection.

This was the setting in which UML was defined, first as a merger of two of the most widely known and most popular software modeling notations of the time—the Booch OO method (3) and the Object Modeling Technique (4) devised by Rumbaugh et al. . These were joined later by the Object-Oriented Software Engineering method and notation of Jacobson et al. (5) As this joint notation was being defined, it was also proposed as an industry standard, in response to a request for proposal issued in 1995 by the OMG, a representative consortium of software product vendors and users. At this point, other experts joined the original UML team of Jim Rumbaugh, Grady Booch, and Ivar Jacobson and the first version of standardized version of UML, UML 1.1, was adopted by the OMG in December 1996.

After the initial adoption, several lesser revisions of the language were produced. With two exceptions, these revisions did not add significant new features, comprising primarily minor fixes and clarifications. The first major addition, the concept of profiles, was introduced with UML version 1.4. Profiles provided a more structured facility for defining domain-specific variations of UML. The second major innovation was the introduction of a model of actions—a more precise definition of the run-time semantics of UML and a corresponding action language. The latter identified a set of basic primitive instructions for creating and manipulating run-time artifacts, such as objects and links, as well as instructions for inter-object communications. (Initially, the actions model was defined as a supplementary specification to the overall standard but has eventually integrated into the standard in version 1.5.)

The addition of the actions model to UML was caused by the growing pressure to extend it beyond being just a relatively informal documentation facility for supporting analysis and design activities. Instead—stimulated by experiences with several successful commercial products—there was a strong motivation to evolve UML into a fully fledged computer language that could be used to specify and even implement software systems. This style of software development in which high-level modeling languages play a primary role in analysis, design, and in some cases, implementation (as opposed to an optional support role) is often called *model-driven development (MDD).* The central idea behind MDD is that, because modeling languages are free of attention-diverting implementation-specific detail, they are better suited to coping with the complexity of modern software design than most common programming languages. Furthermore, if such languages are supported by powerful computer-based tools, which can unburden software developers from having to perform various time-consuming and mechanistic activities (such as translating the modeling specifications into corresponding programming language implementations), then MDD has the potential to improve significantly both the quality of software and the productivity of developers. In response to the growing interest and successes of MDD, the OMG defined a vision and a plan for a series of industry standards in support of MDD, which it named *Model-Driven Architecture (MDA)* (6).

For UML to be an effective MDD tool, it was necessary to provide a much tighter and more extensive specification of its semantics and its syntax. This, along with strong

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

pressure to add some new modeling capabilities, led to a major revision of UML, UML 2.0, which was adopted by the OMG in 2004 (7–11). Several further minor revisions of this standard were defined in subsequent years to fix lesser technical issues and inconsistencies and to add clarifications.

Distinguishing Characteristics of UML

As noted above, software modeling languages have a long history, starting with flowcharts, through to so-called structured analysis and structured design languages (inspired by the principles of structured programming), and on to a variety of object-oriented modeling languages and notations. UML builds on this tradition, reusing many of the proven ideas and methods of its predecessors. However, it is worth noting that modeling language design is still in its infancy, with no systematic design processes defined that are based on well-understood scientific and engineering principles. In other words, unlike programming languages, a sound and complete theory of modeling language construction has yet to emerge.

The principal features of UML 2 that drove its design are the following:

1. Object orientation
2. Visual concrete syntax
3. Separation of views
4. Single underlying model
5. Customizability

Object Orientation. UML emerged at the time of heightened interest in the object paradigm and object-oriented programming languages. Consequently, it was very much influenced by the dominant object-oriented programming languages of the time, in particular C++ and Smalltalk-80. It incorporates many, if not most, of the primary concepts and terminology of those languages, such as the notions of class, inheritance, encapsulation, polymorphism, and the like. Although it is possible to model non-object-oriented systems with UML, the underlying conceptual foundations are still based on the object paradigm. For example, the semantics of UML require that all run-time behaviors, regardless of whether they are in the form of state machines, activities, or actions, are the consequence of the actions of objects, even when such objects are not explicit in the user model. Furthermore, in UML 2. even behaviors are defined as kinds of objects—although this may be transparent to the modeler.

Note, however, that important elements of the relational paradigm as used in database theory are also included, particularly in the area of class modeling (i.e., UML class diagrams). Specifically, in the modeling of associations. UML 2 provides a capability to render an association as either the equivalent of a table entry, to accommodate the relational approach, or, alternatively, as a set of attributes belonging to multiple classes, in support of the object-oriented approach.

Visual concrete syntax. The use of diagrams and graphical forms started with the earliest software modeling languages. This is due to the synthetic nature of visual representations, which seem to appeal to human intuition and cognitive mechanisms. Thus, flowcharts, which provide a static view of dynamic phenomena (the execution of an algorithm), are typically more easily grasped than equivalent textual representations. Similarly, visual representations are generally preferred for depicting structural relationships such as network topologies and inheritance relationships. This is particularly useful in object-oriented systems, since their fundamental operational paradigm is that of a network of collaborating entities (objects). Consequently, UML provides graphical representations for many of its key concepts. These are usually supplemented with textual annotations to capture the more detailed aspects. Several textual versions of UML have been defined, but none of them have been broadly accepted, which confirm the intuitive appeal of visual languages.

Separation of Views. Software invariably reflects the complexity of the real world in which it operates, and this complexity can often overwhelm our cognitive abilities. A traditional means for dealing with this problem is to focus only on those aspects of the system that are of concern to the observer. For example, when trying to understand how a collection of objects collaborate to achieve some emergent system-level behavior, the details of the inheritance structure of the objects involved is not relevant and can be safely ignored. However, when the focus shifts to the implementation of these objects, their inheritance structures become of paramount importance, whereas the interactions become irrelevant. This has motivated many modeling language designers to partition their language into multiple different types of views, with each type of view defined such that it renders only those aspects that are relevant to its specific set of concerns. In such languages, the full system specification is represented by the combination of all individual views. UML too has adopted this approach and defines several different diagram types that describe the structure and behavior of the modeled software system as well as the structure of the model itself. These diagram types are as follows:

- Package diagrams
- Class diagrams
- Instance diagrams
- Structure diagrams (subdivided into collaboration diagrams and composite structure diagrams)
- Interaction diagrams (subdivided into sequence diagrams, interaction overview diagrams, communication diagrams, as well as interaction tables)
- Activity diagrams
- Statechart diagrams
- Use-case diagrams
- Deployment diagrams

The purpose, form, and meaning of these diagrams are explained below.

Single Underlying Model. One of the common problems in many older modeling languages that use multiple types of views is inconsistencies that can be introduced into the model when two or more types of views overlap. Namely, some elements or aspects of a system may be specified in more than one type of view. If the views are constructed independently, it can happen that an element defined in multiple views may have contradictory specifications. To avoid this problem, the diagrams in UML are defined as partial views of a single underlying model. This model is constructed according to the rules of UML as defined by its *metamodel*. The UML metamodel is a formal model, specified using the *Meta-Object Facility*, a standard OMG language used to define modeling languages (12). It specifies all the modeling concepts of UML as well as the rules for how these concepts can be combined to ensure semantic and syntactic consistency of UML models. Thus, when something is specified in any UML diagram, it can be checked against the metamodel rules, and violations of those rules that would lead to inconsistencies in the model can be identified and flagged. (It should be noted, however, that the UML metamodel does not guard against all possible inconsistencies, so that additional consistency checks may still be required.)

Customizability. UML is a general-purpose modeling language that covers a broad spectrum of application domains. This generality implies that UML must abstract out characteristics that may vary from one domain to another or from one technology to another. For instance, different domains may have very different multitasking and scheduling policies. Or, different programming languages might differ in their rules for type compatibility or forms of inheritance (e.g., Java only supports single inheritance, whereas C++ supports multiple inheritance). To cope with this diversity, UML incorporates numerous *semantic variation points,* where the well-formedness rules of the metamodel provide for domain-specific or technology-specific choices to be specified. This implies that standard UML cannot be used as an implementation language, since it is not sufficiently refined to produce a complete implementation. However, it does provide a customization capability, in the form of profile definition mechanisms, with which it is possible to produce a specialized variant or domain-specific interpretation of UML. Such specializations, known as *profiles*, can be taken to any desired degree of precision, including transforming UML into a domain-specific implementation language with all the necessary detailed semantics required to generate complete implementations directly from the model. One important feature of the profile mechanism is that a validly defined profile can be supported by any tool that supports standard UML, potentially eliminating or greatly reducing the need for developing and maintaining custom tooling.

UML Diagram Types

The following discussion is a brief overview of the purpose and form of individual UML diagram types. Not all diagram types are illustrated but only the ones that are most widely used. Furthermore, only the salient aspects of the concepts in those diagrams are described. Readers interested in more detail should refer to the standard itself or one of the references in the Bibliography.

In most UML tools, models are created through the construction of diagrams. Note that a given model element can appear in more than one diagram or diagram type. In each case, only those aspects that are relevant to that view need be shown.

Package Diagrams. Packages are different from most other UML concepts because they are typically not used to model anything (although they can and are sometimes used for that purpose). Instead, they are used to partition the model into convenient groupings. A UML *package* is a named container that houses a collection of related model elements, possibly including other packages. The top-level package that contains all other packages and model elements is called a *model*. UML does not impose or assume any specific grouping criteria for packages, leaving the choice up to the modeler (e.g., grouping for reuse, grouping by ownership, or grouping by functional cohesion).

A package diagram graphically shows packages, their contents, and their relationships to other packages. In Fig. 1, *ModelPackage* contains three subsystem packages and imports the contents of the *UtilitiesLibrary* package. Note that the subsystem packages could have been drawn within the *ModelPackage* graphical element to show that they are contained inside the *ModelPackage.*

Class Diagrams. Class diagrams are the most widely used diagrams in UML. They are based on classic entity-relationship diagrams from database theory, but they have been adapted to the needs of the object paradigm. *A class* in UML is a specification of an object type, including all of its structural features (called properties), and behavioral features (called *operations*), as well as their visibilities with respect to other objects (public, protected, private or package). When an instance of a class is created, the result is an object with all the features specified for the class.

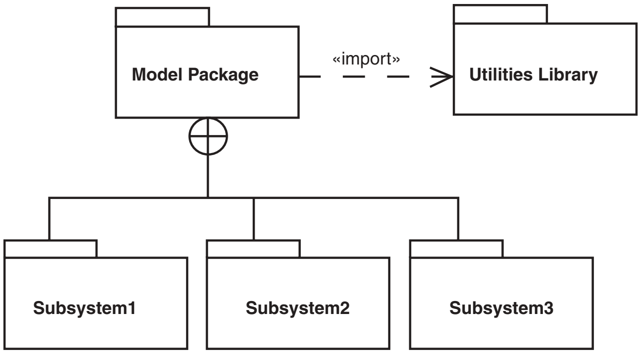

Figure 1. A package diagram.

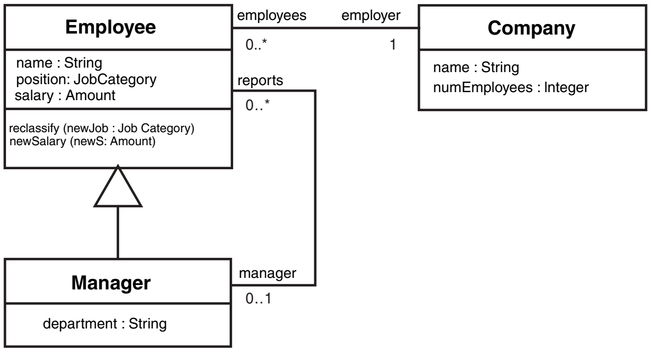

Figure 2. A class diagram.

A class is represented in a class diagram by a rectangle with the name of the class inside the rectangle. The diagrammatic representation may optionally include partial or complete lists of attributes and operations of the class. Each list is contained in its own subcompartment as shown in Fig. 2. The *Employee* class in the diagram is shown with three typed attributes and two operations, whereas the *Company* class is only shown with two attributes and no operations.

The class diagram in Fig. 2 also illustrates some important relationships that can exist between classes in UML. The arrow with the triangular arrowhead denotes *generalization*. That is, the class *Manager* is a special case of the more general class *Employee*. As such, *Manager* automatically inherits all the features (attributes and operations) of its parent class, but it may add its own additional features (e.g., the name of the *department* that the manager manages). The other lines in this diagram represent *associations*, which show how instances of the class at one end of the association relate to instances of the class at the other end. For example, the association between *Employee* and *Company* indicates that for each instance of *Employee* there is exactly one corresponding *Company* that is that employee's employer (the meaning of an association for a class is read at the far end), and that for each instance of the *Company* class, there is a *set* of zero or more (indicated by the "*" character) instances of the class *Employee* who are the employees of that company.

Instance Diagrams. These are also known as object diagrams, because they usually show how specific objects (class instances) relate to each other. Note that class diagrams abstract out individual object characteristics and only capture what is common across all instances of the classes shown in a diagram.

To distinguish more easily instances from classes, the names of instances in instance diagrams are underlined and the name of their type (class) is shown following a colon symbol. The instance diagram in Fig. 3 shows a set of object instances and is a particular case of the specification defined by the class diagram in Fig. 2. It depicts an instance of a company (named "Big Co.") that has four employees, one of which is the manager of the HR department who manages the other three employees. The lines that connect the objects are instances of corresponding associations and are called *links*.

Structure Diagrams. Whereas class diagrams specify what is common across all potential instances of a class independently of time, instance diagrams describe "snapshots" of a running system, showing specific instances at specific points in time. Structure diagrams belong in between these two extremes: Although they represent instances and their mutual relationships, they abstract away details of which particular instances are involved as well as the time of occurrence. This makes them useful for generic modeling of instances and their interconnection patterns. Figure 4 shows a *collaboration*, which is one kind of structure diagram that identifies a structural pattern of collaborating object instances (note that this diagram is a kind of generalization of the diagram in Fig. 3). The nodes represent generalized instances (generalized in the sense that their identities and attribute values have been abstracted out) and are called *roles*, whereas the lines represent generalized links and are called *connectors*.

Structure diagrams are also used to describe the implementation structure of complex classes that consist of collaborations of encapsulated objects. This internal structure is described by a collaboration structure drawn within a frame that represents the outer shell of the complex class (in contrast to the dashed oval frame used for collaborations).

Interaction Diagrams. UML interactions capture end-to-end scenarios that result from the collaborative actions of

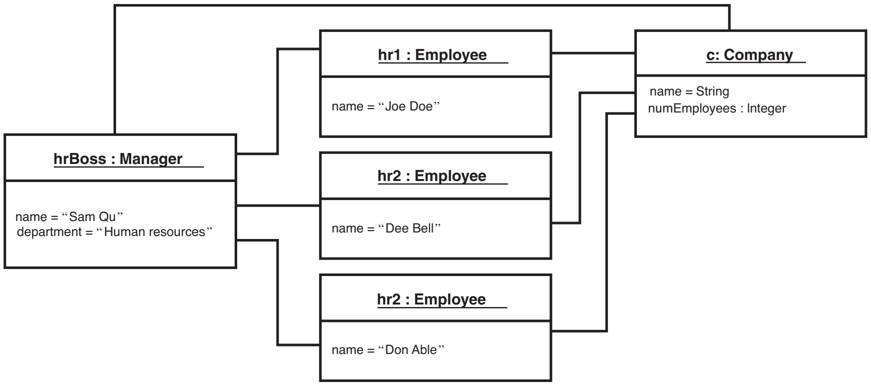

Figure 3. An instance diagram.

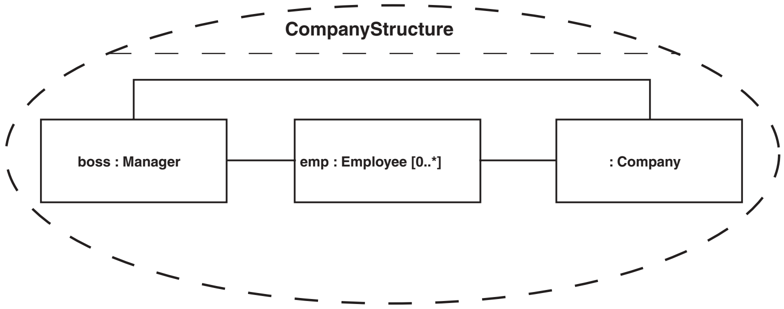

Figure 4. A structure diagram showing a collaboration.

multiple objects, which communicate with each other across links. Consequently, interactions are tightly coupled to collaboration structures, since these structures are used to identify both the participants of an interaction as well as the links (connectors) through which the communications takes place. The most common form for representing interactions in UML is the *sequence diagram*. These are diagrams in which the vertical axis represents the passage of time (although in some cases, it may run horizontally), whereas the horizontal axis identifies the participants in the interaction, shown as labeled vertical dashed lines called *lifelines*—as illustrated in Fig. 5. Communications between participants are represented by labeled lines with arrowheads that indicate the direction in which the messages are flowing. Several shorthand notations are defined to simplify complex interactions or to designate special semantics, such as the box labeled “loop” in Fig. 5, which indicates that the enclosed message sequence may be repeated multiple times. The thin rectangles overlapping the lifelines are called *execution occurrences* and model states during which the respective object is actively executing some behavior.

UML also provides other ways of representing interactions including communication diagrams, interaction overview diagrams, and interaction tables.

Activity Diagrams. Activity diagrams are an extended version of classic flowcharts and are used to represent algorithmic behaviors (e.g., business processes). The extensions include the ability to model the passing of data from one algorithmic step to the next (data flows) and to model concurrent execution.

The nodes in an activity graph represent either primitive actions or invocations of other activities (to support hierarchical functional decomposition). The directed arcs that join these nodes either represent the flow of data between nodes (*object flows*) or the passing of execution control from one node to another (*control flows*). A flow can be split into multiple concurrent flows, and conversely, concurrent flows can be reduced to a sequential flow. As an option, the individual nodes in an activity can be associated with the entities responsible for their execution, using a tabular format called *swimlanes*. An example of an activity diagram with swimlanes is shown in Fig. 6. When this activity starts, the *boss* role first waits for the arrival of a *start* signal and, when it comes, creates an order that is sent out to two employees (*emp[1]* and *emp[2]*). The employees then work on their respective copies of the order in parallel (the vertical bar with one incoming and two outgoing flows designates a concurrency fork). Note that the flows from *GetOrder* to the two *ProcessOrder* nodes are examples of object flows, which is signified by the labeled rectangle placed over the flow. The label identifies the type of data that flows between the nodes. Flows that do not have data placed over them are control flows, which means that execution control is passed from the source node to the destination node as soon as the source node completes. The activity then waits for both employees to complete the

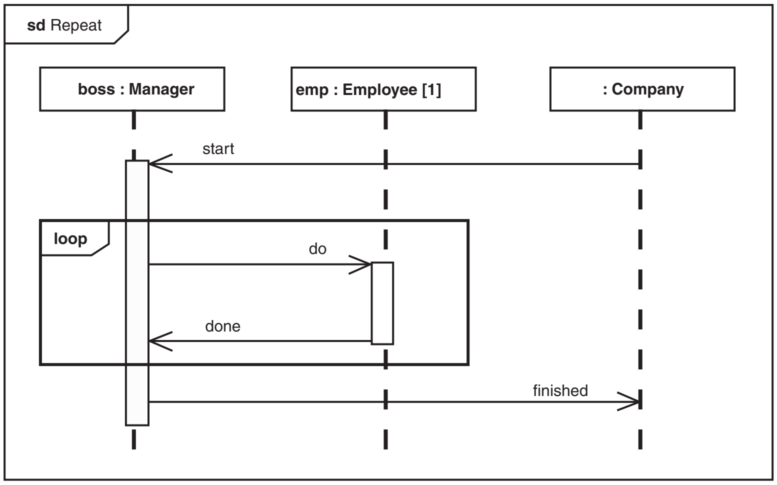

Figure 5. Sequence diagram.

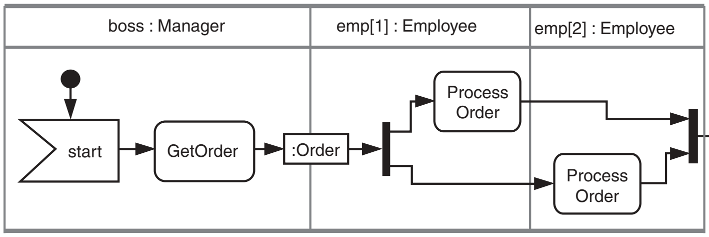

Figure 6. An activity diagram with swimlanes.

processing of their orders (indicated by the vertical bar with two incoming and one outgoing flow), and when that happens, the activity terminates.

Statechart Diagrams. State machines are used to describe event-driven behaviors in UML. An event can be the reception of a communications message, the expiry of some instant in time, or a change of state of some entity. The specific finite state machine formalism used in UML is a variant of David Harel's statecharts (13). Statecharts introduce several graphical shortcuts that enable the specification of some very complex behaviors in very concise ways. They also provide for hierarchical modeling so that a state at one level of abstraction can be decomposed into a statechart in its own right at the next lower level as illustrated by state *ProcessingOrder* in Fig. 7. Note also the transition from the edge of the *ProcessingOrder* state to the terminal state (indicated by a diagonal cross icon). This transition is taken when the *stop* event occurs regardless of which substate of the *ProcessingOrder* state is current at the time of the event. This is a shorthand representation for two separate transitions from the two inner states, each triggered by the same *stop* event.

Use-Case Diagrams. These diagrams are used to model requirements expressed in the form of use cases (i.e., ways in which the system under consideration is used to provide the desired functionality). Use case diagrams (see Fig. 8) identify the *actors*, who interact with the system to achieve the desired use case. They can also show various relationships between different use cases, such as when one use case incorporates another more primitive use case. In fact, use-case diagrams are merely a special form of class diagrams. However, these diagrams are not suitable for viewing the actual contents of use cases, which are typically captured as text.

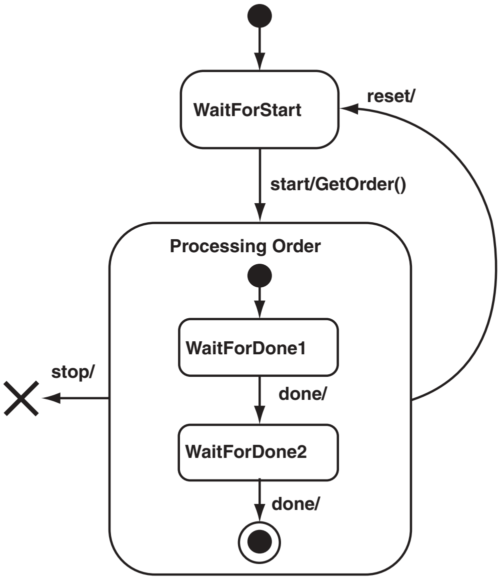

Figure 7. Statechart diagram.

Deployment Diagrams. Deployment diagrams are used to specify how software is distributed across an execution platform. In these diagrams, the software is represented by its physical manifestations, such as files, binary executables, deployment descriptors, and the like. Standard UML provides relatively rudimentary capabilities for modeling deployment, which is why this type of diagram is used less often in practice than any of the others. Where more sophisticated modeling of deployment is required, it may be necessary to define appropriate profiles. One such profile, adopted as an OMG recommendation, is the profile for *Modeling and Analysis of Real-Time and Embedded systems (MARTE)*(14).

UML Profiles

Profiles are a means for defining domain-specific interpretations of UML. Profiles usually consist of several refinements of standard UML concepts such that these refinements capture the specific characteristics of the concepts of a particular domain. For example, in the domain of concurrent programming, a mutual exclusion semaphore concept can be defined as a specialization of the general UML class concept. Such an extension would add suitable constraints and features that distinguish a semaphore from

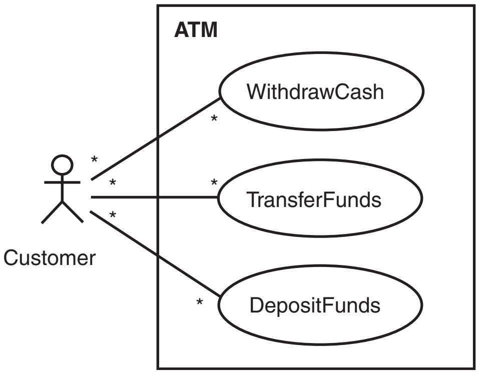

Figure 8. Use-case diagram.

other types of objects. These types of modeling concept extensions are called *stereotypes*, and once defined, they can be used like any other first-class UML language constructs. Since they are derived from standard UML concepts, they are compatible with any tool that supports the UML standard. Another important advantage of this approach to designing domain-specific modeling languages is that it reuses the design and validation efforts that went into standard UML.

Profile users have the choice to restrict their models to only use the domain-specific extensions defined in the profile, or alternatively, they can decide to combine the extensions with the general UML concepts. By selecting the first option, it is possible to derive a compact domain-specific language that is significantly smaller than the UML standard.

In addition to using profiles to construct domain-specific languages, it is possible to use them as domain-specific model filters. This is because of the ability for a UML profile to be dynamically applied to a UML model without corrupting the model. That is, when that profile is removed ("unapplied") at a later time, the original model, emerges unchanged. Such a "model filter" profile can be used to define a domain-specific interpretation of the original model. For example, it may be desired to determine the performance characteristics of a UML-based design. By applying a performance-based profile to the design model, it becomes possible to recast the UML model as a performance model, which can then be analyzed by appropriate methods and tools. Since the performance model is derived directly from the original model, the likelihood of translation errors from one formalism to another can be greatly reduced.

VIENNA DEVELOPMENT METHOD

The Vienna Development Method (VDM) is one of the longest established *model-oriented formal methods* for the development of computer-based systems and software. It consists of a group of mathematically well-founded languages and tools for expressing and analyzing system models during early design stages, before expensive implementation commitments are made. The construction and analysis of the model help to identify areas of incompleteness or ambiguity in informal system specifications, and to provide some level of confidence that a valid implementation will have key properties, especially those of safety or security. VDM has a strong record of industrial application, in many cases by practitioners who are not specialists in the underlying formalism or logic. Experience with the method suggests that the effort expended on formal modeling and analysis can be recovered in reduced rework costs that develop from design errors.

VDM models are expressed in a specification language (VDM-SL) that supports the description of data and functionality. Data are defined by means of types built using constructors that define structured data and collections such as sets, sequences, and mappings from basic values such as Booleans and numbers. These types are very abstract, which allows the user to add any relevant constraints as data type invariants. Functionality is defined in terms of operations over these data types. Operations can be defined implicitly by preconditions and postconditions that characterize their behavior, or explicitly by means of specific algorithms. An extension of VDM-SL, called VDM++, supports object-oriented structuring of models and permits direct modeling of concurrency.

Because the modeling language has a formal mathematical semantics, a wide range of analyses can be performed on models, both to check internal consistency and to confirm that models have emergent properties. Analyses may be performed by inspection, static analysis, testing, or mathematical proof. To assist in this process, extensive tool support is available for building models in collaboration with other modeling tools, to execute and test models, to carry out different forms of static analysis, and to generate executable code in a high-level programming language.

The origins of VDM lie in work done in the IBM Laboratory at Vienna in the 1970s, where a formal specification language (Meta-IV) was developed to define the programming language PL/I. Meta-IV was subsequently used to define minimal BASIC, parts of FORTRAN and APL, ALGOL 60, Ada, and Pascal. The first description of this form of VDM, which was based on Meta-IV, was published in 1978 (1). Dines Bjørner and colleagues at the Dansk Datamatik Center developed the language definition capabilities of VDM that delivered the first European Ada compiler to achieve validation. Their modeling style, which emphasized explicit definition of functions, came to be known as the Danish School of VDM. Cliff Jones and colleagues, working at IBM Hursley, Oxford, and Manchester Universities subsequently developed the parts of VDM that were not specifically aimed at programming language definition into a more general modeling framework (2); their style, which emphasizes abstract modeling and validation by proof, became known as the English School of VDM. An account of the scientific decisions embodied in VDM can be found in Jones' summary (3).

The standardization of VDM-SL by the British Standards Institution and the International Organization for Standardization (ISO) sought to define a language that could accommodate the Danish and English Schools. It also provided an impetus for the development of tools to support the analysis of models written in the newly standardized language. At the same time, discussion surrounded the possibility of a "lightweight" application of formal modeling technology, which stressed the carefully targeted application of formal modeling, with strong industry-standard tool support. In spite of the 'Method' in its name, the use of VDM does not prescribe a particular development process or methodology. Instead, the components of the method may be used as developers see fit. This pragmatic approach (4) led to substantial advances in the application of VDM and later extended to the VDM++ language (5).

The major part of this article is an overview of the elements of the modeling language, validation technology, tool support, and industrial application. More advanced technical aspects of the semantics of the modeling language and its associated proof theory are briefly introduced. Current trends and open questions are identified. The leading source of current information is the VDM Portal (www.vdmportal.org), and the most current text on the tool-supported approach to system modeling and validation in VDM++ is Fitzgerald et al. (5). Texts on more detailed topics are cited in the body of the article.

SYSTEM MODELING IN VDM

The use of VDM involves the development and analysis of models to help understand systems and predict their properties. Good models exhibit abstraction and rigor. Abstraction is the suppression of detail that is not relevant to the purpose for which a model is constructed. The decision about what to include and what to omit from an abstract model requires good engineering judgment. A guiding principle in VDM is that only elements relevant to the model's purpose should be included; it follows that the model's purpose should be clearly understood and described. Rigor is the capacity to perform a mathematical

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

analysis of the model's properties to gain confidence that an accurate implementation of the modeled system will have certain key characteristics.

In computing systems development, modeling and design notations with a strong mathematical basis are termed *formal*. VDM is based on a formal specification language VDM-SL, the semantics of which are given mathematically in an ISO Standard (6). VDM models, although often expressed in an executable subset, are developed primarily for analysis rather than for final implementations.

Model Structure

In VDM, models consist of representations of the *data* on which a system operates and the *functionality* that is to be performed. Data includes the externally visible input/output and internal state data. Functionality includes the operations that may be invoked at the system interface as well as auxiliary functions that exist purely to assist in the definition of the operations. The ISO Standard (6) defines a (nonmandatory) module framework for VDM-SL models. This framework includes traditional import and export features as well as module parameterization and instantiation.

The VDM++ language extends VDM-SL with facilities for specification of object-oriented systems, and structures models into class definitions, each of which has similar elements to a single VDM-SL specification, with the state variables taking the role of instance variables and the operations playing the part of methods. The remainder of this section will restrict consideration to VDM-SL, with VDM++ considered at a later stage.

Modeling Data

Data models in VDM are founded on basic abstract data types together with a set of type constructors. A full account of VDM-SL data types and type constructors is provided in current texts (5).

Basic types include numbers (natural, integer, rational, and real) and characters. Note that, in accordance with VDM's abstraction principle, no predetermined maximum representable numbers or real number precisions exist. If a user wishes to specify these limits because they are relevant to the problem being modeled, then it is possible to do so explicitly by means of invariants. Invariants are logical expressions (predicates) that represent conditions to be respected by all elements of the data type to which they are attached.

Throughout this article, the ASCII syntax of the VDM-SL will be used. An alternative mathematical syntax is used in the older texts but, although both are permitted by the ISO Standard, the ASCII syntax is considered the more accessible for readers unfamiliar with the notations of discrete mathematics. Keywords are, by convention, shown in bold face. Consider, as a simple example, a system for monitoring the flight paths of aircraft in a controlled airspace. A simple data type definition that represents the Latitude of an aircraft would be given as follows:

```
Latitude = real
```

If it is desired to restrict the `Latitude` to the range of numbers from –90 to 90 inclusive, then an additional condition is added to the data type in the form of an *invariant*. This extended type definition is as follows:

```
Latitude = real
inv lat == lat >= -90 and lat <= 90
```

The invariant is an integral part of the data type. Thus, it is not possible to create a value of type `Latitude` that does not respect the invariant. The modeler must ensure that all functions and operations that create such elements respect the invariant.

More sophisticated data types are built using constructors. A record type constructor permits the definition of tuples with named fields. For example, assuming definitions of types that represent `Latitude`, `Longitude`, and `Altitude`, it is possible to define a type of values representing aircraft position, as follows:

```
Position :: lat :Latitude
            long:Longitude
            alt : Altitude
```

A value of type `Position` is a composite whose component values can be extracted by giving the field names. Thus, the `Longitude` component of a position `p` is given by `p.long`. VDM-SL also contains type constructors for building union and Cartesian product types.

Models are typically built around structured collections of values, so VDM-SL provides type constructors that support several collection types: sets (finite unordered collections), sequences (finite ordered collections or arrays), and mappings (finite functions). For example, one may wish to define a type to model the path of an aircraft as a finite sequence of positions. The corresponding definition is:

```
FlightPath = seq of Position
```

Thus, an element of type `FlightPath` is a finite sequence of position records. Given a value `fp` of type `FlightPath`, the initial `Altitude` is expressed as `fp(1).alt`. If modeling a flight control system that must manage several aircraft, then it would be appropriate to define a type that relates aircraft identifiers to their flight paths as a mapping:

```
FlightDetails = map AircraftId to FlightPath
```

A mapping in VDM is the abstract model of an associative array; individual associations are represented using an "arrow" notation. For example, '`{ 3 |-> "text1", 7 |-> "text2" }`' represents an association between numbers and character strings. In the flight details example, the mapping represents a finite collection of flight paths indexed by the aircraft identifier. Given a flight details mapping '`fd`' and an aircraft identifier '`a`', the following expression denotes the initial `Altitude` of '`a`':

```
fd(a)(1).alt
```

Several special basic types also facilitate abstraction. The *token* type is used to denote values whose representations are immaterial. Tokens can be compared for equality, but they have no internal representation so no other operators may be applied to them. Tokens are particularly useful for defining types that are necessary to a model but for which no individual elements are required. For example, if the air traffic model is concerned primarily with flight paths rather than call signs, then the modeler may choose not to give a detailed representation for the `AircraftId` type, preferring to use a token type:

```
AircraftId = token
```

Modeling Functionality

Functionality is described in terms of functions and operations that accept input values and deliver output values that belong to the types defined in the model. As with data, VDM-SL contains features to support abstraction of functionality.

Each basic type and type constructor has associated syntax allowing values to be expressed. For example, a sequence of four natural numbers might be expressed directly as follows:

```
[3, 7, 7, 2]
```

Comprehension notations allow more sophisticated constructions. For example, the following expression represents a sequence of all the squares of numbers up to 25:

```
[ n**2 | n in set{ 1,...,25} ]
```

The types are equipped with operators that allow complex expressions to be constructed. For example, given a value `s` that belongs to a sequence type, the expression **`len`** `s` denotes the length of the sequence. Two sequences `s1` and `s2` may be concatenated by an infix operator: `s1^s2`.

As in programming languages, some operators are *partial*, (i.e., undefined for certain values of their arguments.) For example, a sequence lookup such as the expression `s(i)` is undefined if the sequence `s` contains fewer than `i` elements. Such misapplications of partial operators correspond to potential run-time errors in a corresponding implementation. The behavior of a real computing system when such an error occurs is not usually predictable. An error message may be returned, or an infinite loop may be entered, for example. Because such behavior can rarely be known at modeling time, VDM treats them all as mathematically undefined in the semantics.

Functions may be described explicitly or implicitly. An explicit function definition is an expression that denotes the result to be returned in terms of input parameters. Returning to the air space management example, the modeler may wish to specify a function that adds a new position on to the end of a flight path. The function definition is given as follows:

```
AddPos: FlightPath * Position -> FlightPath
AddPos(fp,p) == fp^[ p]
```

Implicit function definitions provide an important abstraction capability in VDM. Although an explicit definition like the one shown above is concise, it may be considered to bias a reader implementing the model toward a particular implementation, for example using a corresponding concatenation operator built in to a programming language if present. An implicit definition describes a function purely in terms of the result to be delivered, with no direct reference to any algorithm to be used in the computation. This definition is given in terms of a logical (Boolean) expression that must be satisfied by the result. This expression is termed a *postcondition.* A classic example is a specification of a function for computing the square root `r` of a natural number `n`:

```
SQRT(n:nat)r:real
post r* r = n
```

Here the required result is merely characterized, with no bias toward any particular implementation. In particular, it will be noted that the postcondition does not constrain the result to be either positive or negative; the modeler has indicated that either result will suffice provided that it is a square root of the input `n`. Such implicit specification is valuable where the provision of an algorithmic description would obscure the meaning of the model. The disadvantage is that an implicit operation specification is not directly executable. In the airspace management example, an implicit specification might be used for a function to select a specific aircraft for landing, specified as follows, where the '**`in set dom`**' construction means that the result returned is present in the domain of the flight details mapping structure:

```
Select(fd:FlightDetails)a:AircraftId
post a in set dom fd
```

Both explicitly and implicitly defined functions may not always be applicable. For example, the function above cannot return a result if the flight details mapping `fd` were empty. The function description therefore cannot be satisfied for all valid inputs. Nonemptiness of the input `fd` is a *precondition* on the successful application of the function. Such preconditions are recorded explicitly in VDM. Thus, a satisfiable specification of the `Select` function would be as follows, where the precondition is shown in italics:

```
Select(fd:FlightDetails)a:AircraftId
pre dom fd <> { }
post a in set dom fd
```

Preconditions, like invariants, provide a means of recording constraints that are often left unrecorded in informal descriptions of computer-based systems. In the example above, the precondition is required to ensure that the function can return a correct result in accordance with the postcondition. An implicit specification can be considered a contract: An implementation of the operation promises to return a result that satisfies the postcondition provided the calling environment ensures that the precondition is satisfied. If the precondition is not satisfied, then no guarantees about behavior are made.

Modeling State and Operations

Many systems have persistent state variables that are read and modified by operations and that retain data between operation invocations. In VDM, such systems are modeled by defining a distinguished state variable of a defined type and operations that, like functions, deliver outputs from inputs but that may also have side effects on the state variables.

A state-based version of the airspace management system might have a single state variable of type `FlightDetails`, modeling the current state of the airspace:

```
state Airspace of
      fd: FlightDetails
end
```

An operation to add a new aircraft with a single position `p` in its flight path might be specified implicitly as follows. Note the use of the prefix '~' to denote the state variable's value before execution of the operation. This decorated version is required because the postcondition describes a mathematical relation between the preoperation and postoperation states. The `munion` operator used in the postcondition here forms the union of two mappings provided the two mappings do not disagree (any values in both domains map to the same range value).

```
New(a:AircraftId,p:Position)
ext wr fd: FlightDetails
pre a not in set dom fd
post fd = ~fd munion { a |-> [p] }
```

Operations may be specified explicitly as well as implicitly. Where state variables may be modified, the language for expressing such explicit operation definitions is close to that of a classic imperative programming language, albeit one with very abstract data types. For example, the following explicit definition of the `New` operation contains a single assignment to describe the updating of the `fd` state component. The signature of the operation, which is shown in the first line of the definition, shows only the visible input and output types. Because this operation produces no external output, but merely updates the state, the return type is empty, as indicated by the "()".

```
NewOp: AircraftId * Position ==> ()
NewOp(a,p) == fd := fd munion { a |-> [p] }
pre a not in set dom fd
```

Full details of implicit and explicit specification styles for both functions and operations can be found in the VDM literature (4, 5).

Modeling Object-Oriented and Concurrent Systems in VDM++

VDM++ provides facilities for the description of object-oriented systems. The elements of classic VDM-SL are all present, but the extended language provides for models based on class definitions in which each object's local state is represented as instance variables and operations are treated as methods. Information hiding and inheritance are also supported.

VDM-SL is limited to the description of sequential system models, although such models may be implemented in a parallel-computing framework. The challenge in modeling concurrent computation is that separate threads (independent sequences of computations) may communicate through shared variables and inconsistencies can develop when two or more independent threads access a shared variable simultaneously. Considerable research has been performed on handling shared variable concurrency in VDM, notably by extending the pre/postcondition framework with *rely* and *guarantee* conditions that state, respectively, the properties that an operation requires to be invariant and the properties that it guarantees to maintain during its execution (7).

The rely/guarantee approach has been a significant contribution to design methodologies for concurrent systems generally. VDM++ takes a rather pragmatic line. Here inconsistencies may develop through simultaneous access to shared objects by separate threads. These inconsistencies are avoided by providing synchronization constraints in the form of *permission predicates* that describe the conditions under which an operation may be carried out. A permission predicate may refer to an instance variable used as a flag to prevent other threads from an object being used in a critical way by another thread. It may also access special variables that represent the number of times each operation in an object has been requested, activated, or completed, or representing the number of currently active invocations of the current operation. Consider a simple model in which a sensor produces data, writes it to a buffer object, and then these data are consumed by a consumer object. The buffer object provides a data model of the buffer and methods (operations) to `Put` and `Get` data. The consumer object should only invoke the `Get` operation on the buffer when data is available to get. This restriction could be modeled by allowing a special value **`nil`** to indicate emptiness of the buffer, in which case the permission predicate (denoted by the keyword **`per`**) on the `Get` operation in the buffer object is of the form shown below:

```
per Get => data <> nil
```

If such a special **`nil`** flag is not available, one could count the number of completed `Put` and `Get` operations and permit a `Get` operation under the condition specified as follows:

```
per Get => #fin(Put) - #fin(Get) = 1;
mutex(Put,Get)
```

Here the expression '**#fin**`(op)`' represents the number of completed occurrences of the operation `op`. The `mutex` condition enforces mutual exclusion of the `Put` and `Get` operations.

It is worth emphasizing the difference between preconditions and permission predicates on operations. An operation's precondition records a fundamental assumption about the circumstances under which the operation will be invoked. If an operation is called in violation of its precondition, then no guarantees are given about the system's subsequent behavior (the modeling equivalent of a run-time error). In contrast, a permission predicate determines whether a request to perform an operation will be granted or denied. If permission is denied, then the request is blocked and another thread may be executed; a particular thread of computation may be held up when a permission predicate evaluates to false, but other threads can progress.

MODEL VALIDATION

Validation is the process of gaining confidence that the model describes the behavior that one would expect of an accurate representation of the system of interest. As a consequence of VDM-SL's formal definition, a particularly wide range of validation checks can be performed, with automated support, to identify potential static and run-time errors in a model as it is constructed. Most checks are described as *proof obligations* because they are observed as requirements on the modeler. Once the proof obligations have been discharged, the model's emergent behavior can be checked against expectations, which is described as *validation conjectures*.

Proof Obligations and Validation Conjectures

A range of basic proof obligations is common to all VDM models. For example, it should always be possible to tell whether a value belongs to a specified data type. Consequently, any invariants must be expressions that always return a value (true or false), given any element of the restricted supertype. For example, the definition of the `Latitude` data type defined earlier uses an invariant '`lat >= -90` **and** `lat <= 90`'. It must be possible to evaluate the invariant for any real number, so that it is possible to tell whether the number is a valid `Latitude`. This task seems trivial in this example, but it need not always be so. In particular, if an invariant makes use of a partial operator, then it is necessary to ensure that the partial operator is not applied outside its domain of definition. Consider a general type definition of the following form:

```
T = Rep
inv t == P(t)
```

The proof obligation for the invariant is shown below, where '**inv**-`T`' refers to the invariant as a Boolean function. The '**forall**' keyword is a quantifier over the type `Rep`, where `t` is the "bound variable" that ranges over the type, so this formula literally states that "for all values t of type Rep, the invariant yields a valid Boolean value" (the '&' symbol is merely used as a syntactic separator):

```
forall t:Rep & inv-T(t) : bool
```

One of the more significant and useful proof obligations is that of invariant preservation. When a function `f` returns a result of type `R` and the definition of `R` has an invariant, an obligation exists to show that the function respects the invariant on `R`. Formally, consider a function with the following signature (a signature is a summary of input and result types):

```
f: I -> R
```

In this case, the proof obligation is stated formally as follows:

```
forall i:I & pre-f(i) => f(i):R
```

For example, a function to increase a `Latitude` by adding an increment must be shown to take proper account of the invariants and behave correctly at the extremes of the range.

Versions of invariant preservation also exist for implicitly defined functions and particularly for implicitly specified operations, where the obligation is termed *satisfiability*. Consider an operation `Op` taking an input `i` of type `I` and operating on a state variable `s` of type `S`, returning a result `r` of type `R`. The operation is said to be satisfiable provided that, for all inputs satisfying the precondition, there exist a state after execution and result that together satisfy the postcondition. Formally, the obligation is to show the following:

```
forall i:I, ~s:S & pre-Op(i,s) =>
     exists s:S, r:R & post-Op(i,~s,s,r)
```

In practice, satisfiability is one of the most important checks to be performed on a model. Because invariants frequently embody safety constraints, checking that functionality respects them is one means of early detection of subtle defects in an implementation.

Validation Techniques

Once a model's proof obligations are satisfied, its other properties may be explored using a range of techniques. Again, because of the formality of the modeling language's semantics, analysis by mathematical proof is possible, and it is often done for critical applications. At a less rigorous level, models can also be explored by testing.

Explicitly defined functions and operations can be executed directly by means of an interpreter, provided they are expressed within an executable subset of the language. The expressiveness of modeling languages like VDM-SL is such that useful expressions can be written that are nevertheless not readily executable. One main cause of nonexecutability is quantification over unbounded data types. For example, the following function definition is not executable because it quantifies over the whole unbounded type of natural numbers.

```
is_square(i) == exists j:nat & i = j**2
```

In this example, an interpreter could be expected to iterate over the natural numbers until a suitable value for `j` is found. In the case where `i` is not a square, the iteration might not terminate unless some additional reasoning is performed, using information from the problem domain to halt it. The main existing VDM and VDM++ interpreters forbid attempts to execute formulae involving unbounded quantifications. Quantifications over other collections such as finite sets are permitted, however, so one might define the `is_square` function as follows:

```
is_square(i) == exists j in set{0,...,i} &
i = j**2
```

The disadvantage of building this extra knowledge into the model is that it is information added for the specific purpose of executing the model, and so may compromise abstraction (8,9).

Despite the caveats about executability, VDM models used in industrial applications are often built within the executable subset and validated mainly through testing. Tool support allows very efficient interpretation of the model, and additional tools facilities support batch-mode testing as well as test-coverage analysis. The level of confidence gained by model testing is limited by the quality of the test set. However, the level of abstraction means that validation tests used on a model provide a strong basis for designing tests used on subsequent system implementations.

Formal proof provides a much more general validation technique than testing. The formal semantics of VDM-SL has generated a well-documented proof theory (10), and the development of automated support for proof is the subject of research in the Overture project (www.overturetool.org). Experiments suggest that typically up to 90% of proof obligations can be automatically discharged by a theorem prover. However, user-guided proof, given adequate tool support, can be an effective means of exploring a model when an automated analysis simply identifies the presence of defect.

TOOL SUPPORT

VDM's recent industrial application has been closely tied to its tool support. Early tools for VDM, such as Adelard's SpecBox (11), (Adelard LLP, London, UK) were largely confined to basic static checking and pretty-printing of specifications. However, the availability of the ISO VDM-SL Standard (6, 12) gave impetus to the development of a toolset based on a parser, type-checker, and interpreter for the executable subset of the language. The product that ultimately resulted from this work, VDMTools (13), was primarily aimed at cost-effective industrial use rather than expressive completeness. VDMTools originated with the Danish company IFAD, but it is now maintained and further developed by the Japanese corporation CSK Systems.

A feature of successful tool support is that it should be capable of integration with existing tools in the development environment. VDMTools supports models written with the aid of any environment that can output a text file (or Microsoft Word (Microsoft corporation, Redmond, WA) file using a VDM style), but it has also been important to develop a link between the VDMTools environment and other object-oriented design tools. A bidirectional link exists with the IBM Rational Rose (IBM, Armonk, NY) toolkit that allows modelers to design the model structure as a UML class diagram and convert this directly to a VDM++ model. Subsequent changes to the VDM++ model can be reflected in the UML model and vice versa. Once a model has been written, it can be syntax checked and type checked. Proof obligations can be generated automatically and checked manually. This interplay between UML and VDM++ models, kept in sequence as a design evolves, is an instance of an approach sometimes referred to as "round-trip engineering."

To support validation, the VDMTools contain an interpreter for test-based analysis of specifications written within an executable subset. Testing is supported by a coverage analyzer. A CORBA-based application programmer interface (API) allows models to be executed on the interpreter but accessed through a graphical user interface, so that domain experts unfamiliar with the modeling language can explore the behavior described by the model by playing out scenarios or other test cases. The interpreter has a dynamic link library feature that allows external modules to be incorporated. Interpretation of an abstract model is typically slow compared with program code, so automatic code generation can be used to derive programming language implementations (e.g., in Java or C++) direct from the model.

The emphasis in VDM tool support has been on the provision of facilities that allow the formalism to be applied within existing development processes and in conjunction with existing tools. This emphasis has meant that the priority for tool support has been the provision of an efficient interpreter and the supporting features. Support for proof has been limited to research activity. A major spur to the development of a proof system for VDM was provided by the Mural tool (14), developed as part of the IPSE2.5 project in the 1990s. Mural provided an environment that supported manual construction of proofs by human users, with the tools managing the bookkeeping aspects of proof production. For example, the tool ensured that all the inference steps in a proof were sound applications of previously defined or proven rules, and it also managed the structuring of large numbers of rules into structured collections. Such a user-led proof is extremely time consuming if it all has to be done manually. However, advances in automated proof technology have allowed experimental use of theorem provers to discharge most proof obligations derived from VDM models. The expressiveness of the modeling language means that not all proof obligations or validation conjectures that are true can be proven completely automatically. Future extensions to VDMTools will support automatic proof of most obligations, but the provision of fully integrated manual and automatic proof support remains a research goal.

INDUSTRIAL APPLICATIONS

VDM has a strong record of industrial application in a wide variety of application domains. After the development of VDMTools, the approach advocated in industry concentrated on the construction of abstract models and test-based analysis. Several examples of industrial application give an indication of the ways in which the modeling technology is applied. More detailed analysis of these applications has been reported elsewhere (15).

The ConForm project (16) was an industrial case study rather than a commercial application. British Aerospace Systems and Equipment (BASE) studied two concurrent developments of a security-related software component using, in one stream, current best practice and, in the other stream, model-oriented specification using VDM-SL. Comparison of the two developments suggested a shift of effort from implementation to analysis phases in the system development and also indicated a shift in the volume and types of query raised against informal requirements. The project involved both systems and software engineers applying the modeling technology.

DustExpert (developed in 1995–1997 by Adelard LLP) is a safety-related knowledge-based system to advise on the construction of industrial plants that contain potentially explosive dusts. A VDM-SL model of 12kLOC is derived from about 450 pages of requirements formed the basis of manual proofs concerning safety properties as well as test-based analysis using the interpreter. Together these contributed to the product's safety case. The defect density of the completed product (implemented in Prolog and C++) was reported by the developers as lower than 1 defect/kLOC.

In 1996, Praxis reported on the development of the *Central control function Display Information System* (CDIS), an air traffic control support system for use in the London area (17). Several modeling approaches were used, including a modular variant of VDM. The operational software was about 197kLOC in size and exhibited 0.75 defects per kLOC, which made it one of the larger projects to have applied formal modeling techniques at the time.

TradeOne (developed between 2000 and 2002) is a back-office system for securities trading, developed by JFITS, now the CSK Systems part of CSK. Metrics from the development process were reported in 2005 (5). Two complex subsystems that handle tax exemptions and options were modeled in VDM++ prior to implementation in C++ and Java. The defect densities were reported as zero and 0.05 defects per kDSI in the two running subsystems. The effort profile for the development was also analyzed, which suggested an increase in the proportion of effort devoted to analysis. Overall development costs were compared extremely favorably against regular COCOMO (18) estimates.

Felica Networks Inc. in Japan have reported an application of VDM++ to the development of the firmware for a next generation mobile Integrated Circuit chip, which is based on contactless card technology (15). VDM++ models were developed alongside UML models as part of the process of improving requirements descriptions prior to implementation. The model was validated by performing over a high volume of tests to achieve very high path coverage. Most defects uncovered in requirements were attributed to the use of formal modeling. Of these, slightly more than half were attributed to issues raised during construction of the model, and the remainder was attributed to testing the model.

Industrial application of proof technology has so far been restricted largely to specialist high-integrity systems in areas such as the nuclear industry (19), although the variety of domains covered in the examples presented here suggests that model-oriented formalisms like VDM have the potential to be applied widely. However, a tendency exists to restrict the use of proof to areas in which high quality is the dominant concern or the complexity of functionality or data threatens the success of a development.

REIFICATION: FROM MODELS TO DESIGNS

Formal models often serve as abstract specifications of systems to be implemented in high-level programming languages. Each model typically contains representations of elements of the problem domain (for example, aircraft identifiers and flight plans), but an implementation must be expressed in terms of concepts present in the chosen programming language. Reification (more widely known as refinement) is the process of transforming an abstract model in VDM into a concrete one that includes representations of data and functionality that are expressed readily in the target programming language. The reification process is typically done in a series of steps, in which each introduces small changes to the model and involves verification that the modified (concrete) model still describes the same behavior as its more abstract predecessor. By composing several reification steps, a sufficiently concrete model may be reached. VDM pioneered the use of proof obligations to govern this stepwise reification process (2). Rules govern the reification of state definitions and operations.

Data Reification

In data reification, an abstract type representation is replaced by a more concrete counterpart. For example, an abstract set of aircraft (an unordered collection of objects) might be reified by a more concrete ordered sequence (array) structure. This structure might, in turn, be reified even more to a model of a linked list prior to translation into a programming language that supports linked list structures.

A data reification step is correct if every abstract state has a concrete counterpart. The correctness is typically checked by proposing a *retrieve function* that recovers the abstract counterpart from any concrete model. The retrieve function must be *total* and *adequate*. A total retrieve function is one that is defined on any possible concrete value. An adequate retrieve function is one that ensures every abstract value has a concrete counterpart (in mathematical terms, the function is "surjective"). Formally, given a concrete type `C`, an abstract type `A`, and a retrieve function `r`:

```
forall c:C & retr(c):A                    Totality
forall a:A & exists c:C & r(c)=a          Adequacy
```

In the example, the retrieve function simply gathers the elements of the array and generates the set that contains all those elements. Stated formally in VDM-SL, this appears as follows:

```
retr: seq of AircraftId -> set of AircraftId
retr(c) == elems c
```

Note that, in this example, the concrete type introduces redundancy because a sequence may contain duplicate values, whereas a set suppresses duplication. A set that contains a single aircraft identifier might be represented by a sequence that contains just one element or by a sequence that contains two or more repetitions of the same aircraft identifier.

When a model is subjected to data reification, the operation specifications that work on the abstract state must be adjusted to the new concrete form. Informally, the concrete operation may have a more liberal ("weaker") precondition than the abstract version, but it must have at least as restrictive a postcondition (i.e., one that is "stronger"). If an operation `OpA` is reified to a concrete counterpart `OpC`, then two conditions must be satisfied. First, `OpC` must be defined to operate on at least the states that `OpA` worked on (when viewed through the retrieve function). Second, `OpC` must define a relation between states that respects the relation between states defined by the abstract form (when viewed through the retrieve relation). These two conditions are expressed formally as the Domain Rule and Result Rule shown below.

```
forall c:C & pre-OpA(retr(c)) =>
pre-OpC(c)                                Domain Rule

forall ~c,c:C &                           Result Rule
    pre-OpA (retr(~c)) and post-OpC(~c,c) =>
       post-OpA(retr (~c),retr(c))
```

A full discussion of the data reification proof obligations is given by Jones (2).

Operation Decomposition

In reifying functionality, operations are broken down into simpler suboperations linked by control constructs such as sequential compositions, conditionals, or loops. Successive decomposition steps add control constructs and reduce the complexity of the suboperations. Rules governing such decomposition steps are given in a "triple" format. In such a format, the expression

$$\{P\}\ \mathrm{Op}\ \{Q\}$$

is written to indicate that the operation Op, when invoked in a state that satisfies the Boolean condition P, terminates and results in a condition satisfying the condition Q, where Q is a logical expression over both the before and after states. As a simple example, consider a rule for introducing conditionals. Specifically, suppose an operation with precondition *pre* and postcondition *post* is to be decomposed into a structure of the following form:

$$\text{if } \mathtt{test} \text{ then } \mathit{TH} \text{ else } \mathit{EL}$$

where *test* is a Boolean expression, and *TH* and *EL* are operations that correspond to the functionality to be executed in each limb of the conditional. The condition under which the decomposition is sound is given as follows:

$$\frac{\{pre\ \textbf{and}\ test\}TH\{post\};\quad \{pre\ \textbf{and not}\ test\}EL\{post\};\ pre \Rightarrow \delta(test)}{\{pre\}(\text{if}\ test\ \text{then}\ TH\ \text{else}\ EL)\{post\}}$$

Here the decomposition shown below the line is asserted to be sound under the conditions shown above the line. It is necessary to show that the postcondition is established in both the *TH* and *EL* branches of the conditional. The "δ(*test*)" condition is a requirement that the test actually terminates. All three conditions may be established under the assumption that the precondition *pre* holds. Other rules for operation decomposition are presented in Jones' book (2).

SEMANTICS AND FORMAL REASONING

VDM was one of the first modeling languages to have a mathematical semantics codified in an ISO standard (6,12). The semantics are denotational in style and give the meaning of models expressed in a core language into which full VDM-SL may be translated. The semantics is defined in terms of domains built on complete partial orders. The meaning of a VDM model is defined as a collection of possible environments that define domains for each of the defined data types. Operations are denoted as sets of valid relations over the domains that correspond to the types of the inputs and state (20).

As noted earlier, VDM has several features that support a level of abstraction in models that is not typically found in programming languages. These features lead to the more interesting aspects of the denotational semantics. One of the most significant features is the ability to use a style of loose specification. Loose specification develops where the model permits a level of choice. For example, an implicitly specified function or operation presents a choice over which of possibly many results satisfying the postcondition is to be returned. Loose specification is also supported by other constructs in the language, which allow choices to be arbitrarily from sets of values, for example. Two possible semantics are used for loose expressions. The first, termed underdeterminedness, interprets the construct as defining a set of possible different deterministic implementations. The second, termed nondeterminism, allows implementations that are themselves nondeterministic. The VDM-SL semantics treat looseness in function definitions as underdeterminedness, although operations are potentially nondeterministic. Functions that contain loose-choice operators are thus denoted as sets of possible deterministic functions, each representing a different choice. For operations, the possibility of nondeterminism is retained to allow the modeler to describe behavior that may be governed by factors outside the collection of inputs to the operation (21).

Logic and Proof in VDM

VDM has a well-established theory that supports the construction of proofs about models and reifications. One of the most distinctive features of VDM is the handling of undefinedness. Undefined terms can develop naturally in an abstract modeling framework as well as in program code. For example, an expression that looks up a value in a sequence has the possibility of yielding an undefined value if the index is out of range. The user can also define functions that may not terminate for certain inputs. The following simple example is regularly used in discussions about logics handling undefinedness. The `subp` function takes two integers `i` and `j` as inputs and returns `i−j` provided `i = j`, but otherwise its result is undefined:

```
subp: int* int -> int
subp(i,j) == if i=j then 0 else subp(i,j+1)
```

In reasoning about this function, the following assertion is plausible:

```
forall i,j:int & i < j or subp(i,j) = i−j
```

If `i < j`, then the right hand term using `subp` in this expression is undefined, and so the whole conjecture is meaningless in a classical logic.

The problem of how to reason about undefined values is a significant one in formal methods. Many approaches aim to use classical two-valued logic. Some approaches ban potentially undefined terms, and they generate proof obligations to enforce this. Other approaches allow undefinedness but insist that terms such as `subp(i,j)` always yield a valid (type correct) but unknown value. VDM's approach is unusual in that its logic is nonclassical, which allows undefined value terms and undefined logical values the logic of partial functions (LPF) (22) underpins reasoning about models and reification in VDM (23,24). LPF is in many respects similar to a classic logic, but the definitions of operators are extended to cope with undefined, as well as true and false terms. For example, the truth tables for disjunction and negation are shown below, where ⊥ represents an undefined Boolean expression:

A	B	A **or** B
true	true	true
true	false	true
true	⊥	true
false	true	true
false	false	false
false	⊥	⊥
⊥	true	true
⊥	false	⊥
⊥	⊥	⊥

A	**not** A
true	false
false	true
⊥	⊥

The truth table for ‘**or**’ may be thought of as describing a parallel lazy evaluation of the operands: the expression ‘A **or** B’ evaluates to true if one operand evaluates to true, even if the other operand is undefined. Returning to the `subp` example above, the use of LPF allows the or-expression to return true even when the second operand is undefined, because under exactly the same conditions, the first operand is true.

The most far-reaching consequence of this definition of logical operators to handle undefinedness is that some laws of classic logic do not hold in LPF. In particular, the law of the excluded middle (that ‘`A or not A`’ is always true) is not valid in LPF. An operator d is introduced to LPF to express definedness: δ(`A`) is true when `A` is Boolean. The theorems of classic predicate logic that are not also theorems of LPF can be transformed to theorems of LPF provided “δ(`A`)” hypotheses are added. The practical consequence of this theorem is that, in performing proofs about VDM models, definedness has to be proved only where it is necessary.

LPF provides a natural way of handling undefinedness in reasoning about VDM models. The most comprehensive account of the application of LPF (10) is a product of the development of the Mural proof support system (14). Unlike Mural, many automated proof support tools focus on supporting classic logics as a priority. Indeed, the attempts to develop proof support systems for VDM have so far stopped short of implementing LPF, instead generating proof obligations to ensure that uses of partial operators are protected. Although LPF provides an intuitive approach in proof-theoretic terms, it is hard to implement in a classic interpreter: operators such as disjunction, as shown above, are symmetric, so implementation requires parallel evaluation of both operands in case one evaluates but the other is undefined. For this reason, the VDMTools interpreter takes a left-to-right lazy evaluation approach (in the case of disjunction, for example, the second operand is not evaluated if the first evaluates to true). Other formal methods take different approaches to dealing with the risk of undefined terms, and these methods are briefly discussed below.

RELATED APPROACHES

VDM is one of a family of model-oriented formal methods that includes Z (25), the B method (26), and the RAISE method and specification language (27,28). All four approaches share the abstract and rigorous modeling of data and functionality, but they differ in their focus. Z emphasizes the description of properties of data and functions, rather than giving direct definitions, which makes it particularly well suited to abstract system specification. A distinctive feature is the schema calculus, which allows for composition of specifications from structural units (schema). B is focused more on the refinement-based development of program code from abstract specifications (given in the Abstract Machine Notation). VDM and Z have been compared in Ref. 29, and VDM and B have been studied with respect to their potential integration (30). The RAISE method is based on the use of a “wide-spectrum” specification language, which is intended to encompass in a single formalism the features needed to move from abstract property-oriented specifications to lower level code. All of these languages share with VDM an extensive history of industrial application.

An interesting area of difference between the formalisms is in their underpinning logics, and in particular the mechanisms for handling undefined terms. The ISO Standards for Z and VDM are neutral about logic and proof theory. In Z, a range of logics have been explored [e.g., (31)] including approaches that seek to avoid undefined terms that develop altogether in the logic. In LPF, which is often used with VDM, undefinedness is handled directly in the logic itself. RAISE addresses the problem of executing expressions that contain symmetric operators with undefined operands by adopting a "conditional logic" (left to right) evaluation of formulae that may contain undefined terms (as does the VDMTools interpreter) (32).

CURRENT TRENDS AND OPEN QUESTIONS

From the original work on programming language and compiler design, the goal of research on VDM has been the development of a usable formal method. This principle influenced the standardization of the VDM-SL semantics, the pragmatic approach to tools, and the principles of lightweight application that have influenced industrial use. The same principle has guided foundational research on the modeling of concurrency, logics, and reification. Many research questions surrounding VDM result from practical need. It is possible to identify several significant trends that are setting the agenda for contemporary research, particularly in the areas of modeling, semantics, proof support, and tools frameworks.

VDM-SL and VDM++ can describe a very wide range of computing system. However, their ease of use is hindered in some application areas by an absence of convenient abstractions. For example, no current support exists for modeling timing characteristics unless one builds clocks and event histories explicitly into an application model. A current challenge is to include timing specifications into VDM++. This extended dialect of VDM++ is known as the VDM++ in constrained environments (VICE) dialect that has its own version of VDMTools. Studies (33–35) suggest that it is potentially valuable in the analysis of distributed embedded control software. Furthermore, VICE admits the possibility of combining discrete time models of controllers with continuous time models of controlled processes and supporting analysis through cosimulation (36). The combined model may provide a basis for improved collaboration between systems and software engineers, which is a weak aspect of many design processes for embedded systems. Aside from the goal of modeling temporal behavior, other current goals include the use of abstractions to model distributed computation and the modeling of faults and their propagation.

The construction of a dependable system requires more than simply the production of trustworthy software to run on a computer. The immediate environment involves other devices, people, and organizations. If assurance is to be gained that a computer-based system (rather than merely the software) is to function as required, then it is appropriate to model and analyze this wider system. A current research goal in the area of control-system design (37) is to provide support for reasoning about this "whole system" view. The contractual character of implicit specifications using preconditions/postconditions, and rely/guarantee conditions is potentially useful here.

Tool support is vital to the successful adoption of formal methods. The increasing power of static analysis, theorem proving, and model checking is making it possible to integrate a range of analysis tools with model generation and editing facilities. Open-platform technologies such as Eclipse (Portland, OR) have the potential to promote interoperability between separately developed specialized analysis tools, in contrast to the tightly coupled architecture of the current VDMTools.

Within the field of proof support, a current goal is to develop implementations of LPF suitable for automatic background discharging of proof obligations and validation conjectures. User guidance will remain a necessity, and so a open question is how to provide a good interface that allows a user to marshal automated tools in support of a structured proof. Such user-guided proof may even be desirable if proof is properly used as a means of exploring models rather than simply a form of automated check. In the longer term, a major research challenge is the development of theories to support reasoning about stochastic properties, such as failure behavior, that affect overall system functionality.

The Vienna Development Method is one of the seminal formal methods for computer systems development. Its evolution since the 1970s has been marked by the development first of sound foundations in the form of semantics and proof theory, then by strong tool support and industrial application. A major trend since the 1990s has been the work to lower the barrier to using the technology by developing tools that support forms of analysis that are already familiar to systems developers, such as high-coverage testing. Current work towards more cost-effective automatic proof and static analysis, more open tools frameworks, and the ability to model and analyze real-time and distributed systems, is likely to increase both the range and quality of applications of this and other formal methods.

VISUAL PROGRAMMING LANGUAGES

INTRODUCTION

Since the advent of modern digital computers in the 1940s, diagrams have played a role in software development. Initially, they were paper-based aids, used by programmers to design and understand the structure of their programs, but as hardware became more powerful and input-output devices such as cathode-ray tube displays, light guns, and tablets became available, researchers began to investigate the direct use of diagrams in the design and coding of software. The arrival of high-quality, relatively low-cost graphics in the 1980s enabled graphical operating systems, making personal computers (PCs) more accessible, greatly accelerating their adoption. The immediate beneficiaries of this innovation were end users, who could now interact with operating systems and applications by directly manipulating concrete visual representations provided by graphical user interfaces (GUIs). Software developers, however, were less fortunate. In addition to writing programs to implement the core functionality of applications, they now had to use the same textual languages and tools to deal with the complexities of GUI programming.

The lack of adequate development tools, together with the availability of low-cost graphics, heightened interest in the direct use of diagrams in software development, leading to research on various fronts, including visual software project management tools, such as those found in integrated development environments (IDEs), visual editors for GUI creation, visual tools for software modeling and engineering (1), and visual programming languages.

A *Visual Programming Language* (VPL) is a language in which significant parts of the structure of a program are represented in a pictorial notation, which may include icons, connecting lines indicating relationships, motion, color, texture, shading, or any other nontextual device. Although text may occur in the pictorial notation, its role should be secondary, naming program entities for example. This definition requires significant parts of program structure to be represented pictorially, but it does not rule out languages that also express other parts of the structure textually.

VPLs are motivated by the observation that in traditional languages, multidimensional program structures and data are coded into strings, requiring an extra layer of syntax, and that by expressing the structure of programs and data pictorially, a more concrete representation of those structures might be achieved, making it easier to build, debug, understand, and reason about programs.

Our focus in this article is on visual *programming* languages, that is, languages for expressing algorithms. Consequently, although visual tools are widely used in other aspects of software development, specification, modeling, metamodeling, and so forth, we do not cover them here.

VPL EXAMPLES

Like a textual programming language, a VPL can be classified in various ways; for example, by the programming model on which it is based, the target user, whether it is general-purpose or domain-specific, declarative or imperative, or whether programs are constructed directly or by demonstration. Like textual programming languages, VPLs exist in their own, perhaps not quite so extensive, Tower of Babel: hence, a small selection of examples will inevitably exclude some features. Here we provide examples, each presented under a heading that emphasizes a particular characteristic, but chosen to illustrate a reasonably broad range of VPL features.

Data Flow

In data flow VPLs, computation at the lowest level is specified by graphs consisting of icons that represent operations on data, connected by lines representing the flow of data between operations.

The earliest implemented data flow VPL that we are aware of was due to W. Sutherland in 1966 (2). In the 1970s and early 1980s, data flow was adopted as a hardware model in projects aimed at building computers for parallel processing. Data flow diagrams were used as programming aids, but in only one project were they used directly, incorporated in a primitive data flow VPL (3). Just as these hardware projects were dying out in the 1980s for lack of viable products, graphical PCs began to appear, prompting researchers and industry practitioners to further investigate data flow as a viable model for visual programming. Data flow is the model most frequently used as the basis for industrial VPLs. We briefly describe two of them.

Prograph is a VPL intended, like Java or C++, for general-purpose application development (4). Figure 1 depicts a Prograph method quicksort that implements the *quicksort* algorithm for sorting lists. The method consists of a sequence of two data flow diagrams, implementing the base case and recursive cases of the algorithm, which are shown in the two windows labeled 1:2 quicksort and 2:2 quicksort. The input list flows from the caller into the base-case diagram through the *root* on the *input bar* at the top of the diagram and into the *match* operation named (). The match compares the incoming value with its own value [the empty list, ()]. If this comparison succeeds, the incoming empty list flows to the *terminal* on the *output bar* and is passed to the caller. If the match fails, the *next-case-on-failure* control ☒ fires, terminating execution of the case and initiating execution of the recursive case. The input list flows into the built-in operation detach-l, which divides the list into its first element (head) and the remaining list (tail), which flow out of the two roots on the bottom of the operation. The partition operation compares the head with each of the elements in the tail, dividing the latter into the lists of

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

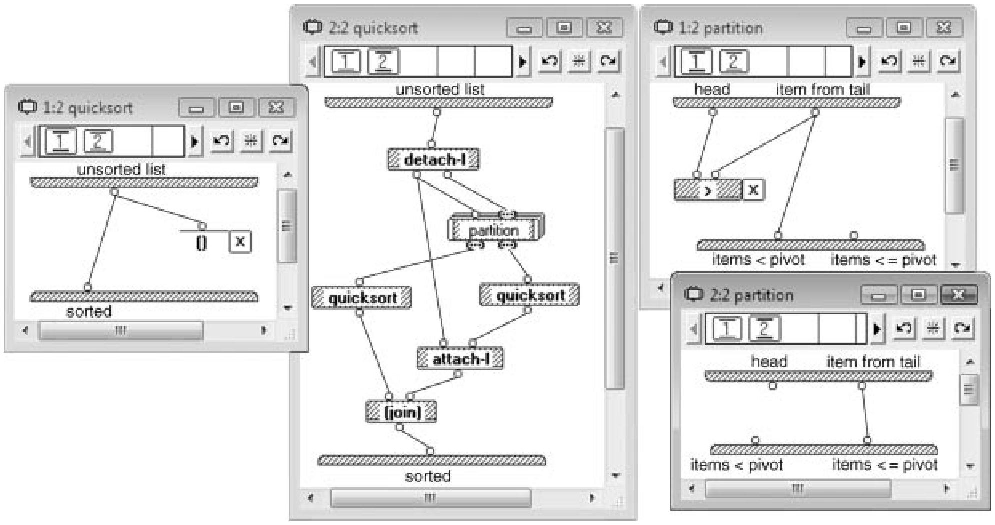

Figure 1. Prograph implementation of the quicksort algorithm for list sorting.

elements less than and greater than or equal to the head. These two lists are sorted by recursive calls to quicksort, the head of the original list is attached to the beginning of the second sorted list, and the resulting list is joined to the end of the first sorted list.

The annotations on the partition operation indicate its repetitive nature. In particular, the list annotation (. . .) on the second terminal requires the input to be a list, each element of which will be consumed by an execution of partition. The same annotation on the roots indicates that lists will be produced, consisting of the values produced by the individual executions of partition. We invite the reader to complete the explanation of this example by examining the diagrams for partition. Note that if there is no data link attached to a terminal on an output bar, no value for that output will be returned to the caller.

Figure 1 illustrates the above comment about concrete representation of program structure in visual languages. For example, the two invocations of quicksort in the recursive case of the algorithm are independent and could be executed in parallel. Representing the computation in a data flow diagram, as in the second case of the quicksort method, clearly exposes this characteristic of the algorithm.

Prograph is an example of a *structured* data flow VPL, in which data flow diagrams are embedded in structures that control how they are invoked. For example, the list annotations on the roots and right-hand terminal of the partition operation in Figure 1 define an iterative, possibly parallel, list-processing construct.

In structured data flow VPLs, diagrams are acyclic, and in each invocation of a diagram, each data link is assigned a value at most once. In contrast, in the unstructured model on which the data flow hardware projects were based, a program consists of a single data flow graph in which iteration is achieved via cycles, and conditional execution by special operations that route values along different data links depending on Boolean input. Because of the difficulty of building and understanding the control structures required for nontrivial programs, unstructured data flow is generally limited to application domains in which cyclic data flow is natural. For example, *Simulink*, a domain-specific, data flow VPL for simulating dynamic systems, is primarily unstructured, although it also provides some control constructs. Figure 2 shows a Simulink program that simulates a bouncing ball by continuously recomputing its velocity and position in a feedback loop consisting of two cycles.

Imperative Programming

Imperative VPLs focus on the flow of control rather than on the flow of data. The earliest example of an imperative visual notation is possibly von Neumann and Goldstine's *Flow Diagrams*, essentially the familiar unstructured flowcharts, consisting of computational blocks connected by lines indicating transfer of control.

Imperative VPLs not based on flowcharts have also been designed. An example is VIPR, a language in which control flow is expressed via containment and connectivity (5). A statement is represented by a circle that may have one or both of a *guard* and an *expression* attached. If the guard (a logical expression) evaluates to true, the expression is

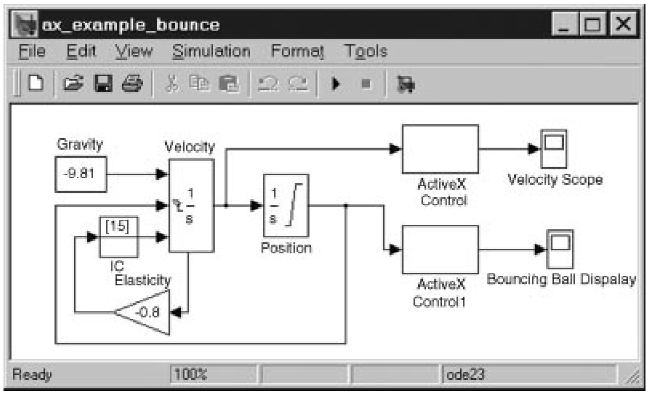

Figure 2. A Simulink program for simulating the motion of a bouncing ball.

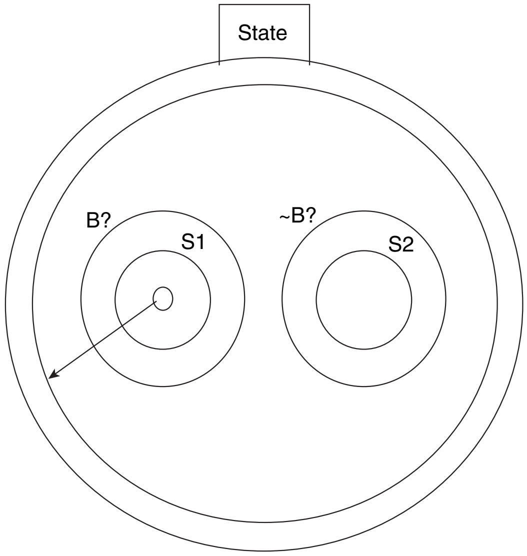

Figure 3. The loop `while` B `do` S1; S2 in VIPR (from Ref. 5).

evaluated. A sequence of statements is represented by concentric circles, which are executed from outside to inside and peeled away as execution proceeds. Circles are also connected in various ways to indicate other kinds of control flow. Figure 3 depicts the form of a VIPR while loop, represented by the circle inside the outer "container" circle. When this statement is executed, the guards on the enclosed statements are executed. If B evaluates to true, the left-hand statement expands to fill the container; the statement inside it is executed, causing the evaluation of S1; and the circle inside that executes, replacing itself with a new copy of the loop structure.

Note that in VIPR, the relationship between a statement and the control structure it invokes is explicitly indicated by a line connecting the two, as illustrated in Fig. 3, in contrast to most VPLs. For instance, in the Prograph example in Fig. 1, the relationship between the partition operation and its diagrams is indicated symbolically.

Imperative VPLs with static representations have not proved to be as useful as data flow. However, VPLs in which the user demonstrates imperative algorithms rather than writing them explicitly have had some success. One such language is *ToonTalk*, which is meant for children and presents the task of programming as direct manipulation of objects in a video game environment (6). A program is represented as a city, in which houses represent processes. The programmer enters a house where he or she trains robots to perform tasks using a small number of tools and assembles them into teams that perform procedures.

There is no static representation of "code" in ToonTalk, so it is not possible to provide diagrams for an example program; however, we will outline the process of building a program for computing factorial, illustrated with some snapshots. First, as shown in Fig. 4(a), the programmer takes a new robot from the toolbox, names it fact start, creates a sample input in the form of a *box* with two slots, and drops it on the robot to initiate training. The sample input slots, labeled N and Answer, respectively contain the input integer, and a *bird* representing a pointer to the location to which to return the result (the bird's *nest*). The environment contains a *toolbox* with an unlimited supply of objects for building programs; a *notebook* for storing any kind of item; a *magic wand* for copying; a *dust-buster* for deleting; and a *pump* for enlarging or shrinking. The programmer is represented by a hand for grasping and moving objects.

Dropping the input on the robot causes an animated transition into the robot's thought bubble, where the robot's task is demonstrated. The final step of this training is shown in Fig. 4(b). The robot has been taught to append to the right end of the box a slot named Factorial containing 1, and two slots, labeled I and must be less, to the left end. Appending boxes is accomplished by juxtaposing them, whereupon a mallet-bearing mouse performs the operation. The slot labeled must be less contains a *balance*, tipped to the right to show how the numbers on either side compare. Terminating training causes an animated return to the environment. At this point, the robot's thought bubble contains a copy of the training input, indicating that this is the only input he will accept. The programmer generalizes this by erasing the 3 from the N slot leaving a green patch indicating that any integer is acceptable, as in Fig. 4(c).

In a similar fashion, the programmer trains a robot named fact loop to accept any five-slot box with integers in the first, third, and fifth slots, and a right-tilted balance in the second, to increment the first integer and to multiply the last integer by the result. Note that given an input, a robot repeats its task until the the input is no longer of the right form, so fact loop will stop when the integers in the first and third boxes are equal. Finally, the programmer trains a robot named fact finish to accept any five-slot box with integers in the first, third, and fifth slots, to remove the last integer from its slot, drop it into the fourth slot on to the bird, which carries the integer to its nest, and clean up by selecting a bomb from the toolbox and detonating it.

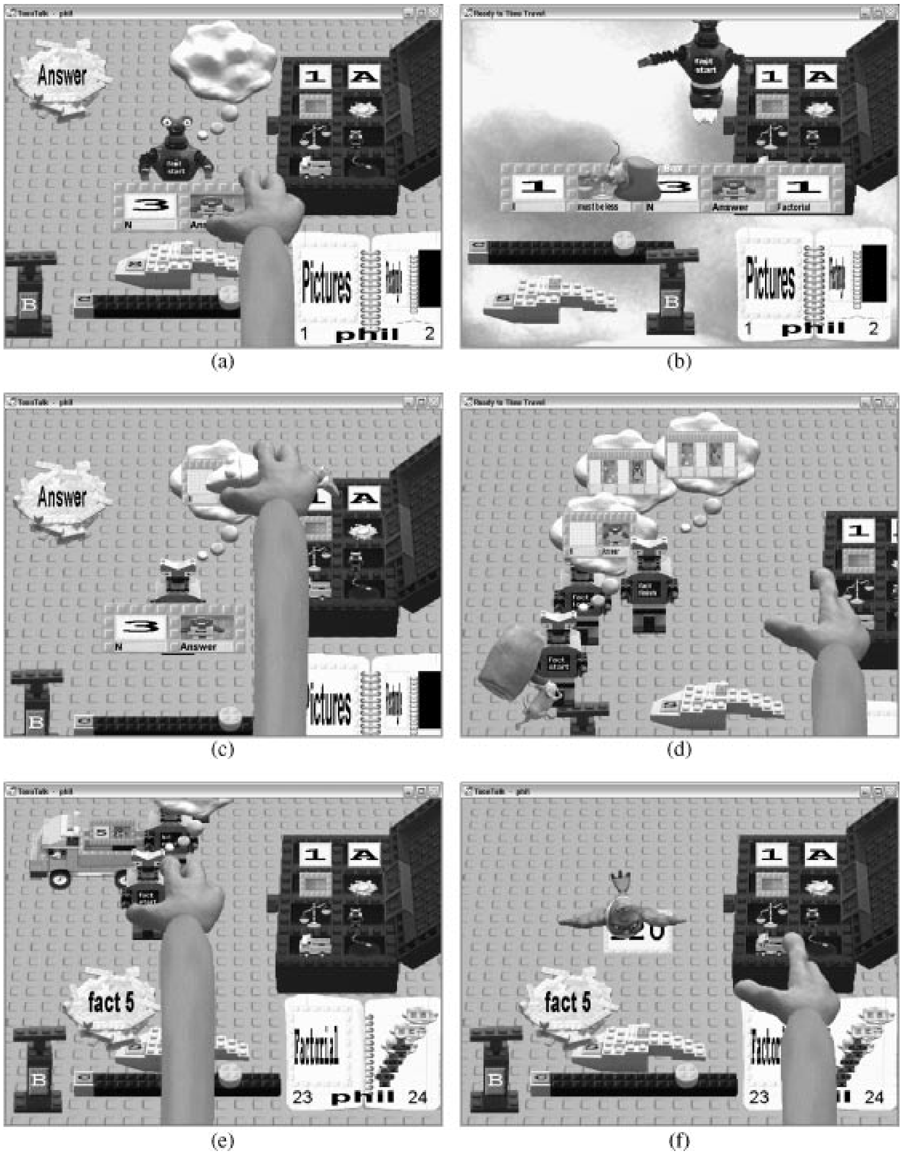
Next, the three trained robots are assembled into a *team*, as shown in Fig. 4(d), with the acceptable input patterns shown in their thought bubbles. A team is a sequence of robots that, when given an input, act on it in order. The team is stored in the notebook.

Finally, the programmer creates a two-slot input box containing bird and integer, takes a truck from the toolbox, and places the box on it, together with a copy of the robot team from the notebook [Fig. 4(e)]. The truck goes to a new house, where the robots act on the provided box, finally blowing up the house to terminate the spawned process. The bird returns the result [Fig. 4(f)].

Although it is not possible to see a program, or to edit a chosen part of it, the environment provides a "time travel" feature that allows the programmer to record the programming, replay from any point, and take control at any point to redo the programming from that point on.

Sheet-Based

Spreadsheets, although introduced before the advent of the graphical PCs that enabled current VPL research, are almost certainly the most popular VPLs. This is possibly



(a) (b)

(c) (d)

(e) (f)

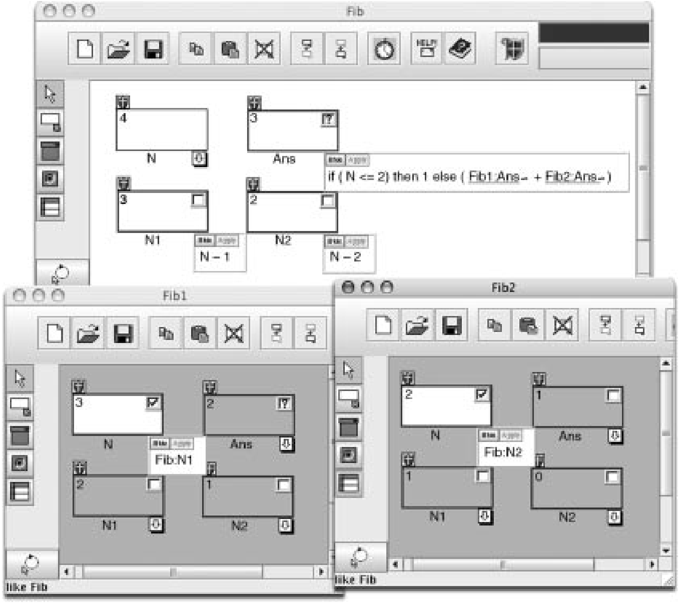
Figure 4. Programming factorial in ToonTalk.

because they are relatively simple, presenting a ledger-like sheet for entering and performing arithmetic on values, a metaphor familiar to the end users for whom spreadsheets are intended. The sheet is the single significant pictorial element that qualifies the original spreadsheet as a VPL, according to our definition, since the implicit acyclic data flow graph, created by formulas in cells referring to other cells, is not visible. Nevertheless, evidence exists that the visual characteristics of the sheet help users build a mental representation of the underlying data flow (7). Spreadsheets have evolved to include more pictorial elements, such as the auditing feature of Microsoft Excel (Microsoft Corporation Redmond WA), which allows the data flow graph to be displayed.

Numerous enhancements to spreadsheets have been proposed. Some are minor refinements of the original idea, such as allowing a spreadsheet program to consist of several sheets that may reference each other, thereby providing a simple type of modularization. Others are aimed at enhancing the programming aspects by adding to or replacing the "formula-in-cell" data flow model, which is not Turing complete.

In the language *Forms/3*, sheets are generalized to forms (8). A Forms/3 program consists of a collection of *forms* containing cells, which are analogous to spreadsheet cells but can be arranged arbitrarily. As in standard spreadsheets, cells contain formulas which may refer to cells on the same form or other forms.

Forms/3 attains Turing completeness by providing recursion and iteration. Recursion is illustrated by the example in Fig. 5, which depicts a collection of forms that compute Fibonacci numbers, constructed as follows. The form named Fib with four cells is constructed first, and formulas 4, N–1 and N–2 entered in the cells N, N1, and N2 respectively, resulting in the values shown in those cells. This form is copied twice, producing the forms Fib1 and



if (N <= 2) then 1 else (Fib1:Ans~ + Fib2:Ans~)

N – 1

N – 2

Fib:N1

Fib:N2

Figure 5. Computing Fibonacci numbers in Forms/3.

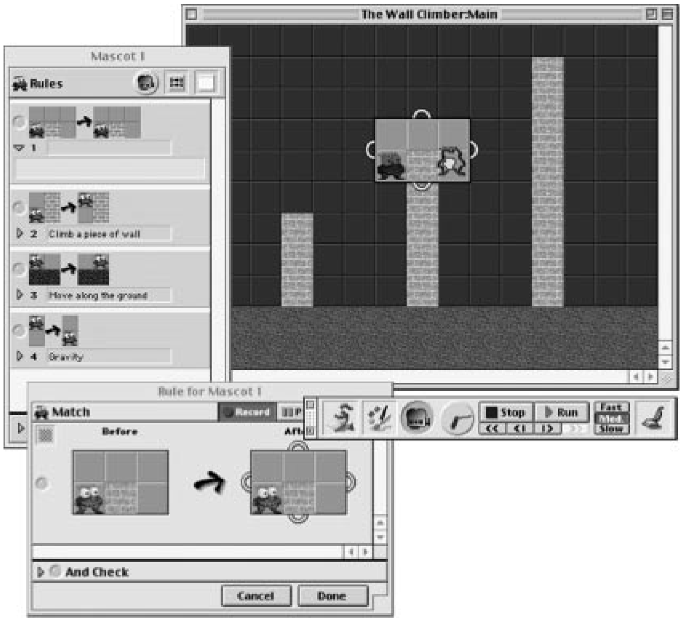


Figure 6. Defining a rule in KidSim.

Fib2, which inherit structure and content from Fib. Their gray background and the annotation like Fib in their bottom left corners show that they are copies. Next, the formula in the N cells of Fib1 and Fib2 are replaced by Fib:N1 and Fib:N2, respectively, referring to the N1 and N2 cells of the Fib form. The edited cells' values are recomputed, and their backgrounds turn white to show that their contents are no longer inherited. Finally, a formula is entered into the Ans cell of the Fib form, as shown, computing a value in terms of the values of the Ans cells of the copies. Clearly, if this formula were propagated directly to the copies, the underlying data flow graph would become cyclic. However, when a formula is propagated from a form A to a copy B, a reference to a cell on a copy C of A is interpreted as a reference to a copy D of B, bearing the same relationship to B as C does to A. When propagated formulas are evaluated, copies are created as required. Hence, in our example, as soon as the formula in the Ans cell of Fib is entered, two copies of Fib1 are created to compute Fibonacci numbers corresponding to the contents of the N1 and N2 cells of Fib1. Note that the base case of the propagated Ans formula applies in each of these copies and in Fib2, so no further forms are required.

Iteration in Forms/3 is achieved by introducing the notion of time as a sequence of "clock ticks" and functions that can be used in formulas to recompute the value of a cell at each tick, and to refer to a cell's value at an earlier tick.

Two-dimensional rectangular grids of cells are also used in VPLs in which visual transformation rules are used for programming games and simulations. One VPL of this genre is *KidSim* (later named Cocoa, then Stagecast Creator), a programming environment for children (9). In KidSim, each cell in the grid may contain an agent, and each type of agent may have a sequence of rules describing its behavior. In the example in Fig. 6, there are three types of agents, "ground," "wall," and "mascot," populating the grid. The window on the left shows the rules for mascot, each defining, by means of "before and after" pictures, how the grid is transformed when certain relationships between adjacent grid cells are met. Rules 2 to 4, respectively, will cause the mascot to move right if above a ground cell and left of an empty cell, and to fall if the cell below is empty. The window at bottom left, and the highlighted region of the grid window, show a new rule being defined: the user is dragging the mascot agent to an new position in the highlighted region to demonstrate how the adjacent cells with the given "before" configuration should be transformed. After the rule is constructed, clicking the "Run" button on the control palette starts the simulation, during which the rules for each agent in the grid are applied at each time tick. The rules for an agent are tried in the order they occur until one is found with a "before" pattern that matches the region around the agent.

Declarative

Declarative VPLs, like their textual counterparts, are descriptive rather than prescriptive; that is, the programmer defines relationships between values rather than providing instructions for computing one value from another. Common declarative models are functional programming and logic programming. *Moment* is a simple, domain-specific, declarative language for defining two-dimensional scenes (10). Each graphic object in a scene corresponds to a function represented by an icon in a *scene graph* diagram. The scene graph may also include functions that perform computations but do not represent objects in the scene. Function icons are connected by data flow links, defining constraints to be enforced when objects in the scene are manipulated.

At the top of Fig. 7 is a Moment scene graph that defines the scene at bottom right, demonstrating Varignon's

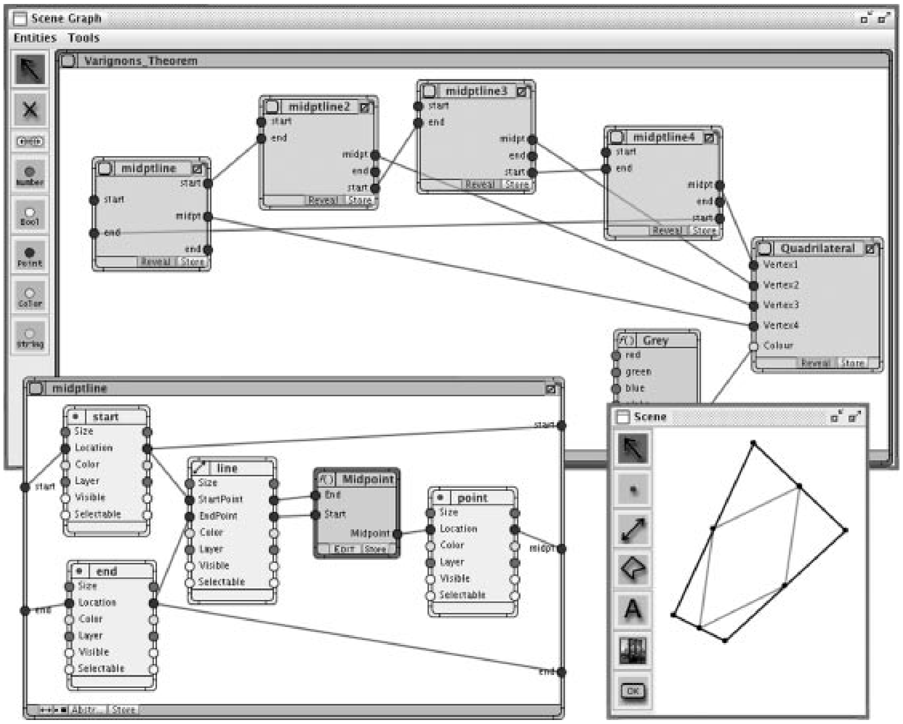

Figure 7. Defining a drawing in Moment.

Theorem: as the sides or vertices of the black quadrilateral in the scene are dragged, the gray quadrilateral deforms but remains a parallelogram. The Scene Graph window contains an *enclosure* called Varignons_Theorem, corresponding to the content of the scene graph. This enclosure contains four instances of a function midptline, defined by the enclosure at bottom left, connected by links that constrain their endpoints to form the black quadrilateral. The gray quadrilateral is represented in the graph by a function Quadrilateral connected by links that constrain its vertices to the midpoints of the lines. We leave it to the reader to determine the structure of the lines that make up the black quadrilateral by inspecting the midptline enclosure.

In *L-sheets*, a recently proposed enhancement to spreadsheets, the standard formula-in-cell data flow programming model is augmented with a logic-based VPL to obtain Turing completeness, and to provide a means for specifying spreadsheet structure (11).

L-sheets is based on the observation that specifying array structure, relationships between arrays and computations that fill arrays, key activities in spreadsheet design, are analogous in logic programming to specifying term structure, relationships between terms and computations that bind variables occurring in terms. Accordingly, L-sheets incorporates a form of logic programming based on unification of visually represented arrays.

An L-sheets *program sheet* consists of a set of *definitions*, each composed of a sequence of *cases*. Figure 8 depicts a program sheet with three definitions, gauss, triangularise, and backsubstitute, which together define Gaussian elimination with partial pivoting for solving simultaneous linear equations. A *case* is analogous to a Prolog clause and consists of a pale gray *head* template, followed by a sequence of dark gray or white *body* templates. In our example, gauss has one case, whereas triangularise and backsubstitute each consist of two. A *template*, analogous to a Prolog literal, has a *name* and sequence of *parameters*, each of which is an *array*, that is either basic or compound.

A *compound* array is a rectangle further subdivided into arrays. A *basic* array is a rectangle of cells, and can have either one or a variable number of rows and one or a variable number of columns. For example, the first parameter in the head of the second case of triangularise consists of three arrays labeled A, B, and C. A consists of two horizontally juxtaposed basic arrays, the left-hand one having one column and a variable number of rows, indicated by the horizontal dotted line. The right-hand basic array in A has variable numbers of rows and columns. The content of a basic array is a variable that may be bound to a set of spreadsheet-style formulas.

The user applies the definition gauss by selecting in the worksheet two rectangular arrays of cells. These arrays are unified with the two parameters in the head of the single case of gauss. The worksheet array bound to A contains the coefficients and the right-hand sides of the equations, and must be n rows by $n + 1$ columns, otherwise, the application of gauss will fail. The worksheet array bound to C must be a single row of length n, for the solution vector. When these unifications have succeeded, execution proceeds in a fashion analogous to Prolog; that is, templates are introduced by the body of the case and executed in order.

The base case of triangularise applies if the coefficient array consists of a single row and two columns,

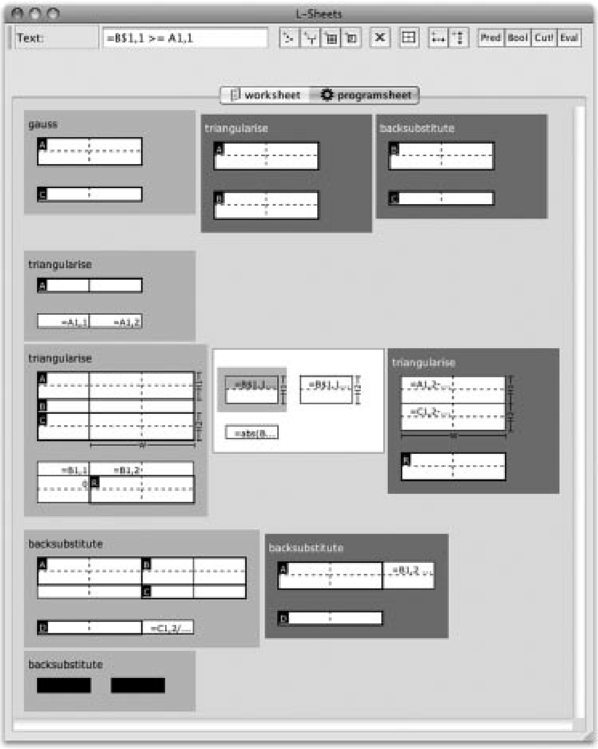

Figure 8. An L-sheets program defining Gaussian elimination for solving simultaneous linear equations.

corresponding to one equation in one variable, the solution to which is computed directly by the formulas in the cells of the second parameter.

In the second case of triangularise, the first body template is a *guard*, the parameters of which have Boolean-valued expressions as contents. For example, the content of the selected parameter, displayed at the top of the window, compares the first element of the row named B of the array to be triangularised with the first element of every row above it. Similarly, the second parameter of the guard compares the first element of B with the first element of each row below it. The third parameter ensures that the absolute value of the first element of B is not zero.

The second case of triangularise illustrates that array unification is not unique. If the array to be triangularised has n rows, there are n possible unifications, generated in succession until the guard template succeeds, indicating that the pivot row has been found.

Observing that a black rectangle represents an array at least one dimension of which is zero, we invite the reader to complete the explanation of this example.

Note that, like textual logic programming languages, L-sheets is an example of a rule-based language, since each case specifies a transformation rule that may be applied to advance an execution state by transforming the structure and content of arrays.

Component Based

Various VPLs have been proposed and implemented based on the metaphor of networked computing devices, or *components*, each performing a variety of tasks in response to messages and data received from other components. An example can be found in IBM's VisualAge products, in which a component-based VPL is layered over a textual programming language (SmallTalk, Java, C++) (12).

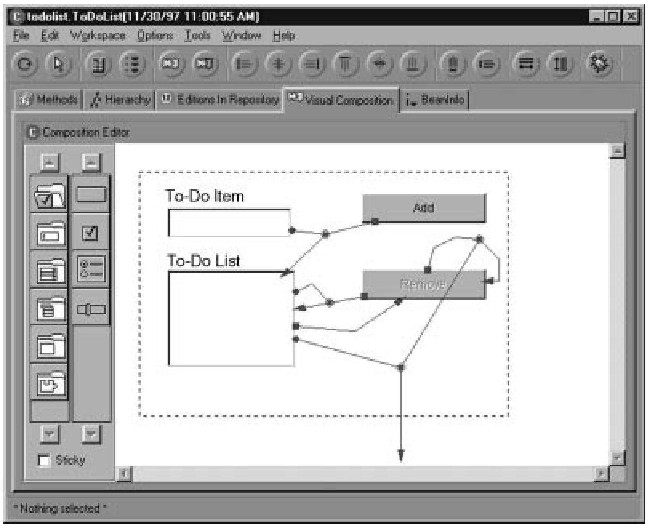

Figure 9. A message-flow diagram in VisualAge for Java.

Figure 9 depicts a VisualAge for Java message-flow diagram that defines interactions between interface components. An arrowed line starting from a square dot on a component indicates that when a particular event originates from that component, a message will be sent to the component at the head of the arrow. A line that originates from a round dot on a component indicates the retrieval of data from that component. For example, the line from the "Add" button to the "To-Do List" scrolling list indicates that, when the button is clicked, a message will be sent to the list, together with the content of the "To-Do Item" text box. Clearly, key information about such interactions is not represented in the diagram and must be viewed separately: for example, the kind of event that triggers the message, the identity of the message to be sent, and the data to be retrieved. Although for a click on the "Add" button in this example, it is clear what these items must be, it is less obvious for interactions between more complex components. Noting that the data arrow pointing out of the dotted boundary refers to a database component, we invite the reader to guess the messages, data, and events involved in the interactions between the "To-Do List" and the "Remove" button.

Component-based VPLs are well suited to programming tasks such as that illustrated in the example; however, they do not facilitate algorithms requiring iteration or conditional execution.

VPL FORMALIZATION AND CLASSIFICATION

All programs, regardless of how they are represented, must be compiled into machine-executable form. In a textual language, compiling a program involves lexical analysis, which divides the string of symbols into larger meaningful chunks (tokens), such as identifiers, operators, and keywords, then parsing the token stream to produce a parse tree. Semantic analysis is usually performed during the construction of the parse tree by using an attribute grammar, a context-free grammar in which nonterminal symbols are annotated with attributes, and productions are augmented with rules that relate these attributes and attach semantic information, such as snippets of assembly language code, to the parse tree. This semantic information is then used for code generation.

Since analogous processes are required for visual programs, the theory of VPLs has largely developed by analogy with the theory of textual languages, with two major differences. First the structure of grammars for VPLs is complicated by the difference between text and two-dimensional pictures. Text is abstract, not a one-dimensional picture, so symbols have no size or absolute position and cannot overlap. Juxtaposition in one dimension is the only relationship between symbols in a string. In contrast, an object in a two-dimensional picture is not just a symbol. It has size and shape, so it may touch, overlap, occlude, or contain another object, or be separated from another object by a vector of any length or orientation.

The other major difference between the theories of textual and visual languages is the way in which they are applied. Strings have a universally accepted representation as sequences of standard codes. Hence, any text editor can be used to write programs and to save them in generic text files. Consequently, although IDEs frequently include syntax-directed editors that either refuse to allow syntactically incorrect input, or highlight and warn about syntax errors, the primary application of grammars is to lexical analysis and parsing. In contrast, there is no universal coding for object-based drawings, so formal descriptions of VPLs tend to be used for building syntax-directed editors, rather than for parsing generic drawings (13).

Among the most widely used formalisms for describing the structure of visual languages are graph grammars, proposed in the late 1960s as a means for describing the structure of graphs (14). A *graph grammar* (GG), analogous to a transformational grammar defining a textual language, consists of a set of rules for transforming a graph by identifying a subgraph by pattern matching, and replacing it with another subgraph. Various derivatives of GGs have been devised to better suit the requirements of visual languages, such as *layered* and *reserved*. Other formalisms developed for visual languages include *positional grammars, relational grammars, relation grammars, constraint multiset grammars, attributed multiset grammars*, and *hypergraph grammars* (15).

As noted, programming languages can be classified in different ways for different purposes. The Chomsky hierarchy classifies textual languages according to syntactic structure, and what it implies about expressive power and algorithmic properties. Classifying VPLs in a similar way is problematic because of the variety of formalisms used to define them. Marriott and Meyer approach this problem by establishing a Chomsky-like hierarchy of VPLs based on copy-restricted constraint multiset grammars (CCMGs), then showing how various VPL grammar formalisms can be mapped on to CCMGs (15). Placing a VPL in this hierarchy provides insights into its limitations, and information with practical implications, such as the complexity of parsing.

Other classifications of VPLs have a more pragmatic flavor. For example, Costagliola et al. define a framework in which a VPL is classified according to the syntactic attributes of visual tokens and spatial relationships between tokens that form the alphabet of the grammar. Their classification leads to a class hierarchy (in the object-oriented programming sense), incorporated into a compiler-compiler for semiautomatically generating VPL compilers and syntax-directed editors (16).

EVALUATION AND DESIGN

In the early days of VPL research, researchers tended to invent new visual notations to explore the possibilities of the medium, assuming that the greater expressive power of pictures would inevitably lead to languages better then textual ones. Results were reported, together with claims of superiority, based largely on intuition. Amid growing concern about the need to validate such claims, Blackwell reduced them to 12 categories, related each category to the cognitive science literature, showing some to be well founded and others to have little or no support, and concluded by pointing out the need to properly account for cognitive processes in VPL design and evaluation (17).

The Cognitive Dimensions (CD), proposed by Green and Petre, has had a significant influence on VPL research, providing a framework within which visual language designers can assess the potential impact of design choices (18). The CD framework consists of the 13 dimensions listed in Table 1, each capturing a significant characteristic of a notation, and supported by empirical evidence.

To illustrate, some applications are as follows.

Abstraction gradient: In Prograph, although the programmer may code complicated computations in a single data flow diagram, as the number of operations and data flow links increases, the diagram becomes cluttered and complicated, encouraging the programmer to collapse meaningful subdiagrams into single operations.

Hidden dependencies: In the original form of spreadsheets, the only way to discover that a cell depended on others was to select it to reveal its formula. Furthermore, there was no way to find the cells dependent on a particular cell.

Progressive evaluation: Spreadsheets deliver the ultimate in progressive evaluation since execution is “always on,” evaluating all affected cells immediately after every edit. This property is preserved in some spreadsheet derivatives, such as Forms/3.

Closeness of mapping: The correspondence between problem and program in Moment is almost one-to-one. Each object in the drawing is represented by a node in the program, and each visually apparent constraint between objects (e.g., endpoints of two lines coincide) is represented by a link between program nodes.

Table 1. Cognitive Dimensions

Dimension	Description
Abstraction gradient	Degree to which abstraction is allowed, encouraged, and supported
Closeness of mapping	Does the notation closely mirror domain objects and relationships
Consistency	The notation represents similar meanings with similar constructs
Diffuseness/Terseness	Are too many or too few symbols required to represent a meaning
Error-proneness	Notation traps the programmer into making errors
Hard mental operations	Notation makes some programming tasks inherently difficult
Hidden dependencies	Significant relationships between program entities are not displayed
Premature commitment	Programming decisions precede the information required to make them
Progressive evaluation	Programs can be run at any time, complete or not
Role-expressiveness	The function of a program structure is implied by its appearance
Secondary notation	Comments or other information not formally part of the program
Viscosity	Is unreasonable effort required to make a change
Visibility	How easily can any part of a program be displayed

Consistency: If the user, knowing some of a language, can reliably guess the structure of the rest, then the language is consistent. Although it seems unlikely that a little knowledge of ToonTalk will allow the user to infer much more, once the user has understood that placing one number on another causes the mallet-wielding mouse to perform addition, he or she may very well conclude that placing other objects in close proximity will cause the mouse to perform an appropriate operation.

Viscosity: In ToonTalk, to rectify a programming error, the programmer must rewind the animation to a point preceding the error, then redo the entire program from there on. This is possible only if the "time travel" feature is turned on.

There are various ways to evaluate the effectiveness of VPLs. One unscientific but telling measure is the degree to which VPLs have been adopted in industry. Some VPLs have had considerable commercial success. For example, LabVIEW, a data flow VPL for programming hardware controllers, has several million users worldwide, and Simulink has a strong user base in the engineering industry. Although the VPLs in both products are general enough to code any algorithm, the products themselves are domain-specific. In contrast, no VPLs for general- purpose application development enjoy such success. A possible explanation is provided by a focus-group study commissioned by Apple Computer in the 1990s to determine the viability of Prograph for industrial development. Despite strongly positive feedback on the Prograph development environment, comments from participants indicated that it would be unlikely for a VPL that did not comply with prevailing software industry standards to be adopted, implying that a VPL must be able to be used interchangeably with a standard textual language such as Java.

More detailed evaluation data are obtained via user studies, reports from users with extensive experience of particular VPLs, and user surveys targeting specific questions about VPL performance. Although results have been mixed, some indicate the superiority of VPLs in certain situations. One user study testing the performance of programmers solving matrix problems in Forms/3, Pascal, and APL showed that 73% of the Forms/3 programs were correct, compared with 53% and 40% of the APL and Pascal programs, respectively (19). Based on extensive experience with LabVIEW in more than 40 projects, Baroth and Hartsough concluded that LabVIEW's VPL contributes significantly to productivity in software development (20). In an extensive survey of LabVIEW users, respondents rated its visual aspects significantly higher than its non-visual ones (21), a result consistent with Baroth and Hartsough's conclusions.

CONCLUDING REMARKS

As Ambler and Kimura noted in their preface to the proceedings of the 1994 IEEE Symposium on Visual Languages, "In 1984, the goal of visual language research was ... using pictures to construct programs and to then watch their execution." Accordingly, the initial focus was on inventing pictorial notations to explore the potential of graphics for representing algorithms and data. As VPL research has evolved, the focus has shifted and widened. Current emphases are as follows:

- Cognitive issues
  - □ Empirical studies of programmers—professionals, novices, children, and end users
  - □ Principles of notational design
- Software engineering
  - □ Theory
  - □ Software modeling
  - □ Software visualization tools
- VPLs for domain-specific and end-user programming
  - □ Languages
  - □ Debugging tools and methodologies
- Formal methods
  - □ Syntax and semantics
  - □ Generating VPLs from specifications
  - □ Diagrammatic reasoning

VISUAL SOFTWARE ENGINEERING

INTRODUCTION

Graphical notations are widely used in software design and development. These notations can greatly help the modeling and representation of software architecture (1) and design (2). There are many benefits of informal graphic notations: First, they can be used to convey complex concepts and models, such as object-oriented design. Notations like those in UML (2) serve a useful purpose in communicating designs and requirements. Second, they can help people grasp a large amount of information more quickly than text can. Third, as well as being easy to understand, drawing diagrams is normally easier than writing text in a predefined language. Fourth, graphical notations cross language boundaries and can be used to communicate with people of different cultures.

Visual software engineering refers to the use of various visual means in addition to text in software development. The forms of the development means include graphics, sound, color, gesture, and animation. The Software development lifecycle involves the activities of project management, requirements analysis and specification, architectural and system design, algorithm design, coding, testing, quality assurance, maintenance, and if necessary, performance tuning. These software engineering activities may be assisted through various visual techniques, including visual modeling, visual database query, visual programming, algorithm animation, program visualization, data visualization, and document visualization. Such visual techniques are sometimes categorized into *software visualization* (3), which in a broader sense may include the objective of education in algorithms, programming, and compilers, as well as that of software development (4,5). Figure 1 illustrates the various aspects of software engineering assisted through visualization.

In the first phase of the software engineering process, software managers are responsible for planning and scheduling project development. They typically use several data visualization forms, such as Gantt charts, to illustrate the project schedule meeting a series of milestones. They may also use activity networks to plan project paths leading to the project completion from one milestone to another, or use Petri nets to model the transitions of project activities.

The second phase involves requirements analysis and specification. This phase is usually conducted using various visual modeling techniques, on graphical formalisms such as Statecharts for dynamic analysis and class diagrams for static analysis. More advanced techniques include executable specifications, which can then be realized through visual specification languages. Specifications can be provided via visual programming.

The third phase of the software engineering process establishes an overall software architecture through system and software design. Visual modeling techniques may continue playing a key role, through architectural visualization using various types of architectural diagrams, such as class diagrams and collaboration diagrams. During this phase, algorithm design is needed and the behavior of the algorithm may be understood through visualization and animation. The detailed functionality may need to be transformed into one or more executable programs. Visual language techniques with their well-founded graph grammar support suit particularly well the design, verification, and reuse of executable programs, which will be the focus of this article.

Many modern software systems access databases for organized and inter-related data items from large quantities of data. The logical organization of data is typically modeled in entity-relationship diagrams in relational databases. Complex database queries can be provided through form-based visual structures. For a database management system, visualizing internal segmentation due to fragmented data storage is extremely useful in guiding efficient data placement policies.

In the fourth and fifth phases, the domain software is implemented and coded via visual programming. Both unit testing and integrated testing may be done through techniques such as program slicing and be visualized on graph formalisms such as dependence graphs and call graphs.

Next, software documentation and online help systems are essential for the quality assurance of any software product. They are designed for end users of the software. A comprehensive online help system has a complex network structure that is usually hierarchical with cross-links. A visualized help graph provides an intuitive road map for tutorial, guiding, or diagnostic purposes.

The final maintenance phase takes the longest time in the software lifecycle. During this period, more bugs or requirements errors may be revealed and corrected through program visualization. Program comprehension and analysis can be achieved effectively through graphical visualization. Also during this phase, the performance of the domain software may be improved after it functions as required. Performance evaluation and comparison can be conducted effectively through data visualization (sometimes called statistical visualization). The major difference between program visualization and data visualization is that the visual notations in the former usually correspond directly to the program semantics, whereas those in the latter correspond quantitatively to certain program measurements. For example, nodes in a call graph represent procedures/functions and edges represent call relationships. A segment in a pie chart is significant only in its size and in what it measures.

The remaining part of this article focuses on one of the visual software engineering approaches, i.e., using graph grammars as the underlying theory to support visual software modeling, requirements analysis, architecture design, verification, and evolution.

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

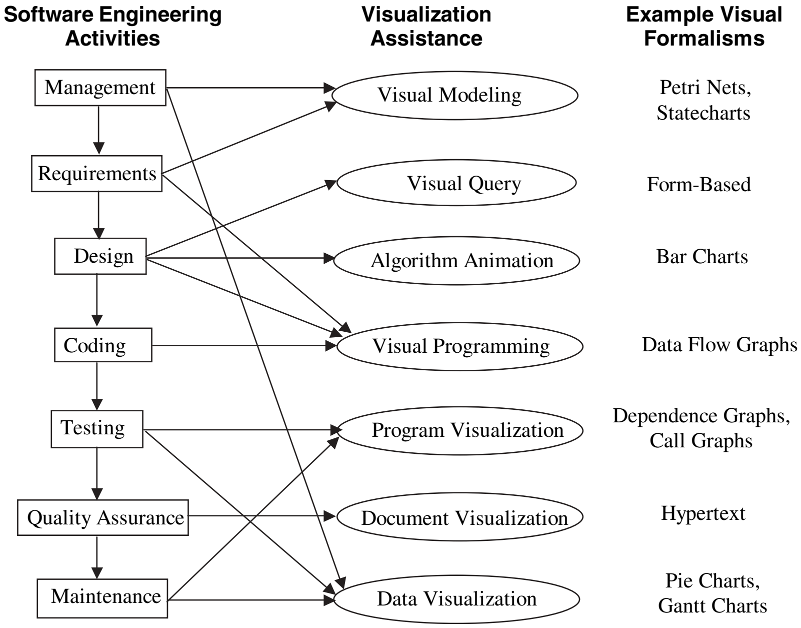

Figure 1. Software engineering assisted by graphical visualization.

A SOUND FOUNDATION

The aforementioned informal graphical notations and formalisms used in various software engineering phases are good at illustration and providing guidance. They are, however, not amendable to automated analysis and transformation. For example, in software architecture design, the developer has to rely on his/her personal experience to discover errors and inconsistencies in an architecture/design diagram. He/she also has to manually redraw the whole architecture/design diagram whenever a change or update is needed. These human tasks are tedious and error-prone. This article presents an approach that can automatically verify and transform design diagrams based on *graph grammars*. The approach abstracts Statecharts, class diagrams, and architecture styles into a grammatical form (as explained in this article). It will then be able to parse a given architecture/design diagram to analyze whether the diagram has some required properties or reconciles some design principles. Moreover, design patterns can be easily visualized and architectural evolution can be achieved through graph transformation.

Graph grammars provide a theoretical foundation for graphical languages (6). A graph grammar consists of a set of rules, which illustrates the way of constructing a complete graph from a variety of nodes. It specifies all possible inter-connections between individual components; i.e., any link in a valid graph can be eventually derived from a sequence of applications of grammar rules (the activity also known as *graph rewriting* or *graph transformation*). Conversely, an unexpected link signals a violation on the graph grammar. A graph grammar can be used to "glue" various components into a complete system. Graph grammars form a formal basis for verifying structures in a diagrammatic notation, and they can be viewed as a model to simulate dynamic evolution. Such an approach facilitates the following aspects of software engineering:

- Graphs are used to specify software by distinguishing individual components and depicting the relationships between the components. A graph grammar specifying design choices and policies provides a powerful mechanism for syntactic checking and verification, which are not supported by most current tools.
- In addition to software design and verification, this approach facilitates a high level of software reuse by supporting the composition of design patterns and uses graph transformation techniques in assisting the evolution and update of software architectures and in reusing the existing products.

A graph grammar is similar to a string (textual) grammar in the sense that it consists of finite sets of labels for nodes and edges, an initial graph, and a finite set of production rules. It defines the operational semantics of a graphical language (6). Graph transformation is the application of production rules that model the permitted actions on graphs representing system structures and states.

In the following explanation of graph grammars, we will use the popular software modeling language Statecharts (7) as our demonstration language, for which a graph grammar can be defined.

In a graph grammar, a *graph rewriting rule,* also called a *production*, as shown in Fig. 2, has two graphs called *left graph* and *right graph*. A production can be applied to a given graph (called a *host graph*) in the form of an *L-application* or *R-application*. A *redex* is a subgraph in the host graph that is isomorphic to the right graph in an R-application or to the left graph in an L-application. A production's L-application to a host graph is to find in the

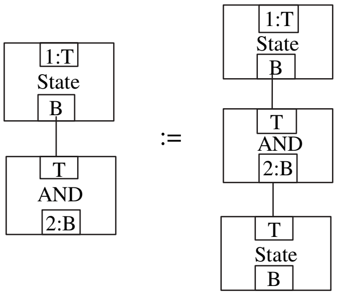

Figure 2. A graph rewriting rule (or a production).

host graph a *redex* of the left graph of the production and replace the redex with the right graph of the production. The L-application defines the language of a grammar. The language is defined by all possible graphs that can be derived using L-applications from an initial graph (i.e., λ) and consist of only *terminals*, i.e., the graph elements that cannot be replaced. An R-application is a reverse replacement (i.e., from the right graph to the left graph) that is used to parse a graph.

A graph grammar is either context-free or context-sensitive. A context-free grammar requires that only one nonterminal is allowed on the left-hand side of a production (8). Most existing graph grammars for visual languages are context-free. A context-sensitive graph grammar, on the other hand, allows the left and right graphs of a production to have an arbitrary number of nodes and edges. Motivated by the need for a general-purpose visual language generator, the authors have developed a context-sensitive graph grammar formalism called the *reserved graph grammar* (RGG) (9).

In an RGG, nodes are organized into a two-level hierarchy as illustrated in Fig. 2. A large rectangle is the first level called a *super-vertex* with embedded small rectangles as the second level called *vertices*. In a node, each vertex is uniquely identified by a capital letter. The name of a super-vertex distinguishes the type of nodes similar to the type of variables in conventional programming languages. A node can be viewed as a module, a procedure, or a variable, depending on the design requirement and granularity. Edges are used to denote communications or relationships between nodes. Either a vertex or a super-vertex can be the connecting point of an edge.

In a context-sensitive grammar, replacing a redex with a subgraph while considering the inter-connection relationship between the redex and its surrounding graph elements is traditionally called *embedding*. The RGG handles the embedding problem using a *marking* mechanism that combines the context information with an embedding rule. The embedding rule states: If a vertex v in the redex of the host graph has an isomorphic vertex v' in the corresponding production's right graph and neither v nor v' is marked, then all edges connected to v should be completely inside the redex. The marking mechanism, will be explained further through examples provided here, makes the RGG expressive, unambiguous, and efficient in parsing.

The RGG formalism uses the object-oriented language Java as a lower level specification tool for instructions and attributes that may not be effectively or accurately specified graphically. These instructions and attributes that are applied to the graph under transformation to perform syntax-directed computations such as data transfer and animation are specified in a piece of Java code (called *action*) attached to the corresponding production. Different actions can be performed on different attributes of the redex of a production to achieve the desired modeling and animation effects. Such an action code is like a standard exception handler in Java by treating each attribute as an object. It associates computation tightly with structural (syntactical) transformation. For example, one can provide the following action code to specify the state transition of a *car* object from *stop* to *star*:

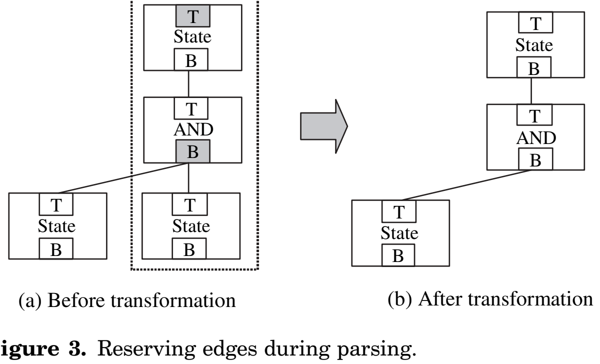
```
action(AAMGraph g) {
    Attribute attributes = g.getAttributes();
    attributes.getObject("car").setState("stop", "start");
}
```

This arrangement allows a software engineer to precisely specify and generate any executable system for visual software modeling and verification as discussed in the next few sections.

The RGG formalism has been used in the implementation of a toolset called VisPro, which facilitates the generation of visual languages using the Lex/Yacc approach (10). As a part of the VisPro toolset, a visual editor that could be used to create visual programs and parsing algorithms is automatically created based on grammar specifications.

MODELING WITH STATECHARTS

This section illustrates the application of the RGG formalism to Statecharts and explains how the marking mechanism works. Figure 3 depicts a snapshot of a subgraph transformation for a Statechart graph using the production in Fig. 2. In Fig. 3(a), the isomorphic graph in the dotted box is a redex. The marked vertices and the vertices corresponding to the isomorphic vertices marked in the right graph of the production are painted gray. The transformation deletes the redex while keeping the gray vertices. Then the left graph of the production is embedded into the host graph, as shown in Fig. 3(b), while treating a vertex in the left graph the same as the corresponding gray vertex. This shows that the marking mechanism allows some edges of a vertex to be reserved after transformation. For example, in



(a) Before transformation

(b) After transformation

Figure 3. Reserving edges during parsing.

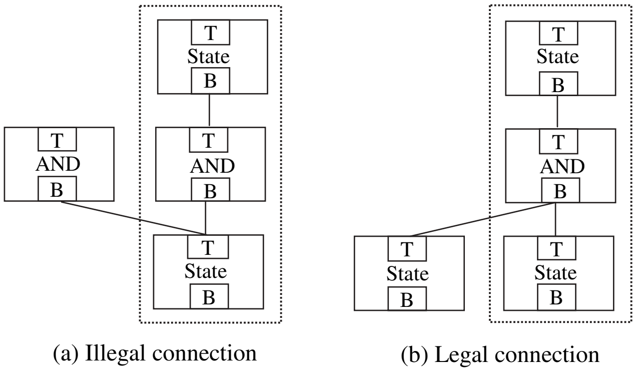


Figure 4. Determining connectivity.

Fig. 3(a), the edge connecting to the "State" node outside the redex is reserved after transformation.

In the definition of the Statecharts grammar, an "AND" node may connect to multiple "State" nodes, indicating the AND relationships among the states. A "State" node, however, is allowed to connect to only one "AND" node. We show how such a connectivity constraint can be expressed and maintained in the RGG. The solution is simple: Mark the B vertex of the "AND" node, and leave the T vertex of the "State" node unmarked in the definition of the production (as illustrated in Fig. 2). According to our embedding rule, the isomorphic graph in the dotted box in Fig. 4(a) is not a redex, because the isomorphic vertex of the unmarked vertex T in the "State" node has an edge that is not completely inside the isomorphic graph. Therefore, the graph in Fig. 4(a) is invalid. On the other hand, the graph in Fig. 4(b) is valid according to the embedding rule. There is a redex, i.e., the isomorphic graph in the dotted box, in the graph, because the isomorphic vertex of B in "AND" connecting to "State" in the right graph of the production is marked, even though it has an edge connected outside the isomorphic graph. Therefore, the marking mechanism helps not only in embedding a graph correctly, but also in simplifying the grammar definition. It allows an implicit representation to avoid most context-specifications while being more expressive. This greatly reduces the complexity of visual expressions and, in turn, increases the efficiency of the parsing algorithm.

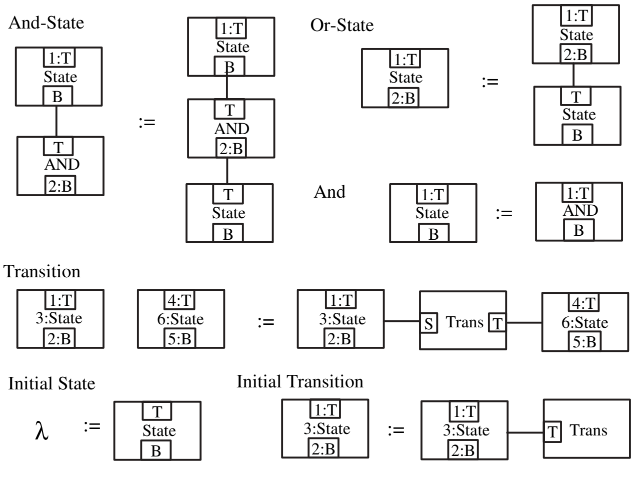

Figure 5. The graph grammar for Statecharts.

The graph grammar expressed in the RGG formalism for a main subset of the Statechart notations is listed in Fig. 5, including the initial state, initial AND, initial transition, general AND state, general OR state, and general transition productions. The last three general productions can all be repeatedly applied during the graph rewriting process. Figure 6 depicts an example Statechart and its representation in the node-edge form that is recognized by the RGG to be parsed by the Statechart grammar. With the Statechart grammar defined, any user-drawn Statechart diagrams like the one shown in Fig. 6(a) can be validated for its syntactical correctness and executed according to the action code attached to each production (action codes are not shown in the figure).

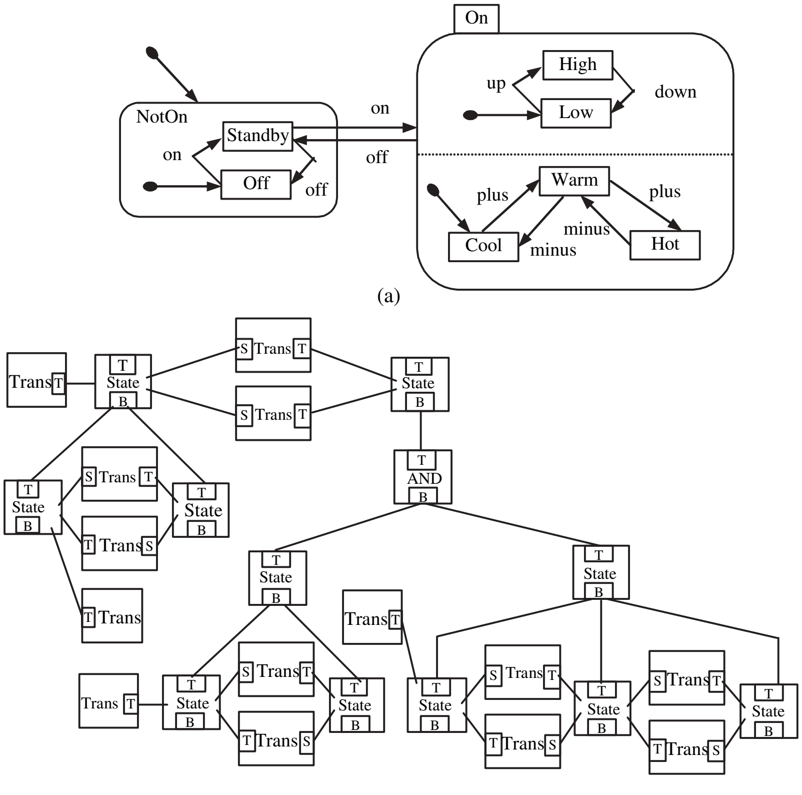
SPECIFYING CLASS DIAGRAMS

This section goes through an example to illustrate the representation of class diagrams in the RGG's node-edge form, and then it defines a graph grammar for class diagrams. A parser can verify some properties of the diagrams. The next section discusses how this graph grammar can help visualizing design pattern applications and compositions in their class diagrams.

Class diagram, one of the most popular diagrams for object-oriented modeling and design, visually models the static structure of a system in term of classes and relationships between classes (2). To verify the structure of a class diagram in Fig. 7(a), one needs to first translate the class diagram into a node-edge format [Fig. 7(b)], on which the RGG parser operates, in the same fashion as for Statecharts presented in the last section.

In a class diagram, classes are represented by compartmentalized rectangles. In its node-edge counterpart, a node labeled *Class* denotes the top compartment containing the class name. A set of nodes labeled *Attri* represents attributes in the middle compartment. Nodes are sequenced by linking two adjacent attributes in the same order as displayed in the compartment, and the sequence is attached to a class by linking the first *Attri* node with the *Class* node. Operations in the bottom compartment are processed in the same manner as attributes when replacing *Attri* by *Oper* nodes.

Associations denoted by straight lines typically used in UML (2) carry the information about relationships between classes. In a node-edge diagram, a node labeled *Asso* is used to symbolize an association. A line connecting an *Asso* node to a *Class* node holds an association relationship between them. Associations may be named, preferably in a verbal form, being either active, like "works for," or passive, like "is hired by," and thus called *verbal constructs* in UML (2). To indicate the direction in which the name should be read, vertex *R* in an *Asso* node is connected to the *Class* node designated by a verbal construct, and vertex *L* to the other *Class* node. On the other hand, if the order is unimportant, one can ignore the difference between *R* and *L*.



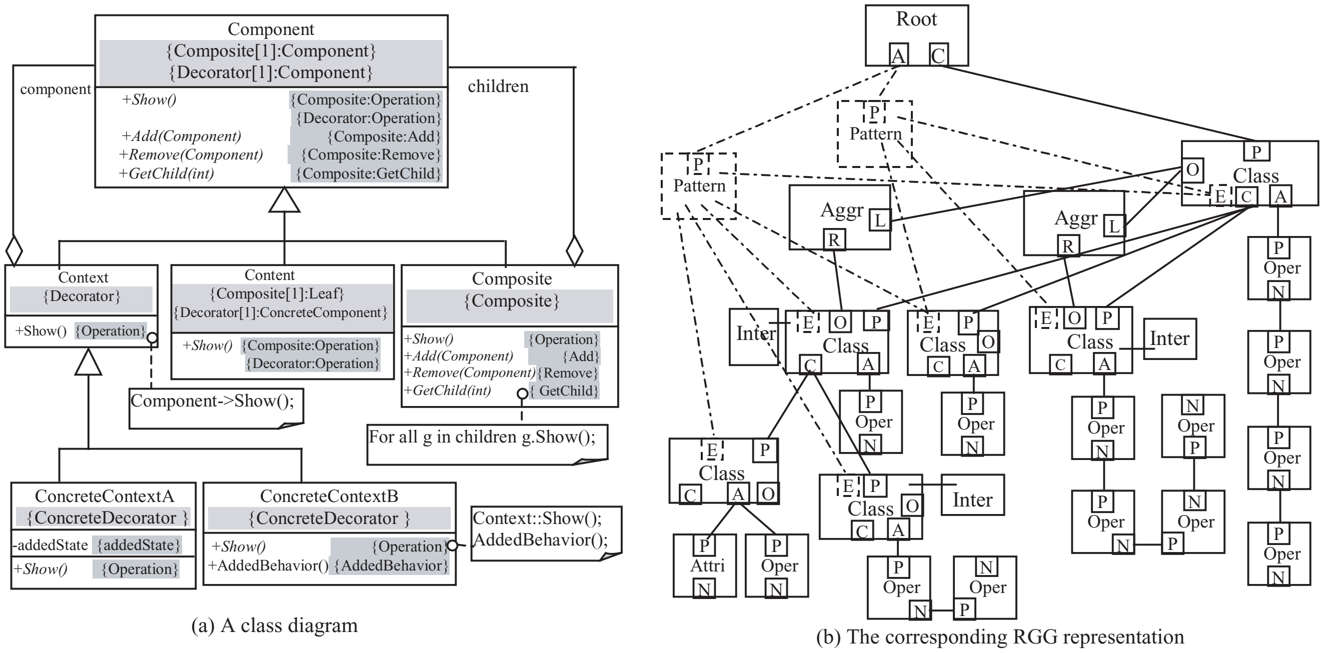
(a)

(b)

Figure 6. An example Statechart (a) and its node-edge representation (b).

For example, Fig. 8(a) specifies an association *Drive* between classes *Person* and *Car*, where a small triangle points to the *Car* class designated by a verbal construct. Correspondingly, in the node-edge representation in Fig. 8(b), vertex *R* in the *Drive Asso* node is connected to the *Car* class node.

Aggregation and *composition*, two special types of associations, are represented by *Aggr* and *Comp* nodes, respectively, in the node-edge representation. An *Aggr*/*Comp* node bridges a pair of *Class* nodes in the same fashion as an *Asso* node does.



(a) A class diagram

(b) The corresponding RGG representation

Figure 7. A class diagram and its corresponding RGG diagram.

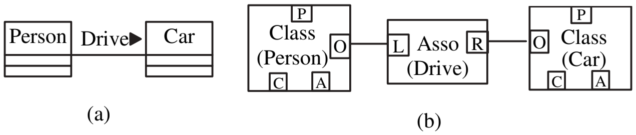


Figure 8. An (a) association and its (b) node-edge representation.

In UML, *generalization* denotes a hierarchical relationship between a general description and a specific description. In the node-edge representation, a directed edge linking from the vertex labeled *c* in a *Class* node to the vertex labeled *p* in another *Class* node designates the generalization relationship from the former class to the latter class. In other words, vertex *c* indicates a general class and vertex *p* denotes a specific class.

To facilitate parsing and verifying the structure of an RGG diagram, we introduce a new node to the node-edge representation, namely *root*, which has no counterpart in the class diagram. A *root* node is connected to any *Class* node that represents a class without a super-class.

Although a graph grammar abstracts the essence of structures, it cannot convey precise information visually. The RGG stores concrete and numeric information in attributes as described. For example, association names are recorded in attributes attached to Asso nodes. Those values of attributes can be retrieved and evaluated in the parsing process.

Figure 7(a) illustrates a class diagram, and Fig. 7(b) presents its corresponding node-edge diagram recognizable by its RGG. The shaded texts in Fig. 7(a) represent pattern names as extended notations to UML, and the dotted rectangles in Fig. 7(b) correspond to the extended UML (11).

A graph grammar can be viewed as a style to which any valid graph should conform; i.e., any possible interconnection between graph entities must be specified in the grammar. Each production defines the local relationships among the graph elements/entities. Collecting together the productions defining all relationships, an RGG grammar specifies the way of constructing a valid class diagram using graph entities represented by different types of nodes.

Figure 9 presents all RGG productions that define class diagrams. Production 1 reduces two attribute nodes into one, which is treated as one entity in later applications. Repetitive applications of Production 1 reduce all attributes of a class to one attribute, which is later treated together with its class by Production 3. Productions 1 and 2 serve to reduce a sequence of attributes and operations. Production 3 specifies the class structure by attaching sequences of operations and attributes to a *Class* node. Production 4 defines the constraints between associations. Productions 5 and 6 specify the template class and the interface, respectively. Productions 7, 12, and 14 all define associations, and Productions 8 and 9 specify aggregation and composition, respectively. Productions 10 and 13 demonstrate the generalization through inheritance. Production 15 represents the initial state. The nodes and vertices in dotted rectangles define pattern-extended class diagrams, which will be explained in the next section.

DESIGN PATTERN VISUALIZATION

UML (2) provides a set of notations to represent different aspects of a software system. However, it is still not expressive enough for some particular problems, such as design pattern applications and compositions (12). This section introduces the idea of using the RGG formalism to visualize design patterns through their corresponding class diagrams.

Design patterns (13) document good solutions to recurring problems in a particular context, and their compositions (12) are usually modeled using UML. When a design pattern is applied or composed with other patterns, the pattern-related information may be lost because UML does not track this information. Thus, it is hard for a designer to identify a design pattern when it is applied or composed. The benefits of design patterns are compromised because designers cannot communicate with each other in terms of the design patterns they use when the design patterns are applied or composed. Several graphical notations have been proposed to explicitly represent pattern-related information in UML class diagrams (11). Although these solutions need to attach additional symbols and/or text, they all suffer from the scalability problem when the software design becomes very large. A solution that can dynamically visualize pattern-related information based on the RGG is illustrated in Fig. 9. A new type of node, called *pattern*, is used to denote a specific pattern, and pattern-related information is expressed by linking a pattern node with its associated class nodes. Figure 7(b) presents the corresponding node-edge diagram by highlighting the newly introduced nodes and edges with dotted lines.

A syntactic analyzer implemented in the parser can dynamically collect separate pieces of information and reconstruct them into a new graph entity if desirable. In the process of parsing, a sequence of applications of Production 17 in Fig. 9 collects all classes belonging to the same pattern to support user interaction and queries. For example, if the user clicks on the *composite* class in Fig. 7(a), the *component* class, *content* class, and *composite* class, which belong to the Composite pattern, are all highlighted. Therefore, there is no need to attach any additional information to the original class diagrams.

AUTOMATIC VERIFICATION

Tools supporting general syntactic checking on class diagrams already exist. They, however, cannot verify certain properties. For example, multi-inheritance may cause ambiguity in the class design and usage. It is desirable to prohibit multi-inheritance when modeling software implemented in conventional programming languages. As explained, each production specifies a local structure. By “gluing” separate structures together, repetitive applications of various productions can generate a complete structure. A graph specifying a structure is invalid if it breaks at least one relationship specified in any production. For example, Production 6 in Fig. 9 defines that one interface can be attached to only one class. If an interface is

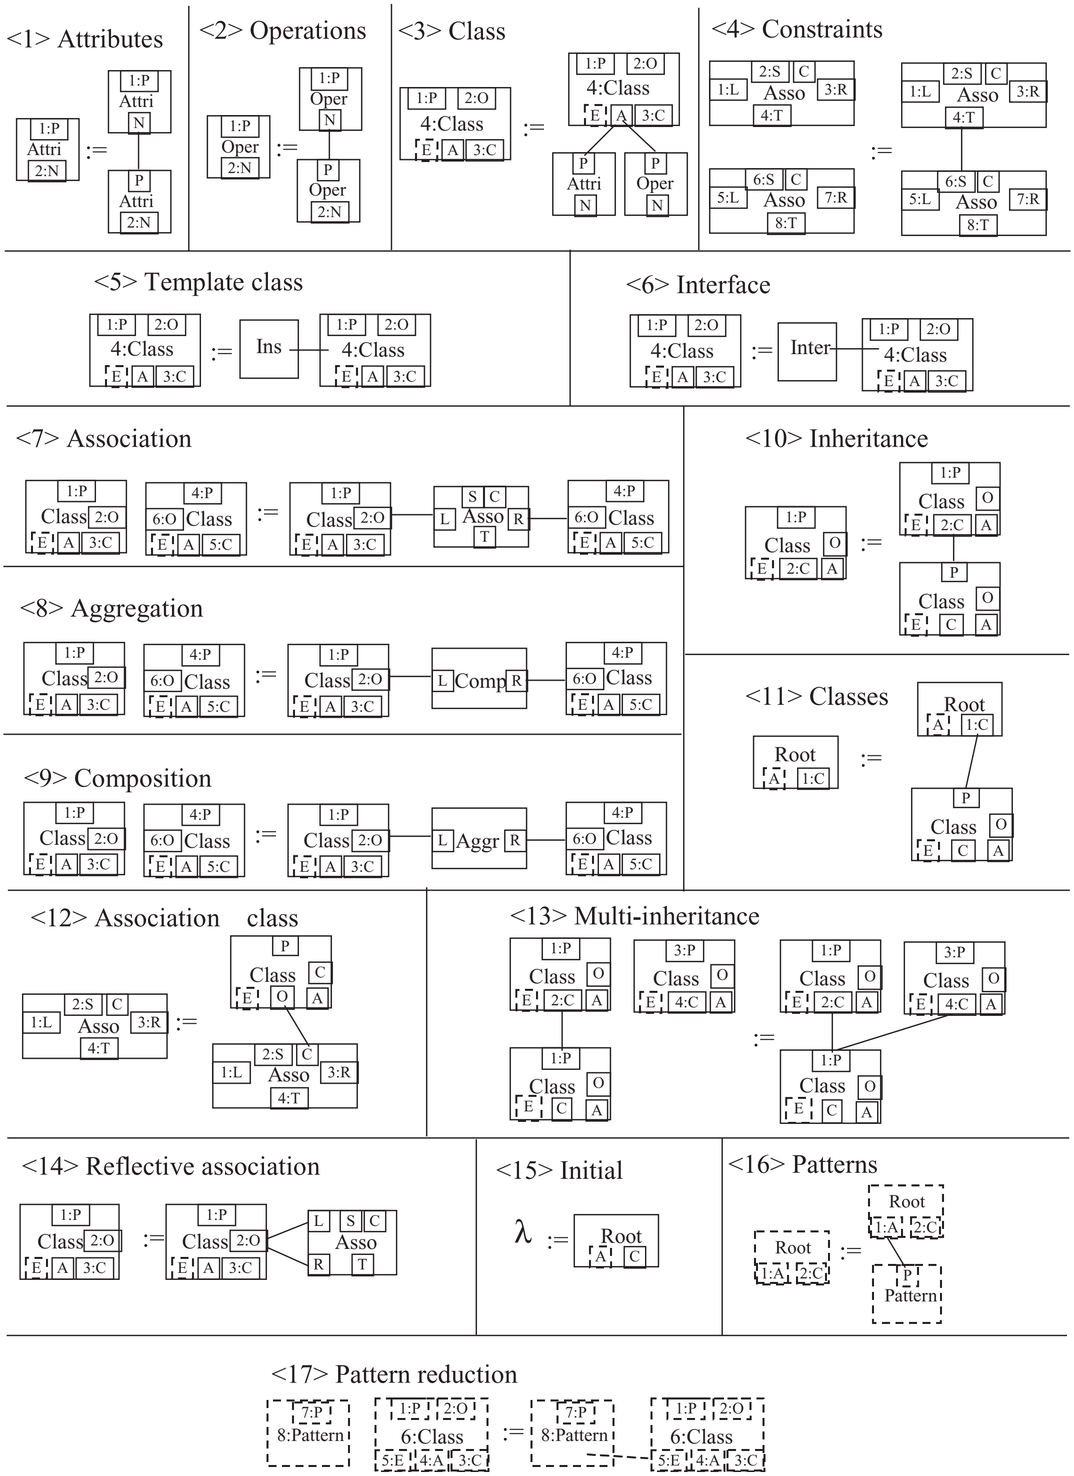

Figure 9. A graph grammar defining class diagrams.

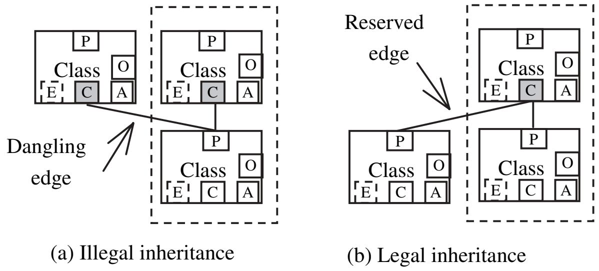
designed to relate to more than one class, a parser can indicate a violation of Production 6.

The following example illustrates how to verify inheritance relationships between classes. In Fig. 9, Production 10 defines the case of single inheritance, and Production 13 specifies that of multi-inheritance. As any valid relationship between components can be eventually derived from the graph grammar for class diagrams, removing Production 13 would implicitly prohibit any multi-inheritance. To explain in detail how to invalidate multi-inheritance, we need to apply the *marking* technique (9) explained earlier. A marked vertex is distinguished by assigning to it a unique integer. It preserves outgoing edges connected to vertices outside a replaced subgraph. In the right graph



(a) Illegal inheritance

(b) Legal inheritance

Figure 10. Inheritance verification.

of Production 10, the edge indicates an inheritance relationship between the classes. The unmarked vertex *p* in the bottom class node representing a subclass requires that any class can only inherit from at most one other class. On the other hand, the marked vertex *c* in the top class node representing a super-class defines that one super-class can have multiple subclasses, conforming to the principle of single inheritance. If the multiinheritance as illustrated in Fig. 10(a) occurs, the application of Production 10 results in an undesirable condition called the *dangling edge* condition (6), which is prohibited in the RGG formalism. In the case in which one class has more than one subclass, a successful application is shown in Fig. 10(b).

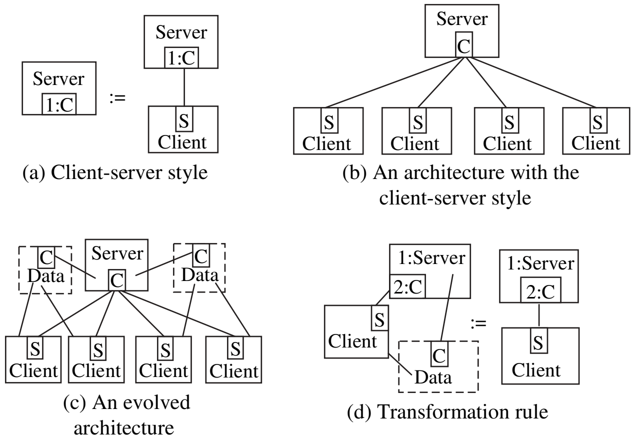
ARCHITECTURAL EVOLUTION

The architectures of software systems are not usually fixed. To meet the changing requirements and/or adapt to a different context, a software architecture may need to be transformed into a new configuration. Furthermore, a high-level software architecture style may gradually be refined into a detailed architecture (14) during software development. This transformation process can be tedious and error-prone without tool support. This section illustrates the automated transformation for software evolution from one architecture style to another. Graph rewriting provides a device for reusing existing software components by evolving them into newly required forms.

A software architecture style defined through an RGG characterizes some common properties shared by a class of architectures. To satisfy new requirements and reuse existing designs, an architecture with one style needs to evolve into another with a more appropriate style in the new context. In general, software architecture transformation proceeds in two steps: (*1*) Verify the style of an architecture, and (*2*) transform an architecture from one style to another style.

Assume that a system is originally implemented in a client–server style, consisting of only one server storing all data. To retrieve data, clients must send requests to, and receive responses from, the server. This communication pattern is abstracted into a graph grammar shown in Fig. 11(a), and an architecture with that style is illustrated in Fig. 11(b).

When the amount of data and communication increases, one server may no longer be able to bear clients' requests. One possible solution is to distribute data to different servers. Therefore, we need to transform the current style to a more advanced one by dividing servers into control and data servers. A system can only contain one control server, but it may have several data servers. A client sends requests to the control server, which forwards them to an appropriate data server. Then, the data server directly replies to the client. Such a communication pattern is defined in Fig. 11(c), which is achieved through the graph rewriting rule for transformation in Fig. 11(d).



(a) Client-server style

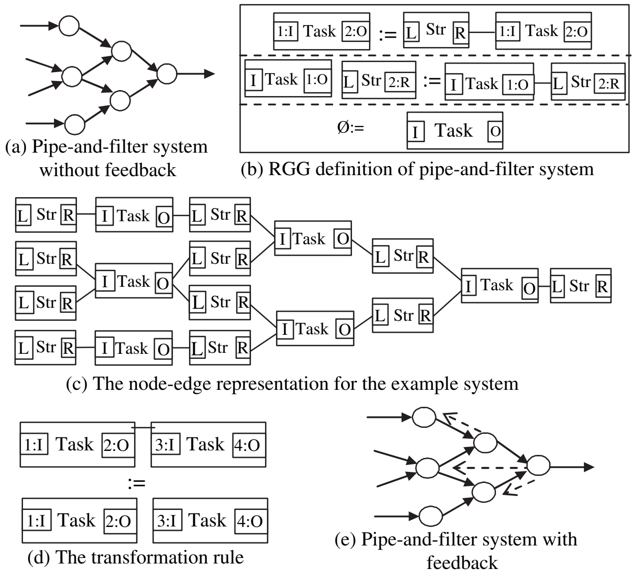
(b) An architecture with the client-server style

(c) An evolved architecture

(d) Transformation rule

Figure 11. Architectural transformation.

Let us go through another example to illustrate the idea of architecture evolution through graph transformation. A simple pipe-and-filter system without feedback is shown in Fig. 12(a), where a circle represents a task and a directed edge indicates a data stream between tasks. Correspondingly, a node labeled *Str*/*Task* simulates a stream/task in the node-edge representation. An edge connecting the *R*/*L* vertex in a *Str* node to the *I*/*O* vertex in a *Task* node expresses an incoming/outgoing stream. Figure 12(c)



(a) Pipe-and-filter system without feedback

(b) RGG definition of pipe-and-filter system

(c) The node-edge representation for the example system

(d) The transformation rule

(e) Pipe-and-filter system with feedback

Figure 12. Pipe-and-filter system.

illustrates the node-edge representation for the system shown in Fig. 12(a). The productions defined in Fig. 12(b) abstract the communication pattern in pipe-and-filter systems without feedback. By allowing an edge between two *Task* nodes to indicate a feedback between them, the graph rewriting rule given in Fig. 12(d) transforms a system without a feedback to one with feedback. Fig. 12(e) illustrates a system with feedback after applying the rule in Fig. 12(d) to the example in Fig. 12(a), where the dotted edges represent feedbacks.

CONCLUSION

Having introduced the basic concept of visual software engineering, this article presents a graph grammar approach to software architecture specification, verification, and evolution. Through this approach, various diagrammatical forms can be translated to the graphical notation recognizable by the RGG formalism and then applied by graph transformation in achieving the desired effect. In summary, the approach facilitates a sound software engineering practice with the following benefits:

- **Consistent:** It expresses software architectures in terms of "box and line" drawings (15), like the common practice of software engineers (16).
- **Scalable:** The underlying graph grammar formalism is applicable to various classes of diagrams. It is easy to accommodate new components by extending the graph schema and revising corresponding grammar rules and, thus, support software reuse.
- **Automatic:** Automatically generated by a visual language generator, such as VisPro (10), a transformation tool is capable of syntactic checking of software architectures. Automatic transformation from one architecture style to another assists software engineers in reusing existing products in new applications.

FURTHER READING

Visual software engineering has been a new relatively concept since the emerging graphical tools, notably UML, have increasingly been used in the software industry in recent years. The more commonly acknowledged term for visual software development and for software education is "software visualization" (3–5). A related active research area is visual programming and visual languages (17), from which the approach presented in this article was originally developed. The following summaries point to the representative early work in using graph transformation techniques to assist software engineering, specifically software architecture design.

Dean and Cordy (18) present a diagrammatic representation of software architectures. A graph visualizes the structure of a software architecture, and a graph grammar abstracts the overall organization of a class of architectures. Based on the equivalent of context-free grammars, Dean and Cordy introduced a pattern matching mechanism for recognizing classes of software architectures.

Métayer (16) also defines the style of architectures using graph grammars that are defined in terms of set theory. Instead of discussing pattern matching over software architectures, Métayer emphasizes the dynamic evolution of an architecture, performed through graph rewriting. An algorithm is presented to check whether an evolution breaks communication constraints.

Radermacher (19) discusses graph transformation tools supporting the construction of an application conforming to a design pattern, which is specified through graph queries and graph rewriting rules. A prototype can be generated by the PROGRES graph rewriting environment (20).

ANSWER SET PROGRAMMING

INTRODUCTION

Computer applications pervade our life, and these days many problems of everyday life are dealt with in an automated way. However, not all problems are easy to solve by a computer, some have an increased intrinsic complexity. Finding efficient and correct methods for solving them is not an easy task. Traditional software engineering is focused on an imperative, algorithmic approach, in which the computer is basically being told what steps should be followed in order to solve the given problem. Finding good algorithms for hard problems requires skill and knowledge and is often not obvious. This can be dealt with by involving an expert, but there is a serious drawback: When the specification of the problem changes slightly, perhaps only because additional information on the nature of the problem becomes available, major reengineering is often necessary. The main problem is that the knowledge about the problem and its solutions has been represented implicitly by representing a specific way of solving the problem rather than the problem itself. The case of updating representations is sometimes called elaboration tolerance.

An alternative that suits elaboration tolerance better is called declarative programming. In this approach, the problem and its solutions are specified explicitly. That is, it is expressed what features the problem and its solution must have, rather than specifying how a solution is to be obtained. Methods like this actually come natural in science but also in everyday life. Before we try to work out how to solve a problem, we usually first try to understand it and figure out how a solution would like, before trying to find a method, to obtain a solution. One of the first to put this approach into perspective in computer science was John McCarthy in the 1950s (1). He also postulated that the most natural language for specifying problems and solutions would be logic and, in particular, predicate logic.

In fact, logic is an excellent candidate for declarative programming: It provides a simple and abstract formalism, and in addition, it has the potential for automation. Similar to an abstract or electronic machine that can execute an imperative model (an algorithm) in order to obtain a solution of the modeled problem, computational logic has produced tools that allow for automatically obtaining solutions, given a declarative specification in logic. Indeed, many people nowadays use this way of solving problems: Queries to relational databases together with the database schemata are indeed declarative specifications of the solutions that the query results provide. And, indeed, the probably most widely used database query language, SQL, is basically predicate logic written in a particular way (2).

However, one wants to go beyond databases as they are used today. It has been shown that relational databases and query languages like SQL can only represent fairly simple problems. For instance, problems like finding the cheapest tour of several cities, or filling a container with items of different size, such that the value transported in the container is maximized, are typical problems that probably cannot be solved using SQL. It might seem unusual to use the word "probably" here, but underlying this conjecture is one of the most famous open problems in computer science—the question of whether P equals NP. These are complexity classes; basically, every problem has some intrinsic complexity, which is based on how many resources are required to solve it on a standard machine model, in terms of the size of the problem input. P is defined as the class of problems, which require at most an amount of time, which can be expressed as a polynomial over the input size (which is variable). NP is just a slight alteration, in which instead of a deterministic machine model, a nondeterministic machine model is assumed. A nondeterministic machine is a somewhat unusual concept: Instead of executing commands one-by-one, always going from one machine state to another, a nondeterministic machine may be in two or more states (at the same time) after having executed a command. In a sense, this means that the machine has the possibility to store and work with an unbounded number of machine states at any time. Intuitively, one would expect that a deterministic and a nondeterministic machine are quite different from each other, and that the nondeterministic machine can solve more problems under the same time constraints. However, up to now, nobody has been able to prove convincingly neither that P and NP are different, nor that they are equal. However, intuitively one would expect that they are different, and people have shown that many more unintuitive results would follow if P and NP coincided.

Logic programming is an attempt to use declarative programming with logic that goes beyond problems in P and, thus, beyond traditional databases. The main construct in logic programming is a rule, a expression that looks like *Head* ← *Body*, where *Body* is a logic conjunction possibly involving negation, and *Head* is either an atomic formula or a logic disjunction. This can be seen as a logic formula (← denoting implication), with the special meaning that *Head* is defined by that rule. In the beginning of the field (as described in the following section), logic programming actually attempted to become a full-scale "programming language." Its most famous language, Prolog (3), aimed at this, but had to renounce to full declarativity in order to achieve that goal. For instance, in Prolog rules, the order inside *Body* matters, as does the order among rules (most notably for termination). Moreover, Prolog also had several nonlogical constructs.

Answer set programming (ASP) is a branch of logic programming, which does not aspire to create a full general-purpose language. In this respect, it is influenced by database languages, as also these are not general-purpose languages, but suffice for a particular class of problems. ASP does, however, attempt to enlarge the class of problems that can be expressed by the language. Although, as

Wiley Encyclopedia of Computer Science and Engineering, edited by Benjamin Wah.

mentioned, SQL probably cannot express hard problems in NP, ASP definitely can. Actually, ASP can express all problems in the complexity class $\sum_2^p$ and its complement $\prod_2^p$, which are similar to NP, but probably somewhat larger (but at least equally large).

In ASP, the rule construct *Head* ← *Body* (where *Head* can be a disjunction) is read like a formula in nonmonotonic logics rather than classical logic. Nonmonotonic logics are an effort to formulate a logic of common sense that is adapting the semantics of logic such that it corresponds better to our everyday reasoning, which is characterized by the presence of incomplete knowledge, hypothetical reasoning, and default assumptions. It can be argued that nonmonotonic logics are much better suited in such a setting than classical logic.

Summarizing, ASP is a formalism that has emerged from logic programming. Its main representation feature are rules, which are interpreted according to common sense principles. It allows for declarative specifications of a rich class of programs, generalizing the declarative approach of databases. In ASP, one writes a program (a collection of rules), which represent a problem to be solved. This program, together with some input, which is also expressed by a collection of rules, possesses a collection of solutions (possibly also no solution), which correspond to the solutions of the modeled problem. Since these solutions are usually sets, the term "answer set" has been coined.

Concerning terminology, ASP is sometimes used in a somewhat broader sense, referring to any declarative formalism representing solutions as sets. However, the more frequent understanding is the one adopted in this article, which dates back to Ref. 4. Moreover, since ASP is the most prominent branch of logic programming in which rule heads may be disjunctive, sometimes the term "disjunctive logic programming" can be found referring explicitly to ASP. Yet other terms for ASP are A-Prolog and stable logic programming. For complementary introductory material on ASP, we refer to Refs. 5 and 6.

LOGIC PROGRAMMING

The roots of answer set programming lie predominantly in logic programming, nonmonotonic reasoning, and databases. In this section, we give an overview on the history of logic programming from the perspective of answer set programming. It, therefore, does not cover several important subfields of logic programming, such as constraint logic programming (7) or abductive logic programming (8).

As mentioned, probably the first to suggest logic, and in particular predicate logic, as a programming language was John McCarthy in the 1950s (1). McCarthy's motivating example was set in artificial intelligence, and involved planning as its main task, an agenda on which was continuously elaborated; see, for instance, Ref. 9.

Developments in computational logic, most notably the specification of the resolution principle and unification as a computational method by J. Alan Robinson in 1965 (10), acted as a catalyst for the rise of logic programming. This development eventually really set off when a working system, Prolog, developed by a group around Alain Colmerauer in Marseilles, France, became available (3). A few other, somewhat more restricted systems had been available before, but Prolog was to make the breakthrough for logic programming.

One of the prime advocates of what would become known as the logic programming paradigm has been Robert Kowalski, who provided the philosophical basis and concretizations of the logic programming paradigm, for instance, in Refs. 11 and 12. Kowalski also collaborated with Colmerauer on Prolog, and in the realm of his group in Edinburgh, Scotland, alternative implementations of Prolog were created. There has also been a standardization effort for the language, which would become known as Edinburgh Prolog and served as the de facto specification of Prolog for many years until the definition of ISO Prolog in 1995 (13).

However, logic programming, and Prolog in particular, was inspired by, but not the same as classical first-order logic. Initially the differences were not entirely clear. The first effort to provide a formal definition for the semantics of logic programming was also undertaken by Kowalski, who together with Maarten van Emden gave a semantics based on fixpoints of operators for a restricted class of logic programs (Horn programs, also called positive programs) in Ref. 14. This fixpoint semantics essentially coincided with minimal Herbrand models and with resolution-based query answering on Horn programs. The major feature missing in Horn programs is negation—however, Prolog did have a negation operator.

Indeed, the quest for finding a suitable semantics in the spirit of minimal models for programs containing negation turned out to be far from straightforward. A first attempt was made by Keith Clark in Ref. 15 by defining a transformation of the programs to formulas in classical logic, which are then interpreted using the classical model semantics. However, the approach gave arguably unintuitive results for programs with positive recursion. In particular, the obtained semantics does not coincide with the minimal model semantics on positive programs. At about the same time, Raymond Reiter formulated the Closed World Assumption in Ref. 16, which can be seen as the philosophical basis of the treatment of negation. Another milestone in the research on the intended semantics for programs with negation has been the definition of what later became known uniformly as perfect model semantics for programs that can be stratified on negation, in Refs. 17 and 18. The basic idea of stratification is that programs can be partitioned in subprograms (strata) such that the rules of each stratum contain negative predicates only if they are defined in other strata. In this way, it is possible to evaluate the program by separately evaluating its partitions in such a way that a given "stratum" is processed whenever the ones from which it (negatively) depends have already been processed.

Although an important step forward, it is obvious that not all logic programs are stratified. In particular, programs that are recursive through negation are never stratified, and the problem of assigning a semantics to nonstratified programs still remained open. There were basically two approaches for finding suitable definitions: The first approach was giving up the classical setting of models that assign two truth values, and introduce a third value, intuitively representing unknown. This approach required a somewhat different definition, because in the two-valued approach, one would give a definition only for positive values, implicitly stating that all other constructs are considered to be negative. For instance, for minimal models, one minimizes the true elements, implicitly stating that all elements not contained in the minimal model will be false. With three truth values, this strategy is no longer applicable, as elements that are not true can be either false or undefined. For resolving this, Allen Van Gelder, Kenneth Ross, and John Schlipf introduced the notion of unfounded sets in Ref. 19, in order to define which elements of the program should be definitely false. Combining existing techniques for defining the minimal model with unfounded sets, they defined the notion of a well-founded model. In this way, any program would still be guaranteed to have a single model, just like there is a unique minimal model for positive programs and a unique perfect model for stratified programs.

The second approach consisted of viewing logic programs as formulas in nonmonotonic logics (see, for instance, Ref. 20 for an overview) rather than formulas of classical logic (with an additional minimality criterion) and as a corollary, abandoning the unique model property. Among the first to concretize this were Michael Gelfond in Ref. 21, who proposed to view logic programs as formulas of autoepistemic logic, and Nicole Bidoit and Christine Froidevaux in Ref. 22, who proposed to view logic programs as formulas of default logic. Both of these developments have been picked up by Michael Gelfond and Vladimir Lifschitz, who in Ref. 23 defined the notion of stable models, which is inspired by nonmonotonic logics, however does not refer explicitly to these, but rather relies on a reduct that effectively emulates nonmonotonic inference. It was this surprisingly simple formulation, which did not require previous knowledge on non-classical logics that has become well known. Different to well-founded models, there may exist no, one, or many stable models for one program. However, well-founded and stable models are closely related; for instance, the well-founded model of a program is contained in each stable model (cf. Ref. 24). Moreover, both approaches coincide with perfect models on stratified programs.

Yet another, somewhat orthogonal line of research concerned the use of disjunction in rule heads. This construct is appealing, because it allows for direct nondeterministic definitions. Prolog and many other logic programming languages traditionally do not provide such a feature, being restricted to so-called definite rules. Jack Minker has been a pioneer and advocate of having disjunctions in programs. In Ref. 25, he formulated the Generalized Closed World Assumption, which gave a simple and intuitive semantics for disjunctive logic programs. This concept has been elaborated on over the years, most notably by the Extended GCWA defined in Ref. 26. Eventually, also the stable model semantics has been extended to disjunctive programs in Ref. 27 by just minimally altering the definition of Ref. 23. On the other hand, defining an extension of well-founded models for disjunctive programs remains a controversial matter to this date with various rivalling definitions, (cf. Ref. 28).

The final step toward answer set programming in the traditional sense has been the addition of a second kind of negation, which has a more classical meaning than negation as failure. Combining this feature with disjunctive stable models of Ref. 27 led to the definition of answer sets in Ref. 4.

FORMAL DEFINITION OF ASP

In what follows, we provide a formal definition of the syntax and semantics of answer set programming in the spirit of Ref. 4, that is, disjunctive logic programming involving two kinds of negation (referred to as strong negation and negation as failure), under the answer sets semantics.

Syntax

Following a convention dating back to Prolog, strings starting with uppercase letters denote logical variables, whereas strings starting with lowercase letters denote constants. A *term* is either a variable or a constant. Note that, as common in ASP, function symbols are not considered.

An *atom* is an expression $\mathcal{P}(t_1,\ldots,t_n)$, where p is a *predicate* of arity n and $t_1,\ldots,t_n$ are terms. A *classical literal* l is either an atom p (in this case, it is *positive)*, or a negated atom $\neg p$ (in this case, it is *negative)*. A *negation as failure (NAF) literal* ℓ is of the form l or not l, where l is a classical literal; in the former case ℓ is *positive*, and in the latter case *negative*. Unless stated otherwise, by *literal* we mean a classical literal.

Given a classical literal l, its *complementary* literal $\neg l$ is defined as $\neg p$ if $l = p$ and p if $l = \neg p$. A set L of literals is said to be *consistent* if, for every literal $l \in L$, its complementary literal is not contained in L.

A *disjunctive rule (rule*, for short) r is a construct

$$a_1 \vee \cdots \vee a_n \leftarrow b_1,\ldots,b_k,\ \text{not}\ b_{k+1},\ldots,\text{not}\, b_m. \qquad (1)$$

where $a_1,\ldots,a_n,b_1,\ldots,b_m$ are classical literals and $n \geq 0,\ m \geq k \geq 0$. The disjunction $a_1 \vee \cdots \vee a_n$ is called the *head* of r, whereas the conjunction $b_1,\ldots,b_k$, not $b_{k+1},\ldots$, not b_m is referred to as the *body* of r. A rule without head literals (i.e., $n = 0$) is usually referred to as an *integrity constraint*. A rule having precisely one head literal (i.e., $n = 1$) is called a *normal rule*. If the body is empty (i.e., $k = m = 0$), it is called a fact, and in this case, the "$\leftarrow$" sign is usually omitted.

The following notation will be useful for additional discussion. If r is a rule of form (1), then $H(r) = \{a_1,\ldots,a_n\}$ is the set of literals in the head and $B(r) = B^+(r) \cup B^-(r)$ is the set of the body literals, where $B^+(r)$ (the *positive body*) is $\{b_1,\ldots,b_k\}$ and $B^-(r)$ (*the negative body*) is $\{b_{k+1},\ldots,b_m\}$. An *ASP program* $\mathcal{P}$ is a finite set of rules. A not-free program $\mathcal{P}$ (i.e., such that $\forall r \in \mathcal{P} : B^-(r) = \emptyset$) is called *positive* or *Horn*,[1] and a $\vee$-free program $\mathcal{P}$ (i.e., such that $\forall r \in \mathcal{P} : |H(r)| \leq 1$) is called *normal logic program*.

[1] In positive programs, negation as failure (not) does not occur, whereas strong negation ($\neg$) may be present.

In ASP, rules in programs are usually required to be safe. The motivation of safety comes from the field of databases, where safety has been introduced as a means to guarantee that queries (programs in the case of ASP) do not depend on the universe (the set of constants) considered. As an example, a fact $p(X)$. gives rise to the truth of $p(a)$ when the universe $\{a\}$ is considered, whereas it gives rise to the truth of $p(a)$ and $p(b)$ when the universe $\{a, b\}$ is considered. Safe programs do not suffer from this problem when at least the constants occurring in the program are considered. For a detailed discussion, we refer to Ref. 2.

A rule is *safe* if each variable in that rule also appears in at least one positive literal in the body of that rule. An ASP program is safe, if each of its rules is safe, and in the following we will only consider safe programs.

A term (an atom, a rule, a program, etc.) is called *ground*, if no variable appears in it. Sometimes a ground program is also called *propositional* program.

Example 3.1. Consider the following program:

$$\begin{array}{ll}
r_1: & \mathrm{a(X)} \vee \mathrm{b(X)} \leftarrow \mathrm{c(X,Y),\ d(Y),\ not\, e(X)}.\\
r_2: & \leftarrow \mathrm{c(X,Y),\ k(Y),\ e(X),\ not\, b(X)}.\\
r_3: & \mathrm{m} \leftarrow \mathrm{n,\ o,\ a(1)}.\\
r_4: & \mathrm{e(1,2)}.
\end{array}$$

r_1 is a disjunctive rule with $H(r_1) = \{a(X), b(X)\}$, $B^+(r_1) = \{c(X,Y), d(Y)\}$, and $B^{\cdot\cdot}(r_1)\} = \{e(X)\}.r_2$ is an integrity constraint with $B^+(r_2) = \{c(X,Y), k(Y), e(X)\}$, and $B^-(r_2) = \{b(X)\}.\, r_3$ is a ground, positive, and nondisjunctive rule with $H(r_3) = \{m\}, B^+(r_3) = \{n, o, a(1)\}$, and $B^-(r_3) = \emptyset.\, r_4$, finally, is a fact (note that ← is omitted). Moreover, all of the rules are safe. □

Semantics

We next describe the semantics of ASP programs, which is based on the answer set semantics originally defined in Ref. 4. However, different than Ref. 4, only consistent answer sets are considered, as it is now standard practice.

We note that in ASP the availability of some preinterpreted predicates is assumed, such as $=, <, >$. However, it would also be possible to define them explicitly as facts, so they are not treated in a special way here.

Herbrand Universe and Literal Base. For any program $\mathcal{P}$, the *Herbrand universe*, denoted by $U_{\mathcal{P}}$, is the set of all constants occurring in $\mathcal{P}$. If no constant occurs in $\mathcal{P}$, $U_{\mathcal{P}}$ consists of one arbitrary constant[2]. The *Herbrand literal base* $B_{\mathcal{P}}$ is the set of all ground (classical) literals constructible from predicate symbols appearing in $\mathcal{P}$ and constants in $U_{\mathcal{P}}$ (note that, for each atom $\mathcal{P}$, $B_{\mathcal{P}}$ contains also the strongly negated literal $\neg p$).

Example 3.2. Consider the following program:

$$\begin{array}{ll}
\mathcal{P}_0 & = \{\\
 & r_1: \mathrm{a(X)} \vee \mathrm{b(X)} \leftarrow \mathrm{c(X,Y)}.\\
 & r_2: \mathrm{c(X)} \leftarrow \mathrm{c(X,Y),\ not\, b(X)}.\\
 & r_4: \mathrm{c(1,2)}.\\
 & \}
\end{array}$$

then, the universe is $U_{\mathcal{P}0} = \{1{,}2\}$, and the base is $B_{\mathcal{P}0} = \{$a(1), a(2), b(1), b(2), c(1), c(2), c(1,1), c(1,2), c(2,1), c(2,2), ¬a(1),¬a(2),¬b(1),¬b(2),¬c(1),¬c(2),¬c(1,1),¬c(1,2),¬c(2,1), ¬c(2,2)$\}$. □

Ground Instantiation. For any rule r, $Ground(r)$ denotes the set of rules obtained by replacing each variable in r by constants in $U_{\mathcal{P}}$ in all possible ways. For any program $\mathcal{P}$, its ground instantiation is the set $Ground(\mathcal{P}) = \cup_{r \in \mathcal{P}} Ground(r)$. Note that for propositional programs, $\mathcal{P} = Ground(\mathcal{P})$ holds.

Example 3.3. Consider again problem $\mathcal{P}_0$ of Example 3.2. Its ground instantiation is:

$$\begin{array}{lll}
Ground(\mathcal{P}_0) = & \{ & \\
 & g_1: \mathrm{a(1)} \vee \mathrm{b(1)} \leftarrow \mathrm{c(1,1)}. & g_2: \mathrm{a(1)} \vee \mathrm{b(1)} \leftarrow \mathrm{c(1,2)}.\\
 & g_3: \mathrm{a(2)} \vee \mathrm{b(2)} \leftarrow \mathrm{c(2,1)}. & g_4: \mathrm{a(2)} \vee \mathrm{b(2)} \leftarrow \mathrm{c(2,2)}.\\
 & g_5: \mathrm{e(1)} \leftarrow \mathrm{c(1,1),\ not\, b(1)}. & g_6: \mathrm{e(1)} \leftarrow \mathrm{c(1,2),\ not\, b(1)}.\\
 & g_7: \mathrm{e(2)} \leftarrow \mathrm{c(2,1),\ not\, b(2)}. & g_8: \mathrm{e(2)} \leftarrow \mathrm{c(2,2),\ not\, b(2)}.\\
 & g_9: \mathrm{c(1,2)}. & \\
 & \} &
\end{array}$$

Note that the atom $c(1,2)$ was already ground in $\mathcal{P}_0$, whereas the rules $g_1, \ldots, g_4$ (resp. $g_5, \ldots, g_8$) are obtained by replacing the variables in r_1 (resp. r_2) with constants in $U_{\mathcal{P}_0}$. □

Answer Sets. For every program $\mathcal{P}$, its answer sets are defined using its ground instantiation $Ground(\mathcal{P})$ in two steps: First the answer sets of positive disjunctive programs are defined, and then the answer sets of general programs are defined by a reduction to positive disjunctive programs and a stability condition.

An interpretation l is a consistent[3] set of ground classical literals $I \subseteq Bp$ w.r.t. a program $\mathcal{P}$. A consistent interpretation $X \subseteq B_{\mathcal{P}}$ is called *closed under* $\mathcal{P}$ (where $\mathcal{P}$ is a positive disjunctive datalog program), if, for every $r \in Ground(\mathcal{P})$, $H(r) \cap X \neq \emptyset$ whenever $B(r) \subseteq X$. An interpretation which is closed under $\mathcal{P}$ is also called *model* of $\mathcal{P}$. An interpretation $X \subseteq B_{\mathcal{P}}$ is an *answer set* for a positive disjunctive program $\mathcal{P}$, if it is minimal (under set inclusion) among all (consistent) interpretations that are closed under $\mathcal{P}$.

Example 3.4. The positive program $\mathcal{P}_1 = \{a \vee \neg b \vee c.\}$ has the answer sets $\{a\}$, $\{\neg b\}$, and $\{c\}$; note that they are minimal and correspond to the multiple ways of satisfying the disjunction. Its extension $\mathcal{P}_2 = \mathcal{P}_1 \cup \{\leftarrow a.\}$ has

[2] Actually, since the language does not contain function symbols and since rules are required to be safe, this extra constant is not needed. However, we have kept the classic definition in order to avoid confusion.

[3] A set $I \subseteq B_{\mathcal{P}}$ is *consistent* if for each positive classical literal such that $l \in I$ it holds that $\neg l \notin I$.

the answer sets $\{\neg b\}$ and $\{c\}$, since comparing $\mathcal{P}_2$ with $\mathcal{P}_1$, the additional constraint is not satisfied by interpretation $\{a\}$. Moreover, the positive program $\mathcal{P}_3 = \mathcal{P}_2 \cup \{\neg b \leftarrow c.;\ c \leftarrow \neg b.\}$ has the single answer set $\{\neg b, c\}$ (indeed, the remaining consistent closed interpretation $\{a,\ \neg b, c\}$ is not minimal). Although, it is easy to see that, $\mathcal{P}_4 = \mathcal{P}_3 \cup \{\leftarrow c\}$ has no answer set. □

The *reduct* or *Gelfond–Lifschitz transform* of a ground program $\mathcal{P}$ w.r.t. a set $X \subseteq B_{\mathcal{P}}$ is the positive ground program $\mathcal{P}^X$, obtained from $\mathcal{P}$ by

- Deleting all rules $r \in \mathcal{P}$ for which $B^-(r) \cap X \neq \emptyset$ holds
- Deleting the negative body from the remaining rules

An *answer set* of a program $\mathcal{P}$ is a set $X \subseteq B_{\mathcal{P}}$ such that X is an answer set of $Ground(\mathcal{P})^X$.

Example 3.5. For the negative ground program $\mathcal{P}_5 = \{a \leftarrow \text{not}\, b.\}$, $A = \{a\}$ is the only answer set, as $\mathcal{P}_5^A = \{a.\}$. For example, for $B = \{b\}$, $\mathcal{P}_5^B = \emptyset$, and so B is not an answer set. □

Example 3.6. Consider again program $\mathcal{P}_0$ of Example 3.2, whose ground instantiation $Ground(\mathcal{P}_0)$ has been reported in Example 3.3. A naÿve way to compute the answer sets of $\mathcal{P}_0$ is to consider all possible interpretations, checking whether they are answer sets of $Ground(\mathcal{P}_0)$.

For instance, consider interpretation $I_0 = \{c(1,2), a(1), e(1)\}$, the corresponding reduct $Ground(\mathcal{P}_0)^{I_0}$ contains rules g_1, g_2, g_3, g_4, g_9, plus $e(1) \leftarrow c(1,1), e(1) \leftarrow c(1,2)$, $e(2) \leftarrow c(2,1)$, and $e(2) \leftarrow c(2,2)$, obtained by canceling the negative literals from g_5, g_6, g_7, and g_8, respectively. We can thus verify that I_0 is an answer set for $Ground(\mathcal{P}_0)^{I_0}$ and therefore also an answer set for $Ground(\mathcal{P}_0)$ and $\mathcal{P}_0$.

Let us now consider the interpretation $I_1 = \{c(1,2), b(1), e(1)\}$, which is a model of $Ground(\mathcal{P}_0)$. The reduct $Ground(\mathcal{P}_0)^{I_1}$ contains rules g_1, g_2, g_3, g_4, g_9 plus both $e(2) \leftarrow c(2,1)$ and $e(2) \leftarrow c(2,2)$ (note that both g_5 and g_6 are deleted because $b(1) \in I_1$). I_1 is not an answer set of $Ground(\mathcal{P}_0)^{I_1}$ because $\{c(1,2), b(1)\} \subset I_1$ is. As a consequence, I_1 is not an answer set of P_0.

It can be verified that $\mathcal{P}_0$ has two answer sets, I_0 and $\{c(1,2), b(1)\}$. □

KNOWLEDGE REPRESENTATION AND REASONING IN ASP

ASP has been exploited in several domains, ranging from classical deductive databases to artificial intelligence. ASP can be used to encode problems in a declarative fashion; indeed, the power of disjunctive rules allows for expressing problems that are more complex than NP, and the (optional) separation of a fixed, non-ground program from an input database allows one to obtain uniform solutions over varying instances.

More importantly, many problems of comparatively high computational complexity can be solved in a natural manner by following a "Guess&Check" programming methodology, which was originally introduced in Ref. 29 and refined in Ref. 30. The idea behind this method can be summarized as follows: A database of facts is used to specify an instance of the problem, whereas a set of (usually disjunctive[4]) rules, called the "guessing part," is used to define the search space; solutions are then identified in the search space by another (optional) set of rules, called "checking part," which impose some admissibility constraint. Basically, the answer sets of the program, which combines the input database with the guessing part, represent "solution candidates" those candidates are then filtered, by adding the checking part, which guarantee that the answer sets of the resulting program represent precisely the admissible solutions for the input instance. To grasp the intuition behind the role of both the guessing and the checking parts, consider the following example.

Example 4.1. Suppose that we want to partition a set of persons in two groups, while avoiding that father and children belong to the same group. Following the guess&check methodology, we use a disjunctive rule to "guess" all the possible assignments of persons to groups as follows:

$$group(P,1) \vee group(P,2) \leftarrow person(P).$$

To understand what this rule does, consider a simple instance of the problem, in which there are two persons: *joe* and his father *john*. This instance is represented by four facts

$$person(john).\ person(joe).\ father(john, joe).$$

We can verify that the answer sets of the resulting program (facts plus disjunctive rule) correspond to all possible assignments of the three persons to two groups:

$$\{\text{person(john)},\text{person(joe)},\text{father(john,joe)},\text{group(john,1)},\text{group(joe,1)}\}$$
$$\{\text{person(john)},\text{person(joe)},\text{father(john,joe)},\text{group(john,1)},\text{group(joe,2)}\}$$
$$\{\text{person(john)},\text{person(joe)},\text{father(john,joe)},\text{group(john,2)},\text{group(joe,1)}\}$$
$$\{\text{person(john)},\text{person(joe)},\text{father(john,joe)},\text{group(john,2)},\text{group(joe,2)}\}$$

However, we want to discard assignments in which father and children belong to the same group. To this end, we add the checking part by writing the following constraint:

$$\leftarrow group(P1,G), group(P2,G), father(P1,P2).$$

The answer sets of the augmented program are then the intending ones, where the checking part has acted as a sort of filter:

$$\{\text{person(john)},\text{person(joe)},\text{father(john,joe)},\text{group(john,1)},\text{group(joe,2)}\}$$
$$\{\text{person(john)},\text{person(joe)},\text{father(john,joe)},\text{group(john,2)},\text{group(joe,1)}\}$$

□

In the following, we illustrate the usage of ASP as a tool for knowledge representation and reasoning by example. In particular, we first deal with a problem motivated by

[4] Some ASP variants use *choice rules* as guessing part (see Refs. 31–33). Moreover, in some cases, it is possible to emulate disjunction by unstratified normal rules by "shifting" the disjunction to the body (31–36), but this is not possible in general.

classical deductive database applications; then we exploit the "Guess&Check" programming style to show how a number of well-known harder problems can be encoded in ASP.

Reachability. Given a finite directed graph $G = (V, A)$, we want to compute all pairs of nodes $(a, b) \in V \times V$ such that b is reachable from a through a nonempty sequence of arcs in A. In different terms, the problem amounts to computing the transitive closure of the relation A.

The input graph is encoded by assuming that A is represented by the binary relation $arc(X, Y)$, where a fact $arc(a, b)$ means that G contains an arc from a to b; i.e., $(a, b) \in A$; although the set of nodes V is not explicitly represented, since the nodes appearing in the transitive closure are implicitly given by these facts.

The following program then defines a relation $reachable(X, Y)$ containing all facts $reachable(a, b)$ such that b is reachable from a through the arcs of the input graph G:

$$\begin{array}{ll} r_1: & reachable(X,Y) \leftarrow arc(X,Y). \\ r_2: & reachable(X,Y) \leftarrow arc(X,U),\ reachable(U,Y). \end{array}$$

The first rule states that that node Y is reachable from node X if there is an arc in the graph from X to Y, whereas the second rule reprents the transitive closure by stating that node Y is reachable from node X if a node U exists such that U is directly reachable from X (there is an arc from X to U) and Y is reachable from U.

As an example, consider a graph represented by the following facts:

$$arc(1,2). \quad arc(2,3). \quad arc(3,4).$$

The single answer set of the program reported above together with these three facts program is $\{reachable(1,2), reachable(2,3), reachable(3,4), reachable(1,3), reachable(2,4), reachable(1,4), arc(1,2), arc(2,3), arc(3,4)\}$. The first three reported literals are inferred by exploiting the rule r_1, whereas the other literals containing the predicate *reachable* are inferred by using rule r_2.

In the following section, we describe the usage of the "Guess&Check" methodology.

Hamiltonian Path. Given a finite directed graph $G = (V, A)$ and a node $a \in V$ of this graph, does a path in G exist starting at a and passing through each node in V exactly once?

This is a classical NP-complete problem in graph theory. Suppose that the graph G is specified by using facts over predicates *node* (unary) and *arc* (binary), and the starting node a is specified by the predicate *start* (unary). Then, the following program $\mathcal{P}_{hp}$ solves the *Hamiltonian Path* problem:

$$\begin{array}{ll} r_1: & inPath(X,Y) \vee outPath(X,Y) \leftarrow arc(X,Y). \\ r_2: & reached(X) \leftarrow start(X). \\ r_3: & reached(X) \leftarrow reached(Y), inPath(X,Y). \\ r_4: & \leftarrow inPath(X,Y),\ inPath(X,Y1), Y \quad <> Y1. \\ r_5: & \leftarrow inPath(X,Y), inPath(X1,Y), X \quad <> X1. \\ r_6: & \leftarrow node(X),\ \mathrm{not}\, reached(X),\ \mathrm{not}\, start(X). \end{array}$$

The disjunctive rule (r_1) guesses a subset S of the arcs to be in the path, whereas the rest of the program checks whether S constitutes a Hamiltonian Path. Here, an auxiliary predicate *reached* is defined, which specifies the set of nodes that are reached from the starting node. Doing this is very similar to reachability, but the transitivity is defined over the guessed predicate *inPath* using rule r_3. Note that as *reached* is completely determined by the guess for *inPath*, no further guessing is needed.

In the checking part, the first two constraints (namely, r_4 and r_5) ensure that the set of arcs S selected by *inPath* meets the following requirements, which any Hamiltonian Path must satisfy: (*1*) there must not be two arcs starting at the same node, and (*2*) there must not be two arcs ending in the same node. The third constraint enforces that all nodes in the graph are reached from the starting node in the subgraph induced by S.

Let us next consider an alternative program $\mathcal{P}'_{hp}$, which also solves the *Hamiltonian Path* problem, but intertwines the reachability with the guess:

$$\begin{array}{ll} r_1: & inPath(X,Y) \vee outPath(X,Y) \leftarrow reached(X), arc(X,Y). \\ r_2: & inPath(X,Y) \vee outPath(X,Y) \leftarrow start(X),\ arc(X,Y). \\ r_3: & reached(X) \leftarrow inPath(Y,X). \\ r_4: & \leftarrow inPath(X,Y),\ inPath(X,Y1),\ Y <> Y1. \\ r_5: & \leftarrow inPath(X,Y), inPath(X1,Y),\ X <> X1. \\ r_6: & \leftarrow node(X),\ \mathrm{not}\, reached(X),\ \mathrm{not}\, start(X). \end{array}$$

Here, the two disjunctive rules (r_1 and r_2), together with the auxiliary rule r_3, guess a subset S of the arcs to be in the path, whereas the rest of the program checks whether S constitutes a Hamiltonian Path. Here, *reached* is defined in a different way. In fact, *inPath* is already defined in a way that only arcs reachable from the starting node will be guessed. The remainder of the checking part is the same as in $\mathcal{P}_{hp}$.

Ramsey Numbers. In the previous example, we have seen how a search problem can be encoded in an ASP program whose answer sets correspond to the problem solutions. We now build a program whose answer sets witness that a property does not hold; i.e., the property at hand holds if and only if the program has no answer set. We next apply the above programming scheme to a well-known problem of number and graph theory.

The Ramsey number $R(k, m)$ is the smallest integer n such that, no matter how we color the arcs of the complete undirected graph (clique) with n nodes using two colors, say red and blue, there is a red clique with k nodes (a red k-clique) or a blue clique with m nodes (a blue m-clique).

Ramsey numbers exist for all pairs of positive integers k and m (37). We next show a program $\mathcal{P}_{ra}$ that allows us to decide whether a given integer n is *not* the Ramsey Number $R(3,4)$. By varying the input number n, we can determine $R(3,4)$, as described below. Let $\mathcal{F}_{ra}$ be the collection of facts for input predicates *node* and *arc* encoding a complete graph with n nodes. $\mathcal{P}_{ra}$ is the following program:

$$\begin{array}{ll} r_1: & blue(X,Y) \vee red(X,Y) \leftarrow arc(X,Y). \\ r_2: & \leftarrow red(X,Y), red(X,Z), red(Y,Z). \\ r_3: & \leftarrow blue(X,Y), blue(X,Z), blue(Y,Z), \\ & blue(X,W), blue(Y,W), blue(Z,W). \end{array}$$

Intuitively, the disjunctive rule r_1 guesses a color for each edge. The first constraint (r_2) eliminates the colorings containing a red clique (i.e., a complete graph) with three nodes, and the second constraint (r_3) eliminates the colorings containing a blue clique with four nodes. The program $\mathcal{P}_{ra} \cup \mathcal{F}_{ra}$ has an answer set if and only if there is a coloring of the edges of the complete graph on n nodes containing no red clique of size 3 and no blue clique of size 4. Thus, if there is an answer set for a particular n, then n is *not* R(3,4); that is, $n < R(3, 4)$. On the other hand, if $\mathcal{P}_{ra} \cup \mathcal{F}_{ra}$ has no answer set, then $n \geq R(3,4)$. Thus, the smallest n such that no answer set is found is the Ramsey number R (3,4).

Strategic Companies. In the examples considered so far, the complexity of the problems is located at most on the first level of the Polynomial Hierarchy (38) (in NP or co-NP). We next demonstrate that also more complex problems, located at the second level of the Polynomial Hierarchy, can be encoded in ASP. To this end, we now consider a knowledge representation problem, inspired by a common business situation, which is known under the name *Strategic Companies* (39).

Suppose there is a collection $C = \{c_1, \ldots, c_m\}$ of companies c_i owned by a holding, a set $G = \{g_1, \ldots, g_n\}$ of goods, and for each c_i we have a set $G_i \subseteq G$ of goods produced by c_i and a set $O_i \subseteq C$ of companies controlling (owning) c_i. O_i is referred to as the *controlling set* of c_i. This control can be thought of as a majority in shares; companies not in C, which we do not model here, might have shares in companies as well. Note that, in general, a company might have more than one controlling set. Let the holding produce all goods in G; i.e., $G = \cup_{c_i \in C} G_i$.

A subset of the companies $C' \subseteq C$ is a *production-preserving* set if the following conditions hold: (*1*) The companies in C' produce all goods in G; i.e., $\cup_{c_i \in C'} G_i = G$. (*2*) The companies in C' are closed under the controlling relation; i.e. if $O_i \subseteq C'$ for some $i = 1, \ldots, m$, then $c_i \in C'$ must hold.

A subset-minimal set C', which is *production-preserving*, is called a *strategic set*. A company $c_i \in C$ is called *strategic*, if it belongs to some strategic set of C.

This notion is relevant when companies should be sold. Indeed, intuitively, selling any nonstrategic company does not reduce the economic power of the holding. Computing strategic companies is on the second level of the Polynomial Hierarchy (39).

In the following discussion, we consider a simplified setting as considered in Ref. 39, where each product is produced by at most two companies (for each $g \in G, |\{c_i | g \in G_i\}| \leq 2$) and each company is jointly controlled by at most three other companies; i.e., $|O_i| \leq 3$ for $i = 1, \ldots, m$. Assume that for a given instance of Strategic Companies, $\mathcal{F}_{st}$ contains the following facts:

- *company(c)* for each $c \in C$
- *prod_by*(g, c_j, c_k), if $\{c_i | g \in G_i\} = \{c_j, c_k\}$, where c_j and c_k may possibly coincide
- *contr_by*(c_i, c_k, c_m, c_n), if $c_i \in C$ and $O_i = \{c_k, c_m, c_n\}$, where $c_k, c_m,$, and c_n are not necessarily distinct.

We next present a program $\mathcal{P}_{st}$, which characterizes this hard problem using only two rules:

$$\begin{array}{ll} r_1: & start(Y) \vee start(Z) \leftarrow prod\_by(X,Y,Z). \\ r_2: & start(W) \leftarrow contr\_by(W,X,Y,Z),\ strat(X), \\ & start(Y),\ start(Z). \end{array}$$

Here *strat*(*X*) means that company X is a strategic company. The guessing part of the program consists of the disjunctive rule r_1, and the checking part consists of the normal rule r_2. The program $\mathcal{P}_{st}$ is surprisingly succinct, given that Strategic Companies is a hard problem.

The program $\mathcal{P}_{st}$ exploits the minimization that is inherent to the semantics of answer sets for the check whether a candidate set C' of companies that produces all goods and obeys company control is also minimal with respect to this property.

The guessing rule r_1 intuitively selects one of the companies c_1 and c_2 that produce some item g, which is described by *prod_by*(g, c_1, c_2). If there was no company control information, the minimality of answer sets would naturally ensure that the answer sets of $\mathcal{F}_{st} \cup \{r_1\}$ correspond to the strategic sets; no further checking would be needed. However, in case control information is available, the rule r_2 checks that no company is sold that would be controlled by other companies in the strategic set, by simply requesting that this company must be strategic as well. The minimality of the strategic sets is automatically ensured by the minimality of answer sets.

The answer sets of $\mathcal{F}_{st} \cup \mathcal{P}_{st}$ correspond one-to-one to the strategic sets of the holding described in $\mathcal{F}_{st}$; company c is thus strategic iff *strat*(c) is in some answer set of $\mathcal{F}_{st} \cup \mathcal{P}_{st}$.

An important note here is that the checking "constraint" r_2 interferes with the guessing rule r_1: applying r_2 may "spoil" the minimal answer set generated by r_1. For example, suppose the guessing part gives rise to a ground rule

$$r_3 : strat(c1) \quad \vee \quad strat(c2) \leftarrow prod\_by(g, c1, c2).$$

and the fact *prod_by(g, c*1*, c*2) is given in $\mathcal{F}_{st}$. Now suppose the rule is satisfied in the guessing part by making *strat*(*c1*) true. If, however, in the checking part an instance of rule r_2 is applied that derives *strat*(c2), then the application of the rule r_3 to derive *strat*(c1) is invalidated, as the minimality of answer sets implies that rule r_3 cannot justify the truth of *strat*(c1), if another atom in its head is true.

FURTHER READING AND RELATED ISSUES

In this section, we consider some additional topics that allow the reader to have a broader picture of ASP. In particular, we introduce the general architecture of ASP systems, and we briefly describe several language extensions that have been proposed so far.

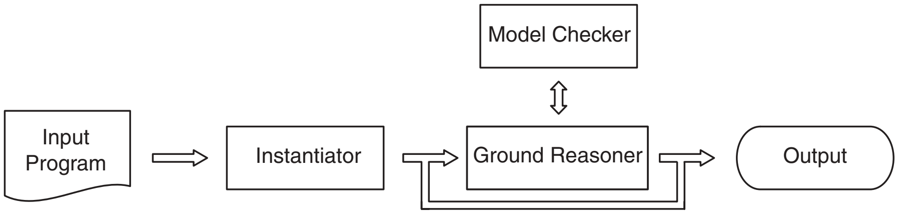

Figure 1. General architecture of an ASP system.

System Algorithms

Initially somewhat impeded by complexity considerations, reasonable algorithms and systems supporting ASP became available in the second half of the 1990s. The first widely used ones were Smodels (33,40), supporting nondisjunctive ASP, and DLV (30), supporting ASP (with disjunction) as defined in Ref 4. These two systems have been improved over the years and are still in widespread use. Later on, more systems for nondisjunctive ASP, like ASSAT (41,42), Cmodels (5), and Clasp (43) became available, and also more disjunctive ASP systems became available with the advent of GnT (44) and cmodels-3 (45).

Although, as discussed below, the systems do not use the same techniques, they basically agree on the general architecture depicted in Fig. 1.

The evaluation flow of the computation is outlined in detail. Upon startup, the input specified by the user is parsed and transformed into the internal data structures of the system.[5]

In general, an input program $\mathcal{P}$ contains variables, and the first step of a computation of an ASP system is to eliminate these variables, generating a ground instantiation *ground*($\mathcal{P}$) of $\mathcal{P}$. This variable-elimination process is called *instantiation* of the program (or *grounding*) and is performed by the *Instantiator* module (see Fig. 1).

A naÿve Instantiator would produce the full ground instantiation *Ground*($\mathcal{P}$) of the input, which is, however, undesirable from a computational point of view, as in general many useless ground rules would be generated. All of the systems therefore employ different procedures, which are geared toward keeping the instantiated program as small as possible. A necessary condition is, of course, that the instantiated program must have the same answer sets as the original program. However, it should be noted that the Instantiator solves a problem, which is in general EXPTIME-hard, the produced ground program being potentially of exponential size with respect to the input program. Optimizations in the Instantiator, therefore, often have a big impact, as its output is the input for the following modules, which implement computationally hard algorithms. Moreover, if the input program is normal and stratified, the Instantiator module is, in some cases, able to compute directly its stable model (if it exists).

The subsequent computations, which constitute the nondeterministic part of an ASP system, are then performed on *ground*($\mathcal{P}$) by both the *Ground Reasoner* and the *Model Checker*. Roughly, the former produces some "candidate" answer set, whose stability is subsequently verified by the latter. The existing ASP systems mainly differ in the technique employed for implementing the *Ground Reasoner*. There are basically two approaches, which we will refer to as *search-based* and *rewriting-based*. In the search-based approach, the *Ground Reasoner* implements a backtracking search algorithm, which works directly on the ground instantiation of the input program. Search-based systems, like DLV and Smodels, are often referred to as "native" ASP systems, because the employed algorithms directly manipulate logic programs and are optimized for those. In the rewriting-based approach, the *Ground Reasoner* transforms the ground program into a propositional formula and then invokes a Boolean satisfiability solver for finding answer set candidates.

As previously pointed out, the *Model Checker* verifies whether an answer set candidate at hand is an answer set for the input program. This task is as hard as the problem solved by the Ground Reasoner for disjunctive programs, whereas it is trivial for nondisjunctive programs. However, there is also a class of disjunctive programs, called Head-Cycle-Free programs (34), for which the task solved by the Model Checker is provably simpler, which is exploited in the system algorithms.

Finally, once an answer set has been found, ASP systems typically print it in text format, and possibly the *Ground Reasoner* resumes in order to look for additional answer sets.

Language Extensions

The work on ASP started with standard rules, but fairly soon implementations extending the basic language started to emerge. The most important extensions to the ASP language can be grouped in three main classes:

- *Optimization constructs*
- *Aggregates*
- *Preference handling*

Optimization Constructs. The basic ASP language can be used to solve complex search problems, but it does not natively provide constructs for specifying optimization problems (i.e., problems where some goal function must be minimized or maximized). Two extensions of ASP have been conceived for solving optimization problems: *weak constraints* (30,46) and *optimize statements* (33).

In the basic language, constraints are rules with an empty head and represent a condition that *must* be satisfied, and for this reason, they are also called *strong* constraints. Contrary to strong constraints, *weak constraints* allow us to express desiderata, that is, conditions that

[5] The input is usually read from text files, but some systems also interface to relational databases for retrieving facts stored in relational tables.

should be satisfied. Thus, they may be violated, and their semantics involves minimizing the number of violated instances of weak constraints. In other words, the presence of strong constraints modifies the semantics of a program by discarding all models that do not satisfy some of them, whereas weak constraints identify an approximate solution, that is, one in which (weak) constraints are satisfied as much as possible.

From a syntactic point of view, a weak constraint is like a strong one where the implication symbol $\leftarrow$ is replaced by $\leftsquigarrow$. The informal meaning of a weak constraint $\leftsquigarrow B$ is "try to falsify B" or "B should preferably be false." Additionally, a weight and a priority level for the weak constraint may be specified after the constraint enclosed in brackets (by means of positive integers or variables). When not specified, the weak constraint is assumed to have weight 1 and priority level 1, respectively.

In this case, we are interested in the answer sets that minimize the sum of weights of the violated (unsatisfied) weak constraints in the highest priority level and, among them, those that minimize the sum of weights of the violated weak constraints in the next lower level, and so on. In other words, the answer sets are considered along a lexicographic ordering along the priority levels over the sum of weights of violated weak constraints. Therefore, higher values for weights and priority levels allow for marking weak constraints of higher importance (e.g., the most important constraints are those having the highest weight among those with the highest priority level).

As an example, consider the Traveling Salesman Problem (TSP). TSP is a variant of the Hamiltonian Cycle problem considered earlier, which amounts to finding the shortest (minimal cost) Hamiltonian cycle in a directed *numerically labeled* graph. This problem can be solved by adapting the encoding of the Hamiltonian cycle problem given in Section 4 in order to deal with labels, by adding only one weak constraint.

Suppose again that the graph G is specified by predicates *node* (unary) and *arc* (ternary), and that the starting node is specified by the predicate *start* (unary).

The ASP program with weak constraints solving the TSP problem is thus as follows:

$$
\begin{array}{ll}
r_1: & \mathit{inPath}(X,Y,C) \vee \mathit{outPath}(X,Y,C) \leftarrow \mathit{arc}(X,Y,C).\\
r_2: & \mathit{reached}(X) \leftarrow \mathit{start}(X).\\
r_3: & \mathit{reached}(X) \leftarrow \mathit{reached}(Y), \mathit{inPath}(Y,X,C).\\
r_4: & \leftarrow \mathit{inPath}(X,Y,\_), \mathit{inPath}(X,Y1,\_), Y <> Y1.\\
r_5: & \leftarrow \mathit{inPath}(X,Y,\_), \mathit{inPath}(X1,Y,\_), X <> X1.\\
r_6: & \leftarrow \mathit{node}(X), \text{not}\, \mathit{reached}(X).\\
r_7: & \leftsquigarrow \mathit{inPath}(X,Y,C).[C,1]
\end{array}
$$

The last weak constraint *(r_7)* states the preference to avoid taking arcs with high cost in the path, and has the effect of selecting those answer sets for which the total cost of arcs selected by *inPath* (which coincides with the length of the path) is the minimum (i.e., the path is the shortest).

The TSP encoding provided above is an example of the "guess, check and optimize" programming pattern (30), which extends the original "guess and check" (see Section 4) by adding an additional "optimization part," which mainly contains weak constraints. In the example above, the optimization part contains only the weak constraint r_7.

Optimize statements are syntactically somewhat simpler. They assign numeric values to a set of ground literals, and thereby select those answer sets for which the sum of the values assigned to literals that are true in the respective answer sets are maximal or minimal. It is not hard to see that weak constraints can emulate optimize statements, but not vice versa.

Aggregates. There are some simple properties, often originating in real-world applications, which cannot be encoded in a simple and natural manner using ASP. Especially properties that require the use of arithmetic operators on a set of elements satisfying some conditions (like sum, count, or maximum) require rather cumbersome encodings (often requiring an "external" ordering relation over terms), if one is confined to classic ASP.

Similar observations have also been made in related domains, notably database systems, which led to the definition of aggregate functions. Especially in database systems, this concept is by now both theoretically and practically fully integrated. When ASP systems became used in real applications, it became apparent that aggregates are needed also here. First, cardinality and weight constraints (33), which are special cases of aggregates, have been introduced. However, in general, one might want to use also other aggregates (like minimum, maximum, or average), and it is not clear how to generalize the framework of cardinality and weight constraints to allow for arbitrary aggregates. To overcome this deficiency, ASP has been extended with special atoms handling aggregate functions (47–53). Intuitively, an aggregate function can be thought of as a (possibly partial) function mapping multisets of constants to a constant.

An *aggregate function* is of the form *f*(*S*), where *S* is a set term of the form {*Vars* : *Conj*}, where *Vars* is a list of variables and *Conj* is a conjunction of standard atoms, and *f* is an *aggregate function symbol*.

The most common aggregate functions compute the number of terms, the sum of non-negative integers, and the minimum/maximum term in a set.

Aggregates are especially useful when real-world problems have to be dealt with. Consider the following example application[6]. A project team has to be built from a set of employees according to the following specifications:

1. At least a given number of different skills must be present in the team.
2. The sum of the salaries of the employees working in the team must not exceed the given budget.

Suppose that our employees are provided by several facts of the form *emp*(*EmpId, Skill, Salary*); the minimum

[6] In the example, we adopted the syntax of the DLV system, the same aggregate functions can be specified also by exploiting other ASP dialects.

number of different skills and the budget are specified by the facts *nSkill*(*N*) and *budget*(*B*). We then encode each property stated above by an aggregate atom, and we enforce it by an integrity constraint:

r_1: $in(I) \vee out(I) \leftarrow emp(I,Sk,Sa).$
r_3: $\leftarrow nSkill(M), not \#count\{Sk{:}emp(I,Sk,Sa), in(I)\} >= M.$
r_4: $\leftarrow budget(B), not \#sum\{Sa,I{:}emp(I,Sk,Sa), in(I)\} <= B.$

Intuitively, the disjunctive rule "guesses" whether an employee is included in the team or not, whereas the two constraints correspond one-to-one to the requirements. Indeed, the function `#count` counts the number of employees in the team, whereas `#sum` sums the salaries of the employees that are part of the team.

Note that thanks to the aggregates, the translation of the specifications is straightforward.

Preference Handling. ASP programs usually follow a "guess and check" programming pattern (see Section 4), where a set of rules (the guessing part) is used to guess a solution (or equivalently, to generate answer set candidates), whereas another set of rules, called the checking part, is added to discard solutions that are not admissible. This methodology allows the programmer to distinguish between solutions and nonsolutions. However, in many realistic applications, the possibility to make more fine-grained distinctions is required, and in particular, distinctions between more and less preferred solutions are needed (see Ref. 54 for a discussion). For this reason, there has been a substantial amount of work on extending ASP programs with preferences, and in particular, the major focus has been on qualitative approaches. This stems from the fact that for a variety of applications, numerical information is hard to obtain (preference elicitation is difficult) and often turns out to be unnecessary (see Ref. 54). Still, language extensions based on quantitative information, such as the weak constraints mentioned above, emulate qualitative preferences under certain conditions, and vice versa. There are two basic possibilities for representing qualitative preferences. In one approach, the preference is specified among rules, mirroring the fact that some rules may be more reliable than others, and striving to use a set of rules that is as preferred as possible for giving a reason to an answer. In the second approach, the preferences are specified among literals, reflecting information on either the likelihood or the desirability of the affirmations represented by the literals.

In the first kind of formalisms, preferences are specified by means of an ordering among rules. Formally, an *ordered logic program* is a pair $(\Pi, <)$ where Π is a logic program and $< \subseteq (\Pi \times \Pi)$ is a strict partial order. Given $r_1, r_2 \in \Pi$, the relation $r_1 < r_2$ expresses that r_2 has higher priority than r_1.

For example, consider the following program:

$$r_1: \neg \mathrm{a}. \quad r_2: \mathrm{b} \leftarrow \neg \mathrm{a}, \mathrm{not\,c}. \quad r_3: \mathrm{c} \leftarrow \mathrm{not\,b}.$$

This program has two answer sets, one given by {¬a, b} and the other given by {¬a, c}. For the first answer set, rules r_1 and r_2 are applied; for the second, r_1 and r_3. However, assume that we have reason to prefer r_2 to r_3 expressed by $r_3 < r_2$. In this case, we would want to obtain just the first answer set and we say say that the first is a *preferred answer set*.

In general, defining which answer sets should be the preferred ones in this setting is not always as obvious as in the example above, and indeed several approaches have been proposed. A comprehensive comparison of three major semantics, defined by Delgrande, Schaub, Tompits (55), by Brewka and Eiter (56), and by Wang, Zhou, Lin (57), has been presented in Ref. 58.

In the second representational approach, preferences are represented among atoms, literals, or formulas. One way of specifying this has been proposed in Ref. 59, which is the use of *ordered disjunction* in rule heads. In particular, the operator × in rule heads acts as a disjunction also specifying preferences. The meaning of a rule $a_1 \times \cdots \times a_n \leftarrow body$, is that if the body is satisfied, then some a_i must be in the answer set, most preferably a_1, if this is impossible, then a_2, and so on. The formal semantics is defined by means of answer sets of split programs and of rule satisfaction degrees. There are some degrees of freedom when aggregating the satisfaction degrees of several rules, leading to different semantics, the main ones being cardinality-based, set-inclusion-based, and Pareto-based.

In the ordered disjunction approach, the construction of answer sets is amalgamated with the expression of preferences. *Optimization programs* (60), on the other hand, strictly separate these two aspects. An optimization program is a pair (P_{gen}, P_{pref}). Here, P_{gen} is an arbitrary logic program used to generate answer sets. All we require is that it produces sets of literals as its answer sets. P_{pref} is a preference program. Preference programs consist of preference rules of the form $c_1 > \cdots > c_n \leftarrow body$, where the c_i are Boolean combinations of literals built from ∨, ∧, ¬ and not. As in the case of ordered disjunction, the semantics of these programs is based on the degree of satisfaction of preference rules, and as in the case of ordered disjunctions, there are several options for aggregating these satisfaction degrees for defining semantics.

Another ASP extension suitable for preference handling has been presented in Ref. 61. There, standard ASP has been enriched by introducing consistency-restoring rules (CR-rules) and preferences, leading to the CR-Prolog language. Basically, in this language, besides standard ASP rules one may specify CR-rules, which are expressions of the form: $r : a_1 \vee \cdots \vee a_n \overset{+}{\leftarrow} body\,(n \geq 1)$. The intuitive meaning of the CR-rule r is as follows: If *body* is true, then one of $a_1, \ldots, a_n$ is "possibly" believed to be true. Importantly, the name of CR-prolog rules can be directly exploited to specify preferences among them. In particular, if the fact *prefer*(r_1, r_2) is added to a CR-program, then rule r_1 is preferred over rule r_2. This allows one to encode partial orderings among preferred answer sets by explicitly writing preferences among CR-rules.

Other Extensions. ASP has been extended in other directions in order to meet the requirements of different application domains; hence, there is a number of interesting languages having the roots on ASP. For instance, ASP has been exploited for defining and implementing *action languages* (i.e., languages conceived for dealing with actions and change) $\mathcal{K}$ (62), and $\mathcal{E}$ (63), whereas in Ref. 64, a framework for *abduction with penalization* has been proposed and implemented as a front-end for the ASP system DLV. A logic language called *ID-Logic* (65) has been introduced to deal with classical logic with inductive definitions (which correspond semantically to logic rules). Other ASP extensions have been conceived to deal with *Ontologies* (i.e., abstract models of a complex domain). In particular, in Ref. 66, an ASP-based language for ontology specification and reasoning has been proposed, which extends ASP in order to deal with complex real-world entities, like classes, objects, compound objects, axioms, and taxonomies. In Ref. 67, an open world semantics for ASP programs has been proposed. Moreover, in Ref. 68, an extension of ASP, called *HEX-Programs*, which supports higher order atoms as well as external atoms has been proposed. External atoms allows one to embed external sources of computation in a logic program. Thus, HEX-programs are useful for various tasks, including meta-reasoning, data type manipulations, and reasoning on top of Description Logics (DL) (69) ontologies. *Template predicates* have been introduced in Ref. 70. Template predicates are special intensional predicates defined by means of generic reusable subprograms, which have been conceived for easing coding and improving readability and compactness of programs. Finally, nested programs, allowing for nested logical expressions to occur in rules, have also been studied (71,72).

Applications

Answer set programming has been successfully applied to many areas, including:

- *Information integration*. ASP has been exploited for supporting consistent query answering, in information integration systems under the so-called Global-as-View approach (73–75), also in the presence of data inconsistencies and data incompleteness.
- *Configuration and verification management*. In product configuration (76), ASP has been used as a declarative semantics providing formal definitions for main concepts in product configuration, including configuration models, requirements, and valid configurations. And, in particular, in the field of software configuration, a prototype configurator for the complete Debian Linux system distribution has been implemented by using ASP (17).
- *Knowledge management*. ASP has a strong potential for exploitation in the area of knowledge management and semantic technologies.

  An ASP-based system for ontology representation and reasoning, called OntoDLV (66), is employed in many real-world applications, ranging from e-learning to enterprise ontologies and agent-based applications. In Ref. 78, an ASP-based approach to the problem of recognizing and extracting information from unstructured documents has been presented. In Refs. 79 and 80, a system for content classification, called OLEX, is presented, which exploits ASP to extract concepts and semantic metadata from documents.
- *Security engineering*. In Ref. 81, it is shown how security protocols can be specified and verified efficiently and effectively by embedding reasoning about actions into logic programming. In particular, two significant case studies in protocol verification have been modeled: the classical Needham–Schroeder public-key protocol and the Aziz–Diffie key agreement protocol for mobile communication.

Moreover, applications from various areas can be found in the literature, including auctions (82), scheduling (83), policy description (84), workflow management (85), outlier detection (86), linguistics (87), multiagent systems (88–90), and e-learning (90).

Concluding, ASP is an appealing tool for knowledge representation and reasoning, and thanks to the applicability of the implementations of ASP solvers to real-world problems, ASP is tackling many industrially relevant applications.

It is worth noting that ASP systems are currently away from comfortably enabling the development of industry-level applications, and like any other programming language, ASP needs tools and development methodologies to facilitate and improve the coding process. At the time of this writing, the field of software engineering for ASP has been already settled by the ASP community (91), and it is currently evolving. Indeed, both methodologies (see Section 4) and prototype tools are already available (see Refs. 66, 70, and 91–94).
